ABSTRACT *Staphylococcus aureus* is an opportunistic bacterial pathogen that often results in difficult-to-treat infections. One mechanism used by *S. aureus* to enhance survival during infection is the stringent response. This is a stress survival pathway that utilizes the nucleotides (p)ppGpp to reallocate bacterial resources, shutting down growth until conditions improve. Small colony variants (SCVs) of *S. aureus* are frequently associated with chronic infections, and this phenotype has previously been linked to a hyperactive stringent response. Here, we examine the role of (p)ppGpp in the long-term survival of *S. aureus* under nutrient-restricted conditions. When starved, a (p)ppGpp-null *S. aureus* mutant strain ((p)ppGpp⁰) initially had decreased viability. However, after 3 days we observed the presence and dominance of a population of small colonies. Similar to SCVs, these small colony isolates (p⁰-SCIs) had reduced growth but remained hemolytic and sensitive to gentamicin, phenotypes that have been tied to SCVs previously. Genomic analysis of the p⁰-SCIs revealed mutations arising within *gmk*, encoding an enzyme in the GTP synthesis pathway. We show that a (p)ppGpp⁰ strain has elevated levels of GTP, and that the mutations in the p⁰-SCIs all lower Gmk enzyme activity and consequently cellular GTP levels. We further show that in the absence of (p)ppGpp, cell viability can be rescued using the GuaA inhibitor decoyinine, which artificially lowers the intracellular GTP concentration. Our study highlights the role of (p)ppGpp in GTP homeostasis and underscores the importance of nucleotide signaling for long-term survival of *S. aureus* in nutrient-limiting conditions, such as those encountered during infections.

IMPORTANCE *Staphylococcus aureus* is a human pathogen that upon invasion of a host encounters stresses, such as nutritional restriction. The bacteria respond by switching on a signaling cascade controlled by the nucleotides (p)ppGpp. These nucleotides function to shut down bacterial growth until conditions improve. Therefore, (p)ppGpp are important for bacterial survival and have been implicated in promoting chronic infections. Here, we investigate the importance of (p)ppGpp for long-term survival of bacteria in nutrient-limiting conditions similar to those in a human host. We discovered that in the absence of (p)ppGpp, bacterial viability decreases due to dysregulation of GTP homeostasis. However, the (p)ppGpp-null bacteria were able to compensate by introducing mutations in the GTP synthesis pathway that led to a reduction in GTP build-up and a rescue of viability. This study therefore highlights the importance of (p)ppGpp for the regulation of GTP levels and for long-term survival of *S. aureus* in restricted environments.

KEYWORDS (p)ppGpp, GTP, *Staphylococcus aureus*, stringent response

Pathogenic bacteria, including *Staphylococcus aureus*, have complex gene regulatory mechanisms to promote survival in changing environments such as the human host. The stringent response is a global stress adaptation pathway used by bacteria to deal with environmental challenges, including nutrient starvation and pH and temperature

stresses (1, 2). This response is coordinated by the rapid synthesis of the nucleotides guanosine tetra- and pentaphosphate, collectively termed (p)ppGpp, which control a cellular switch resulting in slowed growth and stress adaptation (1, 3). Numerous reports to date also highlight a role for the stringent response in *S. aureus* virulence and its contribution to persistent and chronic infections (4 to 9).

In *S. aureus*, (p)ppGpp is synthesized by three synthetase enzymes, Rel, RelP, and RelQ (9). While RelP and RelQ respond to stresses like cell-wall-targeting antibiotics and alterations in pH (10), Rel synthesizes (p)ppGpp during amino acid depletion, leading to large transcriptional changes, including the downregulation of protein synthesis machinery and upregulation of amino acid transport and metabolism genes (4). As *S. aureus* is a conditional auxotroph for a number of amino acids (11, 12), this regulation of amino acid uptake is essential for survival in starved conditions (9). In proteobacteria, (p)ppGpp modulates changes in transcription of these genes by binding to two sites around the β' subunit of the RNA polymerase, leading to altered expression of roughly a third of the genome (13). However, in *S. aureus*, and other Firmicutes, these interactions with the RNAP core enzyme do not occur (14 to 16). Instead, (p)ppGpp mediates changes by inhibiting a number of proteins, including those involved in DNA replication and ribosome assembly and translation, as well as by active depletion of GTP (1, 15, 17, 18).

Upon induction of (p)ppGpp synthesis, GTP levels drop due to its use as a substrate for pppGpp synthesis. In addition, (p)ppGpp also inhibits a number of GTP biosynthetic enzymes, including the IMP dehydrogenase GuaB and the guanylate kinase Gmk, both involved in the *de novo* GTP synthesis pathway (1, 19). This reduction in cellular GTP reduces transcription from promoters that use GTP as their initiating nucleotide, which includes promoters for rRNA synthesis, profoundly impacting cellular physiology (14, 15, 20, 21). Additionally, in the Firmicutes, the decrease in GTP level allows for the derepression of genes under the control of the CodY transcriptional repressor. CodY is a global regulator, where it functions to repress genes involved in amino acid biosynthesis, amino acid uptake, and some virulence genes (22). Studies using (p)ppGpp-null strains of *Bacillus subtilis* have observed that subjecting strains lacking (p)ppGpp to amino acid-depleted media for a 10 min shock resulted in cell death. This was attributed to elevated GTP concentrations, making (p)ppGpp-mediated control of GTP levels crucial for cell viability (16, 19, 23).

Persistent and recurring *S. aureus* infections are often associated with a small colony variant (SCV) phenotype on solid media (24, 25). Classical SCV phenotypes from clinical strains include colonies that are nonhemolytic, nonpigmented, slower growing, resistant to antibiotics, and often auxotrophic for menadione, hemin, or thymidine (24, 25). Additionally, these SCV strains can have an unstable small colony phenotype that can revert to normal-sized colonies (24, 26, 27). In some SCVs, an activated stringent response has been reported. A clinical *S. aureus* SCV strain isolated from a patient with a persistent and recurrent infection had a point mutation resulting in permanent activation of the stringent response (5). This contributed to slowed growth and reduced virulence, and highlighted the survival advantage that the stringent response provides during infection.

In this work, we sought to determine the requirement of (p)ppGpp for long-term survival of *S. aureus*, with the aim of providing further insights into its importance for recurrent infection. We observed that the absence of (p)ppGpp resulted in an *S. aureus* strain with increased GTP levels and an initial viability defect when cells are grown in nutrient-restricted media. However, over time, the bacterial culture was subsequently dominated by a population of smaller-sized colonies, distinct from traditional SCVs, that restored viability counts to wild-type levels. Whole-genome sequencing of the smaller colonies revealed the presence of mutations arising within *gmk*, encoding an enzyme of the GTP synthesis pathway. The overall effect of this was lowered enzyme activity and GTP levels in these cells, which allowed for the survival of strains lacking the stringent response in nutrient-limited media. Our data suggest that, similar to *B. subtilis*,

