Abstract

The amount of detailed experimental data on the mechanical properties of brick masonry available in the literature is limited as regards the orthotropic compression behaviour. These properties include both the strength and the fracture energy. This paper attempts to determine the mechanical properties of the masonry composite as a function of the properties of its components.

In this paper a combined experimental/numerical methodology is proposed for the derivation of the macro scale properties of masonry. The experimental aspect deals with the mechanical characterization of the individual materials, small masonry samples and, finally, masonry wallettes and includes the relation of couplet to wallette compressive strength. The numerical aspect is the calculation of the macroscopic properties of the masonry composite through calculations using discrete cracking models of the wallettes. Unknown material properties are taken from the available literature. The calculations are performed in two orthogonal in-plane directions. For evaluation, material properties for the meso-models are taken from laboratory testing and from the literature. The results of the numerical analyses are compared with the experimental stress-strain results and Digital Image Correlation (DIC) analysis. Parameters such as the Young's modulus and compressive fracture energy for the masonry composite are able to be derived. The results are analysed in view of the resulting anisotropy of masonry and the obtained failure modes.

26   This paper is a revised and expanded version of a paper entitled "Mechanical characterization of masonry on

27   the macro scale from experimental testing and numerical meso scale modelling" presented at the 10th International

28   Masonry Conference, Milan, Italy, 9-11 July 2018.

30   Numerical analysis, masonry, discrete cracking, meso-modelling, macro-modelling

1. Introduction

1.1   State of the art

33   The derivation of the macroscopic mechanical properties of masonry composites from experimental and

34   numerical testing is a complicated matter (Sarhosis, 2016). This derivation requires one of two approaches to be

35   adopted: either testing of entire masonry samples or testing of small material samples, i.e. units, mortar and

36   couplets, and subsequent upscaling. The first approach requires the construction of large samples, i.e. masonry

37   prisms or wallettes (Adam, Brencich, Hughes, & Jefferson, 2010), which can be time-consuming and costly.

38   Additionally, either of these approaches may require sample extraction (Pelà, Canella, Aprile, & Roca, 2016) in

39   the case of existing structures where the material properties cannot be easily or reliably determined through non-

40   destructive testing. As such the second approach is far more appealing and straightforward in execution.

41   Substantial complexity arises from size effects influencing the mechanical testing, the compressive strength in

42   particular (Drougkas, Roca, & Molins, 2016; Segura, Pelà, & Roca, 2018). This can affect both the units, from

43   which it is difficult to extract compression samples with proper dimension ratios, and mortars, which may have

44   different properties in stand-alone samples and in the joint. Further complexity is introduced by the well-

45   documented variability of masonry materials, particularly in the case of existing and historic structures (Laefer,

46   Boggs, & Cooper, 2008). This second approach is further associated with the additional step of calculating the

47   macroscopic properties of the masonry composite from the individual properties of the component materials,

48   which is not an easy task.

49   The construction and testing of masonry couplets and triplets requires far fewer resources and time than that

50   of wallettes. Couplets are particularly advantageous for the investigation of existing and historic masonry

51   structures due to the requirement of smaller amounts of original material. Extraction of masonry samples for

compressive testing is well documented in the literature, both for composites using lime (Pelà, Kasioumi, & Roca, 2017; Pelà, Roca, & Benedetti, 2016) and cement mortar (Brencich & Sterpi, 2006) and further proposed by recommendations for the assessment of existing masonry structures (International Union of Railways, 2011). However, a clear relation between the compressive strength of couplets and wallettes has not been established, despite related work with large 4- or 5-unit prisms (Gumaste, Nanjunda Rao, Reddy, & Jagadish, 2007; Vermeltfoort, Martens, & van Zijl, 2007). Given the large percentage of brick masonry structures built in running bond or similar variants, it is essential to establish a relation for the compressive strength of the two typologies.

A valuable tool during the execution of mechanical tests on masonry materials and members is digital image correlation (DIC). Through the use of a single digital camera monitoring a prepared surface of the sample, it is possible to obtain the full-field displacements of the sample. Strain maps can be subsequently created and related to the applied stresses at any given moment for the determination of the Young's modulus and the Poisson's ratio. Since no physical contact and no attached instruments are required for the application, DIC can be applied to samples of small size, on which the attachment of physical measurement devices is difficult or impossible. This technique has been applied to both masonry materials (Drdácký, Masin, Mekonone, & Slizkova, 2008) and entire members (Bejarano-Urrego, Verstrynge, Giardina, & Van Balen, 2018; Thamboo, Dhanasekar, & Yan, 2013). The use of DIC on masonry at the member scale has been generally used for the tracking of the formation of cracks and the evaluation of their width under increasing load, at which point the deformations are mostly concentrated at the failure lines and of a significant magnitude (Cotič, Jagličić, & Bosiljkov, 2014; Nghiem, Al Heib, & Emeriault, 2015; Ramos et al., 2015). A promising application of the method is for the evaluation of the elastic properties of the masonry composite in the elastic range under low loads and low strain magnitude.

For the numerical modelling of masonry structures different approaches may be adopted, distinguished by the level of detail. A unified terminology for the different approaches has not yet been established, necessitating the definition of the terminology followed in this paper. Micro-modelling requires the individual simulation of the units, the mortar and the unit-mortar interface. This approach additionally demands that the models account for the three-dimensional confinement of mortar in compression in order for the compressive strength of the composite to be correctly estimated (Drougkas, Roca, & Molins, 2019; Petracca et al., 2017; Sandoval & Arnau, 2017). In meso-modelling the behaviour of the interfaces in tension, compression and shear is lumped in nonlinear

3

79   interfaces between the units, which may themselves be linear elastic, nonlinear elastic or featuring potential cracks

80   through the introduction of nonlinear interfaces in their area (Lourenço & Rots, 1997). Finally, macro-models

81   treat the entire masonry as a homogenous nonlinear elastic continuum which may feature orthotropic behaviour

82   (Pelà, Cervera, & Roca, 2013). This approach requires the experimental determination of the orthotropic

83   properties of masonry since it cannot directly account for the geometric interlocking of the units and the orthotropy

84   that it induces in the composite. Concerning the choice between methods, Noort (Noort, 2012) has recommended

85   the use of meso-models rather than micro-models since the micro-models were found to be numerically unstable.

