

Foveal Word Reading Requires Interhemispheric Communication

Zoë R. Hunter¹, Marc Brysbaert¹, and Stefan Knecht²

Abstract

■ The left cerebral hemisphere is dominant for language processing in most individuals. It has been suggested that this asymmetric language representation can influence behavioral performance in foveal word-naming tasks. We carried out two experiments in which we obtained laterality indices by means of functional imaging during a mental word-generation task, using functional transcranial Doppler sonography and functional magnetic resonance imaging, respectively. Subsequently, we administered a behavioral word-naming task, where participants had to name foveally presented words of different lengths shown in different fixation locations shifted horizon-

tally across the screen. The optimal viewing position for left language dominant individuals is located between the beginning and the center of a word. It is shifted toward the end of a word for right language dominant individuals and, to a lesser extent, for individuals with bilateral language representation. These results demonstrate that interhemispheric communication is required for foveal word recognition. Consequently, asymmetric representations of language and processes of interhemispheric transfer should be taken into account in theoretical models of visual word recognition to ensure neurological plausibility. ■

INTRODUCTION

One of the striking features of the visual system is the crossing of the nasal optic fibers in the optic chiasm. Because of this crossing, stimuli presented in the left visual field (LVF) are initially projected to the right half of the brain, and stimuli presented in the right visual field (RVF) are projected to the left hemisphere. This characteristic of the visual field has been used in thousands of experiments to investigate brain asymmetry on the basis of the visual half field (VHF) technique. The split of the visual field in two halves is also the reason why memories of faces are predominantly based on information from the LVF (Brady, Campbell, & Flaherty, 2004).

Surprisingly, limited attention has been paid to the question of what happens at the border where LVF and RVF meet. For a long time the general assumption was that the hemifields overlap in the center of the visual field, so that foveal vision is projected bilaterally and stimuli have to be presented in parafoveal vision to ensure unilateral projection (Bradshaw & Nettleton, 1983). This assumption was also shared by psycholinguists whose models of visual word recognition did not include any reference to brain asymmetry or the need of interhemispheric communication.

Several reviews of the literature have shown, however, that the assumption of a bilaterally represented fovea is wrong (e.g., Lavidor & Walsh, 2004; Brysbaert, 1994, 2004). For instance, Corballis and Trudel (1993) examined whether split-brain patients were able to recognize centrally presented four-letter words that could not be guessed on the basis of the first or the last two letters. Two patients were examined (L.B. and D.K.). They were both unable to recognize foveally presented words, although their performance was good when the stimuli were presented in the LVF or RVF. Similar findings were reported by Fendrich and Gazzaniga (1989) and Fendrich, Wessinger, and Gazzaniga (1996) for the patients V.P. and J.W.

A second argument that has been made for the conjecture that cerebral asymmetry and interhemispheric transfer do not constrain visual word recognition in foveal vision is that in healthy participants, interhemispheric communication is so fast and abundant that it does not limit word processing to a greater extent than the equivalent intrahemispheric connections. This view has been phrased most explicitly by Dehaene, Cohen, Sigman, and Vinckier (2005), who wrote: "It has been proposed that 'foveal splitting,' whereby the left and right halves of a centrally fixated word are initially sent to distinct hemispheres, has important functional consequences for reading. However, beyond V1, callosal projections have the precise structure required to guarantee the continuity of receptive fields across the midline and allow convergence to common visual representations.

¹Royal Holloway University of London, UK, ²University of Münster, Germany

We believe that these connections minimize the functional impact of the initial foveal split” (p. 338).

Brybaert (1994) argued that the discussion about whether interhemispheric transfer has functional consequences for foveal word recognition can be settled quite easily on the basis of empirical data. All that is needed is to compare a group of participants with right-hemisphere language dominance to a group of participants with left-hemisphere language dominance. Although language is lateralized to the left in most individuals (Szaflarski et al., 2002; Knecht et al., 2000; Pujol, Deus, Losilla, & Capdevila, 1999), there is a small percentage of people with right-hemisphere language dominance. Comparing the performance of left and right language dominant individuals in a foveal word-recognition task would reveal to what extent higher cognitive processes such as reading rely on interhemispheric transfer and information integration. If foveal vision is bilateral or if interhemispheric connections minimize the functional impact of the initial foveal split, then there should be no difference in the performance of both groups, at least not for short words that subtend a visual angle of less than 2° (under most reading conditions there are three to four letters per degree of visual angle).

Brybaert (1994) made use of the optimal viewing position (OVP) effect (O’Regan & Jacobs, 1992) to investigate the issue. The OVP effect is obtained by asking participants to read words after initial fixation on the first, the second, . . . , and the last letter. The usual finding is that participants are fastest in recognizing a word when they are allowed to fixate a letter within the first one third of the word (called the OVP) and that there is a considerable time cost for fixations toward the end of the word, in particular for long words (see Figures 3 and 6). Brybaert recruited a group of nine participants with atypical brain laterality (i.e., with signs of right-hemisphere language dominance or bilateral language representation) and observed that the OVP was shifted more toward the end of the words for these participants compared to a control group of participants with left-hemisphere language dominance.

Unfortunately, when Brybaert (1994) ran his experiments, there were no other noninvasive means of assessing cerebral dominance than VHF tasks. Hence, participants were classified as left or right dominant on the basis of their LVF–RVF asymmetry in a VHF task with parafoveal word presentation. A major weakness of this approach was that variables other than cerebral dominance could account for the correlation between VHF asymmetries and the preferred landing position in the OVP task as observed by Brybaert. These include, for example, an individual bias in attention allocation across the VHFs (Kim & Levine, 1991), established reading habits, and asymmetries in the information distribution within words (Efron, 1990).

In the years since the early 1990s, major breakthroughs have been realized to assess cerebral domi-

nance in a noninvasive way. Two techniques stand out. The first involves functional transcranial Doppler sonography (fTCD), through which the differences in blood flow velocity toward the left and right cerebral hemispheres can be measured while participants are performing a language-related task, usually word generation. Individuals with left-hemisphere language dominance are expected to require a higher blood flow to their left hemisphere than to their right hemisphere while doing the task and this asymmetry can be picked up with fTCD. In a series of studies, Knecht and colleagues showed that the technique makes it possible to reliably assess cerebral dominance in a test session of less than 30 min. Knecht et al. (2001), for instance, applied this technique to a group of 326 healthy participants and obtained evidence for left-hemisphere dominance in 264 participants (80%), bilateral representation in 31 participants (10%), and right-hemisphere dominance in 31 participants (10%). The technique was further validated by comparing its laterality index (LI) to the LI based on the well-documented invasive Wada test. Fifteen patients with epilepsy underwent both tests as part of a presurgery evaluation. The LIs of fTCD and WADA agreed in all patients (11 left dominant and 4 right dominant; Knecht et al., 1998).

