# $\alpha$ -stable laws for noncoding regions in DNA sequences

N. Crato<sup>a</sup>, R.R. Linhares<sup>b</sup> and S.R.C. Lopes<sup>b\*</sup>

<sup>a</sup>Cemapre, ISEG, Technical University of Lisbon, Lisbon, Portugal; <sup>b</sup>Mathematical Institute, UFRGS, Porto Alegre, RS, Brazil

(Received 17 April 2009; final version received 7 September 2009)

In this work, we analyze the *long-range dependence* parameter for a nucleotide sequence in several different transformations. The long-range dependence parameter is estimated by the approximated maximum likelihood method, by a novel estimator based on the spectral envelope theory, by a regression method based on the periodogram function, and also by the *detrended fluctuation analysis* method. We study the length distribution of coding and noncoding regions for all *Homo sapiens* chromosomes available from the European Bioinformatics Institute. The parameter of the tail rate decay is estimated by the Hill estimator  $\hat{\alpha}$ . We show that the tail rate decay is greater than 2 for coding regions, while for almost all noncoding regions it is less than 2.

**Keywords:** long memory models;  $\alpha$ -stable law; generalized pareto distribution; hill estimator

*AMS Classification:* Primary: 60G10, 62G05, 62G35, 62M10, 62M15; Secondary: 62M20

## 1. Introduction

The statistical properties of DNA genomes are of great interest since they reflect biological features that are important for life [21]. One of the main recent findings is the existence of correlation on the sequence, i.e. occurrence of a nucleotide in a specific position depends statistically on the previous nucleotides (memory). Moreover, it has been found that the memory of genome structure decomposition is of a particular type: the so-called *long memory*.

The search for intrinsic patterns, correlations, and parameters measuring self-similarity by scaling exponents has been carried out in the past years by several statistical methods. Peng *et al.* [19], Buldyrev *et al.* [4], Li and Kaneko [17] and Stanley *et al.* [24] use the *detrended fluctuation analysis* (DFA) to characterize long-range correlations in both coding and noncoding regions of DNA sequences. Karlin and Brendel [16] show the relationship between the effect of patchiness and correlations in genome sequences. Bernardi *et al.* [3] show that the DNA nucleotides form a mosaic of long homogeneous segments or ‘isochores’.

In order to study the long-range correlations in genomes, it is necessary to transform them into numerical sequences. There are many studies on correlations in DNA sequences using different representations for the four nucleotides [7,13,18,22,24].

One of the most appropriated methods proposed in recent years for the study of long-range correlations in genomes is the DFA [4,11,20,22]. More recently, Crato *et al.* [6] estimate the fractional parameter  $d$  by considering semiparametric regression method based on the periodogram function, in both classical and robust versions. They also use the semiparametric R/S( $n$ ) method, proposed by Hurst [15], and the maximum likelihood method [10], with the approximation suggested by Whittle [7].

Here we study the behavior of the *long-range dependence* parameter of one DNA sequence for the most relevant transformations of the type  $f : \{A, C, G, T\} \rightarrow \{0, 1, 2, 3\}$ , where A, C, G and T are the four nucleotides, by considering the DFA and other estimation methods for the *fractional parameter*  $d$ .

A common problem in analyzing long nucleotide sequence data is the proper identification of coding (cds) regions dispersed throughout the sequence and separated by noncoding (ncds) regions [2]. Here we are interested in analyzing the distribution of coding and noncoding regions, based on the length distribution of these two regions [26]. From the tail rate decay estimator, we identify differences between length distribution of coding and noncoding regions of DNA sequences.

This paper is organized as follows. Section 2 describes the DFA and other estimation methods for the *fractional parameter*  $d$ . Section 3 presents the most relevant transformations for the four nucleotides. We study the long-range dependence for a DNA sequence numerically transformed into several different maps. Section 4 presents the relationship between the long-range dependence and the tail index parameter and also the Hill estimator  $\hat{\alpha}$ . Section 5 presents the discussion of the length distribution for coding and noncoding regions for all *Homo sapien* chromosomes available from the European Bioinformatics Institute (EBI, <http://www.ebi.ac.uk/>). Section 6 concludes the paper.