86   Micro-models are also associated with significantly increased computational cost and model preparation time and

87   effort. However, the main drawback of the meso-models, shared with micro-models but absent in macro-models,

88   is the necessity for an approximation of the non-linear behaviour of the joint interface. While having been used

89   for the study of walls under combined compression and in-plane shear, meso-models have not been employed for

90   the evaluation of the orthotropic properties of masonry composites in compression.

1.2   Objectives

92   This paper proposes a meso-modelling based methodology to determine the orthotropic material properties of

93   masonry composites using the isotropic properties of their components. The methodology initiates with a

94   laboratory testing campaign to determine the mechanical properties of the masonry components. The methodology

95   comprises of compression and bending tests on brick and mortar samples, as well as vertical compression tests on

96   masonry couplets. Moreover, it includes compression tests on masonry panels, with about 43 cm side length,

97   loaded vertically and horizontally (in a direction perpendicular and parallel to the bed joints respectively). The

98   tests on the panels are monitored with Linear Variable Differential Transformers (LVDTs) as well as DIC which

99   monitors and calculates the horizontal and vertical full-field displacement contour maps during the whole test.

100   The DIC displacement fields are used for the determination of the orthotropic elastic properties of the masonry

101   composite.

102   The next step includes the development of non-linear discrete cracking meso-models of the masonry panels

103   subjected to compression in both orthogonal loading directions. The material characterization for the models is

104   based on the laboratory testing campaign results and relevant literature. From these models, the stress-strain curves

4

105 for compression are determined and thus the masonry composite properties are obtained. These properties include

106 the Young's Modulus E_m, compressive strength $f_{c,m}$ and Poisson's ratio ν_m.

107 Meso-modelling of masonry allows the calculation of the mechanical properties of masonry composites based

108 on the results of experimental tests on small material samples. Micro-modelling can serve the same purpose, but

109 involves far greater computational cost and modelling complexity. This aspect was investigated by Noort (Noort,

110 2012), who introduced an initial methodology using several bond types and considering the properties of the brick,

111 mortar as well as the brick-mortar interface, for which micro-models instead of meso-models were used. However,

112 several issues were faced regarding the numerical instability of such micro-models together with a lack of

113 sufficient experimental data. The current methodology therefore implements the meso-modelling approach as well

114 as a laboratory testing campaign on different sample sizes.

115 2. Lab Testing Campaign

116 2.1   Overview and scope

117 To characterize the mechanical properties of the masonry, an experimental campaign was performed on small

118 samples of the masonry constituents as well as masonry couplets. Tests on masonry panels were executed as well.

119 Mortar and brick samples were tested under compression and bending, while couplets and masonry panels were

120 tested under compression, the latter ones in two orthogonal in-plane directions. Numerical meso-models of

121 masonry panels under pure compression were built considering the obtained experimental material properties.

122 From these meso-models, smeared material properties are determined aimed at characterizing macro-models.

123 The testing of couplets serves as an intermediate step between the testing of individual material samples and

124 the testing of masonry wallettes. The construction and testing of wallette samples presents substantial advantages

125 compared to wallettes in terms of economy and time investment. Further, in the particular case of historic masonry,

126 the construction of couplets requires a very limited amount of extracted material. It is therefore worthwhile to

127 attempt the determination of the properties of masonry composites as input for meso-scale models from the testing

128 of masonry couplets.

129   The masonry is composed of solid clay bricks with dimensions $188 \times 42 \times 88$ mm^3 and hybrid lime-cement

130   mortar composed of river sand 0/2 (68.0 %), Portland cement CEM I 52.5 (5.6 %), hydrated lime (11.4 %) and

131   water (15.0 %).

2.2   Material characterization on small samples

133   The compressive strength f_c and Young's modulus E were derived from uniaxial compression tests on mortar

134   and brick cubes as well as on couplets. Six mortar samples and eight brick samples with dimensions $40 \times 40 \times 40$

135   mm^3 were tested (Figure 1a). The loading scheme consists in an initial cyclic sequence and a final monotonic

136   sequence. The cyclic sequence consisted in 3 loading and unloading branches, reaching the 10%, 25% and 50%

137   of the anticipated peak stress. All loads were applied in displacement control at a rate of 0.2 mm/min in order to

138   accurately register the softening branch. Measurements were taken from four LVDTs which were fixed on the

139   loading plates at each corner of the cubes. The brick cubes were produced through cutting using a circular saw

140   and were tested without the use of a compensating layer between sample and load plate, a smooth loading surface

141   being produced by the cutting process. This approach precludes the deformation of a compensating layer in the

142   case where the LVDTs are placed on the load plates. While a standard for the testing of masonry units in

143   compression is available (CEN, 2011), it prescribes the testing of entire units and the adjustment of the results

144   using numerical factors based on dimension ratios. The production of cubic samples allows the partial alleviation

145   of size effects, as well as allowing the execution of the compressive testing of both mortar and units on similarly

146   shaped samples using the same setup.

147   Three masonry couplets arranged with two bricks bound with a 12 mm mortar bed joint were also tested in

148   compression at the age of 28 days using a cyclic load setup. The load was applied in displacement control at a

149   rate of 0.5 mm/min. Two LVDTs were fixed on the opposite long sides of the couplets, as shown in Figure 1b. A

150   gypsum layer was applied at the load surfaces of the samples to ensure a plane loading surface. Finally, a Teflon

151   sheet was subsequently added between the gypsum layer and the load plates in order to reduce friction between

152   the load plates and the samples.

153   The characterization of the flexural strength of bricks and mortar was done using three-point bending tests on

154   specimens with size $40 \times 40 \times 160$ mm^3 following EN1015-11 (CEN, 2007), as shown in Figure 1c. Loading was

155   applied in displacement control at a rate of 0.2 mm/min.

