Abstract: Laser Raman microspectroscopy was applied to quartz inclusions in coesite- and diamond-grade metapelites from the Kokchetav ultrahigh-pressure metamorphic (UHPM) complex, Northern Kazakhstan, and diamond-grade eclogite xenoliths from the Mir kimberlite pipe, Yakutiya, Russia to assess the quantitative correlation between the Raman frequency shift and metamorphic pressure. Quartz crystals sealed in garnets have a higher frequency shift than those in the matrix. Residual pressures retained by quartz inclusions depend on the metamorphic history of the garnet host. The Raman frequency shift of quartz inclusions in garnet from coesite-grade and diamond-grade metamorphic rocks shows no systematic change with increasing peak metamorphic pressures. The highest shifts of the main Raman bands of quartz were documented for monocrystalline quartz inclusions in garnets from a diamond-grade eclogite xenolith. Calibrations based on experimental work suggest that the measured Raman frequency shifts signify residual pressures of 0.1–0.6 GPa for quartz inclusions from coesite-grade metapelites from Kokchetav, 0.1–0.3 GPa for quartz inclusions from diamond-grade metapelites from Kokchetav, and 1.0–1.2 GPa for quartz inclusions from the diamond-grade eclogite xenoliths from the Mir kimberlite pipe. Normal stresses and internal (residual) pressures of quartz inclusions in garnet were numerically simulated with a 3-shell elastic model. Estimated values of residual pressures are inconsistent with the residual pressures estimated from the frequency shifts. Residual pressure slightly depends on P – T conditions at peak metamorphic stage. Laser Raman microspectroscopic analysis of quartz is a potentially powerful method for recovering an ultrahigh pressure metamorphic event. Monocrystalline quartz inclusions yielding a residual pressure greater than 2.5 GPa might indicate the presence of a former coesite.

Key-words: quartz, coesite, diamond, UHPM petrology, Raman spectroscopy, 3-shell elastic model, residual pressure.

1. Introduction

Ultrahigh-pressure metamorphic (UHPM) complexes are common features of suture zones of lithospheric plates (Chopin, 2003). Despite an extensive search for new UHPM indicators, coesite and diamond remain the most reliable indicators among others. Diamond inclusions are quite rare and have been identified so far only in a limited number of localities (Sobolev & Shatsky, 1990; Massonne, 1999; Mposkos & Kostopoulos, 2001; Van Roermund *et al.*, 2002; Mposkos & Krohe, 2006; Perraki *et al.*, 2006), whereas the presence of coesite has been confirmed

for 18 complexes (Chopin, 2003). Unfortunately, the complex metamorphic history of UHPM rocks often erases the peak metamorphic assemblages and prevents reliable estimation of the peak metamorphic conditions.

Since the first findings of coesite, the high-pressure SiO₂ polymorph in crustal rocks (Chopin, 1984; Smith, 1984), it has become a very powerful mineral-indicator of ultrahigh-pressure metamorphism. Unlike diamonds, the presence of only one coesite inclusion undoubtedly provides evidence for an UHPM origin of the host mineral (Korsakov *et al.*, 2004). However, due to the fast kinetics of the coesite-to-quartz transformation (Mosenfelder &

Bohlen, 1997; Perrillat *et al.*, 2003 and references therein), coesite rarely survives even when it is included in robust minerals. In most cases, relics of coesite are present in the core of polycrystalline quartz aggregates, surrounded by a radial crack pattern. These partial or complete pseudomorphs of quartz after coesite are quite abundant over a wide range of lithologies. They are sometimes used together with other mineralogical indicators to prove that the rocks experienced UHP metamorphic conditions (Gilotti & Krogh Ravna, 2002).

The most reliable method for documenting the presence of quartz and coesite is laser Raman microspectroscopy (Scott & Porto, 1967; Sharma *et al.*, 1981; Boyer *et al.*, 1985). Raman band positions of minerals are known to be dependent on composition, pressure, and temperature. Quartz is generally a virtually pure end-member and it is stable over a wide range of metamorphic conditions. Hence, it is a potential Raman geobarometer. The effect of pressure and temperature on quartz Raman bands positions is experimentally well known (Hemley, 1987; Schmidt & Ziemann, 2000). A quartz geobarometer has been calibrated recently on metamorphic quartz from quartz-eclogite, epidote-amphibolite, and amphibolite-facies rocks (Enami *et al.*, 2007). In this paper, we study the application of the quartz geobarometer to coesite- and diamond-grade metapelites from the Kokchetav complex, Northern Kazakhstan and diamond-grade eclogite xenoliths from the Mir kimberlite pipe, Yakutiya, Russia.

