ABSTRACT: Dense prehydrated geosynthetic clay liners (DPH-GCLs) are a particular type of GCL which, unlike conventional GCLs manufactured with dry bentonite, contain bentonite prehydrated during manufacturing. DPH-GCLs are produced by a patented process that includes bentonite prehydration with a polymer solution and vacuum extrusion. This paper describes the results of permeability tests that were carried out using flexible-wall permeameters to investigate the hydraulic conductivity of a DPH GCL to water, natural seawater and a 12.5 mmol/l CaCl₂ solution. Moreover, the efficiency of the 0.1 m overlap seams between DPH-GCL panels has been investigated by means of a medium-scale permeameter able to accommodate specimens 0.305 m in diameter. Test results showed that the DPH GCL has very low hydraulic conductivity to water (10^{-12} – 10^{-11} m/s) and preserve low permeability, of the order of 10^{-11} m/s, in the presence of relatively high calcium concentration in the permeating liquid. However, the efficiency of overlap seams can be affected by the permeant type. In the presence of permeant liquids that inhibit swelling (e.g. seawater), the hydraulic efficiency of the seams needs to be improved by adding bentonite paste at the overlap interface. The hydraulic performance of the DPH-GCL is attributed to the combination of prehydration, densification and chemical amendment.

1. INTRODUCTION

Geosynthetic clay liners (GCLs) are prefabricated hydraulic barriers consisting of a thin layer of unhydrated bentonite (~ 5–15 mm) sandwiched between two geotextiles or glued to a polymeric geomembrane. In the last 20 years GCLs have gained wide acceptance in various applications, including bottom liners and cover systems of landfills (Giroud *et al.* 1997; Li *et al.* 2002; Cazzuffi and Crippa 2004; Benson *et al.* 2007; Heerten and Koerner 2008; Scalia and Benson 2011). GCLs offer several advantages over traditional compacted clay liners including cost-effectiveness, ease of installation, limited thickness, low permeability to water (Bouazza 2002) as well as self-healing capacity (Mazzieri and Pasqualini 2000; Babu *et al.* 2001; Egloffstein 2001; Sari and Chai 2013). GCLs have also found applications in structural waterproofing (Reither and Eichenauer 2002), in

linings of artificial ponds and canals (Fleischer and Heibaum 2008) and, more recently, in containment of residues and process liquors from mining applications (Gates *et al.* 2009; Benson *et al.* 2010; Bouazza 2010; Hornsey *et al.* 2010; Shackelford *et al.* 2010).

The hydraulic efficiency of a barrier system comprised of a GCL as a single liner depends on the low hydraulic conductivity, k , attained by the sodium montmorillonite (the main mineral component of bentonite) when permeated with water. Under effective stresses of 10–20 kPa, k is of the order of 10^{-11} m/s (Estornell and Daniel 1992; Petrov *et al.* 1997; Mazzieri and Pasqualini 2000; Shackelford *et al.* 2000; Jo *et al.* 2001; Bouazza 2002; Kolstad *et al.* 2004a; Lange *et al.* 2007; Meer and Benson 2007).

The low permeability of Na-montmorillonite is associated with ‘osmotic swelling’, namely the macroscopic expansion of the clay volume as a result of water absorption upon

hydration (McBride 1994). Most of the water retained by the clay is bound, leaving little pore space available for hydraulic flow and resulting in low k (Jo *et al.* 2001). In the presence of inorganic electrolyte solutions, osmotic swelling is hindered by high electrolyte concentrations of monovalent cations (>100 mmol/l) or by moderate concentrations of polyvalent cations (>25 mmol/l), resulting in increased permeability. In the case of multiple cationic species in solution, the hydraulic conductivity depends both upon the ionic strength of the solution and upon the relative abundance of monovalent and divalent cations (Kolstad *et al.* 2004a). Organic permeants with low dielectric constants can also cause drastic increases in k of GCLs (Petrov *et al.* 1997; Mazzieri *et al.* 2000).

It is widely recognised that prehydration of GCLs with pure water (e.g. deionised or distilled water) or a dilute aqueous solution (e.g. tap water) determines a lower k than the k of non-prehydrated GCLs in direct contact with a given potentially aggressive solution ('first exposure' effect) (Mazzieri *et al.* 2000; Shackelford *et al.* 2000; Bouazza 2002; Malusis and McKeehan 2013). However, considering operational conditions in the field, prehydration with unpolluted water cannot always be ensured. One possible means to ensure acceptable performances is to utilise GCLs containing amended or polymer-modified bentonites capable of swelling even in the presence of high electrolyte concentrations (Onikata *et al.* 1996; Lo *et al.* 1997; McRory and Ashmawy 2005; Di Emidio 2010; Scalia *et al.* 2011). Another option is to use special GCLs products, known as dense prehydrated GCLs (DPH-GCLs), that are prehydrated during manufacturing through a patented process.

DPH-GCLs were introduced in the 1990s by a British company (Rawell Co., UK) and are currently on the market. The patent registered in the USA is available online (Flynn and Carter 1998). The principle of these products is to confer during manufacturing the benefits of prehydration, chemical amendment and densification to the k of bentonite. Relatively few studies are available in the literature regarding the characteristics and performance of these materials.

This paper presents the results of a research programme carried out jointly at Technical University of Marche (Italy) and at Laboratory of Soil Mechanics of Ghent University (Belgium). In particular, the aim of the study was to illustrate the permeability of a DPH GCL product to water, natural seawater and a 12.5 mmol/l CaCl_2 solution, and to compare the results with those obtained on conventional GCL, when available. A crucial aspect for the overall efficiency of any GCLs barrier is the efficiency of seams between adjacent panels. Therefore, some of the factors that may impact the efficiency of seams of DPH-GCLs such as the confining pressure and the nature of the permeant liquid have been investigated. The practical implications of the experimental findings are discussed.