The second technique that has been used to assess brain dominance in a noninvasive way is functional magnetic resonance imaging (fMRI). Knecht et al. (2003) showed that participants with left and right language dominance (as assessed by fTCD) showed much higher activation levels in the expected hemisphere in the areas related to speech production (Broca’s area and the surrounding regions, including Brodmann’s area (BA) 44 and BA 45). Similar findings were reported by Pujol et al. (1999) and Szaflarski et al. (2002).

In the experiments below we will repeat Brybaert’s (1994) OVP study with groups of participants whose brain asymmetry has been assessed with either fTCD or fMRI. If brain laterality has no functional consequences for foveal word recognition, we expect to find similar OVP curves for left-dominant and right-dominant participants, at least for short words that subtend a visual angle of less than 2° of visual angle. In contrast, if interhemispheric communication constrains foveal word recognition, we expect to find that participants who are left dominant for language will perform better than right-dominant participants after fixating the first letters of the words, whereas they will perform worse after fixating the last letters of the words. This is because fixation of the first letters of a word make the word fall mainly in the RVF, whereas if the last letters are fixated the word falls predominantly in the LVF.

EXPERIMENT 1

In experiment 1 we tested the OVP effect for German words of three, five, and seven letters in participants

whose brain laterality had previously been assessed as typical or atypical by means of fTCD.

Methods

Procedure

Participants were chosen from a cohort of people that had previously been assessed for language dominance by fTCD at the Universitätsklinikum Münster (Germany), such that this information was available for preselection purpose. All participants gave informed consent and had to complete a questionnaire on handedness based on the Edinburgh Handedness Inventory prior to participation. The experimental paradigm employed in the Doppler sonography setting is well documented and has successfully been used in a range of language lateralization studies so far (Knecht et al., 2000, 2001, 2003). All participants were native German speakers.

Because previous laterality assessments had taken place more than a year ago, hemispheric language dominance was reassessed with fTCD during performance of a verbal fluency task. Subsequently, participants performed an OVP task in which they had to name three-, five-, and seven-letter words presented briefly between two vertically aligned lines at different fixation locations.

Functional Transcranial Doppler Sonography

Twenty participants were selected from the available cohort of people (13 men, 7 women; mean age 28.1 years; 12 left-handed, 8 right-handed). A 2-MHz transcranial Doppler sonography device (Multidop T; DWL, Sippligen, Germany) was used to measure increases in cerebral blood flow velocity (CBFV) within the left and right middle cerebral arteries (MCAs) during performance of a verbal fluency task. Participants were seated in front of a monitor while a head device, supporting the 2-MHz ultrasound probes, was fitted and the MCAs were located (Ringelstein, Otis, Niggemeyer, & Kahlscheuer, 1990). The verbal fluency experiment started out with a 15-sec *rest period* followed by an auditory signal that indicated the *cue* phase, during which a random letter of the alphabet was displayed on screen for 5 sec. A second auditory signal marked the beginning of the *wordgen* phase, lasting 6 sec, which required the participant to silently generate as many words as possible starting with the displayed letter. A third auditory cue signaled the onset of the *speak* phase, during which the words that had been found had to be repeated out loud (12.5 sec). The end of the first cycle was indicated by a fourth auditory cue (Figure 1). Twenty of these experimental cycles were recorded, lasting an entirety of approximately 20 min. The Doppler signal resulted in spectral envelope curves that were stored for off-line analysis.

Data Analysis and LI Calculations

fTCD data were analyzed with the software package AVERAGE (Deppe, Knecht, Henningsen, & Ringelstein, 1997). After preprocessing and automatic artifact rejection, the data were integrated over the corresponding cardiac cycles, segmented into epochs that related to the different experimental phases (rest period, cue, wordgen, speak), and averaged. Mean CBFV values from the 15-sec rest period were taken as baseline value. The relative CBFV (rCBFV) changes in relation to the baseline value were calculated and compared for each experimental phase with the formula:

$$\text{rCBFV} = \frac{V_{(t)} - V_{(\text{rest_mean})}}{V_{(\text{rest_mean})}} \quad (1)$$

where $V_{(t)}$ is the CBFV over time and $V_{(\text{rest_mean})}$ refers to the mean velocity in the rest period.

The Wilcoxon test was employed to statistically analyze the differences in blood flow velocity between the left and right MCAs at each sample point, resulting in an LI for each participant for the experimentally crucial wordgen phase. We found eight participants to be right dominant for language with fTCD_LI values ranging from -1.17 to -4.93 , and 12 participants showed typical language dominance with values ranging from 1.39 to 7.79 (Table 1). For the current data set and the previously recorded fTCD LIs a test-retest correlation was calculated for purpose of comparison ($r = .78$, $p < .01$, $t(18) = 5.286$), revealing a strong consistency across time for this measurement technique.

Behavioral OVP

The behavioral word-naming task was performed by the same group of people who were assessed with fTCD.

Stimuli. Seventy each of three-, five-, and seven-letter words served as stimuli. The stimulus sample contained German nouns only, which were selected through WinWordGen (downloadable online users.ugent.be/~wduyck/wwgdown.htm) and were controlled for frequency and neighborhood size. Words were displayed in their common format, with the initial letter capitalized.

Design. Each word, independent of its length, could be seen at seven possible fixation locations shifted horizontally across the screen. We chose this design (seven fixation locations even for the shorter words) to be able to present the same number of three- and five-letter words as seven-letter words, in equal fixation locations. This design also allowed us to examine whether there was a continuity between foveal and parafoveal word recognition (Brybaert, Vitu, & Schroyens, 1996). A three-letter word was presented such that participants were