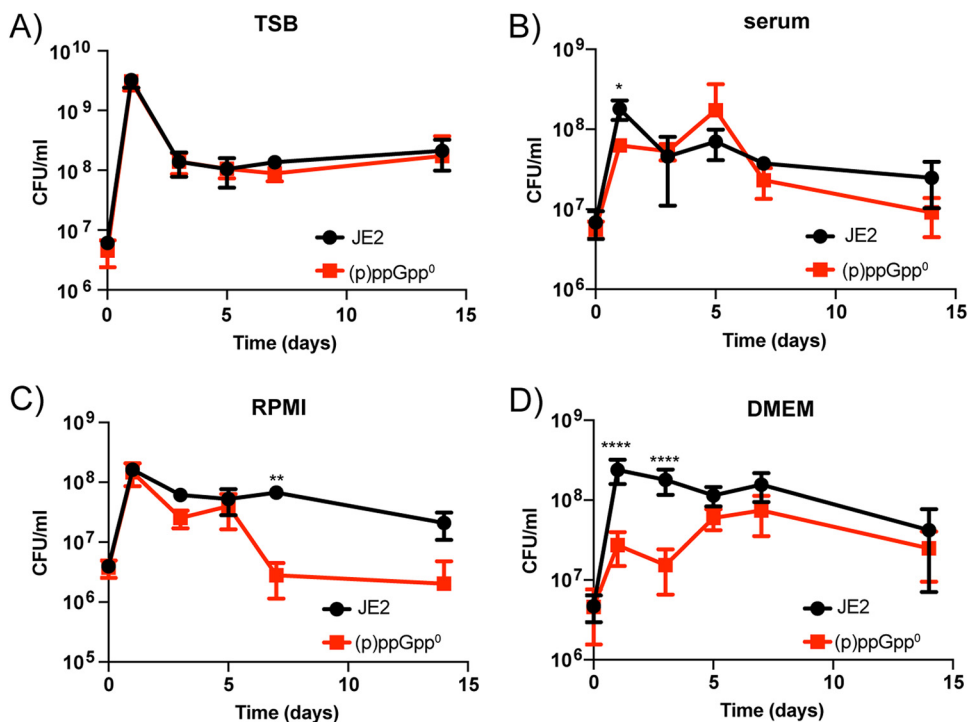

FIG 1 Survival of wild-type and (p)ppGpp⁰ strains in nutrient-rich and nutrient-restricted media. Changes in viable count (CFU/mL) were measured over 14 days for JE2 (black) and (p)ppGpp⁰ (red) in (A) TSB, (B) human serum, (C) RPMI, and (D) DMEM with L-glutamine and FBS. Survival curves were carried out in triplicate, with error bars representing standard deviation. Data were analyzed by two-way ANOVA with Šidák's multiple-comparison test, *, $P \leq 0.05$; **, $P \leq 0.01$; ****, $P \leq 0.0001$.

(p)ppGpp is an important regulator of GTP homeostasis in *S. aureus* but that this regulation can be otherwise compensated for by suppressor mutations in the GTP synthesis pathway.

RESULTS

(p)ppGpp⁰ *S. aureus* form smaller colonies when starved. (p)ppGpp, while not essential when strains are grown in rich laboratory media, is required for the growth of *S. aureus* in nutrient-restricted media (2). To examine the requirement of (p)ppGpp for long-term survival in media that is more physiologically relevant, we first constructed a (p)ppGpp-null mutant in the methicillin-resistant USA300 *S. aureus* strain JE2 (JE2 $\Delta relQPA$) by introducing silent in-frame deletions in the three (p)ppGpp synthetases: *rel*, *relP*, and *relQ*. The triple mutant, termed (p)ppGpp⁰, was unable to produce (p)ppGpp after a 30-min shock with mupirocin (Fig. S1A in the supplemental material), a known inducer of (p)ppGpp synthesis (28). A concurrent increase in GTP levels was also observed (Fig. S1A), as has been noted for *B. subtilis* (p)ppGpp⁰ strains (19). (p)ppGpp⁰ also displayed characteristic growth defects when grown in amino-acid-starved conditions (Fig. S1B and C), with whole-genome sequencing verifying the absence of secondary mutations in the strain.

We then compared the ability of both wild-type JE2 and (p)ppGpp⁰ strains to survive long-term starvation in nutrient-rich tryptic soy broth (TSB) and three nutrient-deplete conditions: human serum, RPMI (iron-depleted cell culture media), and DMEM (minimal essential cell culture media) supplemented with glutamine and fetal bovine serum (FBS) over 14 days (Fig. 1). Following an initial increase in CFU at day one in TSB, both the wild-type and the (p)ppGpp⁰ strains ceased growing with a log drop in viable cells by day three (Fig. 1A). The number of cells for both strains then remained constant over the remainder of the 14-day period, demonstrating that in rich media both strains are capable of long-term survival. In human serum, there were only minor differences in viable cell counts between the strains over the 14 days (Fig. 1B); however,

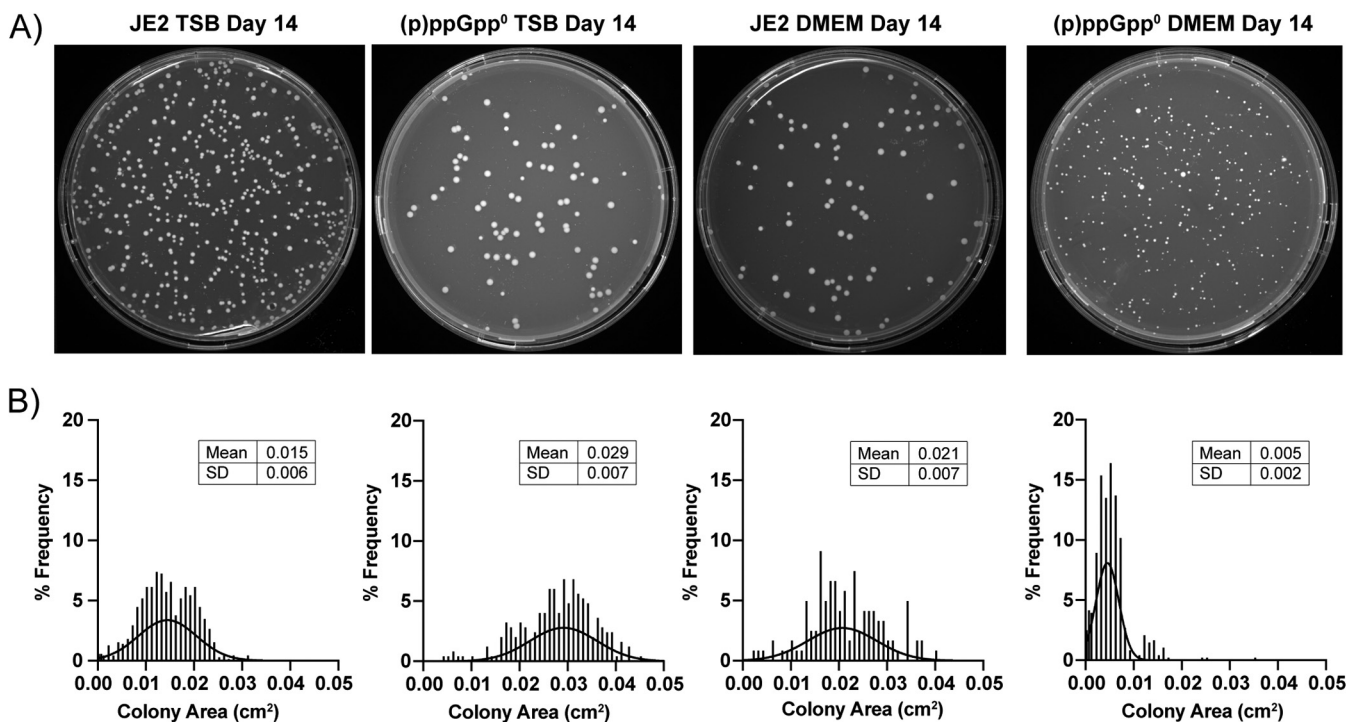

FIG 2 (p)ppGpp⁰ *S. aureus* form smaller colonies when starved. (A) Representative agar plates displaying JE2 and (p)ppGpp⁰ colony morphology after 14 days culture in TSB or DMEM. (B) Histograms showing the % frequency of colonies for a given size (in cm²) for JE2 and (p)ppGpp⁰ populations after 14 days in TSB or DMEM. Experiments were performed in triplicate.

in RPMI, a two-log drop in CFU was observed for the (p)ppGpp⁰ mutant after 7 days (Fig. 1C). RPMI is a cell culture medium originally formulated to grow human lymphocytes, and is rich in amino acids but restricted in iron content. (p)ppGpp has previously been reported as important for maintaining iron homeostasis in *S. aureus* (29, 30), in line with what was observed here.