2. DENSE PREHYDRATED GCLs

The reported information regarding the manufacturing process of the DPH-GCL was drawn from the patent

(Flynn and Carter 1998). Dry bentonite clay is first mixed with a solution of water and additives in a high-speed, high-shear mixer. The exact composition of the hydrating solution of the DPH-GCL bentonite is undisclosed, since the patent only reports a range of possible dosages of the different additives. Therefore, it is possible that different production lots have slightly different compositions. The hydrated bentonite is extruded under vacuum into a bentonite sheet about 5.0 mm thick. The production process induces a densification of the bentonite hydrated core, analogous to the effect of mechanical consolidation (average void ratio $e = 1.5$), and a nearly parallel alignment of montmorillonite platelets in the sheet plane (Figure 1), which contributes to the particularly low k in the direction normal to the sheet (Egloffstein 1995). Carrier and cover geotextiles are then united to the bentonite and a roll is formed. To prevent dehydration, each roll is wrapped in airtight stretch film.

It is understood from the manufacturer technical information that various DPH GCL products are available, which differ mainly in the geotextile type and mass per unit area whereas the processing of the bentonite core is essentially the same. The different products have different fields of application (structural waterproofing, landscaping, environmental, etc.) and also have different technical specifications (e.g. seaming procedure and overlap width). The seaming procedures of the particular DPH-GCL product used in the study are detailed in the following sections. The readers are warned to consult the technical specifications of each particular product.

Previous studies have reported that DPH-GCLs contain the polymer sodium carboxymethyl cellulose (Na-CMC) and methanol (Kolstad *et al.* 2004b; Katsumi *et al.* 2008). These substances have fungicidal and preserving action; moreover, they make the bentonite flexible such that the thin hydrated bentonite sheets can be bent to form rolls (Figure 1) without fissuring (Schroeder *et al.* 2001). Studies of montmorillonite-Na-CMC mixtures by X-ray diffraction (XRD) and Fourier transform infrared spectroscopy (FTIR) have shown that Na-CMC macromolecules intercalate in the interlayers of montmorillonite, as indicated by the increase of the basal distance, d_{001} (Mitchell 1993) of the crystal from 1.25 to 1.47 nm (Qiu and Yu 2008),

A recent study on the effect of amendment with Na-CMC on the characteristics of a sodium bentonite has shown an increase in the swelling capacity and a reduction of the k of treated bentonite clay (known as HYPER clay) in comparison with the untreated bentonite in the presence of various permeant solutions (Di Emidio 2010). The reduction in k can be ascribed to the intercalation of strongly hydrophilic Na-CMC molecules, which increase the water adsorption and retention capacity of the clay (McBride 1994).

Possible components of the hydrating solution mentioned in the patent are sodium hexametaphosphate and sodium polyacrylate. Hexametaphosphate and polyphosphate anions are known to impart a dispersing action on clay suspensions by preferentially absorbing to the exposed aluminium cations at the edge of clay platelets,

Figure 1. Manufacturing of DPH-GCLs (modified after Flynn and Carter (1998))

preventing edge-to-face aggregations. Polyacrylate polymers possess water-absorbency properties that are similar to those of Na-CMC (Qiu and Yu 2008) and are utilised in other polymer-amended clays (Scalia *et al.* 2011). Coating of the solid surfaces with Na-CMC or polyacrylates may prevent conversion of treated bentonite into calcium or other multivalent cations form (Flynn and Carter 1998). Moreover, excess dispersant anions may bind to cations in the pore water, thus reducing or retarding the interaction with the charged surface (e.g. cation exchange). It is well known that the latter process can affect the overall performance of the bentonite as a hydraulic barrier (e.g. Lin and Benson 2000; Mazzieri and Pasqualini 2000). In this regard, addition of salts and polymers in their sodium form probably contributes to enrichment in sodium of the clay exchange complex.

A few studies in the literature have investigated the permeability of materials identified as ‘factory-prehydrated’ or ‘dense prehydrated’ GCLs. In the first study (Schroeder *et al.* 2001), permeability tests were performed in a rigid-wall apparatus, using various permeant liquids (standard water, CaCO₃-saturated water, seawater, landfill leachate) under different vertical effective confining stress (σ'_v). The measured k values were always lower than 5.0×10^{-11} m/s, even under the lowest confining stress adopted in the study ($\sigma'_v = 3.8$ kPa). Moreover, specimens simulating actual overlap seams (with and without the addition of supplemental bentonite paste in the overlap) were permeated with standard water (made of 25% distilled water and 75% CaCO₃-saturated water). Schroeder *et al.* (2001) did not report the overlap width they tested but stated that standard conditions recommended

for joints were adopted. They also reported that the permeability of overlap specimens (with and without bentonite paste) was practically the same as that of single-layers specimens.

Kolstad *et al.* (2004b) reported the k of a DPH-GCL permeated with deionised water (DI), and with aqueous solutions containing 1 mol/l NaCl, 1 mol/l CaCl₂, HCl (pH = 1.2) and NaOH (pH = 13). The tests were conducted in flexible-wall permeameters at an average isotropic effective stress, $\sigma'_i = 20$ kPa. The measured k values were always lower than 1.0×10^{-11} m/s, except for the HCl solution for which k was equal to 1.6×10^{-10} m/s.