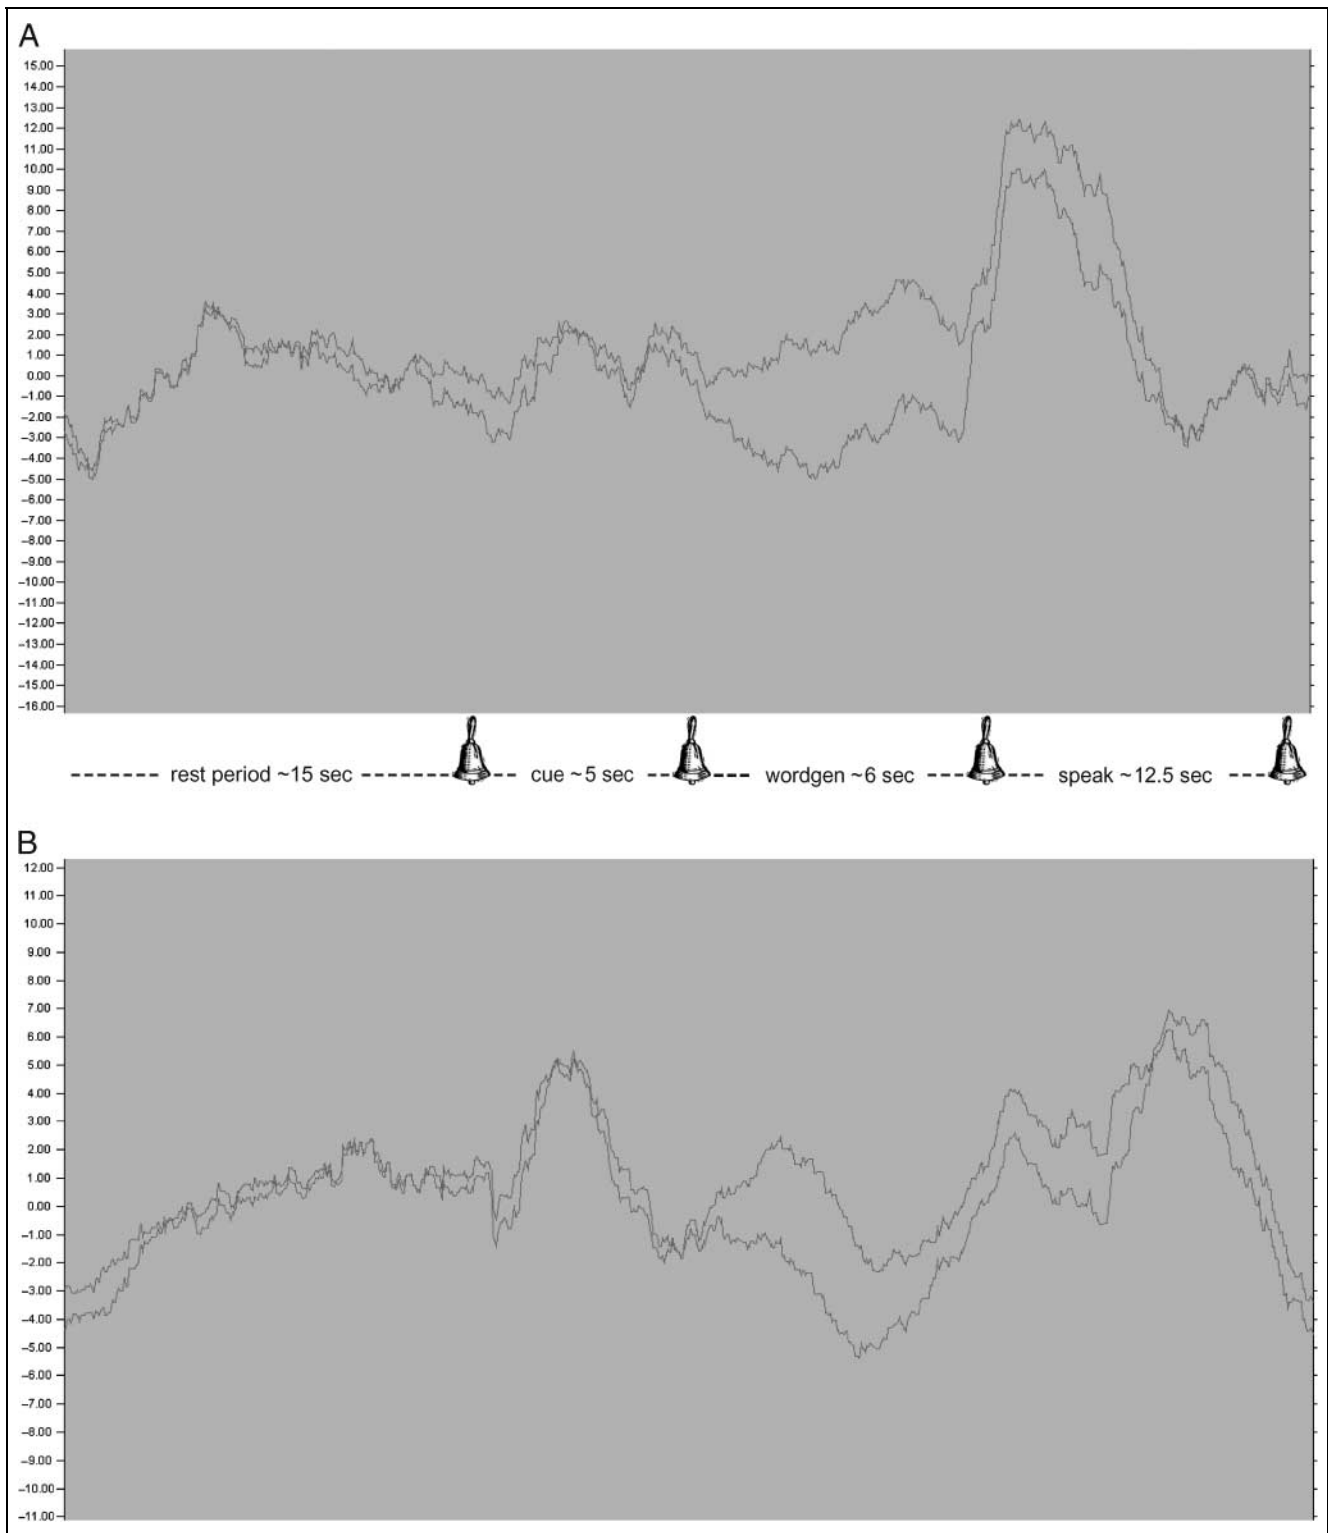

Figure 1. Doppler curves for two representative participants. Average curves for CBFV changes in the left and right MCAs throughout the different experimental phases. Green = right MCA; Red = left MCA. (A) A clear increase in CBFV in the left MCA during the wordgen phase indicates typical left-hemisphere language dominance for this individual. $fTCD_{LI} +5.84$. (B) Atypical language dominance is illustrated through an increase in CBFV in the right MCA. $fTCD_{LI} -4.25$.

fixating the blank space two letter positions before the word (-2; i.e., the complete word was in RVF), the blank space before the word (-1), the first letter of the word (L1), the second letter of the word (L2), the third

letter of the word (L3), the blank space after the word (1), or two letter positions after the word (2; see Figure 2). A five-letter word could be fixated on each letter of the word (L1, L2, L3, L4, L5) or on the space before

(-1) or after the word (1). A seven-letter word could be fixated on each possible letter position (L1, L2, L3, L4, L5, L6, L7). Because it would have taken too many repetitions of the stimuli, each participant did not see each

individual word at every possible fixation location, but at three different positions only (i.e., the set of 210 stimuli were repeated in three lists). Therefore, each participant was eventually exposed to 630 trials. The fixation

Figure 2. OVP design. Words of all lengths were presented at seven possible fixation locations shifted horizontally across the screen. Participants had to name the word as fast as possible.

locations for the different words were counterbalanced across the left- and the right-lateralized groups, so that the results could not be due to the words that were seen at the different fixation locations. This was done as follows. First, seven lists were made according to a Latin square design, so that each list contained all possible words and all possible fixation locations and over the lists all words were presented at all fixation locations. Next List 1, 2, 3 were seen by the first individual, List 4, 5, 6 by the second individual, List 7, 1, 2 by the third, and so forth, such that the OVP patterns for the left- and right-dominant groups were independent of the words selected for the experiment.