2. Experimental techniques

Raman spectra were obtained using a Kaiser System Hololab 5000R modular Raman microspectrometer (f/1.8) (KOSI, Ecully, France). The microscope was fitted with a 100× objective (PL Fluotar L, N.A. 0.75, W.D. 4.7 mm, Leica). Samples were excited using 45–50 mW

of a 785 nm laser light from a diode laser (Toptica Photonics AG, Martinsried/ Munich, Germany). The scattered light is guided to the spectrograph through a confocal, 15 µm aperture collection fibre. A back-illuminated deep depletion Pelletier cooled CCD detector (Andor, Belfast, Northern Ireland) operating at –70 °C was used for the detection of the scattered light. The Raman signal was collected in the spectral interval of 100–3100 cm⁻¹ with a spectral resolution of 4 cm⁻¹. Further details of the calibration procedure can be found in Hutsebaut *et al.* (2005).

3. Samples

Five representative samples were chosen for this study (Table 1): three samples of coesite-grade mica-schists (K86, K26C, B01-3), one sample of a diamond-grade garnet-kyanite-quartz rock (B9-04) from the Kokchetav massif (Fig. 1.) and one sample of a diamond-grade eclogite xenolith (TM90-1) from the Mir pipe (Yakutiya), with different metamorphic history.

3.1. Coesite-grade micaschist samples K86, B01-3, K26C from the Kokchetav massif

The mineral assemblage in the studied micaschists studied here is: garnet + phengite + quartz ± kyanite. Rutile, apatite, monazite, zircon and graphite are common accessory minerals. Phlogopite and chlorite occur as retrogressive breakdown products of garnet and kyanite. Garnet porphyroblasts generally constitute 20–40 vol% of the rock. They are subhedral, rounded, and equigranular with a diameter ranging from 0.2 to 5.0 mm. Larger than 2 mm porphyroblasts display a sharp optical boundary between clear pinkish cores and reddish mantles and rims. The

small garnet grains and the mantles and the rims of the large garnet porphyroblasts contain numerous microscopic rutile rods. These rods are generally less than 1 μm wide and 5 μm long. Coesite-grade micaschist samples have a zonal distribution of SiO_2 inclusions. Monocrystalline quartz inclusions predominantly occur in the core. Coesite or quartz pseudomorphs after coesite dominate in

the external zone of the garnet porphyroblasts. Other inclusions comprise in decreasing order of abundance: rutile, ilmenite, kyanite, phengite, phlogopite, coesite, graphite, apatite and chlorite.

The three mica-schist samples (K86, B01–3, K26C) were selected because of their different garnet chemistry (Table 2) and metamorphic history (Korsakov *et al.*, submitted).

3.1.1. Sample K86

The sample K86 contains large garnet porphyroblasts with a manganese-rich core (MnO up to 12 wt%, Table 2.). Abundant euhedral monocrystalline quartz inclusions (Fig. 2), similar to those described by Parkinson (2000), are present. The external zone of the garnets is rich in relics of coesite surrounded by a polycrystalline quartz shell, and in polycrystalline quartz inclusions, representing pseudomorphs after coesite.

3.1.2. Sample K26C

Garnet porphyroblasts from the sample K26C also contain abundant quartz inclusions. No prograde zoning in the garnet porphyroblasts was observed. MnO content is less than 1 wt% (Table 2). Coesite relics are present in the core of the garnet porphyroblasts. Monocrystalline quartz inclusions also occur (Fig. 3). Quartz grains behave optically as a single grain (see Korsakov *et al.*, submitted). A weak birefringent halo is observed around some quartz

Fig. 2. Garnet porphyroblasts from the Kulet micaschists, eastern Kokchetav (sample K86). Abundant monocrySTALLINE quartz inclusions are seen as small black spots in transmitted light photomicrograph (a) and BSE image (b). Quartz pseudomorphs after coesite, surrounded by dense radial crack patterns, can be recognized in the external mantle and rim zones. Compositional zoning with Mn-rich irregular core is observed (b). (c)–(d) Plane-polarized and cross-polarized light photomicrographs of low-pressure monocrySTALLINE quartz in the Mn-rich core. There is no optical halo around this type of quartz inclusions.