DMEM is another cell culture medium that can support the growth of many cell types, but it is lacking in a number of amino acids, including asparagine, aspartic acid, and proline. In this medium, the (p)ppGpp⁰ strain displayed a significant decrease in CFU compared to the wild-type up until day five, when the colony numbers recovered to similar levels (Fig. 1D). By observing the colony morphology over time, it was apparent that colonies with a smaller phenotype began to appear for the (p)ppGpp⁰ strain in DMEM from day three, while the wild-type colony size was unaffected. By day 14, the (p)ppGpp⁰ population was dominated by the smaller colonies (Fig. 2A), with the mean colony size reducing from 0.021 ± 0.007 cm² for the wild-type to 0.005 ± 0.002 cm² for the mutant when grown in DMEM (Fig. 2B). To uncover whether the initial survival defect and the emergence of the smaller colonies observed when grown in DMEM were due to one specific (p)ppGpp synthetase or to the presence of the (p)ppGpp alarmones in general, strains with single deletions in *relP* and *relQ* and a double *relP relQ* mutant were compared to the triple mutant (Fig. S2A). As deleting *rel* individually in the presence of RelP and RelQ is not possible due to toxic accumulation of (p)ppGpp, a strain with a non-functional *rel* synthetase domain was also compared to the triple mutant to specifically examine the contribution of Rel (Fig. S2B). We also compared a mutant in *codY*, the transcriptional repressor interlinked with (p)ppGpp signaling (Fig. S2A). No survival defects or small colonies were observed in these strains (Fig. S2), suggesting that the presence of (p)ppGpp itself is required to survive in nutrient-limited DMEM medium.

(p)ppGpp⁰ small colonies are phenotypically distinct from traditional SCVs.

S. aureus SCVs can arise within a wild-type population when the cells are placed under stress, including sublethal concentrations of hydrogen peroxide, antibiotic stress, osmotic stress, low temperature, and acidic pH (31, 32). One typically reported characteristic of

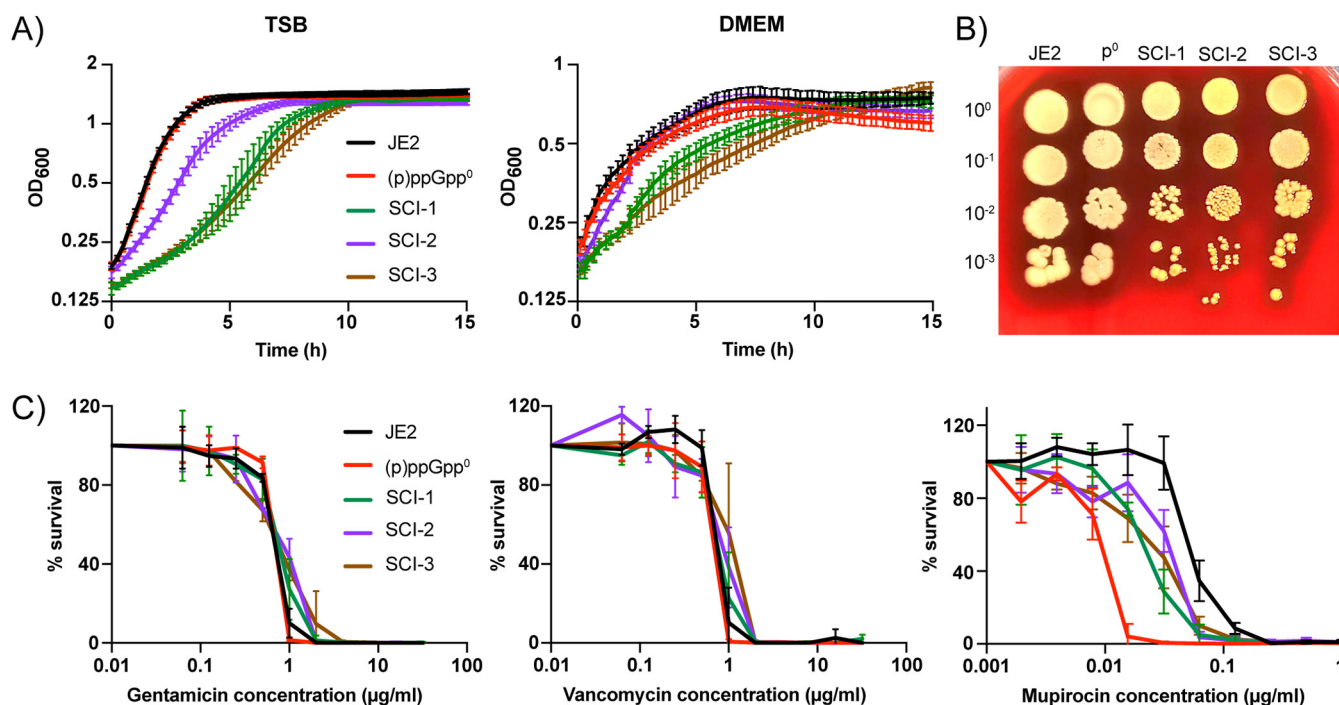

FIG 3 Phenotypic analysis of *S. aureus* (p)ppGpp⁰ small colony isolates. (A) Growth curves of JE2, (p)ppGpp⁰, p⁰-SCI-1, p⁰-SCI-2, and p⁰-SCI-3 in TSB and DMEM. Overnight cultures were diluted to an OD₆₀₀ of 0.05 and grown for 15 h. Graphs show the mean OD₆₀₀ of three replicates, with the standard deviation shown. (B) Serial dilutions of JE2, (p)ppGpp⁰, p⁰-SCI-1, p⁰-SCI-2, and p⁰-SCI-3 were spotted onto TSA plates containing 5% sheep's blood and incubated at 37°C for 48 h. (C) MIC values of JE2, (p)ppGpp⁰, p⁰-SCI-1, p⁰-SCI-2, and p⁰-SCI-3 for gentamicin, vancomycin, and mupirocin were determined after overnight growth of each strain in the presence of doubling dilutions of each antibiotic. OD₆₀₀ readings were determined after 24 h growth and plotted as % growth compared with the growth in the absence of antibiotic. Plots show the mean OD₆₀₀ of three replicates and their corresponding standard deviation.

SCVs is their slow growth in comparison to wild-type strains. Often this slow growth phenotype is a result of a defect in cellular respiration (33), with mutations in genes involved in the electron transport chain (34, 35). The growth of three *S. aureus* (p)ppGpp⁰ small colony isolates (SCIs) from three separate biological experiments (p⁰-SCI-1, p⁰-SCI-2, and p⁰-SCI-3) were monitored for 15 h in both TSB and DMEM (Fig. 3A, Table S1). In TSB, the wild-type and the (p)ppGpp⁰ parental strain had a similar growth profile, while all three SCIs exhibited a growth defect. The growth defect of p⁰-SCI-2, however, was less pronounced than that of p⁰-SCI-1 and p⁰-SCI-3. In DMEM, all strains exhibited decreased growth compared to TSB-grown cells, with p⁰-SCI-1 and p⁰-SCI-3 growing less well than JE2 and (p)ppGpp⁰, as in rich media. Most notably, the growth rate of p⁰-SCI-2 was recovered in the nutrient-poor DMEM media, reaching stationary phase at a similar time as the wild-type and the (p)ppGpp⁰ strain, suggesting that this strain has an adaptation to nutrient-poor media that increases fitness and which differs to p⁰-SCI-1 and p⁰-SCI-3.