Katsumi *et al.* (2008) conducted permeability tests for up to 5 years using flexible-wall permeameters ($\sigma'_i = 25$ kPa) to investigate the performance of a DPH-GCL and found $k < 5.0 \times 10^{-12}$ m/s for electrolyte solutions with concentrations of up to 1 mol/l CaCl₂. Mazzieri *et al.* (2013) permeated a DPH-GCL in two stages: the first was carried out with distilled water (DW), the second was carried out with a synthetic solution having pH = 2.0 and containing Cu²⁺, Zn²⁺ and Pb²⁺, each at concentrations equal to 25 mmol/l. The k to DW was 3.7×10^{-12} m/s and increased to 1.3×10^{-11} m/s upon permeation with the synthetic solution. In short, the available experimental data, based on laboratory studies, indicate that DPH-GCL products may be able to maintain very low permeability in the short-term, even in the presence of permeant solutions that have been proven to increase the permeability of conventional GCLs.

One of the most critical issues related to field performance of conventional GCLs is desiccation, which has been shown to impair the hydraulic performance if combined with cation exchange (Lin and Benson 2000; Meer and

Benson 2007). The manufacturer claim that DPH-GCLs will not desiccate in the field as they are highly hydrophilic and that once in the ground they will suck up moisture from the surrounding soil or concrete. The issue of desiccation of the same DPH-GCL product used in the present study was addressed in two laboratory studies. In the first (Mazzieri and Pasqualini 2008) dry–wet cycles were simulated by repeatedly drying the DPH-GCL in an oven at 35°C and rehydrating the DPH-GCL using DW or a calcium solution (12.5 mmol/l CaCl₂). Dry–wet cycles using DW had little or no effect on the *k* of the DPH-GCL product. Combination of desiccation and permeation with the calcium solution eventually resulted in a drastic increase in *k*. The increase was ascribed to the presence of desiccation cracks that did not heal upon rehydration. However, the simulated drying conditions were very severe (water content, *w*, equal to 5–10% in the dry stages) and probably unlikely to occur in the field. In the second study (Mazzieri *et al.* 2009) dry–wet cycles with milder desiccation states (*w* ranging from 85 to 35% in the dry stages) were simulated with a 12.5 mmol/l CaCl₂ solution being used as permeant liquid. The *k* of the DPH-GCL remained relatively low ($\leq 2.0 \times 10^{-11}$ m/s) for *w* \geq 45%. For *w* = 35% the *k* increased irreversibly. Unhealed cracks were responsible for the increase in *k*. From a practical point of view, the test results indicated that the response of the DPH-GCL product to dry–wet cycles depends upon the permeant liquid and the extent of desiccation. Therefore, more focus is necessary in order to assess the extent of desiccation that DPH-GCL products may encounter in typical applications. At present, the writers are not aware of any published study that addresses the DPH-GCLs long-term field behaviour, in which samples from actual installations were examined. Several cases of application, including a landfill base liner, are listed in the manufacturer's website. According to the manufacturer, no leaks have been reported.

3. MATERIALS AND METHODS

3.1. GCLs

The DPH-GCL product used in this study is recommended by the manufacturer primarily for waterproofing of structures where an oversite blinding has been specified. The

product has a high-strength woven polypropylene cover geotextile (average mass per unit area 119 g/m²) and a perforated polyester scrim carrier geotextile (average mass per unit area 17 g/m²), which presents large voids (about 1 mm in diameter), through which prehydrated bentonite can be seen. The geotextiles are united to the bentonite by simply pressing them against the bentonite (no glue or reinforcement connecting the geotextiles is present). Therefore, although no direct assessment was carried out in this study, the internal shear strength of this product is expected to be low. In the as-manufactured state, bentonite is sufficiently hard to resist extrusion through the voids of the geotextile, even if walked on by workers during installation.

The standard rolls of the product used in this study are 1 m \times 5 m in size, but larger sizes are possible. The manufacturer's specifications state that the rolls are wrapped in airtight stretch films and packaged into boxes containing 20 rolls each. The boxes are sealed with polyethylene covers for weatherproofing. The manufacturer's specifications suggest that the surface onto which the product is to be laid should be smooth concrete, free from abrupt irregularities with all lumps removed and voids filled with mortar or bentonite paste. The product should be laid with the nonwoven perforated scrim geotextile in contact with the blinding concrete and with the woven geotextile uppermost. The manufacturer recommends placing a 50 mm concrete blinding to protect the GCL from the steel fixers and inclement weather.

In Table 1 the main physical and chemical properties of the DPH-GCL product used in this study are listed together with the properties of a conventional needle-punched GCL (C-GCL) used for some comparative testing. The swell index of the DPH-GCL is less than the C-GCL. However, the traditional swell index test (ASTM D5890) does not fully reflect the swelling behaviour of DPH-GCLs; firstly, because the clay must be oven dried before testing, secondly, because the presence of polymers may interfere with the settling of the clay and thus affect the test results (Di Emidio 2010). The swelling test cylinders were left standing longer than specified in the test methods (24 h); however, no significant increase in the free swell of the DPH-GCL was observed.

In Figure 2 the diffraction spectra of the air-dried powdered clays from the two GCLs are shown. The basal

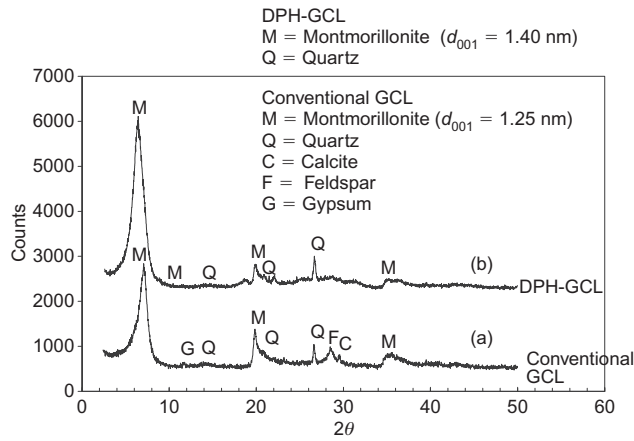

Figure 2. XRD spectra of air-dried powdered bentonites: (a) C-GCL; (b) DPH-GCL

distance of montmorillonite crystals of C-GCL was 1.25 nm, typical of sodium montmorillonite. The basal distance of DPH-GCL bentonite was $d_{001} = 1.40$ nm. The increase in the basal distance of montmorillonite can be ascribed to the intercalation of polymer molecules in the interlayer (Qiu and Yu 2008).