156

157   **Figure 1   Experimental setup for small samples: a) compression test on cubes, b) compression test on**

158   **couplets and c) three-point bending test on small beams (clay brick shown here). Colour figure available in**

159   **online version.**

160   Figure 2 shows the stress-strain curves from the compression tests on the different samples. The naming

161   convention for the 8 unit samples consists in a numerical value indicating the parent brick unit (1 through 4) and

162   a letter (A or B) indicating the two samples extracted from the unit. A similar convention is followed for the

163   mortar samples, with a parent mortar prism, tested in bending, and the two resulting halves indicated by a number

164   and a letter respectively. Table 1 presents the average values of the test results. The brick samples, despite being

165   of moderate strength, are clearly stronger than the mortar in compression. The compressive behaviour of the

166   couplets is closer to the mortar, indicating the lower strength of the masonry joints compared to the units, but also

167   a moderate confinement effect. The Young's modulus of the samples was measured as the secant modulus of the

168   final loading branch of the cyclic loading sequence. The very low scatter of the couplet compressive strength is

169   noteworthy, particularly in comparison with the higher scatter obtained from the brick tests.
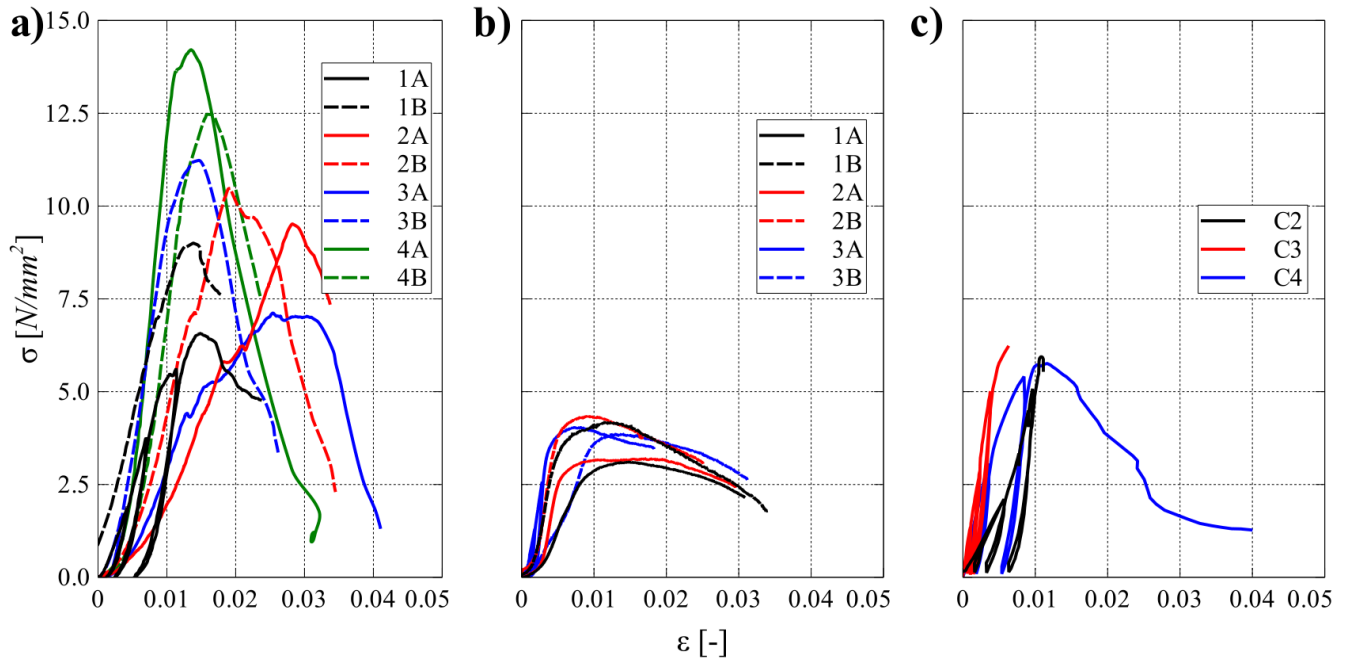

Figure 2   Stress-strain curves from compression tests: a) brick cubes, b) mortar cubes and c) couplets. Colour figure available in online version.

For couplet C4 it is possible to calculate the compressive fracture energy through integration of the area beneath the stress-displacement curve at the post-peak (Figure 2c). The choice of including only the post-peak part of the curve for this calculation is consistent with the compressive hardening/softening curve used in the combined cracking-shearing-crushing model employed in this paper (Lourenço & Rots, 1997), as well as the parabolic constitutive law proposed by Feenstra (Feenstra & Borst, 1996). This can be performed in a straightforward manner through trapezoidal integration of the data points according to the equation:

$$G_c = \sum_{n=2}^{N} H \cdot (\varepsilon(n) - \varepsilon(n-1)) \cdot \frac{\sigma(n-1) + \sigma(n)}{2}$$

(1)

where N is the total number of data points beyond the peak stress and H the total length of the sample along the direction of applied force. The high sampling rate allows for an accurate calculation using this numerical integration method. The equation yields a compressive fracture energy of 5.56 N/mm.

8

183 **Table 1** **Average mechanical properties obtained from tests on small samples.**

| Material	f_c [N/mm^2]	E [N/mm^2]	f_{flex} [N/mm^2]
Brick	9.62 (0.227)	2570 (0.297)	3.65 (0.066)
Mortar	3.00 (0.217)	920 (0.382)	0.92 (0.250)
Couplets	6.01 (0.035)	2025 (0.332)	-
Note: coefficient of variation indicated in parentheses			

184 ## 2.3 Tests on masonry panels

185 Additional compression tests were performed on four stretcher bond masonry panels, with 12 mm mortar

186 joints, composed of 7 courses in height (426 mm), 2 brick units in width (391 mm) and 1 half brick in thickness

187 (88 mm). Two masonry panels were loaded perpendicular to the bed joints, while the other two were loaded

188 parallel to the bed joints, as shown in Figure 3. While a relevant standard was consulted for the construction and

189 geometrical arrangement of the samples (CEN, 1999), the arrangement of the measurement setup was adapted

190 according to the specific needs of this investigation and the placement of other sensors. Additionally, only two

191 samples were tested in each direction as opposed to the suggested minimum of three.