## 2. Estimation methods

In this section, we want to emphasize the existence of a long memory in a DNA sequence, without separately considering its coding and noncoding regions [6]. With this purpose, we consider the estimation of the fractional parameter  $d$  in four different methods. First, the approximated maximum likelihood estimator ( $\hat{d}_W$ ), proposed by Fox and Taqqu [10]; the  $\hat{d}_{WS}$  estimator, obtained by using the spectral envelope theory proposed by Stoffer *et al.* [25]; the regression method using the periodogram function ( $\hat{d}_{GPH}$ ), a very well-known estimator proposed by Geweke and Porter-Hudak [12] and, finally, the DFA estimator ( $\hat{d}_{DFA}$ ), proposed by Peng *et al.* [19].

The parameter of interest is the *fractional integration parameter*  $d$ , which can be introduced in the general framework of the autoregressive fractionally integrated moving average processes (ARFIMA).

An ARFIMA( $p, d, q$ ) process is defined as follows. Let  $\{\varepsilon_t\}_{t \in \mathbb{Z}}$  be a white noise process with zero mean and variance  $\sigma_\varepsilon^2 > 0$ , let  $\mathcal{B}$  be the backward-shift operator, that is,  $\mathcal{B}^k(X_t) = X_{t-k}$ , and let  $\Phi(\cdot)$  and  $\Theta(\cdot)$  be polynomials of orders  $p$  and  $q$ , respectively. If

$$\Phi(\mathcal{B})(1 - \mathcal{B})^d(X_t - \mu) = \Theta(\mathcal{B})\varepsilon_t, \quad t \in \mathbb{Z}, \tag{1}$$

where  $\mu$  is the mean of the process and  $(1 - \mathcal{B})^d = \sum_{k=0}^{\infty} \binom{d}{k} (-\mathcal{B})^k$ , then  $\{X_t\}_{t \in \mathbb{Z}}$  is an ARFIMA( $p, d, q$ ).

If  $d \in (-0.5, 0.5)$  then the process  $\{X_t\}_{t \in \mathbb{Z}}$  is stationary and invertible and its spectral density function is given by

$$f_X(w) = f_U(w) \left[ 2 \sin \left( \frac{w}{2} \right) \right]^{-2d}, \quad \text{for } 0 < w \leq \pi, \quad (2)$$

where  $f_U(\cdot)$  is the spectral density function of the ARMA( $p, q$ ) process,  $U_t \equiv (1 - \mathcal{B})^d(X_t - \mu)$ .

*Persistence* or *long memory* property has been observed in time series from different fields such as meteorology, astronomy, hydrology and economy. One can characterize the persistence by two equivalent forms:

- in the time domain, the autocorrelation function  $\rho_X(\cdot)$  decays hyperbolically to zero, that is,  $\rho_X(k) \simeq k^{2d-1}$ , when  $k \rightarrow \infty$ .
- in the frequency domain, the spectral density function  $f_X(\cdot)$  is unbounded when the frequency is near zero, that is,  $f_X(w) \simeq w^{-2d}$ , when  $w \rightarrow 0$ .

The ARFIMA( $p, d, q$ ) process exhibits the property of long memory when  $d \in (0.0, 0.5)$ , of intermediate memory when  $d \in (-0.5, 0.0)$  and of short memory when  $d = 0$ . Important properties for ARFIMA( $p, d, q$ ) processes can be found in Beran [1].

## 2.1 Estimator $\hat{d}_W$

Let  $\{X_t\}_{t \in \mathbb{Z}}$  be an ARFIMA( $p, d, q$ ), defined in expression (1). The estimator for  $d$ , by using the maximum likelihood method, denoted by  $\hat{d}_W$ , is the value

$$\boldsymbol{\eta} = (\sigma_X^2, d, \phi_1, \phi_2, \dots, \phi_p, \theta_1, \theta_2, \dots, \theta_q) \quad (3)$$

that minimizes the function

$$\mathcal{Q}(\boldsymbol{\eta}) = \sum_{j=1}^{\lfloor (n-1)/2 \rfloor} \left( \frac{I(w_j)}{f_X(w_j, \boldsymbol{\eta})} \right), \quad (4)$$

where  $\boldsymbol{\eta}$  is the vector of unknown parameters given in Equation (3),  $f_X(\cdot, \boldsymbol{\eta})$  is the spectral density function of the  $\{X_t\}_{t \in \mathbb{Z}}$ ,  $[\cdot]$  is the greatest integer function,  $w_j = 2\pi j/n$  is the  $j$ th Fourier frequency,  $j \in \{1, \dots, \lfloor n-1/2 \rfloor\}$ , and  $I(\cdot)$  is the periodogram function.

