Dye-sensitized Solar Cells (DSCs), despite the continuous advances of the last years, show still a certain difficulty in realizing devices able to guarantee at the same time

✓ high photovoltaic performances

 \checkmark long term stability

✓ reliable reproducibility

The reason is that the cells are assembled with different and heterogeneous layers, each one affected by intrinsic variability; moreover the layers influence each other. But people still perform their optimizations investigating one variable at a time.

Design of Experiment (DoE) is a powerful technique based on multivariate mathematical models. This approach is useful for:

the interpretation of any experimental procedure in which several variables may influence the result

It allows to determine:

✓ significant factors

 \checkmark interactions

AIM OF THE WORK

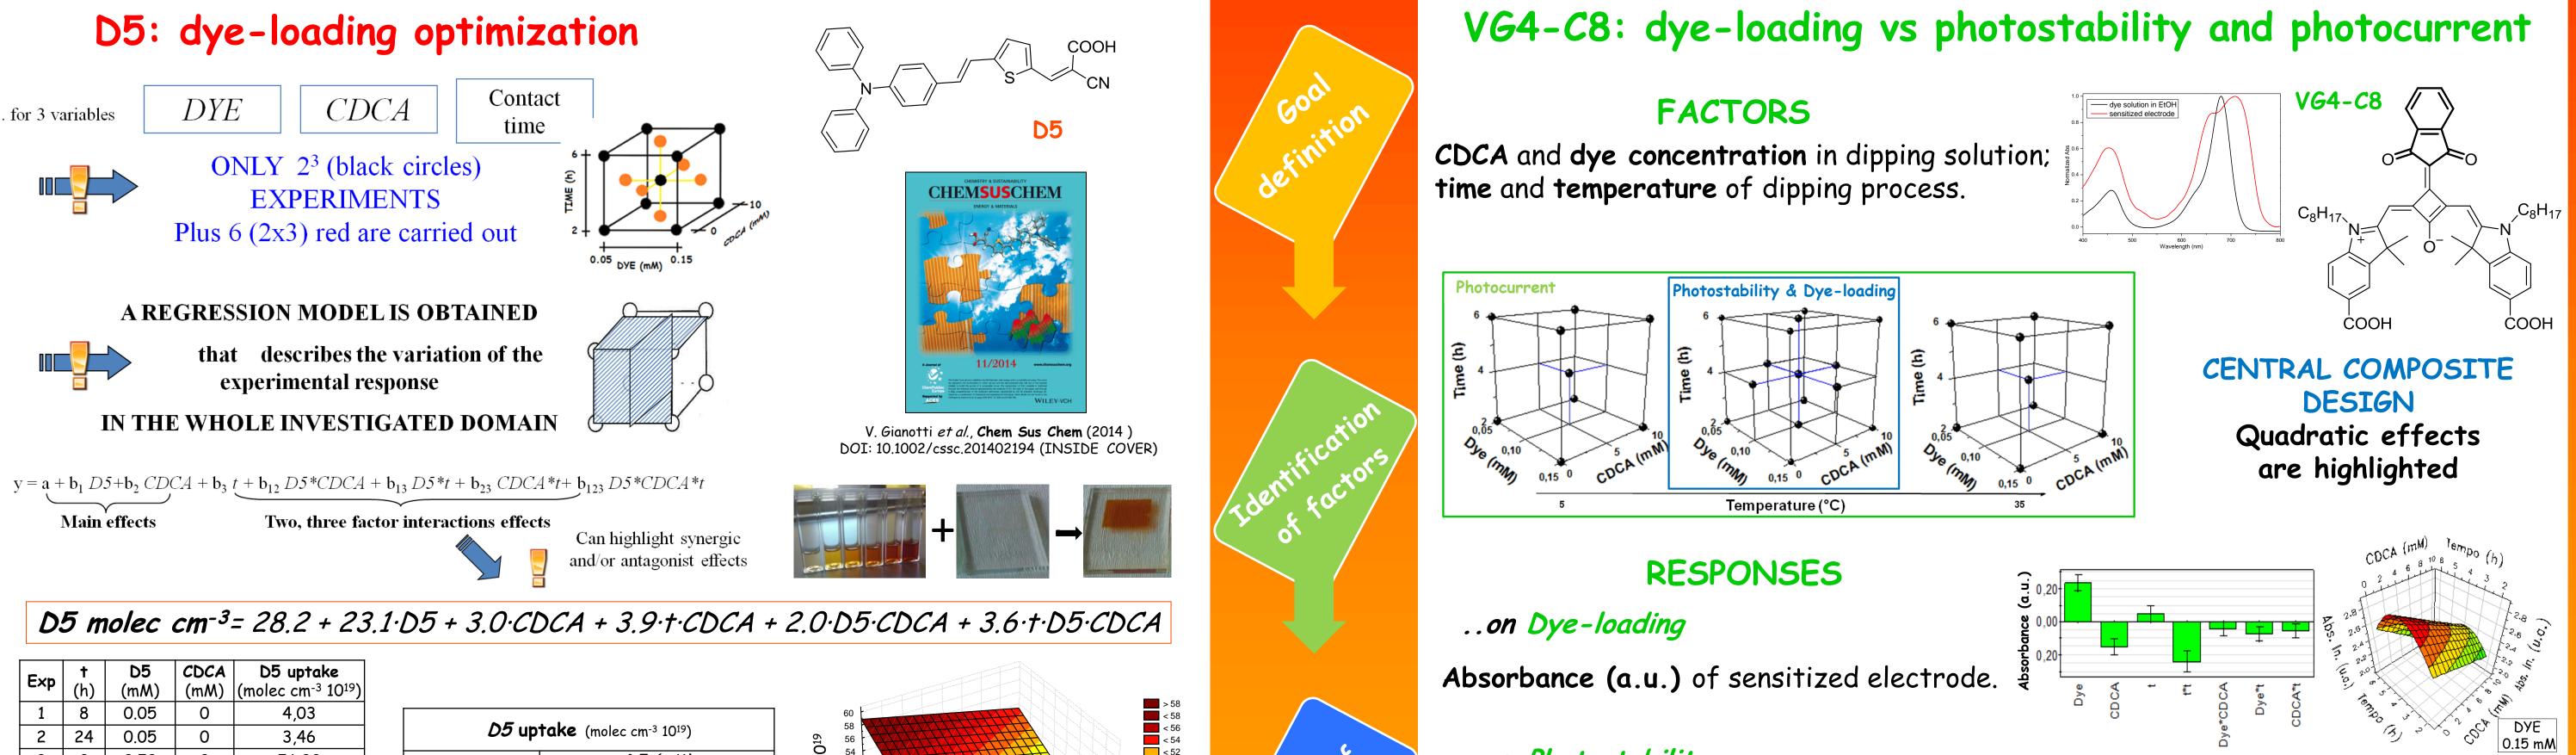

Metal-based or Metal-free, Dye solution (pH, time, concentration), Aggregation, Photostability Type, Conductivity Rugosity, Stability

Type of semiconductor, Nanostructure (type, dimension, conductivity, surface area), Annealing (time and temperature), Stability

that have influence on the selected responses.

