Abstract

The optimal stimulus to repair or regenerate cartilage is not known. We therefore modulated collagen deposition, collagen cross-linking and GAG deposition simultaneously during cartilage matrix production and integrative repair, creating more insight in their role in cartilage repair processes.

Insuline-like Growth Factor 1 (IGF-1, increases proteoglycan and collagen synthesis), Beta-aminopropionitrile (BAPN, a reversible inhibitor of collagen crosslinking) and para-nitrophenyl-beta-d-xyloside (PNPX, interferes with proteoglycan production) were used. Bovine articular chondrocytes were cultured in alginate beads for three weeks with or without IGF-1, BAPN or PNPX alone and in all possible combinations followed by three weeks in control medium. DNA content, GAG and collagen deposition and collagen cross-links were determined. Cartilage constructs were cultured under same conditions and histologically analysed for integration of two opposing cartilage matrices.

In alginate cultures, inhibition of collagen cross-linking with BAPN in combination with promotion of matrix synthesis using IGF1 was most beneficial for matrix deposition. Addition of PNPX was always detrimental for matrix deposition. For integration of opposing cartilage constructs, the combination of BAPN, IGF1 and temporary prevention of proteoglycan formation with PNPX was most beneficial.

When a new matrix is produced, proteoglycans are important to retain collagen in the matrix. When two already formed cartilage matrices have to integrate, temporary absence of proteoglycans and temporary inhibition of collagen cross-linking might be more beneficial in combination with stimulation of collagen production by for example IGF1. Therefore, the choice of soluble factors to promote cartilage regeneration depends on the type of therapy that will be used.

1. Introduction

Once damaged, adult articular cartilage has a poor repair capacity, which is probably due to the ineffective repair of the collagen network, since proteoglycan depletion is often reversible (Lafeber 1992). Although collagen turnover is increased in osteoarthritis (OA), this does not lead to the formation of a functional network (Aigner 1993; Billingham 1997; Nelson 1998; Verzijl 2000). This suggests an activated repair mechanism in OA that appears however ineffective in repairing or maintaining the ECM homeostasis.

Several strategies are under investigation to promote matrix regeneration in cartilage repair. Growth factors are used to modulate matrix production, by directly adding them to chondrocytes in culture (Gooch 2002; Veilleux 2005) or by inducing over expression of the growth factor of interest (Madry 2002; Kaul 2006). For example, we and others found that addition of IGF1 to chondrocytes in culture resulted in more proteoglycans and collagen than in the control condition without IGF1 (Blunk 2002; Mauck 2003; De Mattei 2004; Jenniskens 2006)

In addition to growth factors, modulation of collagen network formation is also employed to understand cartilage matrix formation and functionality, for example by the inhibition of collagen cross-linking by inhibition of lysyl oxidase (LOX) with β -aminopropionitrile (BAPN). It was found that collagen cross-links are important for the integrative repair and adhesive strength of cartilage (DiMicco 2002) and that transient inhibition of the formation of these cross-links improved integrative repair and collagen cross-link maturation (McGowan 2005). In cultures of chondrocytes in alginate, inhibition of collagen cross-link formation with BAPN resulted in an increase of collagen production (Beekman 1997; Wong 2002; Bastiaansen-Jenniskens 2008a). In concordance with earlier explant studies (McGowan 2005), transient

1
2
3 inhibition of LOX in alginate cultures resulted in accelerated cross-link maturation and
4
5 improved functionality of the newly formed matrix (Bastiaansen-Jenniskens 2008a).
6