Typical *S. aureus* SCVs have been described as having decreased hemolytic activity (36). As such, we investigated the hemolytic activity of the three (p)ppGpp⁰ SCIs by plating 10-fold serial dilutions of the strains onto blood-agar plates; however, lytic activity was apparent for all strains (Fig. 3B). *S. aureus* SCVs are also commonly associated with recurring, antibiotic-resistant infections that can be difficult to treat (37). Here, the MICs of the three (p)ppGpp⁰ SCIs to mupirocin, vancomycin, and gentamicin were determined (Fig. 3C). Gentamicin and vancomycin resistance has been associated with SCVs (37, 38), while mupirocin is an antibiotic that inhibits the isoleucyl tRNA-synthetase and induces amino acid starvation, activating (p)ppGpp synthesis in a wild-type strain (28). The MIC of mupirocin for all three SCIs was determined to be 0.0625 μ g/mL, a 4-fold increase compared to their (p)ppGpp⁰ parent strain and only a 2-fold decrease compared to the wild-type (Fig. 3C). However, the MIC of the SCIs for vancomycin and gentamicin showed no significant difference. These data suggest that in the absence of (p)ppGpp, when strains

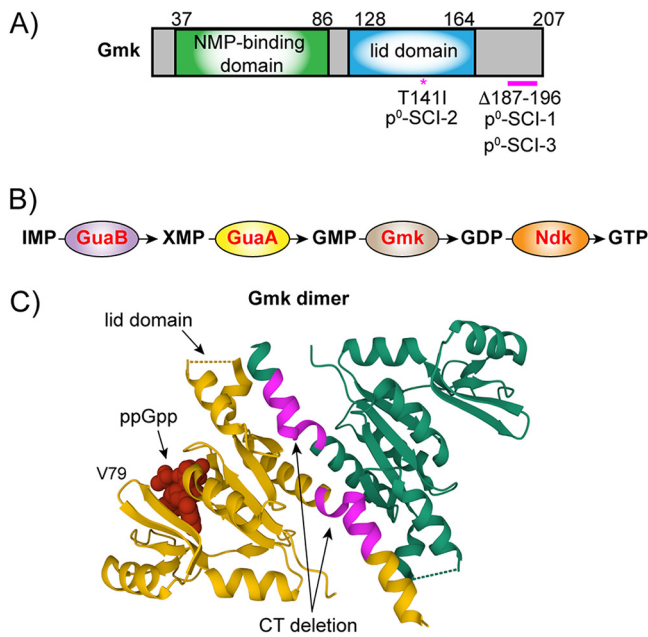

FIG 4 *S. aureus* (p)ppGpp⁰ small colony isolates contain mutations within Gmk. (A) Schematic representation of the mutations found in Gmk. Gmk contains two domains, the nucleoside monophosphate (NMP)-binding domain in green and the lid domain in blue. The sizes of each domain are indicated by numbering. Deletions found in p⁰-SCI-1 and p⁰-SCI-3 are represented by a pink line. *, an amino acid change in the lid domain in p⁰-SCI-2. (B) GTP synthesis pathway. Gmk (brown) catalyzes the conversion of GMP to GDP, a reaction that is inhibited by (p)ppGpp. (C) The crystal structure of Gmk from *S. aureus* as a dimer (PDB: 4QRH), with one monomer in yellow bound to ppGpp (red). The lid domain region containing the T141I mutation that is not resolved is indicated. Regions from amino acids 187 to 196 at the dimer interface that are lacking in both p⁰-SCI-1 and p⁰-SCI-3 are highlighted in pink.

should be more sensitive to amino acid starvation, mutations have arisen in the SCIs to improve survival.

Mutations in the *gmk* gene are present in all three (p)ppGpp⁰ small colony isolates. To ascertain whether mutations had arisen in the three (p)ppGpp⁰ SCIs that were now allowing the strains to survive in DMEM, whole-genome sequencing was performed. Both p⁰-SCI-1 and p⁰-SCI-3 contained identical in-frame deletions of a sequence encoding 10 amino acids toward the C terminus of the protein Gmk (Fig. 4A). Both strains also had either a single nucleotide polymorphism (SNP) in the promoter region (p⁰-SCI-1) or a SNP introducing a frameshift mutation (p⁰-SCI-3) in SAUSA300_RS12245, encoding a small 56 amino acid protein of unknown function. However, sanger sequencing of both *gmk* and SAUSA300_RS12245 from the isolates at day 5, from each biological replicate, showed that only mutations in *gmk* were present. This rules out the direct involvement of SAUSA300_RS12245 in forming the small colony phenotype that arose on day three, though it may have been introduced later to aid growth. Isolate p⁰-SCI-2, on the other hand, had only one unique SNP compared to the parental (p)ppGpp⁰, a transition mutation yielding Gmk T141I (Fig. 4A).

Gmk is a guanylate kinase responsible for the conversion of GMP to GDP, which is then converted to GTP by the nucleoside diphosphate kinase Ndk (Fig. 4B). (p)ppGpp is a known binder of Gmk, where it can competitively inhibit guanylate kinase activity, and thus, when the stringent response is triggered in wild-type cells, GTP levels decrease as less GDP is present for conversion (16, 19, 39). This decrease in GTP then relieves repression by the transcriptional repressor CodY, increasing transcription of amino acid biosynthesis genes, allowing cells to survive amino acid starvation (22, 40, 41).

When active, the *S. aureus* Gmk is dimeric (42), with the C terminus of the protein crucial for dimer formation (Fig. 4C). When unbound by nucleotides, this protein is in an open conformation. The binding of ATP and GMP causes a conformational change to the closed state, whereby the lid domain moves and forms bonds with the ATP. The