As recommended in the technical specification sheets of the DPH-GCL product used in this study, the seams are obtained by overlapping the edges of the adjacent panels for at least 0.10 m. The overlap zone is marked by a red line printed on the woven geotextile, which must be installed facing upwards. According to technical specification, the openings in the perforated scrim allow the bentonite to swell out upon wetting and to seal the interface.

The suggested minimum overlap width of this product (0.10 m) is less than the range commonly recommended for conventional GCLs (0.15–0.3 m). The motivation probably resides in the type of application recommended for this product: in waterproofing of structures large deformation of the subgrade that may cause panel separation are not expected (as opposed, for example, to landfill covers). Moreover, GCLs installed under structures are less exposed to dry–wet cycles, which may cause shrinking (Thiel *et al.* 2006; Rowe *et al.* 2010) and separation of conventional GCLs panels (Koerner and Koerner 2005a, 2005b; Thiel and Richardson 2005). To improve the sealing of seams or to seal pipe penetrations, the manufacturer recommends a bentonite paste (mastic) with composition similar to the bulk DPH-GCL but with a higher water content (144%), which enables spreading of the paste on the overlap edges and around pipe penetrations. The manufacturer states that for applications where an immediate seal against hydrocarbons, contaminants or gases is required, a liberal application of bentonite mastic

must be made to the woven geotextile prior to lapping. Thus, the need for bentonite paste must be assessed on a case-by-case basis depending on the permeant fluid to be contained.

3.2. Permeability tests

Permeability tests on single-layer GCL (i.e. no overlap) were carried out in flexible-wall permeameters accommodating 0.10 m diameter specimens, in general agreement with ASTM D5084 (except for the limitations on the applied hydraulic gradient, which was usually higher than recommended in the test method). A constant average isotropic effective stress (σ'_i) was maintained during the test. Tests were performed at different stress levels (14, 27 and 275 kPa). The permeant liquids used were DW, natural seawater (NSW) and a 12.5 mmol/l CaCl_2 solution. The chemical composition of the NSW used in this study is described in Table 2.

Permeability tests on the overlaps were carried out in a medium-scale flexible-wall permeameter able to accommodate circular specimens 0.305 m in diameter and to conduct two separate tests simultaneously, although subjected to the same cell pressure (Figure 3a). The DPH-GCL seams were simulated by overlapping two specimens 0.305 m in diameter, shaped as circular segments (Figure 3b). The resulting overlap section was 0.1 m in width and shaped as a double-based circular segment, whereas an actual overlap section is of rectangular shape. To have a uniform thickness of the testing layout and to allow hydraulic flow, the removed portions of the DPH GCL were replaced by nonwoven geotextile layers (Figure 3a). The geotextiles were wetted prior to the test assembly to promote saturation.

Four permeability tests (two pairs) on the overlaps were performed. Tests were conducted in pairs, as the medium-scale permeameter allows conducting two tests simultaneously and using different permeant liquids, if desired. The first test pair was conducted without bentonite paste on the overlap, using DW and NSW as permeant liquids, respectively. To examine the effect of the confining stress on the seam efficiency, the isotropic effective stress σ'_i was applied in four stages of 14, 28, 55 and 110 kPa, respectively. The minimum applied effective stress (14 kPa) was selected to simulate conditions where the GCL is placed under relatively thin cover layers (soil or concrete), whereas the maximum applied effective stress (110 kPa) depends on the allowable cell pressure of the medium-scale apparatus.

The second test pair was conducted to investigate the effect of bentonite paste on the overlap. In the absence of precise specifications, a 1 mm thick layer was applied on each side of the overlaps, 1 mm being considered to be the minimum layer of bentonite paste that could be applied

uniformly on the overlap. The bentonite paste was spread with a spatula and the obtained thickness was measured by a caliper. The average σ'_i was equal to 14 kPa throughout the test; the permeant liquids used were DW and NSW, respectively.

4. RESULTS AND DISCUSSION

4.1. Permeability to water

Figure 4 illustrates the trend of k versus time of DPH-GCLs specimens permeated with DW under different σ'_i (14, 27 and 275 kPa). All tests were permeated for a longer time than required to meet the termination criteria as per ASTM D5084. As expected, the value of k decreased with increasing σ'_i . In particular, the k values were consistently lower than 10^{-11} m/s . The graph of k plotted against time of a C-GCL specimen permeated at average σ'_i equal to 27 kPa is also displayed in Figure 4 for comparison. For the given effective stress, the k of the C-GCL ($1.5 \times 10^{-11} \text{ m/s}$) was about four times higher than the DPH-GCL ($3.7 \times 10^{-12} \text{ m/s}$). The lower permeability to water of the DPH-GCL relative to the C-GCL results from a combination of factors: the densification of bentonite through the vacuum extrusion process, the presence of additives and polymers as well as the higher mass of bentonite per unit area (Table 1).