7
8 The influence of glycosaminoglycans (GAGs) on cartilage growth and matrix
9
10 production is also under investigation, but gets less attention than collagen. GAG
11
12 depletion in cartilage explants resulted in less expansive growth and a more mature
13
14 matrix with increased tensile integrity (Asanbaeva 2007). Preventing GAGs from
15
16 binding to the proteoglycan core protein with para-nitrophenyl xyloside (PNPX) in the
17
18 newly forming cartilage matrix of chondrocytes cultured in alginate resulted in less
19
20 collagen deposition and a decrease in stiffness and ability to hold water
21
22 (Bastiaansen-Jenniskens 2008b). The difference between these two studies is that in
23
24 the explant study collagen was already deposited and cross-linked, whereas in the
25
26 alginate cultures no collagen was yet deposited when GAG incorporation was
27
28 inhibited. Both studies however indicate that modulating GAGs can influence the
29
30 collagen network in an already existing cartilage matrix or during new cartilage matrix
31
32 synthesis.
33
34
35
36
37

38
39 Most of the approaches mentioned above focused on modulating one matrix
40
41 component (either collagen or proteoglycans). However, increasing collagen
42
43 synthesis alone is not sufficient for cartilage repair. Because of the differential and
44
45 potentially complementary effects of these approaches, our hypothesis was that
46
47 combining IGF1, BAPN and PNPX in one experiment has the potential to stimulate
48
49 matrix production and integrative repair more than each single component.
50
51 Chondrocytes cultured in alginate were used to examine the effect of the soluble
52
53 factors on new matrix production, either alone or in all possible combinations.
54
55 Cartilage explants were used to examine the effect of the factors mentioned above
56
57
58
59
60 on integration of two existing cartilage matrices.

2. Materials and Methods

2.1 Cell culture

Articular cartilage was harvested from the metacarpophalangeal joints of calves aged 6–12 months. Chondrocytes were isolated, suspended in alginate in a concentration of 4×10^6 cells per mL of alginate, and alginate beads were made as described previously (Jenniskens 2006). Beads were cultured in a six-well plate (BD Falcon, Bedford, MA, USA), with 75 μ l/bead DMEM/F12 supplemented with 10% fetal bovine serum (GibcoBRL), 50 μ g/ml L-ascorbic acid 2-phosphate (Sigma), 50 μ g/ml gentamicin and 1.5 μ g/ml fungizone (both GibcoBRL). Chondrocytes were cultured for 21 days in the presence of 25 ng/ml IGF-1, 0.25 mM BAPN and/or 0.25 mM PNPX based on previous results (Jenniskens 2006; Bastiaansen-Jenniskens 2008a; Bastiaansen-Jenniskens 2008b) followed by 21 days in control medium. As known from these previous studies, BAPN inhibits collagen cross-linking and PNPX prevents incorporation of GAGs into the matrix. In the 21 days of additional culture without supplements, cross-links had the ability to form and GAGs to incorporate into the matrix. Culture medium was changed three times a week. Alginate beads were harvested after 42 days of culture.

2.2 Preparation of cartilage explants for integration study

Articular cartilage samples were harvested from the metacarpophalangeal joints of calves aged 6–12 months. Full-thickness cartilage explants of 8 mm diameter and with a thickness of 0.9–1.2 mm were prepared using a dermal biopsy punch and scalpel. From the centre of the explants, 3-mm cores were punched out. All samples (both outer ring and inner core) were incubated for 24 hours in 10 U/ml highly purified collagenase VII (Sigma-Aldrich Chemie BV, Zwijndrecht, The Netherlands) in DMEM-