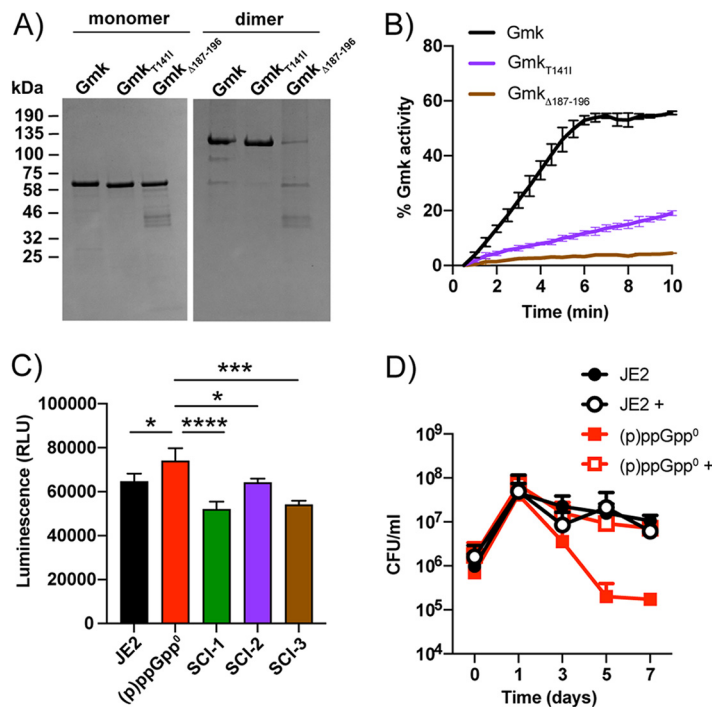

FIG 5 Gmk from the (p)ppGpp⁰ small colony isolates are less active than wild-type. (A) Coomassie stained gel of purified recombinant Gmk from wild-type JE2 and (p)ppGpp⁰ variants p⁰-SCI-2 and p⁰-SCI-3. Equal concentrations of Gmk, Gmk_{T141I}, and Gmk_{Δ187-196} were run on 10% polyacrylamide gels under denaturing (left) or nondenaturing (right) conditions. Sizes in kDa are indicated on the left. (B) Gmk activity assay. The conversion of NADH to NAD⁺, in a Gmk-dependent manner, was monitored over time at an absorbance of 340 nm. Activity assays were performed in duplicate, with the standard deviation shown. (C) Relative cellular GTP levels. Overnight cultures of each strain were lysed and normalized by protein concentration. Relative intracellular GTP concentrations were determined via luminescence. Average luminescence values and standard deviations of triplicate experiments are plotted. Data were analyzed by one-way ANOVA with Dunnett's multiple-comparison test, *, $P \leq 0.05$; **, $P \leq 0.001$; ***, $P \leq 0.0001$. (D) Changes in viable count (CFU/mL) were measured over 14 days for JE2 (black) and (p)ppGpp⁰ (red) in the presence (open symbols—decoyinine in DMSO) and absence (closed symbols—DMSO only) of decoyinine. Survival curves were carried out in duplicate, with error bars representing standard deviation.

closure of the lid allows the protein to form a catalytically active state, forming GDP from ATP and GMP. Mapping the SCI mutations onto the structure of Gmk revealed that the 10 amino-acid C-terminal deletions within p⁰-SCI-1 and p⁰-SCI-3 are within helix 8, which is crucial for dimer formation, while the T141I mutation found in p⁰-SCI-2 is within the lid domain. Both of these regions are important for enzyme function (42) and suggest that these Gmk variants might have altered guanylate kinase activity.

(p)ppGpp⁰ small colony isolates have reduced GTP levels. To examine the impact of these mutations on the activity of Gmk, the Gmk proteins from the wild-type, p⁰-SCI-2 (Gmk_{T141I}), and p⁰-SCI-3 (Gmk_{Δ187-196}), which is identical to the variant from p⁰-SCI-1, were purified. When equal concentrations of the proteins were analyzed by SDS-PAGE under denaturing conditions, all three migrated at the same size of approximately 68 kDa (Fig. 5A). However, under nondenaturing conditions, Gmk_{Δ187-196} failed to efficiently form a dimer, which could be expected given the importance of helix 8 for dimer formation (42). This variant also appeared to be more susceptible to degradation. The enzymatic activity of the Gmk proteins was subsequently monitored over time with an assay that uses the conversion of GMP to GDP to ultimately measure the oxidation of NADH to NAD⁺ (19). While the wild-type enzyme was active (Fig. 5B), Gmk_{T141I} showed a marked reduction in activity, while the activity of Gmk_{Δ187-196} was not detected.

To examine the impact of these mutations on the cell, the GTP levels from the wild-type, (p)ppGpp⁰, and the three p⁰-SCIs were measured. In the absence of (p)ppGpp, cells had elevated levels of GTP (Fig. 5C), which is to be expected given the role of

(p)ppGpp in regulating GTP homeostasis in *B. subtilis* (19, 23, 41). Compared to the (p)ppGpp⁰ parental strain, all three p⁰-SCIs had significantly reduced levels of GTP. This was more evident with p⁰-SCI-1 and p⁰-SCI-3 than with p⁰-SCI-2 (Fig. 5C), in line with the reduced but not abolished activity observed for Gmk_{T1411} (Fig. 5B). In fact, the GTP level from p⁰-SCI-2 was similar to the wild-type, which may explain why this strain had improved growth in DMEM, unlike p⁰-SCI-1 and p⁰-SCI-3 (Fig. 3A). Taken together, these data suggest that in order for *S. aureus* strains to survive long-term starvation in the absence of (p)ppGpp, mutations that will decrease the levels of GTP to equal or lower than wild-type levels are selected, further implicating (p)ppGpp as an important regulator of GTP homeostasis in bacteria.

Reducing cellular GTP levels allows long-term survival of a (p)ppGpp⁰ strain.

Our data suggest that when a (p)ppGpp⁰ strain is grown in amino-acid-depleted DMEM, toxic increases in GTP levels could impede cell proliferation. To overcome this, cells with mutations that lower levels of GTP are selected, allowing proliferation, albeit more slowly than the wild-type. To test this, we repeated the long-term survival assays in DMEM but included decoyinine, an inhibitor of the GMP synthase GuaA. This inhibitor has been shown to artificially lower GTP levels and promote derepression of CodY in other organisms (43 to 45), which we hypothesize will negate the need for the (p)ppGpp⁰ strain to mutate and form small colonies. When the wild-type JE2 was grown with decoyinine, no effect on survival was observed. However, when the (p)ppGpp⁰ strain was grown in the presence of decoyinine, survival was restored to wild-type levels (Fig. 5D), and small colonies did not appear. This supports our hypothesis that during long-term starvation in amino-acid-deficient media, GTP levels increase in cells lacking (p)ppGpp, resulting in the formation of suppressor mutations. These suppressors circumvent the need for (p)ppGpp-mediated regulation of GTP homeostasis by introducing mutations in Gmk to directly reduce GTP levels and restore growth.

The small colony phenotype of (p)ppGpp⁰ SCIs is not stable. The ability of *S. aureus* SCVs to phenotypically switch back to a wild-type morphology under favorable conditions is a well-reported characteristic and is implicated in the ability of *S. aureus* to cause relapsing, chronic infections (31 to 33). To examine the phenotypic stability of the p⁰-SCIs, we plated out the strains on tryptic soy agar (TSA) after subculture for a number of days (Fig. 6A and B). All three isolates had a small colony phenotype when freshly plated out from frozen stocks (Fig. 6A). After plating an overnight culture and a number of subsequent subcultures, all three isolates had reverted to a large colony morphology similar to the wild-type and (p)ppGpp⁰ parental strains (Fig. 6A and B).

To determine if further mutations had arisen to allow the reversion to a large colony phenotype, whole-genome sequencing of three revertants, p⁰-SCI-1r, p⁰-SCI-2r and p⁰-SCI-3r, was performed. For all three, additional mutations occurred in or upstream of the *gmk* gene (Fig. 6C). Revertants p⁰-SCI-1r and p⁰-SCI-3r still contained the Δ 187-196 amino acid deletion at the C terminus, but now also contained SNPs altering valine 79 to either an alanine (p⁰-SCI-1r) or a glutamic acid (p⁰-SCI-3r). V79 is within the nucleotide binding domain of Gmk (Fig. 4C) and is highly conserved across Gmk proteins within the Firmicutes (16). Furthermore, mutations were observed in the promoter region of *gmk* for both p⁰-SCI-2r and p⁰-SCI-3r, suggesting that the production of Gmk will be reduced in these revertants. This is in addition to the altered enzyme activity of any produced protein. To assess this, levels of GTP in the revertant strains were measured and compared to those of the original SCIs. All three revertants had lower levels of GTP compared to the original SCI (Fig. 6D), suggesting that further reduction of GTP levels can restore SCI colony size to wild-type. Altogether, this highlights the importance of regulating cellular GTP levels for bacterial viability.