192 Three vertical and one horizontal LVDTs were placed on one side of the panels to obtain displacements in

193 both directions and to allow the calculation of the planar Poisson's ratio ν (Figure 3). On the other side of the

194 panels, full-field vertical and horizontal displacements were monitored by means of stereo-vision digital image

195 correlation (DIC) (Sutton, Orteu, & Schreier, 2009; Verstrynge et al., 2018). The application of DIC for the

196 measurement of displacement fields on masonry structures under mechanical loading is a relatively novel but

197 promising technique (Mojsilović & Salmanpour, 2016). The tests were executed using displacement control

198 conditions at a loading rate of 0.5 mm/min. Both cyclic and monotonic compression tests were performed on the

199 wallettes. Cyclic loads were applied up to about 10 kN, 20 kN, 30 kN and 40 kN of load, the final value

200 corresponding to about 50% of the expected peak force.

201 The naming convention for the loading direction is based on the orientation of the masonry bond in actual

202 structures. Therefore, vertical loading indicates an application of a load perpendicular to the bed joints and

203 horizontal loading indicates an application of a load parallel to the bed joints.
204

205   **Figure 3   Setup of compression tests on masonry panels: a) perpendicular to the bed joints (vertical**

206   **loading) and b) parallel to the bed joints (horizontal loading). Colour figure available in online version.**

207   The initial cyclic tests are presented in Figure 4. Both the strains along the axis of loading and in the lateral

208   direction are presented. The pairs of wallettes in either direction presented similar behaviour, as can be ascertained

209   through comparison of the obtained curves. The higher stiffness of the wallettes in the horizontal direction is

210   particularly apparent in the case of the H1 wallette, even for the low loads applied in the cycles. None of the

211   wallettes presented visible cracking at the end of the cycles, nor was there any reduction in stiffness apparent in

212   the obtained stress-strain curves.

213
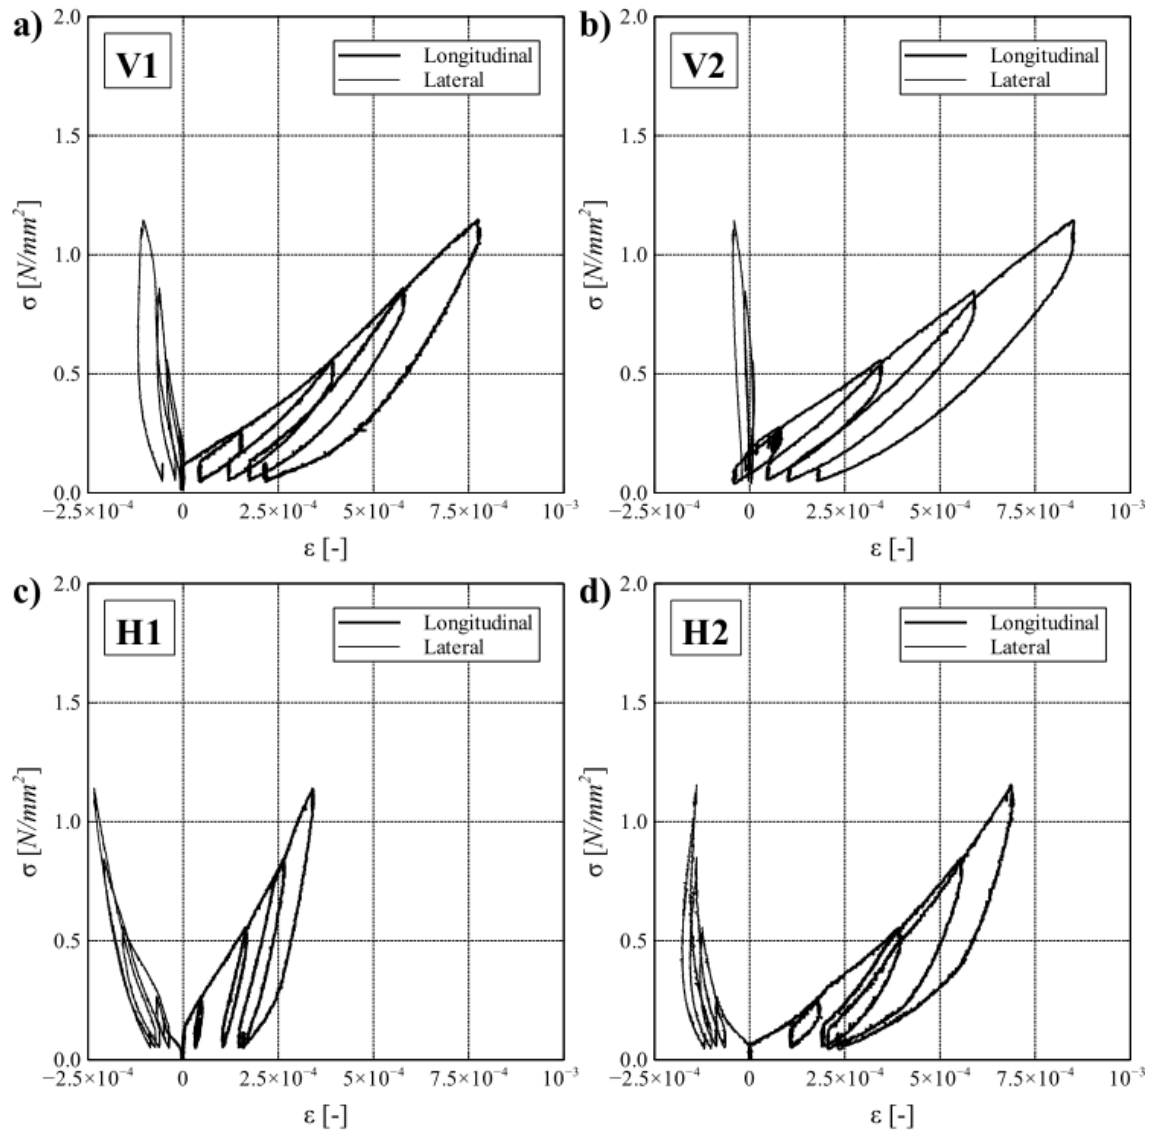

Figure 4   Stress-strain graphs for wallettes in cyclic compression: a) V1, b) V2, c) H1 and d) H2 samples. V1 and V2 are wallettes subjected to vertical loading. H1 and H2 are wallettes subjected to horizontal loading.