Fig. 3. MonocrySTALLINE quartz inclusions in coesite-grade metamorphic rocks. (a–b) Plane-polarized and cross-polarized light photomicrographs of coesite inclusions coexisting in the same garnet area with monocrySTALLINE quartz inclusions in garnet from a micaschist (sample K26C). (c–d) Plane-polarized and cross-polarized light photomicrographs of partial quartz pseudomorphs after coesite in the core of the inclusion.

inclusions. We did not find any correlations between the halo size and intensity and the size of the quartz inclusions. Large anhedral quartz inclusions (up to 1 mm in size) occur also in the core of such garnet porphyroblasts. No halo was observed around the large anhedral inclusions. Rare relics of coesite occur within the same growth zone and were identified by Raman spectroscopy. The mantle regions of these garnets contain quartz inclusions with palisade textures indicative of pre-existent coesite and relics of coesite (Fig. 3) coexisting side by side with both euhedral and anhedral monocrySTALLINE quartz inclusions. Around some of these inclusions intense radial fracturing has been developed in the garnet host, whereas only very small barely visible cracks occur around others. Coesite relics in the studied samples are surrounded by a visible palisade quartz corona (Fig. 3). The thickness of the corona is highly variable even within the single samples.

3.1.3. Sample B01–3

Garnet porphyroblasts from the sample B01-3 preserve a prograde zonation in their core. They are characterized by a significantly lower Mn-content (only up to 5 wt%, Table 2) compared to garnets from sample K86. Almost all quartz inclusions are characterized by an optical birefringent halo varying in intensity (Fig. 4). Some quartz inclusions are surrounded by radial crack patterns (Fig. 4f–e). Similar features (*e.g.*, an optical halo and crack patterns) were observed around “monocrySTALLINE” coesite inclusions in garnet from diamond-bearing clinzoisite gneisses (Korsakov *et al.*, 2007).

3.2. Diamond- and coesite-bearing garnet-kyanite-quartz-rock B9–04, from the Kokchetav massif

Garnets from the sample B9-04 (Fig. 5) exhibit similarities in their morphology with the garnets of the sample K86 described above (Fig. 2). They have homogeneous cores whereas slight variations in their composition occur in narrow (~100 μm) external zones (Shatsky *et al.*, 1995; Korsakov *et al.*, 1998; Hermann *et al.*, 2001; Korsakov *et al.*, 2002; Korsakov & Hermann, 2006). Diamond and coesite inclusions identified in the garnet porphyroblasts point to peak metamorphic conditions of $P \sim 4\text{--}6$ GPa and $T \sim 950\text{--}1000$ °C (Sobolev & Shatsky, 1990; Hermann *et al.*, 2001; Korsakov *et al.*, 2007). Higher peak metamorphic conditions of $P \sim 6\text{--}8$ GPa and $T = 1100$ °C have been reported by Ota *et al.* (2000), Massonne (2003) and Dobrzhinetskaya *et al.* (2006). MonocrySTALLINE quartz inclusions occur in the core of garnet porphyroblasts similarly to the coesite-grade samples. PolycrySTALLINE quartz inclusions (up to 200 μm in size), representing pseudomorphs after coesite, occur predominantly within the external garnet zone. Intergrowths of monocrySTALLINE quartz with diamond were found as inclusions in some garnets (Fig. 5c–d). No optical birefringent halo was observed around the quartz inclusions in the sample B9-04. Similar behaviour of monocrySTALLINE quartz

Fig. 4. Photomicrographs of high to ultrahigh (?) pressure monocrystalline quartz inclusions in garnet porphyroblast (sample B01-3). An optical birefringent halo with different intensity is observed around quartz inclusions (a)–(d). Weak halo also can be seen for partly exposed quartz inclusions (f)–(e). This inclusion is surrounded by radial crack patterns.

inclusions was observed in diamond-bearing samples from the Rhodope Massif, Greece (Mposkos *et al.*, 2009).

3.3. Diamond-bearing eclogite xenolith from the Mir kimberlite pipe, Yakutiya

This rock consists of garnet and strongly altered clinopyroxene (Tomilenko *et al.*, 2005). Only monocrystalline quartz and needles of rutile were identified as inclusions in garnet porphyroblasts (Fig. 6).

All quartz inclusions (up to 100 μm) in garnet are euhedral. They are surrounded by a very intense halo (Fig. 6). Tiny radial cracks occur at apices, probably formed due to expansion of quartz inclusions. Exposed at the thin-section surface the inclusions lose the halo and the residual pressure is partly eliminated. Sometimes, these cracks are filled with fluid (Tomilenko *et al.*, 2005).