Procedure. Participants viewed a monitor at a distance of ~60 cm and were asked to fixate a gap (fixation space) between two vertically aligned lines (visible throughout the experiment) in the center of the screen. The whole set of stimuli was shuffled and presented in pseudo-randomized order, such that there was no blocking of word length. Words stayed on screen for 180 msec each. The participants responded by naming the words as fast as possible. Responses were collected by means of a voice trigger, where the onset of speech was registered as the reaction time for a specific stimulus. To control for eye movements, digits in the range from 0 to 9 were presented in the fixation space at a word/digit ratio of 5.3:1 at randomized time intervals. The digits were on screen for 80 msec only and had to be reported correctly. This was a strong incentive for the participants to constantly fixate the space between the two vertical lines (Brysbaert, 1994). Words and digits were masked with a sequence of ASCII codes 35 (#) that had the same length as the preceding stimulus to prevent any afterimage.

Results

Preceding the OVP data analysis, timing (>1500 msec) and naming errors were eliminated from the data set (mean mixed error rate 1.77%). Subsequently, mean response times (RTs) for each fixation position were calculated, resulting in an OVP curve for each individual and each word length.

The mean RT data were entered in a three-way analysis of variance (ANOVA) including laterality group (two levels, between subjects), word length (three levels, within subjects), and viewing position (seven levels, within subjects). We found a main effect of viewing position, $F(6,108) = 44.184, p < .01$, and an interaction between laterality group and viewing position, $F(6,108) = 5.744, p < .01$, as well as an interaction between word length and viewing position, $F(12,216) = 10.599, p < .01$.

Subsequently, RTs were standardized for every participant per word length by subtracting the overall mean from the observed RTs (e.g., a participant who had an average RT of 500 msec for three-letter words and whose RT after fixating the first letter was 490 msec, would get a

standardized value of -10 msec for that fixation location). In this way, the curves of the two laterality groups could be compared in a straightforward way by getting rid of the nonsignificant group differences in reading times. The raw data (before standardization) are given in Table 2.

Figure 3 shows the standardized OVP curves for the group of right-dominant individuals and the group of left-dominant individuals for each of the three word lengths. This figure clearly illustrates the differences between both laterality groups. Participants with left-hemisphere dominance named the short words faster when they fixated the space in front of the words or the initial letters, whereas faster reaction times were seen in the right-hemisphere-dominant participants when they fixated the end letters of the words or the space after the words. Within the group of atypical language dominant participants we found no significant differences in performance between left-handed (4) and right-handed (4) individuals (95% confidence interval [CI] = 9 msec for three-letter words, 10 msec for five-letter words, and 12 msec for seven-letter words; based on the mean square error [MSE] of the interaction between viewing position and laterality group; Masson & Loftus, 2003).

To measure the correlation of the fTCD LIs with the left-right asymmetries of the OVP curves over all participants, we rewrote each OVP curve as a second-order polynomial and looked at the regression weight of the linear component.¹ Hence, the OVP curve of each participant was rewritten as:

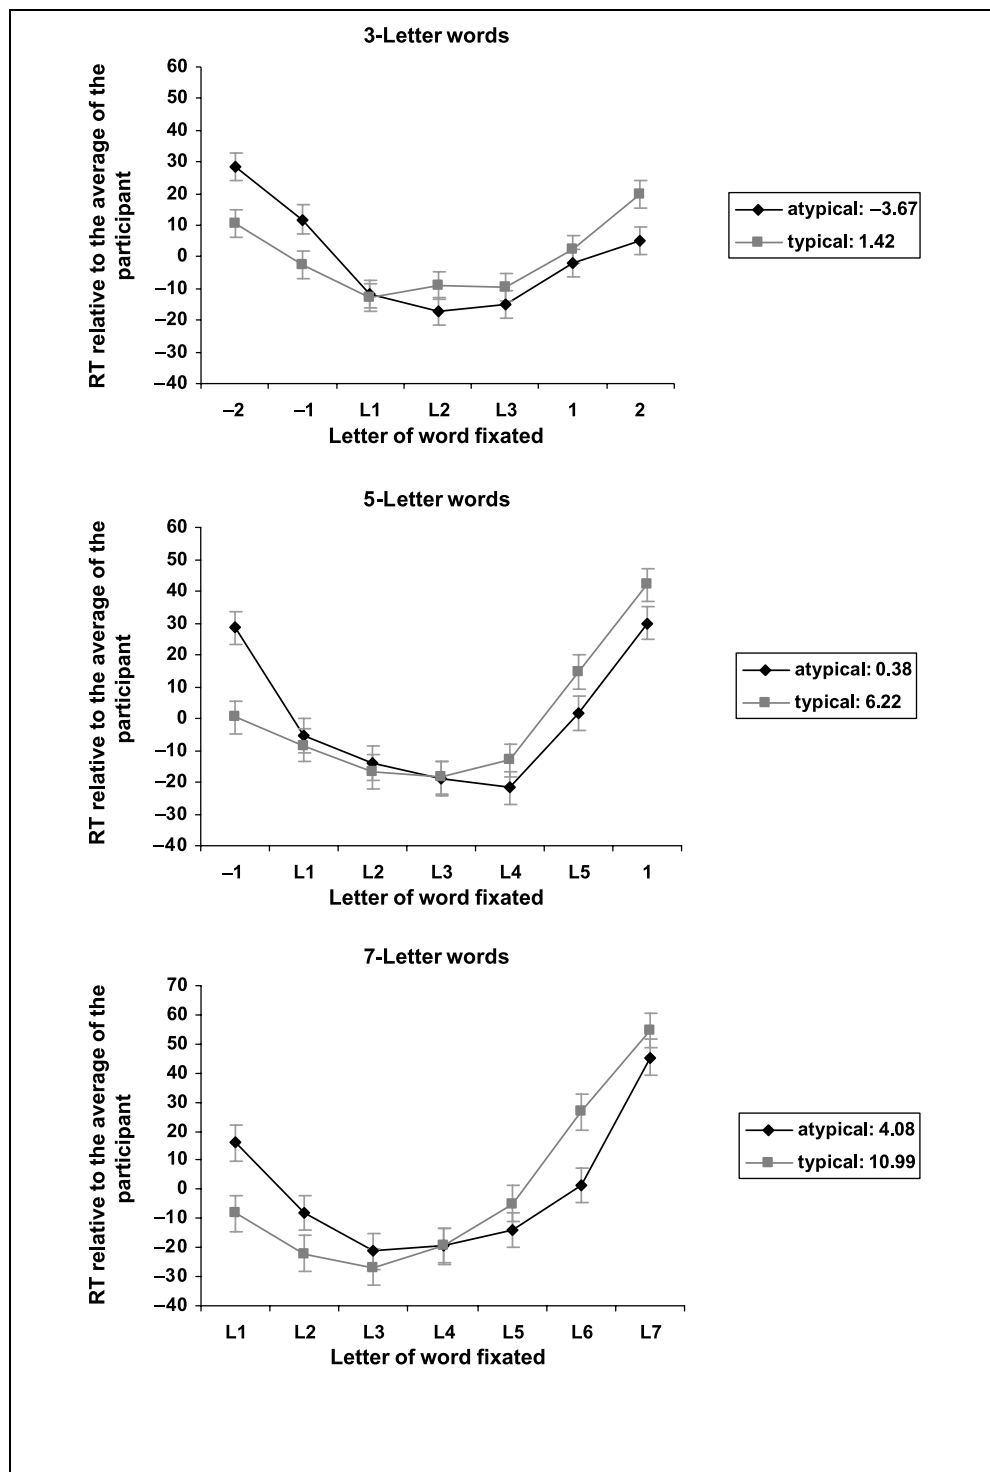

$$RL_i = a + b(l_i - m) + c(l_i - m)^2 \quad (2)$$

where RL_i = reaction latency for fixation location i , l_i = rank number of the letter fixated, m = middle of the word, a = constant, b = linear component, c = quadratic component.