The stress-strain curves as obtained in the subsequent monotonic compression tests for all the panels are shown in Figure 5. The strains in both the longitudinal and lateral direction relative to the load application are presented. They indicate a slightly higher stiffness on the panels loaded parallel to the bed joints (H1 and H2). The compressive strength obtained was on average 2.66 N/mm^2, excepting one of the panels loaded vertically, which only reached 1.85 N/mm^2. Table 2 shows the summary of the mechanical properties obtained from the tests on the panels loaded in both directions. A small difference can be seen in the Poisson's ratio regarding the loading

223   direction. Due to a malfunction of the horizontal LVDT, the Poisson's ratio of the second wall tested horizontally

224   (H2) was not correctly measured.
225

226   **Figure 5   Stress-strain graphs for wallettes in monotonic compression: a) V1, b) V2, c) H1 and d) H2**

227   **samples.**

228   It was found that the compressive strength values obtained from the panels are about half of the values

229   obtained from the couplets (6.01 N/mm^2), but just slightly lower than the values from the mortar samples (3.00

230   N/mm^2). The Young's modulus was determined as the secant modulus of the final loading branch of the cyclic

231   load sequence.

232   The compressive fracture energy as calculated by equation (2) yields values much higher than the value

233   calculated for the couplets, which have a single mortar joint. This response can indicate either lateral confinement

234   of the sample by the load plates, confinement of the mortar joint by the units, which can increase the apparent

235   compressive fracture energy of the mortar, or a less localized crushing across several mortar joints, with possible

236   contribution by the energy consumed in the failure of the units in compression and tension.

237   **Table 2   Mechanical properties obtained from compression tests on masonry panels.**

Panel	f_c [N/mm^2]	E [N/mm^2]	G_c [N/mm]	ν [N/mm^2]

238   ## 2.4   Discussion on results

239   The results obtained from the present experimental campaign are compared with results from the literature

240   dealing with lime/cement mortars and solid clay units. The comparison of couplet and wallette test results, as well

241   as of wallette tests in two orthogonal directions, is very uncommon in the literature. A number of instances are

242   presented for comparison in Table 3. In terms of notation, f_{cu} and f_{cm} are the uniaxial compressive strength of

243   the units and the mortar respectively, f_{cwv} and f_{cwh} are the compressive strength of wallettes in the vertical and

244   horizontal direction and f_{cc} is the compressive strength of masonry couplets or triplets.

245   The compressive strength of the wallettes in the present case study appears to be atypical for lime/cement

246   mortar masonry. The expected compressive strength normally lies between that of the units and the mortar in

247   uniaxial compression (Drougkas, Verstrynge, Hayen, & Van Balen, 2019; Segura et al., 2018). The reason behind

248   this low strength of the wallettes is not entirely clear, although it has been previously noted in experimental

249   campaigns with low to moderate strength bricks coupled with moderate to high strength mortars (Binda, Fontana,

250   & Frigerio, 1988; Gumaste et al., 2007; Kaushik, Rai, & Jain, 2007; Sarangapani, Reddy, & Jagadish, 2005).

251   Nevertheless, similar ratios between the strength of couplets and wallettes were encountered in cases of

252   lime/cement mortars (Verstrynge, Schueremans, & Van Gemert, 2011), with the couplets having a much higher

253   strength than wallettes loaded vertically.

A substantial difference between the compressive strength of wallettes and couplets or triplets has been noted for the types of materials used in the present study and from available data in the literature (Drougkas, Roca, et al., 2019; Drougkas, Verstrynge, et al., 2019; Verstrynge et al., 2011). This can be attributed to size effects due to the dimension ratio difference between the samples, the existence of head joints in the wallettes and to less effective compaction of the bed joints during construction. Overall, the ratio of couplet or triplet strength to wallette vertical strength lies between 1.33 and 3.16 in the considered cases, including the present study.

A characteristically anisotropic response has been registered in the masonry wallettes. As in the present study, a slightly higher compressive strength in the horizontal direction over the vertical has been found in similar experimental campaigns (Drougkas, Roca, et al., 2019; Page, 1983). Assuming that the compaction of the mortar is equally well-performed in the head and the bed joints, the function of the bed joints in shear appears to be a factor influencing the response of the masonry wallettes in horizontal compression. The ratio of horizontal to vertical wallette compressive strength, both in the present case and in the literature, varies between 1.08 and 1.13. This agreement indicates that the average values of the compressive strength of the wallettes have been determined with some confidence despite the use of a limited number of samples.

**Table 3   Comparison of present experimental findings with data from the literature.**

Reference	f_{cu} $[N/mm^2]$	f_{cm} $[N/mm^2]$	f_{cwv} $[N/mm^2]$	f_{cwh} $[N/mm^2]$	f_{cc} $[N/mm^2]$	c/b $[-]$

Close examination of the results from the literature and the present study reveals a clear relation between the cement content as a percentage of total binder c/b in the mortar and the ratio of couplet/triplet and vertical running bond wallette strength. The higher the cement content in the mortar the lower the compressive strength ratio. Given that lateral confinement of the joint mortar is of prime importance in the compressive strength of masonry, it follows that couplets and triplets provide much more effective confinement to the joints than running bond wallettes. The decrease of the strength ratio for higher cement content is consistent with the decrease in

276 importance, and in fact in the amount, of confinement for cement mortars with moderate to high compressive

277 strength. The relation is illustrated in Figure 6, along with the least squares linear fit curve, which reads:

$$\frac{f_{cc}}{f_{cwv}} = -1.762(c/b) + 3.025$$

(2)

3. Numerical analysis

282 Numerical analyses of the masonry panels using a meso-modelling approach were performed aiming to

283 determine smeared parameters to characterize macro-models. This procedure was planned and implemented based

284 on the work elaborated by Noort (Noort, 2012). The panel models were subjected to compression, as shown in

285 Figure 7, allowing to obtain the stress-strain curves and parameters such as Young's Modulus E, compressive

286 strength f_c and Poisson ratio ν.