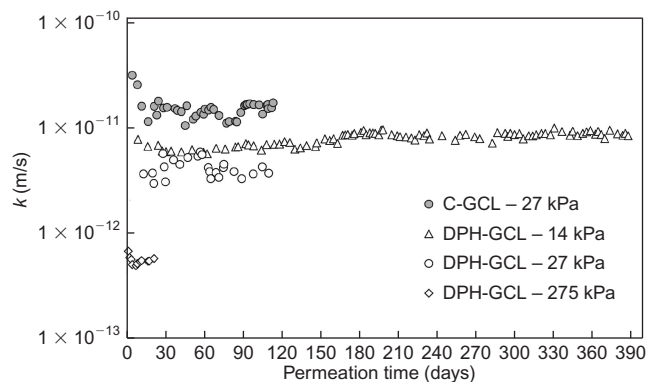

Figure 4. Hydraulic conductivity of the DPH-GCL and of the C-GCL permeated with DW under different confining effective stress

The test conducted at the lower effective stress, which displayed the highest k ($\sim 8 \times 10^{-12} \text{ m/s}$) and allowed a sufficient amount of fluid to be collected, was continued up to about 400 days to characterise the effluent liquid. Samples were regularly collected over time and analysed for electrical conductivity (EC), pH and major dissolved cations (Na^+ , Ca^{2+}) and anions (Cl^- , SO_4^{2-}). The trends of measured EC and of the concentrations of major dissolved ions in the effluent liquid are illustrated in Figure 5. The measured data have been plotted against the number of pore volumes of flow. Sodium (Na^+) was the most abundant cation in the effluent liquid, as indicated also by the similarity of the plots representing EC and sodium concentration. Significant concentrations of chloride (Cl^-) and sulfate (SO_4^{2-}) were measured. However, the sum of equivalent concentration of chloride and sulfate did not balance the cation equivalent concentration. To preserve the electroneutrality of the effluent solution, additional anions must have been present, most probably phosphate, added as phosphate salts in the prehydration solution. Although total phosphate was not measured during this specific test, significant concentrations (up to 600 mg/l) were detected in the effluent liquids of other permeability tests performed with the same DPH-GCL product. At the average pH values measured in the effluent

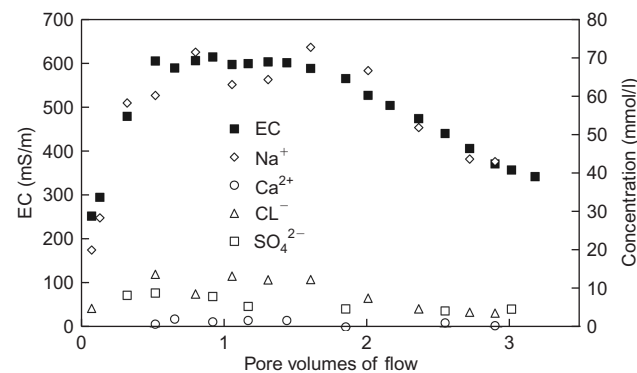

Figure 5. Electrical conductivity (EC) and concentrations of major dissolved ions in the effluent liquid during permeation of the DPH-GCL with DW, plotted against the number of pore volumes (test in flexible-wall permeameter, $\sigma'_i = 14 \text{ kPa}$)

liquid (pH ~ 6.5), phosphate is present as H_2PO_4^- ($\sim 75\%$) and HPO_4^{2-} ($\sim 25\%$).

4.2. Permeability to NSW

Waterproofing to NSW using GCLs requires the assessment of the impact of permeation of the GCL with NSW. Figure 6 illustrates the results of permeation tests of the C-GCL and the DPH-GCL with NSW. Upon direct permeation with NSW the C-GCL displayed very high k (10^{-7} – 10^{-8} m/s), in agreement with other studies (Shan and Lai 2002). Despite the predominance of sodium cations in NSW (Table 2), the ionic strength inhibits swelling of bentonite and the resulting k is very high (Kolstad *et al.* 2004a).

It is widely recognised that needle-punched fibres restrict swelling of bentonite hydrated with water at low confining stresses and that GCLs with intact fibres will generally have a lower k to water than without fibres (e.g. Petrov *et al.* 1997; Lake and Rowe 2000). However, in the case of poor bentonite swelling, bundles of fibres in needle-punched GCLs may not be efficiently impregnated by swollen bentonite and represent preferential flow pathways (Scalia and Benson 2011). Therefore, the test was repeated on a fibre-free specimen prepared with the same bentonite as the C-GCL and the same nominal mass of bentonite per unit area as the commercial product. The permeability of the fibre-free specimen was indeed lower (10^{-9} m/s) but still relatively high for a barrier function. A similar fibre-free specimen was first hydrated and permeated with tap water ('prehydration') and then with NSW. The k to NSW of the prehydrated specimen (10^{-10} m/s) was of about one order of magnitude lower than the non-prehydrated specimen, as a result of the well-known 'first exposure' effect (Shackelford *et al.* 2000). It should be noted that a fibre-free specimen was used only for comparison purpose. A GCL with intact fibres, hydrated with water, would give a lower permeability than a fibre-free GCL during the water permeation stage and probably during the permeation stage with NSW as well.

The k of the DPH-GCL directly permeated with NSW was extremely low (1.6×10^{-12} m/s). This result can be ascribed to the combined effect of prehydration, densification and chemical amendment. Although the DPH-GCL was permeated for more than 6 months, due to the low

permeability only 1.2 pore volumes of flow were permeated. However, permeability tests with a duration of more than 5 years (corresponding to approximately 18 pore volumes of flow) and using strong electrolyte solutions showed no significant increases in the laboratory-measured long-term k of a similar DPH-GCL product (Katsumi *et al.* 2008).

4.3. Permeability to 12.5 mmol/L CaCl_2

The trend of k plotted against time for permeation with 12.5 mmol/l CaCl_2 is illustrated in Figure 7. A 12.5 mmol/l CaCl_2 solution has been used in other studies on GCLs to simulate a calcium-rich permeant liquid (Benson *et al.* 2007). The DPH-GCL was continuously permeated for more than 5 years (1825 days) with the calcium solution. No appreciable increase in k was observed.