1
2
3 F12 with 10% fetal calf serum based on previous results (Bos 2002; van de Breevaart
4
5
6 Bravenboer 2004; Janssen 2006). From the study of Bos et al (Bos 2002), it was
7
8 concluded that there is some loss of matrix proteins by digesting for 24 hours with
9
10 highly purified collagenase, but only on the locations where proteoglycans are lost,
11
12 i.e. the area of the wound edge. Pre-treatment with collagenase is beneficial for
13
14 integration because it increases the number of viable cells at the wound edge
15
16 thereby enabling integration of the wound edges. All the cartilage explants were pre-
17
18 treated with the collagenase irrespective of the condition. After incubation, the
19
20 samples were washed three times for 10 min in culture medium, and the 3-mm inner
21
22 cores were reimplanted in their accompanying 8-mm outer rings. Constructs were
23
24 cultured in parallel to the alginate beads for 21 days in the presence of 25 ng/ml IGF-
25
26 1, 0.25 mM BAPN and/or 0.25 mM PNPX followed by 21 days in control medium.
27
28 Constructs were cultured in 1.5 ml DMEM/F12 per construct supplemented with 10%
29
30 fetal bovine serum (GibcoBRL), 50 µg/ml L-ascorbic acid 2-phosphate (Sigma), 50
31
32 µg/ml gentamicin and 1.5 µg/ml fungizone (both GibcoBRL) in the presence of 25
33
34 ng/ml IGF-1, 0.25 mM BAPN and/or 0.25 mM PNPX during the first 21 days. After 42
35
36 days, constructs were harvested and immediately fixed in 4% phosphate buffered
37
38 formalin.

2.3 Biochemical analysis of alginate beads

50
51 Alginate beads were digested overnight at 56°C in papain buffer (250 µg/ml papain in
52
53 50 mM EDTA and 5 mM L-cysteine). Glycosaminoglycan (GAG) amount in the digest
54
55 was quantified using dimethylmethylene blue (DMB) assay (Farndale 1986). The
56
57 metachromatic reaction of GAG with DMB was monitored with a spectrophotometer,
58
59 and the ratio A530:A590 was used to determine the amount of GAG present, using
60

1
2
3 chondroitin sulfate C (Sigma) as a standard. The amount of DNA in each papain-
4
5 digested sample was determined using ethidium bromide with calf thymus DNA
6
7 (Sigma) as a standard. High-performance liquid chromatography (HPLC) of amino
8
9 acids (hydroxyproline, Hyp) and collagen cross-links (hydroxylsypyrinoline, HP)
10
11 was performed as described previously (Bank 1996; Beekman 1997). The quantities
12
13 of cross-links were expressed as the number of residues per collagen molecule,
14
15 assuming 300 Hyp residues per collagen triple helix. Three samples were taken of 7
16
17 alginate beads per experimental condition for biochemical analyses.
18
19
20
21
22
23

24 25 *2.4 Histochemical analysis of cartilage explants*

26
27 Formalin fixed cartilage constructs were embedded in paraffin. To prevent any
28
29 negative influence of processing the constructs for histological analysis, separate
30
31 cartilage constructs were placed in little porous polymer bags directly after harvesting
32
33 prior to fixation in formalin and processing. However, a certain risk of damage during
34
35 histological procedure is unavoidable. Therefore we embedded all the samples at the
36
37 same time and did the sectioning in a random order to exclude bias. Sections (6 µm)
38
39 were cut using a standard microtome. Prior to the histological stainings, sections
40
41 were deparaffinated in xylene and rehydrated through graded ethanol. For
42
43 histological evaluation, serial sections were stained with Hematoxylin & Eosin (H&E).
44
45 To evaluate integration, paraffin sections were stained with a thionine staining. For
46
47 each sample we assessed the percentage of total interface length that had a matrix–
48
49 matrix connection. A clear distinction could be made between parts with a matrix
50
51 connection and parts of the cartilage touching each other but without a clearly
52
53 connected matrix, which were scored as parts with a gap. Integration was determined
54
55 at both integration sites within a paraffin section. Interface integration percentages
56
57
58
59
60

1
2
3 were obtained by two blinded observers from measurements of three to four different
4
5 sections from each sample, resulting in an average value for each interface.
6
7
8
9

10 2.5 Statistical analysis

11
12 For the alginate bead cultures and the integration study, four pooled cartilage donors
13 were used. Statistical analysis was performed using GraphPad Prism 5.01
14
15 (GraphPad Software, San Diego, CA, USA) software. All data are presented as mean
16
17 \pm standard deviation. Control groups and groups supplemented with PNPX, BAPN
18
19 and/or IGF1 were compared with a ANOVA test followed by a *post hoc* Bonferroni
20
21 test.