3.1   Meso-modelling approach

288 The meso-modelling approach adopted is a discrete cracking model in which the damage is concentrated in

289 relatively weak interfaces simulating the mortar joints by means of discrete non-linear interface elements with

290 zero thickness. The brick elements are expanded to cover half of the width of the mortar joints and are represented

291 by continuum linear elastic plane stress elements (Figure 7).

15

292   In this approach, masonry was modelled as a set of elastic elements bounded by potential fracture interfaces

293   through the mortar joints. The meso-modelling strategy reduces geometrical complexity and computational costs

294   compared to micro-modelling, in which bricks, mortar and the brick-mortar interfaces are modelled as different

295   elements.

296   The non-linear behaviour of the joint interfaces was modelled using a combined cracking-shearing-crushing

297   model proposed by Lourenço (Lourenço & Rots, 1997). The plasticity criterion includes three failure mechanisms:

298   joint tensile cracking (Mode I), joint slipping (Mode II) and crushing (Mode III), in which softening behaviour

299   takes place. The model is based on multi-surface plasticity and includes a Coulomb friction model combined with

300   a tension cut-off and an elliptical compression cap (TNO, 2017). Therefore, all failure modes associated with

301   masonry loaded in-plane are accounted for.

302   Brick units were represented by quadrilateral continuum plane stress elements with about 25 mm sides, with

303   8 nodes and 2×2 integration points, arranged as shown in Figure 7. Line interface elements with 6 nodes were

304   adopted for the joints. The panel models were subjected to displacement uniformly applied on a very rigid plate

305   attached at the side, from which the resulting reaction force was obtained. The opposite side of the panel was

306   pinned.

307   The adopted material properties are listed in Table 4; they were chosen after a calibration procedure

308   (Bejarano-Urrego et al., 2018) taking into account the experimental data from the tests on small samples and

309   panels as well as data from literature (Drougkas, Roca, & Molins, 2015; Giardina, Hendriks, & Rots, 2015; Noort,

310   2012; Rots, 1997; Van der Pluijm, Rutten, & Ceelen, 2000). The interfaces are assigned the compressive strength

311   of the wallettes in the vertical direction. In the general case, where it is intended to avoid tests on wallettes, the

312   compressive strength determined from couplet testing may be modified according to equation (3) and used instead

313   of the wallette strength. The normal stiffness $k_{n,i}$ and shear stiffness $k_{s,i}$ of the joint interfaces are estimated from

314   the tests on the small samples by means of expressions (4), proposed by Lourenço (Lourenço & Rots, 1997), in

315   terms of the Young's modulus of the brick E_b and mortar E_{mo}, the thickness of mortar layer t_{mo} and the Poisson's

316   ratio. The cohesion of the joint interfaces c_i is assumed equal to 1.2 $f_{t,i}$ (Van der Pluijm et al., 2000). Three values

317   were used for the compressive fracture energy: 5.56 N/mm as calculated from the couplet tests, 13.30 N/mm for

16

318   the wallettes in the vertical direction and 18.60 N/mm for the wallettes in the horizontal direction as calculated

319   from the wallette compression experiments.

$$k_{n,i} = \frac{E_b E_{mo}}{t_{mo}(E_b - E_{mo})}; \ k_{s,i} = \frac{G_b G_{mo}}{t_{mo}(G_b - G_{mo})}; \ G_{b,mo} = \frac{E_{b,mo}}{2(1+v_{b,mo})}$$

325   ## 3.2   Numerical analysis results

326   The experimental and numerical stress-strain curves of the panels loaded under compression are presented in

327   Figure 8, indicating the loading direction: either horizontal (Hor.) or vertical (Ver.). Reasonable agreement is

328   obtained between the experiments and the analyses. The masonry properties obtained from these meso-models,

329   for each loading direction, are the Young's modulus E_m, compressive strength $f_{c,m}$ and Poisson's ratio ν_m. All

330   these smeared parameters are shown in Table 5.

331   The obtained peak force and failure mode depend on the direction of the loading. The failure mode is more

332   straightforward in the vertical direction, with the response being dominated by the yielding of the bed joint in

333   compression. The staggered arrangement of the head joints complicates the failure mode in the horizontal

334   direction. This arrangement introduces shear stresses in the bed joints, whose resistance is overcome before sliding

335   at the bed joint unit-mortar interface occurs. This contribution increases the obtained compressive strength in the

336   horizontal direction.

337   In accordance with the experimental results, the model presented higher stiffness in compression when loaded

338   horizontally, having a Young's modulus 1.3 times higher than in the other direction. However, this phenomenon

339   is more marked in the experimental data, in which the Young's modulus of the masonry panels loaded vertically

340   is about double. A similar phenomenon occurs with the Poisson's ratio, which is higher for loading horizontally

341   due to higher transversal deformation (barrel-like distortion under compression). The compressive strength is

342   similar for both models and in agreement with the experimental data.

343   The effect of the compressive fracture energy is also shown in Figure 8. Using the lower value calculated for

344   the couplets results in a post-peak response not registered in the experimental tests. Using the higher value derived

345   from the wallette compression tests yields a numerical result closer to the experimental stress-strain curves,

346   particularly in the case of the horizontal compression.
Figure 8   Comparison of stress-strain experimental and numerical results: a) wallettes with low compressive fracture energy and b) wallettes with high compressive fracture energy. Colour figure available in online version.

**Table 5**   Numerical analysis results from the masonry panel models.

Parameter	Symbol	Vertical	Horizontal	Units
Young's Modulus	E_m	1856	2291	N/mm^2
Poisson's ratio	ν_m	0.15	0.20	-
Compressive strength	$f_{c,m}$	2.31	2.60	N/mm^2

4. DIC results

Figure 9 shows the vertical displacement field at a level of applied force equal to 30 kN (0.87 N/mm^2) and 45 kN (1.31 N/mm^2) as monitored through DIC during the experiment. The coordinates are measured from the centre of the area of interest, or roughly the geometric centre of the wallette surface. Similarly, Figure 10 shows the vertical displacement field obtained from the meso-model for the same levels of applied load for a panel loaded under vertical compression. A speckle pattern coating was applied on the entire surface of the samples, constituting the area of interest for the measurements. This was despite the fact that masonry structures may not require the application of a speckle pattern, the measurements being capable of being acquired through the surface texture of the units and the mortar alone (Verstrynge et al., 2018). While the entire surface of the wallettes was considered in this analysis, it was necessary to exclude the results near the edges of the masonry wallettes. This

362 was due to the distortion they can cause in the presentation of the deformations. A buffer of 13 mm was thus

363 employed, inwards from the edge of the samples.