DISCUSSION

Long-term survival of *S. aureus* in nutrient-depleted media. In this study, we examined the requirement of a functional stringent response for long-term survival of *S. aureus* in nutrient-depleted media. It is well known that *S. aureus* can cause persistent and recurrent infections, displaying an impressive ability to survive within patients

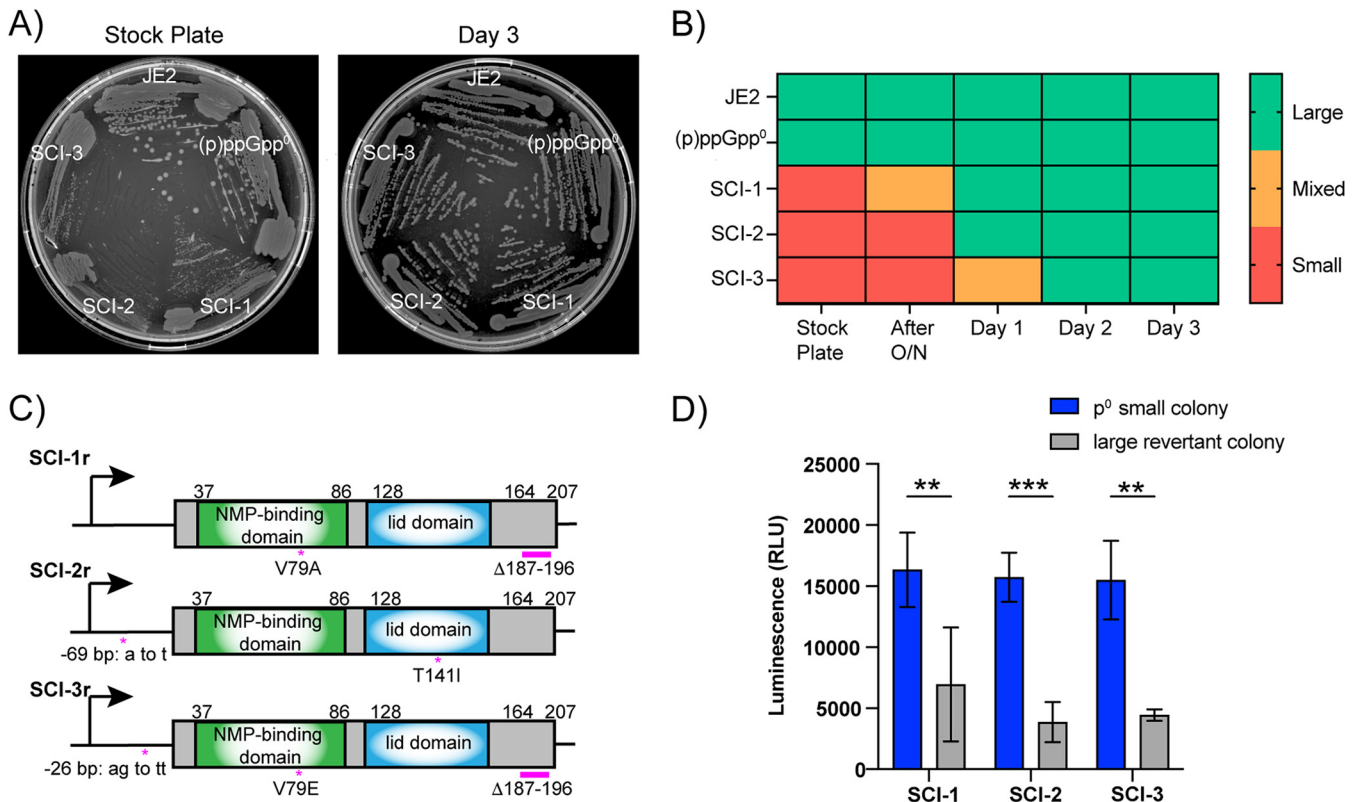

FIG 6 Small colony morphology of (p)ppGpp⁰ variants is not stable. (A) TSA plates showing the colony size of each strain after streaking out from frozen (stock plate) or after 3 days of subculture. (B) Color map displaying colony phenotype at each time point, starting from the original plate of frozen stocks, overnight culture, and subsequent subculture for 3 days. (C) Schematic representation of the mutations found in Gmk in the p⁰-SCI revertants. for years (36). It has been suggested that this survival could require the stringent response, as isolates from chronic infections have activated (p)ppGpp synthesis (5). This requirement may stem from host-induced nutrient restrictions, as host tissues restrict access to many metabolites, including carbon, nitrogen, metals, and amino acids (46 to 49). The evidence for restricted availability of amino acids comes from the observed upregulation of amino acid biosynthetic clusters when strains are isolated from a host (50), and the inability of numerous auxotrophic strains to cause disease (51, 52). As (p)ppGpp is essential for bacteria to respond to nutrient restrictions, this prompted our current work, where we examine the requirement of (p)ppGpp for long-term survival. By incubating wild-type and (p)ppGpp⁰ strains in nutrient-rich and nutrient-depleted media over a 2-week period, we observed survival defects for the mutant strain in both RPMI and DMEM (Fig. 1). These are tissue culture media designed to provide optimal conditions to support host tissue growth, but they differ in both iron content and amino acid composition, respectively. Previous work has suggested that (p)ppGpp is important for reducing cellular iron levels and lowering reactive oxygen species. Horvatek et al. showed that (p)ppGpp overproduction in *S. aureus* strains grown in chemically defined media (CDM) induced transcription of genes involved in iron storage and the oxidative stress response (30). Similarly, Fritsch et al. demonstrated that when an *S. aureus* (p)ppGpp⁰ strain was grown in RPMI with low iron (0.75 μ M FeCl₃), it was more susceptible to reactive oxygen species due to dysregulation of respiratory chain activity and elevated free iron in the cell (29). Here, a (p)ppGpp⁰ strain grown overnight in TSB was washed and then used to inoculate RPMI completely lacking iron. No defect in CFU was observed after 24 h (Fig. 1C), suggesting that iron levels

in the RPMI were low enough to permit growth of a strain lacking (p)ppGpp in the short term. A lack of regulation in the absence of (p)ppGpp, however, may have resulted in the decreased viability observed after 7 days. Future work would be required to analyze what nutritional needs are not being met at these later time points.

Although *S. aureus* contains all the genes for synthesizing the 20 amino acids required for protein synthesis (53, 54), the precise conditions that might induce activity of these operons are unclear, as when cultured in the laboratory setting *S. aureus* is a conditional auxotroph for several amino acids, including arginine, valine, proline, cysteine, and leucine (11, 55). DMEM is deficient in a number of amino acids, including asparagine, aspartic acid, and proline, though *S. aureus* can synthesize proline from arginine (56). Figure 1D shows that a wild-type *S. aureus* strain is able to survive in DMEM over the 2-week period, suggesting that the biosynthetic operons for the missing amino acids may be switched on under this condition or that the requirement for these amino acids is very low as the cells are not actively replicating. In contrast, the (p)ppGpp⁰ strain was unable to proliferate in DMEM initially (Fig. 1D), until the formation of colonies with the smaller colony phenotype that soon dominated the population (Fig. 2). These colonies were distinct from typical SCVs, as although they were slower growing, they did not have mutations in the electron transport or thymidylate biosynthetic pathways, did not exhibit reduced hemolytic activity, and did not demonstrate reduced sensitivity to gentamicin or vancomycin (Fig. 3), all phenotypes traditionally associated with SCVs (25). Instead, these isolates contained mutations in Gmk, a key enzyme in the GTP synthesis pathway, suggesting that the regulation of GTP levels is key to the survival of a strain lacking an active stringent response in nutrient-restricted media.