3. Results

3.1 Chondrocytes cultured in alginate

After 42 days, DNA content, GAG deposition, collagen deposition and collagen cross-linking were determined in the alginate beads. In the control condition, DNA content was $0.49 \pm 0.03 \mu\text{g}$ DNA per alginate bead, which was unaffected by the addition of BAPN, IGF1 and or PNPX during the first 21 days of culture (*Figure 1*).

$4.38 \pm 0.39 \mu\text{g}$ GAG per bead was deposited in the control condition after 42 days of culture. As expected, this was significantly reduced in the condition with 0.25 mM PNPX during the first 21 days. Compared to the control condition, GAG deposition was also less when a combination of PNPX and IGF1 was present, when PNPX and BAPN were present together, and when all three components were present in the culture medium. BAPN or IGF1 alone did not influence GAG deposition, rather their combination resulted in more GAG deposition (*Figure 2*).

Regarding the collagen deposition, $6.16 \pm 0.91 \mu\text{g}$ was deposited in the control condition after 42 days. The presence of PNPX during the first 21 days resulted in less collagen deposition. Inhibition of collagen cross-link formation with BAPN on the other hand resulted in more collagen deposition, as expected. BAPN together with IGF1 increased the collagen deposition even more (*Figure 3*).

The presence of BAPN alone, BAPN with IGF1, BAPN with PNPX and all three factors during the first 21 days resulted in less cross-link formation, in line with the LOX inhibition by BAPN. Addition of IGF1 alone, PNPX alone or PNPX with IGF1 did not change the number of collagen cross-links from the control condition, which was $0.69 \pm 0.03 \text{HP}$ per collagen triple helix (*Figure 4*).

3.2 Cartilage integration

1
2
3 In parallel to the alginate cultures, cartilage explants were cultured to investigate the
4 integrative capacity in the presence of PNPX, BAPN and/or IGF1. As in the alginate
5 cultures, soluble factors were only present during the first 21 days of culture followed
6 by culture in control medium for an additional 21 days. Typical examples of
7 integration after 42 days visualised with a thionine staining are shown in figure 5. The
8 average integration percentage in the control condition was less than 10%. Only
9 when PNPX, BAPN and IGF1 were combined during the first 21 days, integration of
10 the two opposing cartilage explants improved to $41.3 \pm 31.4\%$ ($p < 0.05$). Although
11 not reaching statistical significance, the presence BAPN and IGF1 alone or together
12 also seems beneficial for integration.

4. Discussion

Many factors have been demonstrated to be able to influence proteoglycan production, collagen production or both. However, it is not fully known what the optimal balance of collagen and proteoglycan production is and how they influence each other to form a functional network.

Our goal was to examine the effect of modulating collagen deposition, collagen cross-linking and GAG deposition simultaneously during cartilage matrix production and cartilage integrative repair, thereby creating a wider insight in the role of proteoglycans and collagen in cartilage repair process.

In the alginate cultures, inhibition of collagen cross-linking with BAPN in combination with promotion of matrix synthesis using IGF1 was most beneficial for matrix deposition. Additional PNPX was always detrimental for matrix deposition. For integration, the combination of BAPN, IGF1 and temporary prevention of proteoglycan formation with PNPX was most beneficial.