364
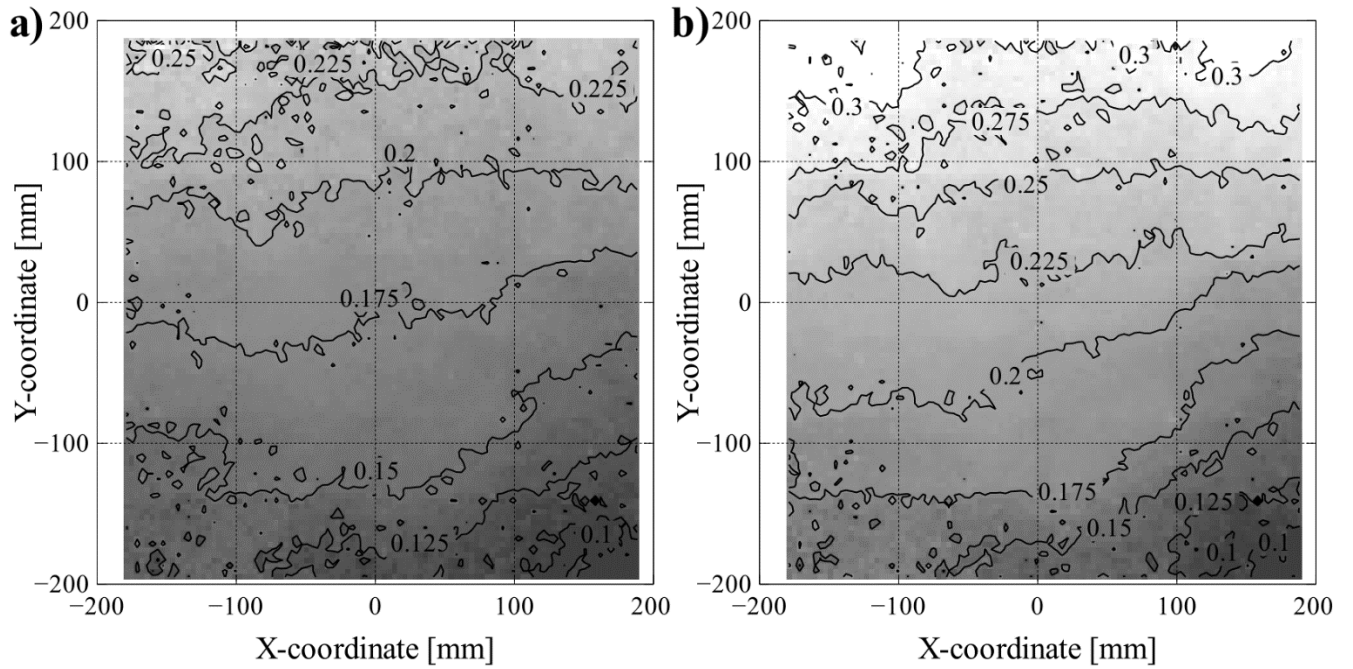

365 **Figure 9   Experimental vertical displacement field in mm at a) 30 kN and b) 45 kN of applied load,**

366 **monitored with the DIC technique for panel loaded under vertical compression (wallette V2).**

367
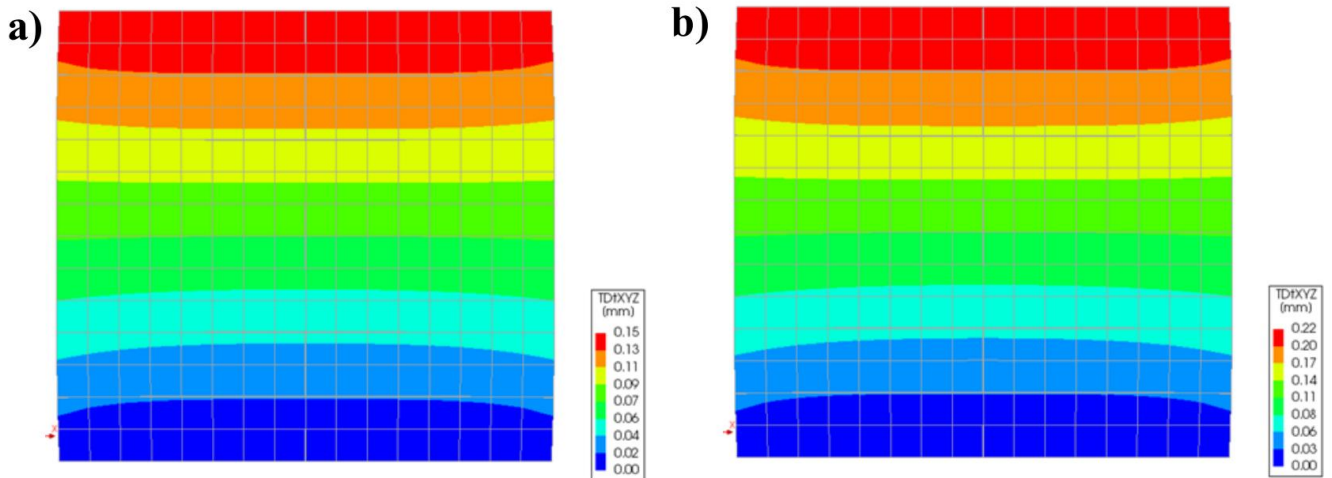

368 **Figure 10   Numerically derived vertical displacement field in mm at a) 30 kN and b) 45 kN of applied**

369 **load, obtained with the meso-model for panel loaded under vertical compression. Colour figure available**

370 **in online version.**

371   Following the processing of the DIC results, a vertical displacement of 0.175 mm is registered at the top of

372   the sample for a load of 30 kN and 0.217 mm for a load of 45 kN. These values were obtained by determining the

373   difference between the average deformation at the top of the measured surface and its base. The corresponding

374   displacements obtained from the finite element meso-model analysis were 0.150 mm and 0.220 mm, meaning that

375   an adequate degree of accuracy was achieved through the finite element models for in-plane compressive loading.