The stringent response is a regulator of cellular GTP levels. The stringent response is most notably associated with adjusting to amino-acid-limiting environments. However, it is becoming apparent that this system is intricately linked to the regulation of cellular nucleotide levels, and has been referred to as a master regulator of GTP homeostasis under both stressed and unstressed conditions (16, 19, 23, 41). Indeed, levels of GTP and (p)ppGpp are inversely linked at multiple points. Under stringent conditions, GTP is utilized as a substrate for pppGpp synthesis. In addition, numerous studies have characterized the inhibition of multiple enzymes in both the *de novo* and salvage purine biosynthesis pathways by (p)ppGpp, including PurF, PurA, Gmk, GuaB, Gsk, HprT, XprT, and AprT (reviewed in reference 1).

In *S. aureus* and other Firmicutes, increased levels of (p)ppGpp and concomitant decreases in GTP relieve repression by transcriptional repressor CodY (40, 41). In *S. aureus*, CodY, in complex with its two cofactors GTP and branched-chain amino acids, binds to over 200 promoters, with 90% of transcripts downregulated and only 10% activated (22). Examples of downregulated transcripts include multiple amino acid biosynthetic pathways, amino acid and peptide transporters, permeases, as well as the major virulence gene regulator *agr* (22). Here, we observed that a (p)ppGpp⁰ strain has increased cellular levels of GTP (Fig. 5C, S1A) and has an initial survival defect in DMEM (Fig. 1D). The observed increase in viability in DMEM after 5 days was accompanied by mutations in Gmk that reduced its enzymatic activity (Fig. 5B), thereby reducing cellular GTP levels (Fig. 5C). Decreases in GTP have been shown to lead to the derepression of CodY and concomitant upregulation of amino acid biosynthesis in other species (43, 44), which here explains the increased viability observed for the (p)ppGpp⁰ strain that had acquired suppressor mutations at later time points (Fig. 1D). Indeed, we show that by inhibiting the uncontrolled build-up of GTP in a (p)ppGpp⁰ strain with the GuaA inhibitor decoyinine, cells no longer die and the small colony phenotype does not arise (Fig. 5D). The mutations observed in Gmk occurred in either the lid domain or within helix 8, which is crucial for dimer formation (Fig. 4). We were curious to see whether mutations in this region arise naturally or were selected for due to the absence of a functional stringent response. To this end, we performed a sequence alignment of Gmk from a collection of 990 clinical *S. aureus* strains isolated from lower respiratory

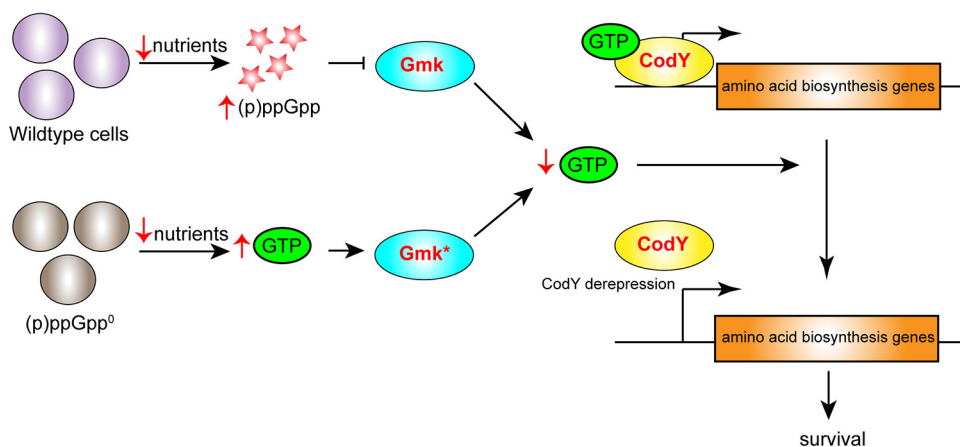

FIG 7 Model of the requirement of GTP for starvation survival. For wild-type *S. aureus* experiencing starvation, (p)ppGpp levels increase. (p)ppGpp directly binds to Gmk and a number of other enzymes in the GTP synthesis pathway, lowering intracellular levels of GTP. GTP is a cofactor required for the activity of transcriptional repressor CodY. When GTP levels are lowered, CodY is derepressed, leading to the transcription of amino acid biosynthesis genes and survival. In the absence of (p)ppGpp, GTP levels rise when cells are starved as there is no inhibition of GTP synthesis enzymes. The bacteria respond by introducing mutations in Gmk (denoted as Gmk*) that lower activity, resulting in lower levels of GTP and survival.

tract infections (57). This analysis revealed that Gmk is very well conserved in *S. aureus*, with few mutations arising between strains and none that would appear to affect enzyme activity. This suggests that the suppressor mutations we observed are only selected for due to the toxic accumulation of GTP that arises in the absence of (p)ppGpp.

From these results, we propose a model that, in line with observations in other species (19), highlights that a major function for (p)ppGpp in cells is the moderation of GTP levels (Fig. 7). When nutrients are limited, cells produce (p)ppGpp, which will inhibit GTP production by the inhibition of several enzymes in the synthesis pathway, including Gmk. In the Firmicutes, lowered GTP levels will induce derepression of CodY and increase amino acid biosynthesis. Similar to these observations, in *B. subtilis* GTP levels reportedly rise uncontrollably in cells that lack (p)ppGpp, leading to toxicity and cell death within a few hours (19, 23). GTP is involved in multiple cellular processes in addition to the regulation of CodY activity, including transcription and ribosome biogenesis, and as such, dysregulation could have pleiotropic detrimental impacts on cell survival. However, our long-term viability study shows that bacteria can introduce suppressor mutations to lower the toxic levels of GTP, alleviating the need for (p)ppGpp-mediated regulation.

Altogether, this work has shown that, similar to *B. subtilis*, (p)ppGpp is crucial for regulating cellular GTP levels in *S. aureus*. Cells lacking (p)ppGpp readily acquire suppressor mutations, allowing for restoration of GTP homeostasis and cell survival. The ability of bacteria to overcome the need for this signaling system would call into question attempts to target (p)ppGpp as a therapeutic strategy.

MATERIALS AND METHODS

Bacterial strains and culture conditions. *E. coli* strains were grown in Luria-Bertani broth (LB). *S. aureus* strains were grown in tryptic soy broth (TSB; Becton, Dickinson); Roswell Park Memorial Institute (RPMI) 1640 medium (Gibco 22400089); low-glucose Dulbecco's Modified Eagle's Medium (DMEM; Merck D6046) supplemented with 2 mM L-glutamine and 10% FBS; or human serum from male AB plasma (Merck H4522) at 37°C.

Plasmid and strain construction. Strains used in this study are listed in Table S2, and primers used are listed in Table S3. Plasmids pVL847-*gmk*_{SCI-2} and pVL847-*gmk*_{SCI-3} were produced by amplifying the respective *gmk* genes using primers RMC920/RMC921. The resulting PCR products were digested with BamHI and EcoRI and cloned into pVL847 that had been digested with the same enzymes. All plasmids were initially transformed into *E. coli* strain XL1-Blue, and the sequences of all the inserts were verified by fluorescence automated sequencing by Eurofins. pVL847 plasmids were subsequently transformed into BL21(DE3) for protein induction.