Inhibition of GAGs from binding to the proteoglycan core protein not only resulted in less GAG deposition in the alginate bead, but also in less collagen deposition. This is in concordance to our previous study were the presence of PNPX during a culture period of 35 days resulted in less proteoglycan and collagen deposition in the alginate bead. In addition, excretion of both matrix proteins into the culture medium was higher due to the absence of an intact matrix network (Bastiaansen-Jenniskens 2008b). Because of the absence of this network and the loss of interaction with other matrix components, combining PNPX with BAPN and/or IGF1 could not counteract the effects seen with PNPX alone. Earlier we found that the inhibition of collagen cross-linking in an alginate culture for 21 days and longer results in higher collagen deposition then when cross-links are formed. During this culture period, proteoglycan

1
2
3 deposition was unaffected (Bastiaansen-Jenniskens 2008a). Even though cross-link
4
5 inhibition by BAPN stimulates collagen synthesis, the retention of collagen is very low
6
7 because of the absence of a proteoglycan network. Previously, we and others
8
9 showed stimulating effects of IGF1 on collagen and proteoglycan deposition (Blunk
10
11 2002; Mauck 2003; De Mattei 2004; Jenniskens 2006). In the present setup, culture
12
13 with IGF1 alone for 21 days did not significantly stimulate matrix deposition after 42
14
15 days, whereas IGF1 did previously already after 21 days (Jenniskens 2006).
16
17
18 However, the combination IGF1 and BAPN increased GAG deposition which is
19
20 probably attributable to the presence of IGF1 since BAPN does not affect the GAG
21
22 deposition. Even though IGF1 might have also stimulated GAG and collagen
23
24 deposition when combined with PNPX or with PNPX and BAPN, GAGs were
25
26 prevented from incorporation into the matrix. A possible positive effect of IGF1 on
27
28 collagen synthesis was counteracted because of low collagen retention in the
29
30 alginate bead. In every condition where the cross-link inhibitor BAPN was present for
31
32 the first 21 days, less collagen cross-links were present even though the culture
33
34 continued for 21 days after removal of BAPN. This might be explained by the fact that
35
36 after removal of BAPN, it takes three weeks for mature HP cross-links to be formed
37
38 (Ahsan 2005). In addition, BAPN binds irreversibly to lysyl oxidase (LOX) (Tang
39
40 1983) and therefore extra time is also needed for LOX to be produced again. Based
41
42 on our previous experiments, we expect that the number of collagen cross-links will
43
44 be equal in all conditions when a longer culture period is used (Bastiaansen-
45
46 Jenniskens 2008a).
47
48
49
50
51
52
53

54
55 The combination of BAPN and IGF1 seems most beneficial for matrix synthesis when
56
57 no matrix is formed yet, as in the alginate cultures. When aiming at the integration of
58
59 two existing cartilage matrices, cross-link inhibition with BAPN and stimulation of
60

1
2
3 matrix production with IGF1 is not sufficient to significantly improve integration.
4
5 Transient inhibition of GAG incorporation in the matrix with PNPX in combination with
6
7 BAPN and IGF1 did improve the integration. In these experiments, stimulation of
8
9 matrix production alone with IGF1 had no effect. Transient inhibition of collagen
10
11 cross-link formation could have resulted in more collagen synthesis, and in addition in
12
13 better penetration of the newly formed collagen fibres in the opposing tissue that was
14
15 partly depleted of GAGs following injury (Bos 2001). The latter is more likely since
16
17 previous experiments with BAPN and cartilage explants did not result in more
18
19 collagen synthesis (McGowan 2005). The study by McGowan *et al* is also in
20
21 concordance with the theory of better integration after BAPN treatment. The addition
22
23 of PNPX and the resulting absence of GAG attachment to the proteoglycan core
24
25 protein might have similar effects as seen with inhibition of cross-link formation.
26
27 Without an intact proteoglycan network at the edges of the cartilage explants, newly
28
29 formed collagen fibres might penetrate better into the opposing cartilage tissue.
30
31 Because of the absence of a proteoglycan network, the collagen network might also
32
33 have a better integrity (Asanbaeva 2007). This explains why the presence of IGF1
34
35 with PNPX or BAPN did not improve integration since the newly formed collagen
36
37 stimulated by IGF1 could not penetrate into the cartilage. PNPX together with BAPN
38
39 but without IGF1 was also not sufficient because of the absence of increased
40
41 collagen production.
42
43
44
45
46
47
48
49