Table 2. Raw Average OVP Data for the Left-dominant (LD) and Right-dominant (RD) Group for All Seven Fixation Positions for Each Word Length (Experiment 1)

	Position						
	1	2	3	4	5	6	7
LD							
3-Letter words	555	542	532	535	535	547	565
5-Letter words	559	551	542	540	546	574	601
7-Letter words	553	539	535	542	557	588	616
RD							
3-Letter words	609	592	569	563	565	578	585
5-Letter words	616	583	574	569	566	589	618
7-Letter words	612	588	575	577	582	598	641

Figure 3. OVP curves for three-, five-, and seven-letter words for the OVP task in Experiment 1. Typical: Mean OVP curves for the group of left-hemisphere-dominant participants, with OVP slopes of 1.42, 6.22, and 10.99 for three-, five-, and seven-letter words. Atypical: Mean OVP curves for the group of right-dominant participants, with OVP slopes of -3.67 , 0.38 , and 4.08 for three-, five-, and seven-letter words. Intervals indicate the standard errors of the means based on the mean square error of the interaction between laterality group and viewing position.

The linear OVP components ranged from -12.2 to 7.1 for the three-letter words, from -7.7 to 18.1 for the five-letter words, and from -1.0 to 21.1 for the seven-letter words (Table 1). There were high positive correlations between the slopes of the different word lengths over all participants: $r = .71, p < .01$ between three- and five-letter words; $r = .61, p < .01$ between three- and seven-letter words; and $r = .72, p < .01$ between five- and seven-letter words.

A comparison between the slopes for the atypical and the typical language dominant individuals revealed that the average slopes for the atypical group were -3.7 for the three-letter words, 0.4 for the five-letter words, and 4.1 for the seven-letter words. The average slopes for the typical language dominant group were $1.4, 6.2,$ and $11.0,$ respectively (Figure 3). A 2×3 ANOVA including laterality group and word length revealed significant main effects of laterality group, $F(1,18) = 12.89, MSE =$

39.65, $p < .01$, and word length, $F(2,36) = 39.13$, $MSE = 9.18$, $p < .01$, and no interaction ($F < 1$).

If we look at the slopes based on the word positions only (L1, L2, L3 for three-letter words; L1, L2, L3, L4, L5 for five-letter words; L1, L2, L3, L4, L5, L6, L7 for seven-letter words), we find a difference between the slopes of the laterality groups as well. Average slopes based on word position only were -1.7 for the three-letter words, 0.6 for the five-letter words, and 4.1 for the seven-letter words in the atypical group and 1.6 , 4.9 , and 11.0 in the typical language dominant group.

Figure 4 shows the correlation between the fTCD LI we obtained for each participant and their average OVP slope based on the three word lengths. The correlation is significant ($r = .55$, $n = 20$, $p < .02$), as could be expected from the previous ANOVA. However, a closer look at Figure 4 shows that the effect is mainly due to the difference between the two laterality groups and not to the differences within the laterality groups. In fact, when we recode the fTCD LI as -1 for the atypical group and 1 for the typical group, the correlation with the OVP slopes increases ($r = .65$, $n = 20$, $p < .01$).

Discussion

Figure 3 clearly shows that the OVP curves of the left-dominant participants differ from those of the right-dominant participants. Left-hemisphere-dominant participants have an overall stronger word beginning superiority effect than right-dominant participants. This replicates the findings of Brysbaert (1994) in a design that is not subject to the criticism that the relationship between the LIs and the left–right asymmetry in the OVP curve could be due to an asymmetrical attention allocation over the visual field.

A second notable finding is that the word beginning superiority is stronger for long words than for short

words, both in participants with typical dominance and in participants with atypical dominance. This too is in line with Brysbaert (1994) and indicates that cerebral dominance is not the only factor influencing the left–right asymmetry in the OVP curve. Other factors that are known to have an impact are the reading direction (left to right in the present experiment) and the fact that in general the word beginning is more informative than the word end (Brysbaert & Nazir, 2005; Rayner, 1998; Farid & Grainger, 1996; O'Regan & Jacobs, 1992). The impact of the reading direction and the information asymmetry in words is stronger for long words than for short words. Interestingly, a similar finding has been reported in the VHF literature. It is well documented that the RVF advantage is larger for long words than for short words (Ellis, Young, & Anderson, 1988). Whereas it is possible to find a LVF advantage for three-letter words (as shown in the top panel of Figure 3 for the atypical group), one never observes such an advantage for seven-letter words in a language that is read from left to right (see the bottom panel of Figure 3).

Finally, we noticed a few limitations of the study. For a start, Figure 4 suggests that the fTCD data were sufficient to determine whether an individual was left or right dominant, but they did not allow us to draw any conclusions about the degree of laterality. This might be a limitation of the fTCD technique or it might indicate that there is no continuous relationship between the OVP slope and the LI. Second, our decision to present three- and five-letter words at seven possible viewing positions limited the certainty with which we can conclude that interhemispheric transfer is required for short words (Figure 3). Although there is good evidence for a continuity between foveal and parafoveal word recognition (see also Brysbaert et al., 1996), the evidence for a difference in OVP curve between left- and right-dominant participants is less strong for the foveal part of the three- and the five-letter words. To address these limitations, we ran Experiment 2.

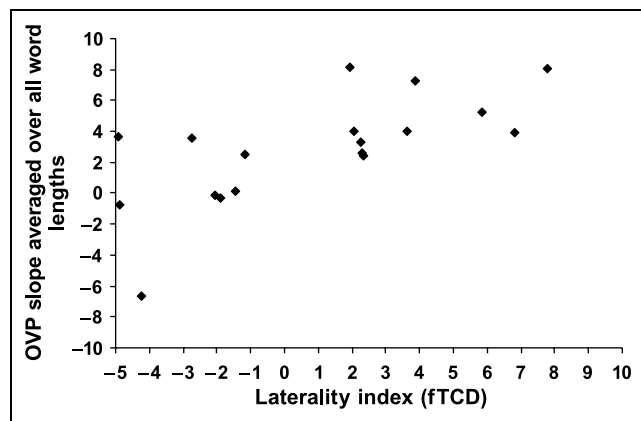

Figure 4. Scatter plot averaged over all word lengths (Experiment 1). fTCD-derived LIs are compared with the average slopes of the OVP curves.