For deletion of the *relP*, *relQ*, and *rel* genes in *S. aureus*, 1-kb fragments up- and downstream of each gene were amplified from JE2 genomic DNA using primer pairs as specified in the primer table. For Rel,

this results in a 234 amino acid in-frame deletion spanning the hydrolase and synthetase domains. For RelP and RelQ, both in-frame deletions lacked 29 amino acids containing the syn3 and syn4 synthetase motifs. Purified PCR products were then fused by splice overlap extension (SOE) PCR using flanking primer pairs. The purified PCR product was cloned into pIMAY and transformed into *E. coli* strain XL1-Blue. The plasmid was subsequently electroporated into RN4220 and stably maintained at 30°C in the presence of 10 µg/mL chloramphenicol (Cam). Electroporation of the plasmids into JE2 then allowed mutant construction as previously outlined (58). Replacement of each gene was confirmed by PCR, and whole-genome sequencing was performed on the final triple (p)ppGpp⁰ strain, to ensure the absence of secondary mutations. Genomic DNA extraction and whole-genome sequencing were performed by MicrobesNG (Birmingham, UK).

Starvation assay. *S. aureus* strains were cultured overnight in 5 mL TSB at 37°C with shaking. Cultures were washed three times with PBS, resuspended in the appropriate media, and used to inoculate 10 mL of either TSB, human serum, RPMI, or DMEM to an OD₆₀₀ of 0.01. Cells were incubated with shaking at 37°C for 24 h (day 1), followed by static incubation until day 14. CFU from days 0, 1, 3, 5, 7, and 14 were enumerated on TSA from plates incubated for 24 h at 37°C. Colony size was determined using the analyze particle tool in ImageJ. Where stated, 50 µg/mL decoynine solubilized in DMSO, or a DMSO-only control, were included at the time of inoculation.

Growth curves. *S. aureus* strains were cultured overnight in 5 mL TSB at 37°C with shaking. Strains were subsequently normalized to OD₆₀₀ of 0.05 in TSB plus or minus 0.05 µg/mL mupirocin as stated in the legend. For growth curves in DMEM, the cultures were washed three times with DMEM before normalization. The OD₆₀₀ was measured every 15 min for 15 h in a Hidex Sense microplate reader.

MICs. Overnight cultures of *S. aureus* strains were adjusted to an OD₆₀₀ of 0.05 in Mueller-Hinton broth and 100 µL incubated in 96-well plates with 2-fold dilutions of various antimicrobials at the following starting concentrations: mupirocin 1 µg/mL, vancomycin 32 µg/mL, and gentamicin 32 µg/mL. Plates were incubated at 37°C overnight with shaking and the OD₆₀₀ determined using a Hidex Sense microplate reader.

Protein purification. Proteins were purified from 500 mL *E. coli* BL21 DE3 cultures. Cultures were grown at 37°C to an OD₆₀₀ of 0.5 to 0.7; expression was induced with 1 mM isopropyl β-D-1-thiogalactopyranoside (IPTG) and incubated for 3 h at 30°C. Cell pellets were resuspended in 5 mL Buffer A (50 mM Tris pH 7.5, 150 mM NaCl, 5% glycerol, 10 mM imidazole) and lysed by sonication upon addition of 20 µg/mL lysozyme. Protein purifications were performed by nickel affinity chromatography. The filtered cell lysate was loaded onto a 1-mL HisTrap HP Ni²⁺ column (GE Healthcare) before elution using a gradient of Buffer B (50 mM Tris pH 7.5, 200 mM NaCl, 5% glycerol, 500 mM imidazole). Protein-containing fractions were dialyzed in 50 mM Tris-HCl pH 7.5, 200 mM NaCl, 5% glycerol before concentrating using a 50-kDa centrifugal filter (Thermo Scientific) and storage at -80°C. For analysis of dimer formation, samples were mixed with a loading dye lacking β-mercaptoethanol and were not heated prior to analysis on SDS-PAGE. For use in Gmk enzymatic assays, proteins were further purified by size exclusion chromatography using a preparative 16/60 Superdex 200 column and a 50 mM Tris pH 7.5, 200 mM NaCl, 5% glycerol buffer system.

Measurement of (p)ppGpp levels in *S. aureus*. *S. aureus* strains were grown overnight in low-phosphate CDM (59) at 37°C. Cultures were diluted to an OD₆₀₀ of 0.05 and grown until an OD₆₀₀ of 0.5. Following this, 3.7 MBq of [³²P]H₃PO₄ was added to 500 µL cultures and incubated for a further 3 h at 37°C. Cultures were subsequently normalized for absorbance, supplemented with 60 µg/mL mupirocin, and further incubated for 30 min at 37°C. Cultures were pelleted and suspended in 100 µL of 600 mM formic acid, before being subjected to three freeze/thaw cycles. Samples were centrifuged at 17,000 × *g* for 5 min. Ten microliters of the supernatant fractions were subsequently spotted on PEI-cellulose F thin-layer chromatography (TLC) plates (Merck Millipore), nucleotides separated, and TLC plates developed using a 1.5 M KH₂PO₄ pH 3.6 buffer. The radioactive spots were visualized using an FLA 7000 Typhoon PhosphorImager, and data were quantified using ImageQuantTL software.

Enzymatic assays. The Gmk activity assay contained 100 mM Tris HCl pH 7.5, 100 mM KCl, 10 mM MgCl₂, 4 mM ATP, 1.5 mM phosphoenolpyruvate, 2 U of pyruvate kinase, 2.64 U of lactate dehydrogenase, 150 µM NADH, and 10 µM Gmk variants. Reactions were initiated by the addition of 1.25 mM GMP, and the absorbance at 340 nm was monitored over time.

Relative GTP concentration determination. A GTPase-Glo bioluminescence assay (Promega) was used, and manufacturer's guidelines were adjusted to measure relative intracellular GTP levels by luminescence. Bacterial cultures were pelleted and resuspended in TSM buffer (50 mM Tris pH 7.5, 0.5 M sucrose, 10 mM MgCl₂) before lysing with 50 µg/mL lysostaphin and 50 µg/mL DNase for 30 min at 37°C. Total protein concentrations were determined using a Bicinchoninic Acid (BCA) assay (Bio-Rad). The protein concentration of each lysate was adjusted to 100 µg/mL and 2.5 µL (250 ng) used in each GTPase-Glo assay.

Stability assay. *S. aureus* strains were plated onto TSA from frozen stocks (stock plate). Single colonies were inoculated in 5 mL TSB and incubated overnight at 37°C with shaking. Overnight cultures were plated onto TSA to examine morphology, and 1:1,000 dilutions were used to inoculate day 1 cultures. Day 1 cultures were incubated for 24 h at 37°C, with shaking. The following day, aliquots were plated onto TSA and day 2 cultures prepared by inoculating 5 µL into 5 mL fresh TSB. The aforementioned steps were repeated until day 3. Colonies were stocked from TSA plates at each time point, and overnight cultures were used to prepare protein lysates and isolate chromosomal DNA for sequencing.

Statistics. Statistical analyses were performed using GraphPad Prism 8.0 software. Statistical differences between samples were assessed using either two-tailed, unpaired *t* testing or one- or two-way analysis of variance (ANOVA), followed by multiple-comparison test, as indicated in the figure legends.

Data availability. Whole-genome sequence data are available from the European Nucleotide Archive (Study Accession number [PRJEB58759](https://www.ebi.ac.uk/ena/record/PRJEB58759)), accession numbers [ERS14397334](https://www.ebi.ac.uk/ena/record/ERS14397334) to [ERS14397338](https://www.ebi.ac.uk/ena/record/ERS14397338). The SAUSA300_FRP3757 (TaxID: 451515) reference genome sequence is available from NCBI, while the clinical isolate sequences used to look at Gmk protein sequences in wild-type strains are available at [PRJEB2756](https://www.ebi.ac.uk/ena/record/PRJEB2756).