376   The Poisson's ratio of the wallettes was evaluated according to vertical and horizontal deformation data at the

377   elastic range of the monotonic loading branch, both at the outer edges of the samples and at the inner third of their

378   surface. The results are summarized in Table 6. The average values of the Poisson's ratio in the vertically loaded

379   wallettes are equal for the outer and inner measurements. In the horizontal loading case, however, the outer

380   measurements are affected by the lateral movement of the unrestrained outer header units, resulting in a higher

381   apparent Poisson's ratio. The Poisson's ratio at the inner third is in relatively good agreement in comparison both

382   with the LVDT results and the FE analysis.

383   **Table 6   Poisson's ratio of wallettes derived from DIC data.**

	Poisson's ratio	
Sample	Inner	Outer
V1	0.198	0.161
V2	0.137	0.174
Average vertical	0.168	0.168
H1	0.216	0.277
H2	0.223	0.785
Average horizontal	0.220	0.531

384

385   The DIC measurements further serve to highlight certain details of the response of the wallettes in

386   compression. The displacement field in the finite elements analysis is purely symmetrical. In the experiment the

387   vertical displacement field indicates slightly higher vertical deformation to the left of the sample. This can be

388   attributed to imperfections of the sample itself, of the contact with the load plates or localized material weakness

389   and failure.

390   Overall, it is demonstrated that DIC can be successfully employed in masonry member destructive tests not

391   only for the tracking of crack widths but also for the determination of the elastic properties of the composite. The

392   main practical advantage of this approach is the lack of need for the attachment of LVDTs or strain gauges. This

393   allows the evaluation of data after the formation of cracks that would cause detachment of physical gauges. The

394   DIC measurements are accurate enough in the elastic range for the elastic properties to be successfully determined,

395   despite the very small displacement magnitude and the surface irregularity of the samples.

5. Remarks and Conclusions

397   This work presents a methodology to determine composite masonry properties from numerical meso-models

398   of masonry panels subjected to compression in two directions, parallel and perpendicular to the bed joints. The

399   numerical analysis is performed using experimental data from small material samples: units, mortar and masonry

400   couplets. An expression linking the compressive strength of couplets and wallettes in the vertical direction is

401   proposed. The methodology eschews both complicated three-dimensional modelling required by micro-models

402   and orthotropic experimental testing of wallettes.

403   The experimental data showed important anisotropy related to stiffness and Poisson's ratio presenting higher

404   values for the panels loaded parallel to the bed joints. This phenomenon was noted in the meso-models, although

405   slightly less pronounced.

406   The calculation of the compressive fracture energy of masonry wallettes from tests on couplets remains

407   challenging. While a fair prediction of the compressive strength and the failure initiation mode may be obtained

408   from couplet tests, the compressive fracture energy may differ significantly between the two setups. Numerical

409   analysis using meso-models serves to highlight this fact, which also has a bearing on simulations using macro-

410   models. Full three-dimensional analysis using micro-models may account for this discrepancy once computational

411   costs can be reduced to acceptable levels.

412   The determination of all necessary material parameters for a meso-model from extracted samples is a

413   challenging task. The paper demonstrates that the orthotropic properties of masonry in compression can be

414   determined from a limited number of compression tests on small samples. Additional work is being carried out

415   for the relation of the compressive strength of full-brick masonry couplets to small diameter cylindrical masonry

416   couplets.

417   Since masonry is a very heterogeneous and anisotropic material, and its mechanical behaviour is influenced

418   by several factors such as loading, type of components and bond type, future work will require an extensive lab

419   testing campaign and related smeared macro-models to validate the presented methodology. In addition, the

420   influence of different brick-mortar compositions will be investigated. Finally, further research will include

421   validation of the methodology by means of smeared cracking models considering the parameters determined

422   through, and the results of, experimental tests on larger masonry elements.

Table 4　Material parameters for the numerical model of the masonry panels

Material	Parameter	Symbol	Value	Units
	Density	ρ_b	1875[a]	Kg/m^3
Brick Units	Poisson's ratio	ν_b	0.2[c, b]	
	Young's modulus	E_b	2570[a]	N/mm^2
	Normal stiffness	$k_{n,i}$	119[a]	N/mm^3
	Shear stiffness	$k_{s,i}$	22 [a]	N/mm^3
	Tensile strength	$f_{t,i}$	0.2[c]	N/mm^2
	Tensile fracture energy (Mode I)	$G_{t,i}$	0.012[c]	N/mm
Joint Interfaces	Cohesion	c_i	1.2 $f_{t,i}$ [c]	N/mm^2
	Friction angle	φ_i	36.9[c]	-
	Dilatancy angle	ψ_i	0	-
	Shear fracture energy (Mode II)	$G_{s,i}$	0.125[c]	N/mm
	Compressive strength	$f_{c,i}$	2.31[a]	N/mm^2
	Compressive fracture energy	$G_{c,i}$	5.56[a], 13.30[b], 18.6[b]	N/mm

Note: [a]: from tests on small samples, [b]: from tests on panels, [c]: from literature

Table 5   Numerical analysis results from the masonry panel models.

Parameter	Symbol	Vertical	Horizontal	Units
Young's Modulus	E_m	1856	2291	N/mm^2
Poisson's ratio	v_m	0.15	0.20	-
Compressive strength	$f_{c,m}$	2.31	2.60	N/mm^2

Table 6   Poisson's ratio of wallettes derived from DIC data.

Sample	Poisson's ratio	
	Inner	Outer
V1	0.198	0.161
V2	0.137	0.174
Average vertical	0.168	0.168
H1	0.216	0.277
H2	0.223	0.785
Average horizontal	0.220	0.531