EXPERIMENT 2

Given the positive findings of Experiment 1, which reveal a direct relationship between hemispheric dominance for language and OVP task performance on a group level, we decided that it was worthwhile to see whether we could repeat those findings on a single-subject level. Regarding the fact that fTCD is a rather crude measure of hemispheric dominance, we wanted to employ a technique that would be able to give us more detailed information on activation patterns in the brain during language tasks. An fMRI setup, in which the extent of brain activation during a language task can be compared between predefined regions of interest (ROIs), allows for a much more detailed investigation of dominance patterns. In addition, we wanted to

obtain more reliable estimates of the OVP curves at an individual level. In Experiment 1 we ensured that the OVP patterns were comparable at the group level; in the present experiment we made sure that the OVP pattern could be interpreted at the individual level and, therefore, could be used to look at the correlation between degree of laterality and degree of word-beginning superiority.

A second reason why we examined whether this type of research is possible at an individual level is that we wanted to see whether it can be done without the backup of a large-scale fTCD study involving more than 300 participants. The nice aspect of Experiment 1 was that we already knew beforehand whether a person was left or right dominant. Do we really need this type of large-scale screening or can we use a more focused (and less expensive) approach? To investigate this, we started from the observation of Knecht et al. (2000) that up to a quarter of the participants who scored high on a questionnaire for left-handedness turned out to have atypical brain dominance (either right dominant or bilateral). We invited left-handed students to take part in a study, which encompassed two VHF tasks for screening purpose, a word production task in an fMRI setting to determine language dominance, and, finally, an OVP task to investigate performance in foveal word naming. The VHF tasks involved the naming of short words and the repeated naming of five pictures presented in the LVF and RVF (Brysbaert, 1994). They were administered because we wanted to limit the brain scans to those participants who were interesting, showing either a clear lateralization or evidence for bilaterality. The VHF screening procedure allowed us to strategically search for and select promising candidates.²

Methods

Participants

All 10 participants (4 men, 6 women; mean age 19.8 years) were native English speakers. Only left-handed participants were tested (based on the Edinburgh Handedness Inventory). They were selected from an original sample of 26 left-handers who had taken part in two VHF experiments in which either words or a small set of pictures had to be named (Hunter & Brysbaert, 2007; Brysbaert, 1994). Six of the participants were chosen because they showed a strong RVF advantage in the VHF tasks (out of 15 showing this advantage), 2 because they showed no clear VHF difference (out of 7), and 2 because they showed a clear LVF advantage (out of 4³).

Procedure

All participants gave informed consent and subsequently took part in two lines of research that were approved

by the departmental ethics committee. All paradigms employed in this study have been well documented and validated elsewhere (Knecht et al., 2003; Brysbaert, 1994). The task to be performed in the scanner was practiced off-line prior to onset of the experimental trials.

First, we assessed the cerebral dominance of the participants. We used fMRI to scan our participants during performance of a mental word-generation task, which was very similar to the fTCD task used in Experiment 1 and is known to produce marked lateralization (Knecht et al., 2000, 2001, 2003). Subsequently, participants performed an OVP task (Brysbaert, 1994), which required them to name four- and seven-letter words that were presented briefly between two vertically aligned lines at different fixation locations.

Functional Magnetic Resonance Imaging

We used a mental word-generation task to assess hemispheric dominance in a Siemens (Germany) 3T Magnetom Trio scanner fitted with an eight-channel head array RF coil. Ten single letters with the highest beginning-of-word frequency were presented in randomized order in the activation blocks. Participants had to silently generate as many words as possible starting with the displayed letter. In a control phase the meaningless letter string “dada” was presented and had to be repeated continuously. Each activation and control block lasted 18 sec, followed by an 18-sec rest interval. The stimulus onset was synchronized with the scanner pulse for each activation block. Blood oxygen level dependent changes were measured using gradient-echo echo-planar T2*-weighted imaging sequences. Whole-brain volumes comprising 36 axial slices each were acquired every 3 sec (TE 32, flip angle 90°, resolution 3 × 3 × 3, matrix 64 × 64, slice thickness 3 mm, bandwidth 1346). In all, 243 scanning volumes were obtained for each participant. In addition, high-resolution anatomical images were acquired (TR 1830, TE 5.56, flip angle 11°, resolution 1 × 1 × 1, 256 × 256 image matrix, 160 sagittal slices).

Data Analysis

The data were analyzed with the SPM2 software package (available online, www.fil.ion.ucl.ac.uk/spm/). Images were realigned to the first functional volume to correct for motion artifacts and normalized into standard Talairach-type space using an EPI template. To reduce effects of random noise, normalized data were spatially smoothed using a Gaussian kernel (full width at half-maximum, 6 mm). In addition, a high-pass filter was applied to the time series with a cutoff period of 100 sec. For statistical analysis, the general linear model was used to map the hemodynamic response curve onto each experimental condition using boxcar regressors. The boxcar function was then fitted to the time series at each voxel, resulting

in a weighted β image. The fitted model was converted to a t statistic image that constitutes the statistical parametric map. Images for each individual were corrected for familywise error at $p = .05$. The minimum cluster size was set to 20 activated voxels.

LI Calculations

After preprocessing and statistical analysis of the scanning data, the degree of cerebral dominance was calculated for each participant regarding those voxels that were significantly more active in the activation than in the control phase. Levels of activation were compared between the left and right hemispheres in predefined anatomical ROIs, which encompassed regions in the inferior frontal cortex in both hemispheres, including BA 44 and BA 45 (Table 3). Each LI (fMRI_LI) was derived by the formula

$$LI = \frac{A_L - A_R}{A_L + A_R} \quad (3)$$

where A_L refers to the number of activated voxels in the left ROI and A_R to the number of activated voxels in the

right ROI. Seven participants showed a positive LI, three participants had a negative LI. Those individuals with $LI > 0.4$ were classed as left dominant (6), those with indices $-0.4 > LI < 0.4$ as bilateral (2), and individuals with $LI < -0.4$ as right dominant (2).

Behavioral OVP

The behavioral word-naming task was performed by the same individuals who took part in the scan. Participants viewed a monitor at a distance of ~ 60 cm and were asked to fixate a gap (fixation space) between two vertically aligned lines (visible throughout the experiment) in the center of the screen. Eighty-eight four- and 88 seven-letter words were presented in randomized order and stayed on screen for 180 msec each. The stimulus sample contained a mixture of English nouns, verbs, adjectives, and function words. These were selected from the Bristol Norms database (accessible online, language.psy.bris.ac.uk/bristol_norms.html) and were controlled for frequency, age of acquisition, familiarity, and imageability. Each word was shown four times, such that for the four-letter words each letter of each word was presented in the fixation space once (L1, L2, L3, L4). The seven-letter words were shown four

times each, at four different fixation locations (L1, L3, L5, L7), each of which was presented in the fixation space once. In this way, each participant formed a self-contained $n = 1$ experiment, because their OVP pattern was independent of the words used. This was done to decrease the noise in the individual data points (which reduces the correlation that can be obtained between the OVP slopes and the LIs). The four-letter words were fixated in each possible letter position to have a more detailed picture of the OVP pattern for short words. In all, participants named 704 words. In addition, digits in the range from 0 to 9 were presented in the fixation space at a word/digit ratio of 5.9:1 at randomized time intervals. The digits were on screen for 80 msec only and had to be named correctly. Responses were collected by means of a voice trigger, where the onset of speech was registered as reaction time for a specific stimulus. Words and digits were masked with a sequence of ASCII codes 35 (#) that had the same length as the preceding stimulus.