A minimum number of suitable selected experiments is needed to obtain the required information in the whole considered experimental region.

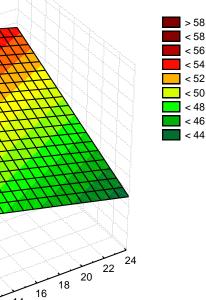

The present work aims at improving the more critical PV cell parameters (dye-loading, efficiency and stability are considered the responses of the system), by studying and optimizing the DIPPING PROCESS of the photoelectrode. By a multivariate approach, several factors, i.e. solvent, concentration of sensitizer and co-adsorbent (CDCA), time and temperature of soaking, are taken into account simultaneously highlighting the importance of their INTERACTIONS. Here we present the same approach tested both on a organic (D5) and a NIR dye (VG4-C8).

Data

E×p	† (h)	D5 (mM)	CDCA (mM)	D5 uptake (molec cm ⁻³ 10 ¹⁹)
1	8	0.05	0	4,03
2	24	0.05	0	3,46
3	8	0.50	0	56,30
4	24	0.50	0	35,71
5	8	0.05	16	5,26
6	24	0.05	16	6,26
7	8	0.50	16	51,34
8	24	0.50	16	60,84
9	16	0.27	8	29,09
10	16	0.27	8	28,94
11	16	0.27	8	29,16

D5 uptake (molec cm ⁻³ 10 ¹⁹)									
		D5 (mM)							
1		0.05		0.50					
CDCA	16.0	51.3	60.8	5.3	6.3				
(<i>mM</i>)	0.0	56.3	35.7	4.0	3.5				
		8.0	24.0	8.0	24.0				
		<i>t</i> (h)		<i>t</i> (h)					