3.4. Raman spectroscopic study of euhedral monocrystalline quartz inclusions

Representative Raman spectra of monocrystalline quartz inclusions of the sample K86 are presented in Fig. 7a. There is no measurable shift of the main quartz Raman bands (Table 3). Raman spectra correspond well with

Fig. 5. Monocrystalline (Qtz) and polycrystalline (Qtz-P) quartz inclusions in diamond-grade metamorphic rocks. (a–b) Plane-polarized and cross-polarized light photographs of garnet porphyroblast with abundant monocrystalline quartz inclusions in the core. A polycrystalline quartz inclusion is identified within the external zone of garnet porphyroblast. (c–d) Plane-polarized and cross-polarized light photographs of representative monocrystalline quartz inclusion from the core of garnet crystal (no cracks or an optical halo can be seen). (e–f) Plane-polarized and reflected light photographs of an intergrowth of monocrystalline quartz and diamonds included in garnet.

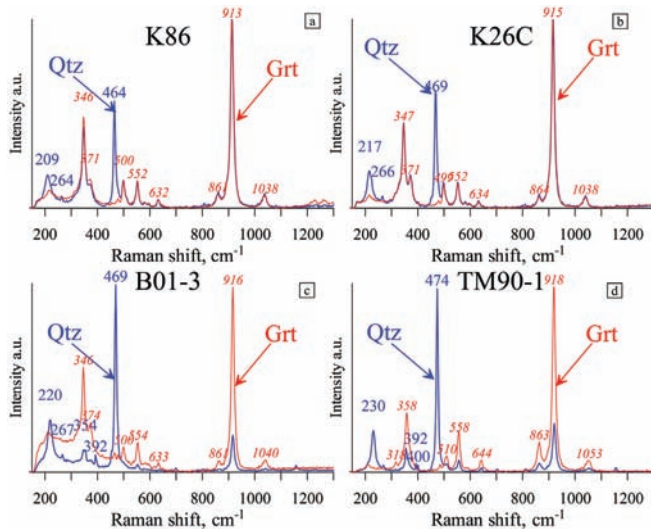

Fig. 7. Representative Raman spectra of monocrystalline euhedral quartz inclusions in garnet porphyroblast. A low residual pressure for quartz inclusions was measured for sample K86 (a), high residual pressures were documented for samples K26C (b), B01-3 (c) and TM90-1 (d).

spectra collected at ambient conditions (Scott & Porto, 1967). There is a significant upshift of the main quartz Raman bands for all quartz inclusions in garnets from the samples K26C and B01-3 (Table 3). Representative Raman spectra are shown in Fig. 7b, c, respectively. The highest shift of the main quartz band (up to 471 cm^{-1}) was measured for an unexposed quartz inclusion. For inclusions partly exposed at the surface the shift is lower (around 467–468 cm^{-1}); however, these values are still higher than those for ambient pressure.

There is no measurable shift for the quartz inclusions in garnet from diamond-grade metamorphic rocks from the Kokchetav massif (Table 3). Raman spectroscopic study of the quartz inclusions in garnet from the eclogite xenolith

revealed that they exhibit the highest upshift of the main quartz band, up to 474 cm^{-1} (Fig. 7d and Table 3). This is the absolute maximum upshift reported so far for monocrystalline quartz inclusions in garnet.

4. Theoretical consideration and a 3-shell elastic model

The transformation of coesite to quartz and internal (residual) pressure in the inclusions can be modelled by a three-shelled composite sphere in linear elasticity. This model is presented below. Similar models but with different initial conditions were developed by Nishiyama (1998).

We assume that a system consisting of j_o layers is formed at the pressure P_o and temperature T_o . The first substance occupies a sphere of the radius r_1 , the second occupies the shell $r_1 < r < r_2$, the j -th substance occupies the shell $r_{j-1} < r < r_j$. We also assume that all processes are slow, so that the temperature will be uniform and the body will maintain mechanical equilibrium. The temperature of the formation is high and the stress tensor σ_{ik} relaxes to an isotropic form: $\sigma_{rr} = \sigma_{\theta\theta} = \sigma_{\varphi\varphi} = -P_o$. The radial displacement in initial stage is expressed by the formula

$$u_o = A_o j r, \quad A_o j = -P_o / (3K_o j)$$

where $K_o j$ is the bulk modulus in the j -th substance in initial state. Let the system change to an environment with the pressure P and temperature T . We assume that during this change the system has the behaviour of an elastic body. Below we indicate the component σ_{rr} of stress tensor as σ_r and $\sigma_{\theta\theta} = \sigma_{\varphi\varphi}$ as σ_t . It is well known (Zhang, 1998), that the conditions of equilibrium give the expression for radial