50 When cartilage transplantations are performed, the surgeon removes the damaged
51 cartilage first. Removing the damaged cartilage will create a fresh wound area,
52 similar to our experimental condition. We hypothesize that the integrative capacity of
53 such an area is different from a long lasting wound area and we are therefore
54 convinced that our explant model is close to the application in this respect.
55
56
57
58
59
60

1
2
3 The cartilage explants used for integration were cultured for 6 weeks *in vitro*. In an
4 earlier study, we investigated the effect of improved integration on mechanical
5 properties of the cartilage-cartilage interface (van de Breevaart Bravenboer 2004).
6 There we observed a relation between the area of integration on histology and the
7 mechanical properties of the interface. Since the previous study is performed after an
8 *in vivo* culture period and our current study evaluates after *in vitro* culture, it is difficult
9 to extrapolate these results. Earlier attempts in the lab have demonstrated us that
10 after *in vitro* culture the bonding is not strong enough to measure reliably in our
11 system. However, the improved histological integration in the present studies looks
12 promising and suggests that when a construct is placed *in vivo* after modulation with
13 our soluble factors (IGF1, PNPX and BAPN), integration might lead to functional
14 cartilage.

5. Conclusions

Based on these results, combining IGF1 and cross-link inhibition with BAPN seems to be most promising in promoting the formation of a new cartilage matrix. When a new matrix is produced, proteoglycans are important to retain collagen in the matrix. When two already formed cartilage matrices have to integrate, the temporary absence of a proteoglycan network and the temporary absence of collagen cross-links might be more beneficial in combination with stimulation of collagen production by for example IGF1. Therefore, the choice of soluble factors to promote cartilage regeneration in OA depends on the type of therapy that will be used. In the case of cell therapy and the synthesis of a new matrix, stimulating both collagen and proteoglycan synthesis is important. The intra-articular administration of growth factors such as IGF1 to promote matrix production is the topic of ongoing research (Madry 2005) and could be a part of future OA therapy. When two cartilage matrices have to integrate, temporary inhibition of proteoglycan network formation and collagen cross-linking together with stimulating collagen production results in better integration. In the case of autologous cartilage transplantation, the transplant can be pre-treated with hyaluronidase or chondroitinase to remove the proteoglycans and be subjected to temporary collagen cross-link inhibition. To generate a tissue engineered cartilage construct, culture in the presence of IGF1 and BAPN might be a promising approach. However, care must be taken with BAPN since it is mutagenic. Other approaches to inhibit collagen cross-linking might be the topic of future research.

Figure legends

Figure 1, DNA content of the alginate beads after 42 days of culture. PNPX (P), BAPN (B) and/or IGF1 (I) were present in the first 21 days of culture, followed by additional culture for 21 days in control medium. Data are shown as mean DNA content per bead \pm sd. N=3.

Figure 2, GAG content of the alginate beads after 42 days of culture. PNPX (P), BAPN (B) and/or IGF1 (I) were present in the first 21 days of culture, followed by additional culture for 21 days in control medium. Data are shown as mean GAG content per bead \pm sd. N=3. * indicates a significant difference ($p < 0.05$) from the control condition without additives.

Figure 3, Collagen content of the alginate beads after 42 days of culture. PNPX (P), BAPN (B) and/or IGF1 (I) were present in the first 21 days of culture, followed by additional culture for 21 days in control medium. Data are shown as mean collagen content per bead \pm sd. N=3. * indicates a significant difference ($p < 0.05$) from the control condition without additives.

Figure 4, Number of HP cross-links per collagen triple helix after 42 days of culture. PNPX (P), BAPN (B) and/or IGF1 (I) were present in the first 21 days of culture, followed by additional culture for 21 days in control medium. Data are shown as mean HP per collagen triple helix \pm sd. N=3. * indicates a significant difference ($p < 0.05$) from the control condition without additives.