Results

As before, timing (>1500 msec) and naming errors were eliminated from the OVP data set (mean error rate, 1.5%) preceding the analysis. To analyze the OVP data, mean RTs for each letter position were calculated, resulting in an OVP curve for each individual. RTs were standardized and mean OVP curves were calculated for the four strongest left-dominant individuals and the two strongest right-dominant individuals, to get an idea of

the difference between left- and right-lateralized individuals, which is shown in Figures 5 and 6 (95% CI = 4.49 for four-letter words and 16.71 for seven-letter words, based on the *MSE* of the interaction effect; Masson & Loftus, 2003). It is clear that these data match those of Experiment 1. There was a stronger word-beginning superiority effect in left-dominant participants than in right-dominant participants, and there was a bigger time cost for fixating the end of a seven-letter word than for fixating the end of a four-letter word. The raw data are given in Table 4.

A three-way ANOVA in a $2 \times 2 \times 4$ mixed design including laterality group (2 levels, between subjects), word length (2 levels, within subjects), and viewing position (4 levels, within subjects) demonstrated a main effect of viewing position, $F(3,12) = 9.153$, $p < .01$, and an interaction between laterality group and viewing position, $F(3,12) = 6.306$, $p < .01$, as well as an interaction between word length and viewing position, $F(3,12) = 5.268$, $p = .015$.

To assess the statistical significance of the findings, the linear components of the OVP curves were calculated from the data set in accordance with Formula 2. Slopes of the linear component were in the range from -2.7 to 10.3 for the four-letter words and from 0.9 to 33.8 for the seven-letter words (Table 3). The slopes of the four- and the seven-letter words showed a significant positive correlation ($r = 0.67$, $p < .05$).

Next, a Pearson correlation was calculated between the OVP slopes and the LIs from the fMRI study. This revealed a highly significant positive correlation for the four-letter words, $r = .85$, $p < .01$, $t(8) = 4.562$, and

Figure 5. Language lateralization in two distinct groups. (A) Mean image in ROI for the four individuals with strongest left-hemisphere dominance (coronal, sagittal, and axial slices at MNI coordinates: $x = -51$, $y = 15$, $z = 22$). (B) Mean image in ROI for the two individuals with strongest right-hemisphere dominance (coronal, sagittal, and axial slices at MNI coordinates: $x = 53$, $y = 17$, $z = 21$).

Figure 6. OVP curves for four- and seven-letter words for the OVP task in Experiment 2. Typical: Mean OVP curves for the four individuals with strongest left-hemisphere dominance, showing a typical OVP effect with the fastest RT on fixating the second letter for both four- and seven-letter words. Atypical: Mean OVP curves for the two individuals with strongest right-hemisphere dominance, depicting an atypical OVP effect with RTs decreasing toward the fourth letter for four-letter words and toward the third letter for seven-letter words. Intervals indicate the standard errors of the means, based on the *MSE* of the interaction between laterality group and viewing position.

a significant positive correlation for the seven-letter words, $r = .70$, $p < .025$, $t(8) = 2.773$ (Figure 7). The lower correlation for the seven-letter words than for the four-letter words was due to the results of one left-dominant participant, who had a lower slope for the seven-letter words than expected on the basis of the four-letter words and on the basis of the fMRI LI (participant Sub_10 in Table 3).

Discussion

The data of Experiment 2 show that for words as short as four letters, there is a strong relationship between the OVP curve and the participant's cerebral dominance on an individual level. Left-dominant participants were 20 msec faster to name a four-letter word when the word was presented in such a way that they were fixating the first letter, as opposed to when the word was presented in such a way that they were fixating the last letter. In contrast, the two participants with right-hemisphere dominance were some 10 msec faster to name the same words after fixation of the last letter than after fixation of the first letter. As in Experiment 1, the word-beginning superiority effect could not be reversed for the seven-letter words, but it was substantially smaller for the participants with right-hemisphere dominance than for the participants with left-hemisphere dominance. The participants with bilateral representation were in-between these two groups, so that across all participants there was a very high correlation between the left-right asymmetry of the OVP pattern and the LI calculated upon the fMRI data. In particular, for the four-letter words the correlation reached ceiling level ($r = .85$). This means that the issue of inter-hemispheric transfer in reading can be examined with

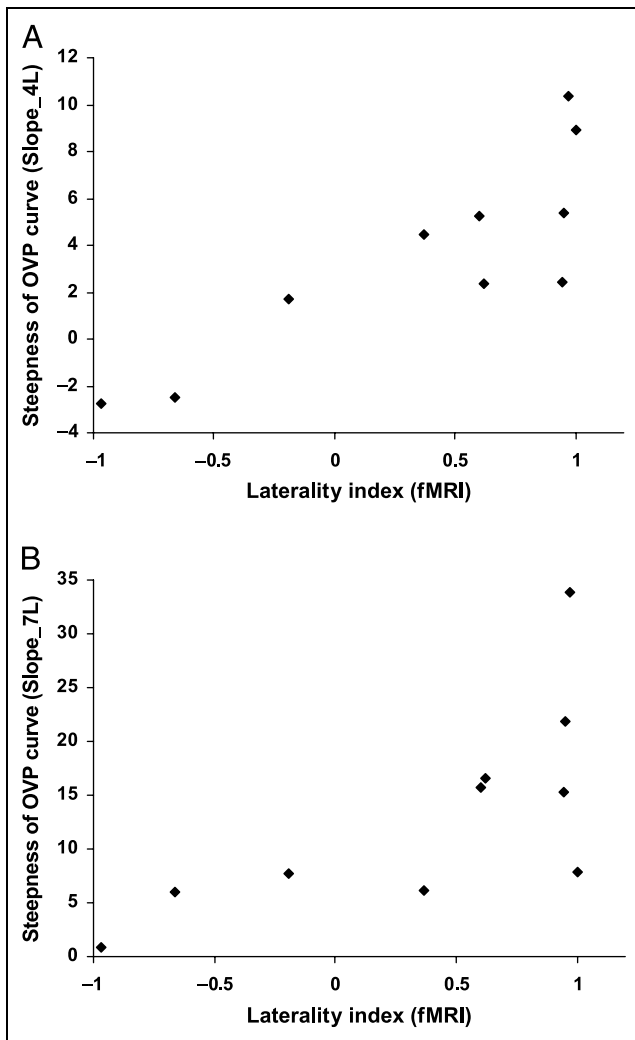

Figure 7. Scatter plots (Experiment 2). Laterality indices calculated upon fMRI data are compared with the slopes of the OVP curves resulting in significant positive correlations for four-letter words ($r = .85$) (A) and for seven-letter words ($r = .70$) (B).

a psychophysical approach, in which a limited number of participants are tested thoroughly.