Table 3. Mean Raman shift ($\bar{\nu}$) of the main bands of monocrystalline euhedral quartz for coesite- and diamond-grade metamorphic rocks from the Kokchetav Massif and Mir kimberlite pipe. Pressure shifts of the Raman modes (dv/dP) of α -quartz after Hemley (1987) and calculated values of residual pressure (P_i , GPa) based on the calibration.

displacement $u(r) = C_1 r + C_2/r^2$ in each layer. In our case it is more convenient to write for the j -th substance

$$u = \left(A_j + B_j \frac{r_{j-1}^3}{r^3} \right) r$$

In this notation the total displacement is $u_{\text{tot}} = u + u_0$. For the stress tensor we have

$$\sigma_r = 3K_j(A_{0j} + A_j - \varepsilon_j) - 4G_j B_j \frac{r_{j-1}^3}{r^3}$$

$$\sigma_t = 3K_j(A_{0j} + A_j - \varepsilon_j) + 2G_j B_j \frac{r_{j-1}^3}{r^3}$$

where ε_j is the coefficient of linear expansion due to temperature change and phase transformation; A, B and C are three constants and G is shear modulus. Note that ε_j can be written as $\varepsilon_j = (\rho_{0j}/\rho_j)^{1/3} - 1$, where ρ_{0j} is the substance density at initial temperature T_0 and zero pressure and ρ_j is the substance density at final temperature T and (may be) another phase state also for zero pressure.

The conditions of finiteness of displacement in the centre, continuity of radial displacement u and normal stress tensor component σ_r at the boundary between layers and the condition on the outer boundary of the body may be expressed thus:

$$B_1 = 0$$

$$A_j + B_j w_j = A_{j+1} + B_{j+1}, \quad j = 1, \dots, j_0 - 1$$

$$\begin{aligned} & 3K_j(A_j + A_{0j} - \varepsilon_j) - 4G_j B_j w_j \\ & = 3K_{j+1}(A_{j+1} + A_{0j+1} - \varepsilon_{j+1}) - 4G_{j+1} B_{j+1}, \\ & j = 1, \dots, j_0 - 1 \end{aligned}$$

$$3K_{j_0}(A_{j_0} + A_{0j_0} - \varepsilon_{j_0}) - 4G_{j_0} B_{j_0} w_{j_0} = -P$$

where $w_j = r_{j-1}^3/r_j^3$. We solve this system numerically.

5. Results of numerical modelling

We consider that (a) the system consists of pyrope and coesite at T_0 and P_0 , with coesite being completely

Table 4. Elastic properties of coesite, quartz and pyrope after Bass (1995), Fei (1995) and Holland & Powell (1990). Here and below the temperature is measured in kelvins and pressure, K and G – in GPa, density – in g/cm^3 . In inclusion $\varepsilon_{py} = \{2.14 \cdot 10^{-5} - 0.02 \text{PIK}_{py}^2\}(T - T_0) + 1.1 \cdot 10^{-8}(T^2 - T_0^2)/2\}$ and host garnet $py = (2.141050.02P/K2py)(TT0) + 1.1108(T2T20)/2/3$. The radius of coesite/quartz inclusion is $r_1 = 10 \mu\text{m}$, the radius of pyrope host is $r_2 = 1 \text{mm}$. Note, that in case $r_1/r_2 \ll 1$ a concrete value of this ratio does not influence the results.

	Coesite	Quartz	Pyrope
K , GPa	113.7	37.8	$150 + 5.3P - 0.02T$
G , GPa	61.6	44.3	$90 + 1.5P - 0.01T$
ρ , g/cm^3	$6.009/(2.064 + 2.2 \cdot 10^{-5}(T - 298))$	$6.009/(2.269 + 2.2 \cdot 10^{-5}(T - 298))$	

replaced by α -quartz and (b) at the final stage the garnet-host is at ambient conditions $T = 293 \text{K}$ and $P = 10^{-4} \text{GPa}$.

The mechanical properties of coesite (index *coe*), α -quartz (index *qtz*) and pyrope are given in Table 4.

In the diagram of Fig. 8, the dependence of the residual pressure in quartz P_{in} on T_0 for different P_0 is given. The residual pressure is high (more than 3 GPa) due to the expansion during the coesite-to-quartz phase transition. Note that in the absence of the coesite-to-quartz transformation residual pressure does not exceed 1.5 GPa.

Garnet composition has a slight effect on its elastic properties (Bass, 1995). Our calculations showed that changes in the mechanical properties of garnet had little effect on internal pressures.