Benson *et al.* (2007) conducted a permeability test on a non-prehydrated conventional GCL (different from the product used in the present study) using a 12.5 mmol/l CaCl_2 solution. The applied stress and hydraulic gradient were very similar to those applied in the present study on the DPH-GCL. A gradual increase in k of the conventional GCL, starting from about 300 days of permeation was observed. The increase in k was ascribed to the progressive cation exchange of sodium adsorbed to the bentonite surface for calcium cations. As the exchange rate is controlled by diffusion of calcium cations in the interlayer, for relatively dilute solutions such as the one used in the study, the concentration gradient driving the diffusion was low and the induced exchange process relatively slow. The k stabilised after about 600 days of permeation to 2.3×10^{-10} m/s, compatible with a calcium-exchanged bentonite.

The difference between the DPH-GCL and the conventional GCL is ascribed firstly to the lower k , which reduces the amount of calcium cations entering the DPH-GCL by advection. Secondly, the presence of various sodium-rich additives contributes to increasing the sodium concentration in pore water (Figure 5), which makes cation exchange of sodium for calcium less favoured. Phosphate anions present in the porewater of the DPH-GCL may also remove part of the calcium cations by precipitation of insoluble compounds. Finally, polymers added to the clay

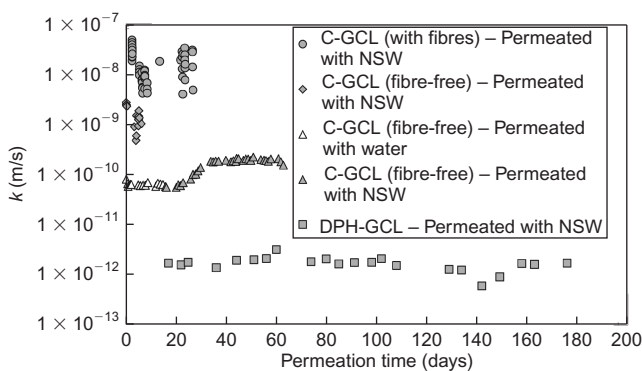

Figure 6. Hydraulic conductivity of the C-GCL, of bentonite specimens without fibres and of the DPH-GCL permeated with NSW (tests in flexible wall permeameter, $\sigma'_1 = 14$ kPa).

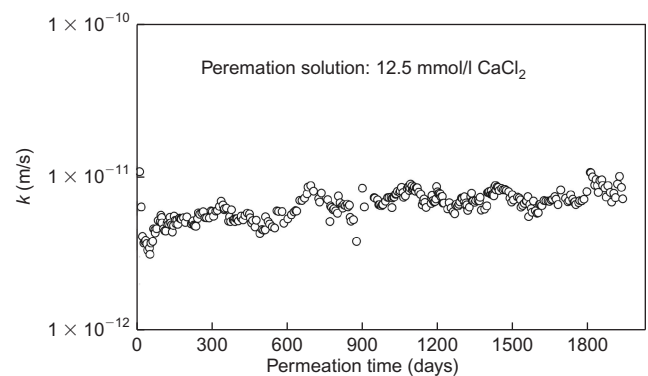

Figure 7. Hydraulic conductivity of the DPH-GCL permeated with a 25 mmol/l CaCl_2 solution (test in flexible-wall permeameter, $\sigma'_1 = 14$ kPa)

are thought to protect it from cation exchange by physical encapsulation (Alther 1984) and prevent the collapse of the double-layers, which is associated with the increase in permeability of cation-exchanged bentonites.

4.4. Permeability of overlap seams

The permeability of GCLs has sometimes been described in terms of the parameter hydraulic permittivity ψ (T^{-1}) defined as (Heyer 1995)

$$\psi = \frac{q}{\Delta h A} = \frac{k}{H} \quad (1)$$

where q is the volumetric flow rate (L^3/T); Δh is head loss across the GCL (L); A is the cross-sectional area of the GCL specimen (L^2), H is the GCL specimen thickness (L). The hydraulic permittivity is equal to the ratio between k and the GCL thickness, and it is a useful parameter when H is not known, such as when permeability tests are performed in flexible-wall permeameters not equipped with a device for measuring the specimen thickness.

In this study, to characterise the permeability of the overlap, the parameter hydraulic permittivity of the overlap, ψ^* (T^{-1}) has been defined as

$$\psi^* = \frac{q}{\Delta h(2A_L + A_s/2)} \quad (2)$$

where q is the measured volumetric flow rate (L^3/T); Δh is the head loss across the overlap specimen set-up (L); A_s is the cross-sectional area of the overlap zone (L^2); A_L is the cross-sectional area of the single-layer portion of the specimens (L^2) (Figure 3b). Due to the geometry of the overlap testing set-up (Figure 3b), even in case of perfect sealing (i.e. no interface flow), the seepage flow through the overlap is not, at rigour, one-dimensional. Assuming one-dimensional seepage flow and absence of preferential interface flow, the following theoretical relationship can be derived

$$\psi^* = \frac{k_{ov}}{H_{ov}} \quad (3)$$

where k_{ov} is the (vertical) hydraulic conductivity of each portion of the overlap (assumed equal) and H_{ov} is the thickness of each portion of the overlap (assumed equal). With the further assumption that, under the same confining effective stress, each portion of the overlap will have the same k and the same H of a single-layer specimen (i.e. $k = k_{ov}$ and $H = H_{ov}$), the following relationship can be obtained

$$\psi^* = \psi = \frac{k}{H} \quad (4)$$

Figure 8 displays the hydraulic permittivity values of the overlap (ψ^*) and of a single-layer specimen (ψ), permeated with DW and NSW, under an average isotropic effective stress of 14 kPa. In the case of water permeation, the values of ψ and ψ^* are practical coincident, in agreement with the theoretical prediction. The efficiency of the overlap is ensured by the swelling of DPH-GCL in the presence of pure water, which is also reflected by the