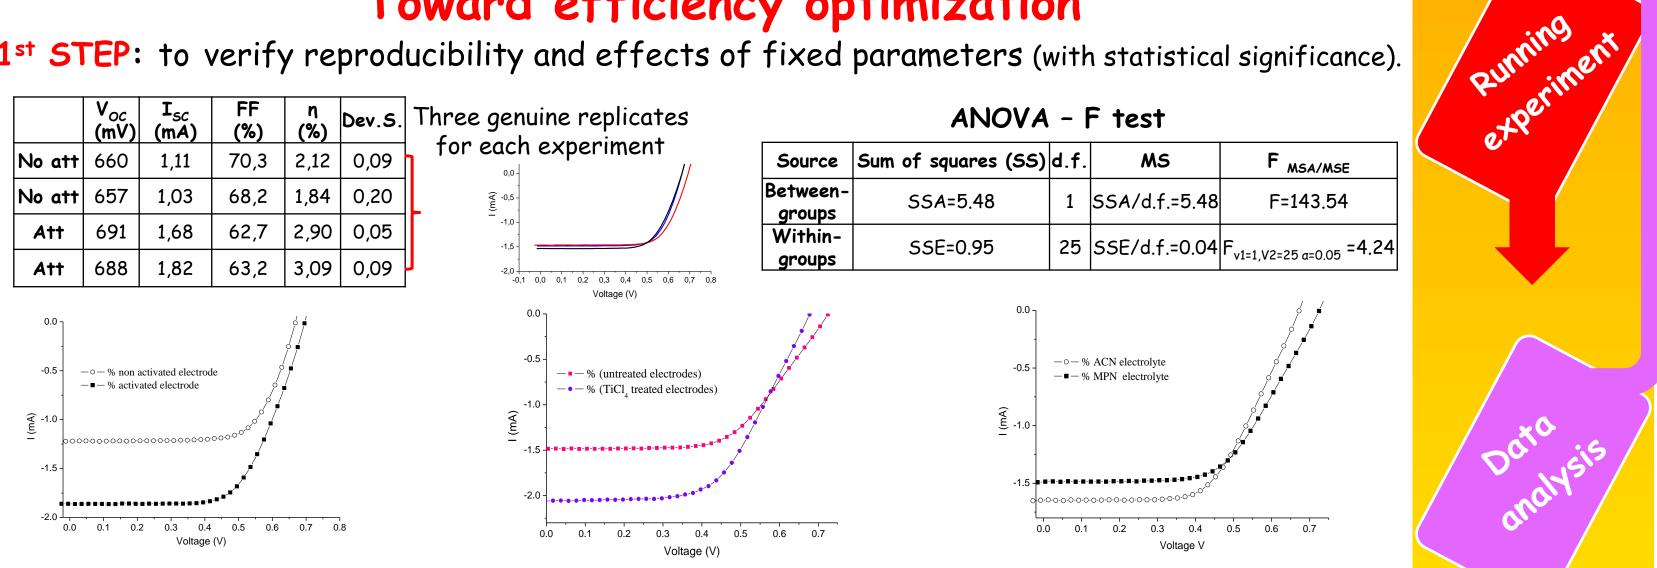

<u>Take-home message</u>: [CDCA] has comparable importance respect to its interaction with **time** and **dye** concentration!

SYNERGIC EFFECT

COCA

Toward efficiency optimization

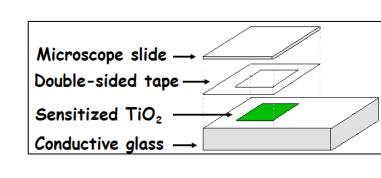

1st STEP: to verify reproducibility and effects of fixed parameters (with statistical significance).

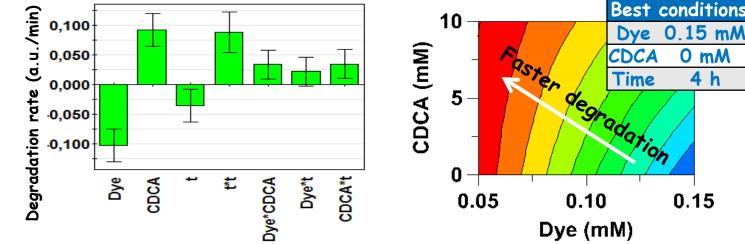

2nd STEP: to select the experimental region (see dipping conditions) and to check the CENTRAL POINT (verify the reproducibility again!).

...on Photostability

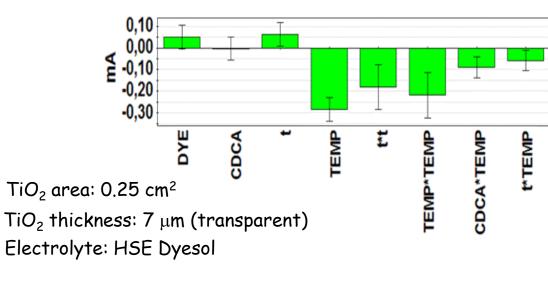

Degradation rate (%), absorbance variation of the main peak in function of irradiating time on dummy cell.

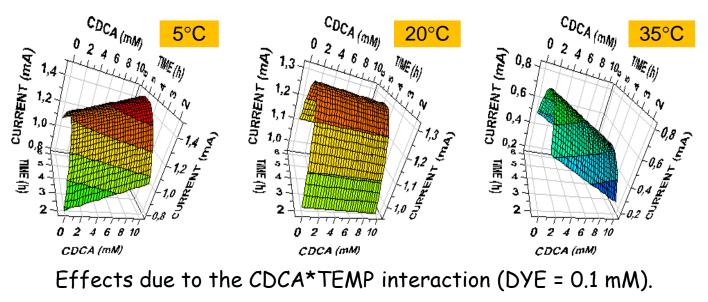

.. on Photocurrent

Current (mA), measured with complete cell under standard conditions (1 Sun).

CONCLUSIONS

- Dye concentration and dipping time, until 4 hours, increase all the responses.
- CDCA concentration and its interaction have negative effect on dye-loading and stability and seem not to affect the photocurrent. Really the presence of CDCA decreases the current at 35°C, while at low temperature it has a significant **positive effect**, that enhance the maximum achievable photocurrent.
- Temperature is the main factor that negative influence the photocurrent.