In Fig. 9 the dependence of stresses σ_r , σ_t and $\hat{\sigma}$ on a radius for the case $P_0 = 6 \text{GPa}$, $T_0 = 1300 \text{K}$, $r_1 = 10 \mu\text{m}$, $r_2 = 1 \text{mm}$ are shown. The value $\hat{\sigma}$ corresponds to the pure pressure without shear stress. Note that in our case $\hat{\sigma}$ is constant inside a layer, but can be different in different layers, as also derived by experimental data. The optical measurements show large deformation of the pyrope near the inclusion, but the pressure measurements show small pressure up to the inclusion. The highest pressure in quartz is related to phase transition.

6. Discussion

Coesite-to-quartz transformation is accomplished with significant volume changes; very high residual pressures can be preserved in ‘‘monomineralic’’ (following the definition of Parkinson, 2000) coesite inclusions, as well as in partly transformed coesite (Parkinson & Katayama, 1999; Sobolev *et al.*, 2000; Ye *et al.*, 2001; Korsakov *et al.*, 2007). The Raman shift of quartz was recently tested on natural samples in order to estimate the effect of peak metamorphic pressure on residual pressure within the quartz inclusions (Enami *et al.*, 2007). For different UHPM complexes the maximum upshift of the main Raman quartz bands (up to 477cm^{-1}) was documented for partly transformed coesite inclusions (Korsakov *et al.*, 2007), corresponding to residual pressures of up to 1.6 GPa, (using the calibration of Hemley, 1987). Unlike Enami *et al.* (2007), we found no correlation between the residual pressure and the size of the inclusions.

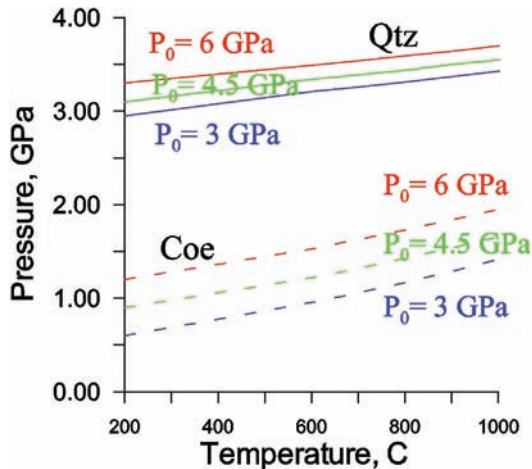

Fig. 8. Dependence of the residual pressure in coesite inclusions P_{in} on T_0 for different P_0 without phase transitions (dashed lines) and quartz inclusions (solid line) formed after complete transformation to quartz of original coesite inclusions.

Ye *et al.* (2001) mentioned that for polycrystalline quartz pseudomorphs after coesite the Raman shift can reach 470 cm^{-1} , corresponding to a residual pressure of $\sim 0.9 \text{ GPa}$. According to our numerical modelling, assuming the complete coesite-to-quartz transformation, the internal pressure for quartz pseudomorphs should be around 3.0 GPa (depending on P_0 and T_0). The radial crack patterns around coesite inclusions in different minerals were interpreted to result from pressure release within the inclusion (Gillet *et al.*, 1984; Van der Molen & Van Roermund, 1986; Nishiyama, 1998; Zhang, 1998). Recently, it was shown that even when exposed at the thin-section surface, coesite inclusions in UHPM garnet from the Kokchetav massif still preserve high residual pressures up to 0.5 GPa (Korsakov *et al.*, 2007). Therefore, it is unlikely that cracks around the inclusions can cause complete relaxation of residual pressure. So far, quartz inclusions with residual pressure above 1.7 GPa and shift above 477 cm^{-1} have not been documented for natural samples. This can be explained by the fact that most UHPM complexes underwent near isothermal decompression during the initial stage(s) of exhumation; therefore plastic deformation of the host garnet at $T \sim 800\text{--}900 \text{ }^\circ\text{C}$ is quite possible (Chen *et al.*, 1995; Karato *et al.*, 1995; Kleinschrodt & Duyster, 2002; Katayama & Karato, 2008).