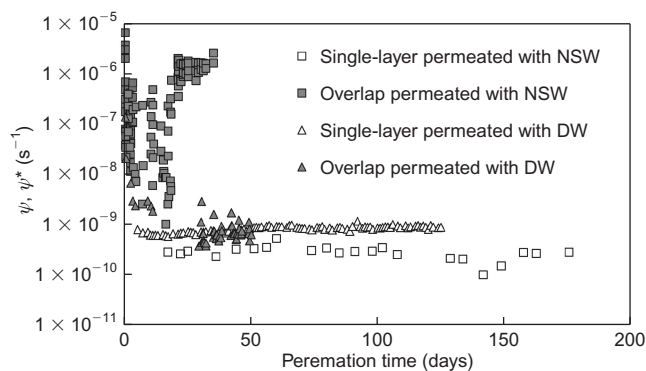

Figure 8. Hydraulic permittivity of the DPH-GCL single-layer (ψ) and overlap seam (ψ^*) permeated with DW and NSW (test in flexible-wall permeameter, $\sigma'_i = 14$ kPa)

increase in specimen thickness during the tests. For example, the thickness of single-layers specimens permeated with DW increased from 5.4 to 9.1 mm (average of two tests). The driving forces for further water adsorption and swelling are probably residual suction and osmotic gradients.

Using NSW as permeant liquid, hydraulic permittivity of the overlap ψ^* stabilised on very high values ($\psi^* = 2 \times 10^{-6} s^{-1}$), of about four orders of magnitude higher than the hydraulic permittivity of the single-layer specimen permeated with NSW ($\psi = 3 \times 10^{-10} s^{-1}$). The high ψ^* depends upon the lack of sealing of the overlap and the resulting preferential flow. The ionic strength of NSW inhibits the swelling of bentonite and hinders the sealing of the overlap. Inhibition of swelling was confirmed by the final thickness of the specimen permeated with NSW (6.0 mm), which was practically equal to the initial thickness (5.4 mm) despite the relatively low confining pressure of 14 kPa. Note that, at the same confining pressure, the k of single-layer DPH-GCLs to NSW remained very low because it is not related to post-installation swelling but rather to the material characteristics conferred by the manufacturing procedure.

To assess the impact of the confining stress on the hydraulic efficiency of the overlap, the effective confining pressure was increased by in steps to 110 kPa. For both tests a reduction in permittivity of about one order of magnitude was observed. However, the permittivity of the overlap specimen permeated with NSW remained high. A coloured dye was introduced in the permeant liquid during the last stage of permeation, under an effective stress of 110 kPa (Figure 9). At the inspection of the specimen after the test, a preferential flow through the overlap interface was evident from the coloured paths (Figure 10)

Permeability tests were repeated on identically prepared overlap specimen except for bentonite paste spread on the overlap area (about 1 mm of bentonite paste on each side). The results were practically coincident for DW and NSW as permeant liquids (Figure 11). Note that in the case of DW the results with and without bentonite paste were also practically coincident. Therefore in applications were contact with NSW is possible, a performance equivalent to that observed with DW can be obtained by application of

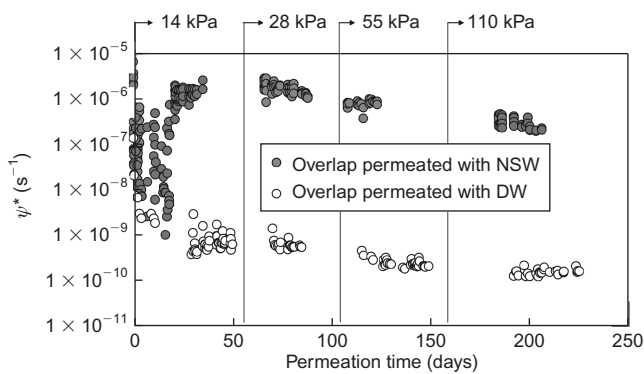

Figure 9. Hydraulic permittivity of DPH-GCL overlap seams (ψ^*) permeated with DW and NSW under increasing effective stress

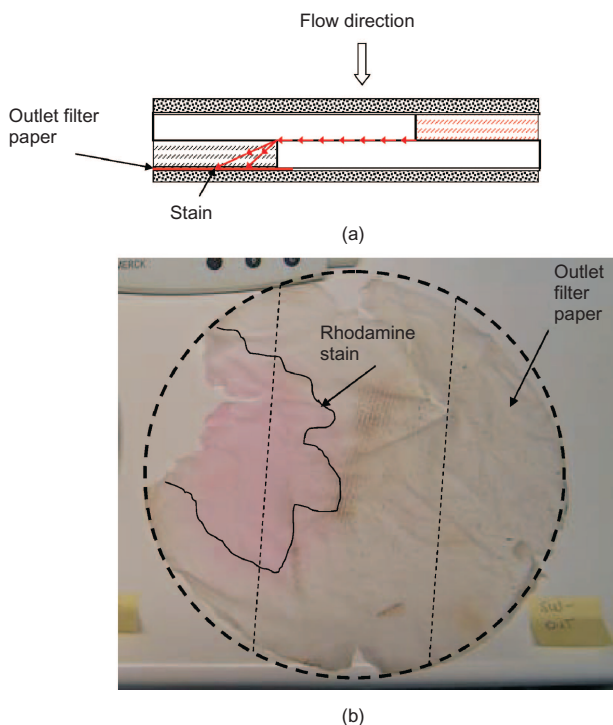

Figure 10. Test on the overlap permeated with NSW: (a) schematic of interface flow through the overlap during dye-assisted permeation with rhodamine; (b) picture of the outlet filter paper stained with rhodamine (note that the filter paper partly tore during disassembly of the apparatus)

bentonite paste on the overlap. Conversely, simple overlap seams (without bentonite paste) do not seem to be able to ensure a good performance in the presence of NSW, even at relatively high confining pressure. From a practical point of view, the need for bentonite paste in overlap seams causes an increase in costs and in installation times.

