**Keywords:** microbial electrosynthesis; stainless steel felt; formate

Microbial electrosynthesis is an electricity driven process to produce organic compounds from CO<sub>2</sub> and precursor organics using microorganisms as catalysts. The key example is acetate production from CO<sub>2</sub>, typically at a carbon cathode using immobilized bacteria on the cathode. However, a key question remaining is whether this attachment of cells is necessary to achieve effective bioproduction. Stainless steel and carbon cathodes were compared at a fixed current density using *Acetobacterium woodii* as a biocatalyst. Acetate production rates of  $536 \pm 226 \text{ mg m}^{-2} \text{ h}^{-1}$  for a steel cathode and  $340 \pm 131 \text{ mg m}^{-2} \text{ h}^{-1}$  for a carbon cathode were achieved. Operation at a fixed current density greatly increased production rates per unit projected surface at similar energy investment per gram of product as compared to previously reported studies at set potentials. Whereas further improvements are needed to make this process competitive with existing approaches, these results show that *in situ* hydrogen production with steel has the potential to rapidly transfer electrons to planktonic cells.