Quartz inclusions in garnets from the eclogite xenolith preserved the highest values of residual pressure $\sim 1.5 \text{ GPa}$ and shift of the main quartz Raman bands. This is probably related to the very fast uplift of the eclogite xenolith by kimberlite melts compared to the exhumation rate of UHPM complexes (Canil & Fedortchouk, 1999; Kelley & Wartho, 2000; Grégoire *et al.*, 2006). Mineral assemblages of this sample formed in the diamond stability field (Tomilenko *et al.*, 2005) at $T = 1100\text{--}1200 \text{ }^\circ\text{C}$ and $P > 5 \text{ GPa}$; therefore the degree of transformation of coesite-to-quartz should not be significant. Kinetics of the

Fig. 9. Calculated radial (σ_r) and tangential (σ_t) stress in garnet host and quartz inclusion, originally trapped as coesite at $P_0 = 6 \text{ GPa}$, $T_0 = 1300 \text{ K}$, $r_1 = 10 \text{ } \mu\text{m}$, $r_2 = 1 \text{ mm}$.

coesite-to-quartz transformation are very fast at temperatures above $400 \text{ }^\circ\text{C}$ (Mosenfelder & Bohlen, 1997; Perrillat *et al.*, 2003) but the absence of dense radial crack patterns makes this transition unlikely during uplift. The exact P – T conditions of the coesite-to-quartz transformation in the eclogite xenolith are unknown.

Coesite-grade micaschist samples have a zonal distribution of SiO_2 inclusions. Quartz occurring in Mn-rich garnet cores was found to have low residual pressure, formed during a prograde stage of metamorphism (Fig. 10a–b). This is in a good agreement with the results of Udovkina (1985) and Parkinson (2000). The quartz crystals with higher internal pressure could also have formed during a prograde stage of metamorphism (Fig. 10c–f). However, the coexistence of these inclusions with coesite relics in the same growth zone of garnet porphyroblasts suggests that most probably they were trapped as coesite (Fig. 3). This hypothesis is further supported by the presence of quartz-diamond intergrowths included in garnet porphyroblasts from diamond-grade metamorphic rocks (Fig. 5e–f). It is worth noting that abundant coesite inclusions were found in the same thin section (Korsakov *et al.*, 2007). A recent investigation of “wet” and “dry” transformation of coesite to quartz was performed by Lathe *et al.* (2005). They found that the transformation rate of “wet” coesite is more than ten times higher than that of the “dry” coesite at the same conditions. This difference may explain why some coesite crystals in our samples were completely converted to quartz, whereas others remained intact. However, in this case the coexistence of monocrystalline quartz and coesite within the same growth zone of garnet porphyroblasts can be explained only if fluid had been distributed extremely heterogeneously and had very low mobility at the UHPM stage.