GENERAL DISCUSSION

On the whole, researchers in the last decades have assumed that the distinction between LVF and RVF does not have any implications for the processing of foveally presented stimuli (Brysaert, 2004). They first pointed to the evidence that the fovea might project bilaterally and, when this evidence could no longer be upheld, to the possibility that interhemispheric communication might be too fast and extensive to put any functional limitation on foveal processing. Given recent advances in noninvasive techniques to assess brain laterality, we can now move beyond the stage of assumption making and empirically test whether cerebral laterality has an impact on the way visually presented stimuli are processed.

Our data are exceptionally clear: As far as the naming of printed words is concerned, there is a significant time cost when part of the word is initially sent to the subdominant hemisphere. This means that for the majority of people (with left-hemisphere language dominance) there is an advantage for fixating the left half of the words (i.e., the beginning of the words in a language read from left to right). These individuals show a clear word-beginning superiority effect in word naming. For a minority of the people (i.e., those with right-hemisphere language dominance), fixating the left half of the word initially sends the word to the subdominant cerebral hemisphere and they show either an advantage for fixating the right half of the word (for short words) or no advantage at all (longer words). The processing costs of interhemispheric communication are in the order of 20 msec for four-letter words (Figure 6), which is not small when compared to the other effects that have been reported in visual word recognition. In addition, a delay in the magnitude of 15–30 msec accords well with electrophysiological transcallosal conduction plus synaptic transmission delays reported in the literature (Cracco, Amassian, Maccabee, & Cracco, 1989).

Our data are particularly strong because we are able to predict the OVP slope for the processing of visually presented four-letter words on the basis of brain activation patterns in a mental word-generation task. Only a few theories would have predicted this (see below). On the other hand, we deliberately have been very selective about the task we used for the OVP experiment. Participants had to name the words aloud, because we saw this as the type of task that comes closest to what happens in the mental word-generation task during brain imaging, although we hasten to say that not all processes involved in word naming take place in the ROI used (e.g., Dronkers, 1996).

Further research will have to elucidate to what extent lateralization of speech is accompanied by the lateralization of the earlier stages of word processing (e.g., the visual word form area). There are some indications that the lateralization of processes that are involved in lexical decision (deciding whether a string of letters is a word or not) may not be completely congruent with the lateralization of the speech output processes. For instance, Krach, Chen, and Hartje (2006) determined language lateralization using fTCD during a word-generation task and correlated the LI with the VHF asymmetry in a lexical decision task. They did not find a particularly strong correlation, although in our view this also had to do with the small number of trials in their tasks. Another study was run by Lehericy et al. (2000). They compared the LI based on the Wada test with fMRI data in a semantic fluency task (involving the frontal lobes) and story listening (mainly involving temporal regions). The correlation was much stronger in the former task than in the latter. On the other hand, a study by Vigneau, Jobard, Mazoyer, and Tzourio-Mazoyer (2005) suggested

a leftward lateralization for the processing of visually presented words (but not for nonwords) as early as the visual word form area in the occipital-temporal region. Further comparisons of individuals with left and right language dominance will be needed to shed light on this issue. In the meantime, we do not think that it can be assumed that all language processes are lateralized to the same extent within the same hemisphere. Researchers are advised to bear this in mind when designing tasks for language dominance studies.

So far, two computational models have been presented about how the processing costs related to inter-hemispheric communication can be integrated within theories of visual word recognition. In the first model, SERIOL (Whitney, 2001), interhemispheric transfer is part of the processes that translate the visual input into letter representations. Whitney (2001) argues that visual word processing depends on a serial activation of the letter representations from the word beginning to the word end. To achieve this serial firing, two limitations regarding the original input must be overcome: inter-hemispheric transfer and the fact that information at the center of fixation has a higher visual acuity than information further away from the fixation location. In languages read from left to right, these two constraints have particular relevance for the part of the word that falls into the LVF (i.e., the first few letters of the word). Not only does the visual acuity gradient stand in opposition to the serial processing requirement, but this information is also sent to the right half of the brain, which for the majority of people is the subdominant hemisphere. Whitney showed that her model could account for the differences in the OVP curves reported by Brysbaert (1994) by assuming a higher inversion cost of the acuity gradient in the subdominant hemisphere, combined with an interhemispheric transfer cost of 9 msec (see also Whitney, 2004; Whitney & Lavidor, 2004, 2005).

Another approach was taken by Shillcock, Ellison, and Monaghan (2000). These authors started out from the problem of how the brain keeps track of the letter positions in a word (e.g., to distinguish SALT from SLAT). Their solution was that the fixation location provides the brain with an extra anchor regarding the letter positions (in addition to the word beginning and the word end). They also ventured that each hemisphere rather independently activates word candidates that agree with the input it receives and integrates this information with that of the other hemisphere only at a relatively late stage. Finally, they assumed that the encoding is coarser in the subdominant hemisphere than in the dominant hemisphere. On the basis of these assumptions, Shillcock et al. were able to simulate the OVP curves. More importantly, in this model, interhemispheric communication does not take place before the word processing “as such” starts (as in the SERIOL model) but is part of the processing itself. Further research (e.g., on the basis of an item analysis of the

stimuli presented here) will have to decide which of the two models best captures the data of the participants with right-hemisphere dominance and bilateral language representation.

Conclusion

The high positive correlation between LIIs based on blood flow measures and the left–right asymmetry in visual word recognition points to a direct relationship between hemispheric dominance and word processing in foveal vision, such that it is now firmly established that interhemispheric communication is needed for normal word reading. Our results therefore stand in opposition to the assumption of Dehaene et al. (2005) that the functional consequences of interhemispheric transfer are minimal, and demonstrate that hemispheric dominance does have a strong functional impact and consequently affects word reading.

Our findings have far-reaching implications for models of visual word processing. Theoretical modeling approaches, which attempt to integrate interhemispheric transfer into models of visual word recognition (McDonald, Carpenter, & Shillcock, 2005; Whitney, 2001; Shillcock et al., 2000), are now backed up with clear experimental data that prove them to be the most neurologically plausible models.

Notes

1. The same results were obtained when the analyses were done on the difference scores between fixations on the last and on the first letter. We prefer the polynomial, because this takes into account all the data that have been gathered and, therefore, is less vulnerable to measurement error.
2. Given that the study involved the screening of participants on the basis of VHF tasks, it could be objected that the same validity threat as in Brysbaert (1994) applies. However, because of the clear data of Experiment 1 and because we did not obtain a contradiction between the laterality index obtained on the basis of the VHF experiments and the laterality index obtained on the basis of the fMRI study for any of the participants we examined (Hunter & Brysbaert, 2007), we feel confident that the results reported below are not a confound of differences in attention allocation across the visual field.
3. The third and fourth participants with strong LVF advantage could unfortunately not be scanned for the fMRI part of the study.