5. CONCLUSIONS

Dense prehydrated geosynthetic clay liners (DPH-GCLs) are a particular type of GCLs produced by a patented process in which the bentonite is prehydrated and then extruded under vacuum into a dense sheet. The most notable difference with conventional GCLs is that bento-

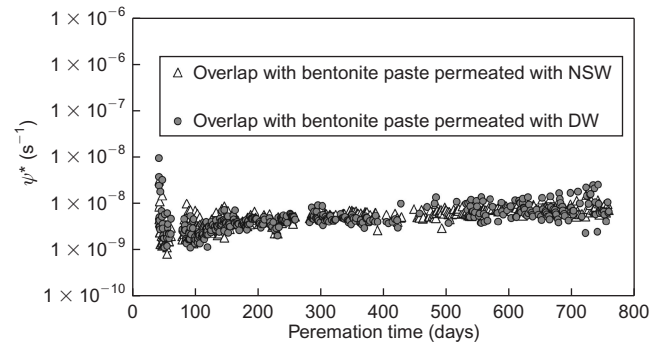

Figure 11. Hydraulic permittivity of DPH-GCL overlap (ψ^*) with addition of bentonite paste permeated with DW and NSW (tests in flexible-wall permeameter, $\sigma'_1 = 14$ kPa)

nite is already hydrated at installation instead of becoming hydrated during the service life. The paper describes the results of permeability tests carried out using water, natural seawater (NSW) and a calcium solution to provide insight into the hydraulic performance of a DPH-GCL product.

The permeability tests on single-layer GCLs specimens were performed using flexible wall permeameters 0.10 m in diameter, whereas the permeability tests on the overlap of the DPH-GCL were performed using a flexible wall permeameter able to accommodate specimens 0.305 m in diameter. Test results showed that the DPH-GCL has very low permeability to water, with k ranging from 8×10^{-12} to 5×10^{-13} m/s with the confining stress ranging from 14 to 275 kPa. Permeation with a 12.5 mmol/l Ca^{2+} solution, which lasted more than 5 years, did not impact significantly on the permeability, unlike the results described in the literature for conventional GCLs subjected to similar conditions. The value of k was found to be very low (1.6×10^{-12} m/s) also in case of direct permeation NSW.

In addition to the low hydraulic conductivity of the GCL, the efficiency of the seams is crucial to the overall efficiency of the hydraulic barrier. According to the technical specifications, the seams of the DPH GCL product used in this study are obtained by overlapping the edges of adjacent panels for a minimum of 0.10 m. This overlap is less than commonly specified for conventional GCLs (0.15–0.30 m). As this product is mainly recommended for waterproofing of below-ground structures, the specified minimum overlap probably accounts for the perception that risks of subgrade deformations and desiccation/shrinking are lower than in other applications (e.g. in landfill covers). Test results indicated that the hydraulic efficiency of the overlap seams strongly depends on the permeant liquid. When DW was used as permeant, bentonite swelling in the overlap prevented preferential flow and ensures sealing of the interface between the overlapped panels. Conversely, NSW inhibited the swelling of the bentonite and prevented the self-seaming mechanism of the overlap. Bentonite paste must be added to ensure sealing of the overlap in the presence of NSW. Therefore, when the permeant liquid to be

contained is different than water it is necessary to carefully assess the need for bentonite paste at overlaps and pipe penetrations.

Although the available evidence on the hydraulic conductivity of DPH-GCLs, mostly based on laboratory tests, consistently showed that low permeability is usually preserved against strong electrolyte solutions, some important issues need to be further addressed for a complete understanding of the overall field performance over time. In particular, the main concerns are the risk of polymer decay or extraction to the surrounding environment and the consequent impact on the hydraulic performances, as well as the risk of desiccation for DPH-GCL products used in applications where desiccation is more likely to occur (e.g. artificial seasonal ponds, waste basins temporarily emptied for maintenance, lining applications with thin covers, landfill covers, landfill liners in case of heat-producing waste). Care should be also exercised in installations even on gentle slopes considering the absence of reinforcement in DPH-GCL products.

ACKNOWLEDGEMENTS

The DPH-GCL used in this study was kindly supplied to the authors by Ekos s.r.l., the former Italian distributor of Rawell Co. (UK). The opinions expressed in this paper are solely those of the authors and do not necessarily reflect those of the producers or distributors.

NOTATION

Basic SI units are given in parentheses

A	cross-sectional area of the GCL specimen (m^2)
A_S	cross-sectional area of the two-layer central portion of the overlap (m^2)
A_L	cross-sectional area of the single-layer lateral portions of the overlap (m^2)
H	thickness of the GCL specimen (m)
H_{ov}	thickness of each layer of the overlap (m)
k	hydraulic conductivity of the GCL (m/s)
k_{ov}	hydraulic conductivity of each layer of the overlap (m/s)
q	volumetric flow rate (m^3/s)
Δh	head loss (m)
ψ	hydraulic permittivity of the GCL (1/s)
ψ^*	hydraulic permittivity of the overlap (1/s)