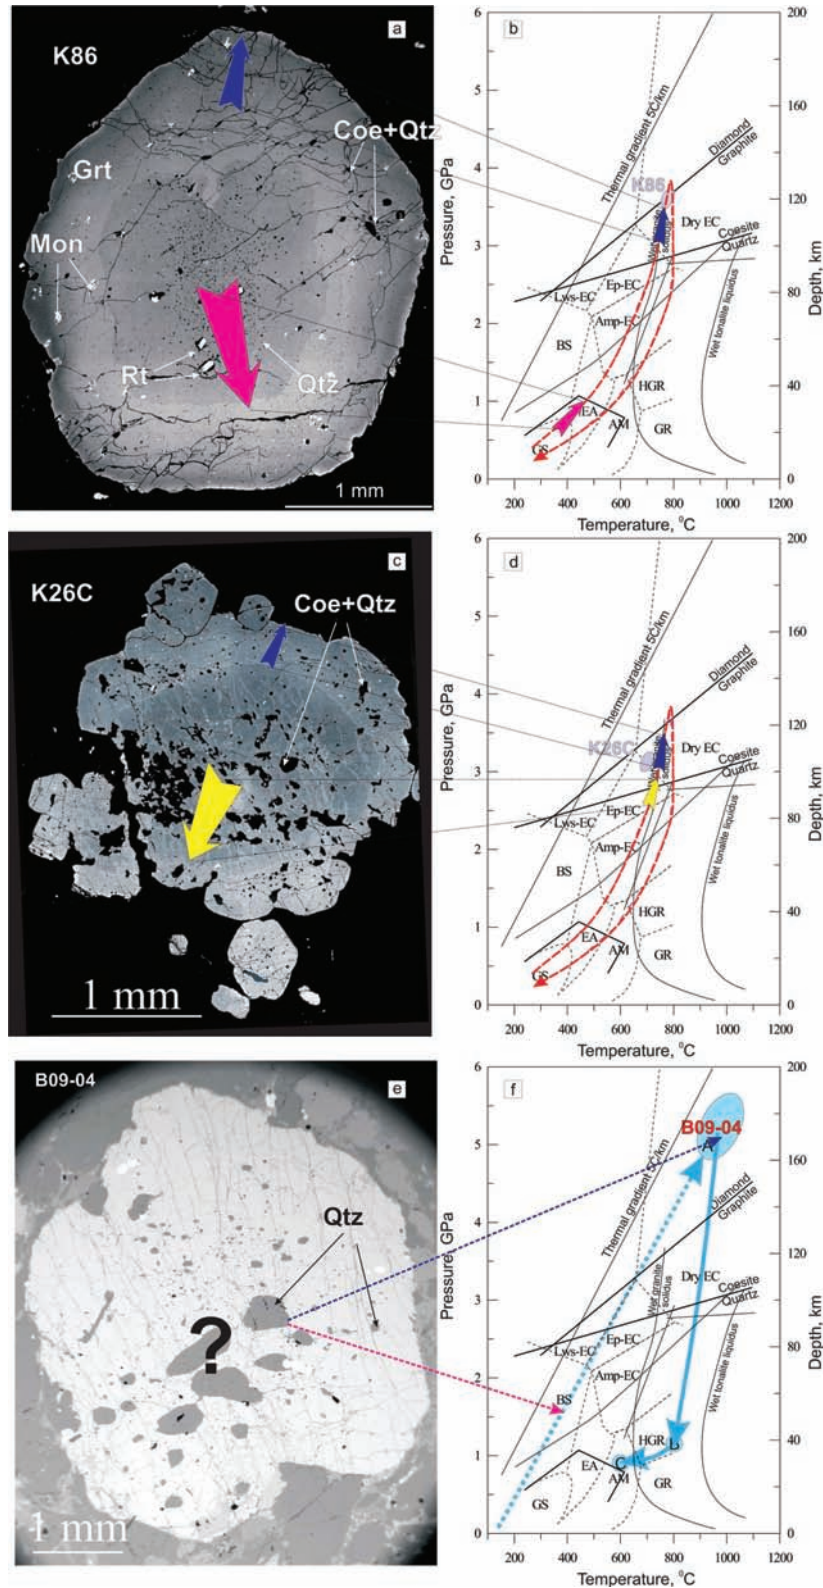

Fig. 10. BSE images of garnet porphyroblasts and P - T paths for coesite- (a–d) and diamond-grade (e–f) metamorphic rocks from the Kokchetav massif plotted on metamorphic facies diagram (after Liou *et al.*, 1998; Okamoto & Maruyama, 1999). The P - T stages indicated along the path of the coesite- and diamond-grade metamorphic rocks are based on petrologic data of Parkinson (2000), Theunissen *et al.* (2007) and Hermann *et al.* (2001), Korsakov *et al.* (2007), respectively. Thick arrows indicate the different stages of garnet growth. A very low subduction-zone geothermal gradient of 5 °C/km is also shown. Metamorphic facies abbreviations are: AM = amphibolite; Amp-EC = amphibolite-eclogite; BS = blueschist; EA = epidote amphibolite; EC = eclogite; EP-EC = epidote-eclogite; GR = sillimanite-bearing granulite; GS = greenschist; HGR = kyanite-bearing granulite; P = prehnite; PA = pumpellyite-actinolite; PP = prehnite-pumpellyite; and ZE = zeolite.

7. Concluding remarks

Euhedral monocrystalline quartz inclusions in garnets from metamorphic rocks recrystallized under diamond- and coesite-facies conditions, that

- (a) are not exposed at the polished thin-section surface,
- (b) lack strong radial crack patterns,
- (c) have a coesite shape or a negative crystal shape of the garnet host and
- (d) are surrounded by a birefringent halo, might be potential UHPM indicators.

High residual pressures of 0.8–1.2 GPa in euhedral monocrystalline quartz inclusions with the above-mentioned characteristics are derived from the Raman shift of the main quartz band varying from 469 to 474 cm^{-1} . The stronger the birefringent halo around such inclusions, the higher is the upshift of the main quartz Raman band. Numerical modelling indicates that complete transformation of coesite to quartz should create significantly higher residual pressure of approximately 3.0 GPa. The absence of such inclusions in natural samples may indicate that plastic deformation of the host garnet during a retrograde metamorphic stage reduces the residual pressure within the inclusion.

Summarizing the results of this study, we suggest that:

- Monocrystalline quartz inclusions with residual pressure up to 1.2 GPa (shift of the main quartz Raman band up to 474 cm^{-1}) might be considered as indirect evidence for UHPM conditions.
- Monocrystalline quartz inclusions with residual pressure above 2.5 GPa would clearly indicate that these quartz inclusions were coesite, which transformed to quartz.