More details on the theory of this estimator can be found in Fox and Taqqu [10] and Beran [1].

## 2.2 Estimator $\hat{d}_{WS}$

Let  $\{X_t\}_{t \in \mathbb{Z}}$  be a categorical-valued process with finite state-space  $\mathcal{C} = \{c_1, c_2, \dots, c_k\}$  and  $p_j = \mathbb{P}(X_t = c_j) > 0$ , for  $j = 1, 2, \dots, k$ . For  $\boldsymbol{\beta} = (\beta_1, \beta_2, \dots, \beta_k) \in \mathbb{R}^k$  denote by  $\{X_t(\boldsymbol{\beta})\}_{t \in \mathbb{Z}}$  the real-valued process corresponding to the scaling that assigns the category  $c_j$  to the numerical value  $\beta_j$ ,  $j = 1, 2, \dots, k$ . Assume  $\{X_t(\boldsymbol{\beta})\}_{t \in \mathbb{Z}}$  is a stationary process. Its spectral density will be denoted by  $f_X(\omega; \boldsymbol{\beta})$ . Our goal is to find scalings  $\boldsymbol{\beta}$  in such a way that one can maximize the power at each frequency  $\omega$ , across all frequencies  $\omega \in (0, \pi]$ , relative to the total power  $\sigma^2(\boldsymbol{\beta}) = \text{Var}(X_t(\boldsymbol{\beta}))$ . That is, we choose  $\boldsymbol{\beta}(\omega)$ , at each  $\omega$  of interest, so that

$$\lambda(\omega) = \max_{\boldsymbol{\beta}} \left\{ \frac{f_X(\omega; \boldsymbol{\beta})}{\sigma^2(\boldsymbol{\beta})} \right\}, \quad (5)$$

over all  $\boldsymbol{\beta}$  not proportional to  $\mathbf{1}_k$ , the  $k \times 1$  vector of ones. The function  $\lambda(\cdot)$  is defined to be the *spectral envelope* of the stationary categorical process  $\{X_t\}_{t \in \mathbb{Z}}$ .

The name *spectral envelope* is very much appropriate since  $\lambda(\cdot)$  envelopes the standardized spectrum of any scaled process. That is, given any  $\beta$  normalized so that  $\{X_t(\beta)\}_{t \in \mathbb{Z}}$  has total power equal to one,  $f_X(\omega; \beta) \leq \lambda(\omega)$ , where equality holds, if and only if,  $\beta$  is proportional to  $\beta(\omega)$ . For more details, we refer the reader to Stoffer *et al.* [25].

Here we suggest an estimator for the fractional parameter  $d$ , denoted by  $\hat{d}_{WS}$ , that consists in replacing the periodogram function in expression (4) by the spectral envelope, given in expression (5).

### 2.3 Estimator $\hat{d}_{GPH}$

Let  $\{X_t\}_{t \in \mathbb{Z}}$  be an ARFIMA( $p, d, q$ ), defined in expression (1). The first estimation method based on the periodogram function was proposed by Geweke and Porter-Hudak [12]. These authors obtain an estimate for  $d$  by considering  $\ln(I(\omega_j))$  regressed on  $\ln(2 \sin(\omega_j/2))^2$ . The estimator  $\hat{d}_{GPH}$  is given by

$$\hat{d}_{GPH} = - \frac{\sum_{j=1}^{g(n)} (x_j - \bar{x})(y_j - \bar{y})}{\sum_{j=1}^{g(n)} (x_j - \bar{x})^2}, \tag{6}$$

where  $y_j = \ln(I(\omega_j))$ ,  $x_j = \ln(2 \sin(\omega_j/2))^2$  and  $\bar{x} = 1/g(n) \sum_{j=1}^{g(n)} x_j$ , with  $g(n) = n^\alpha$ , for  $\alpha \in (0, 1)$ .

### 2.4 Estimator $\hat{d}_{DFA}$

Given a time series  $\{X_t\}_{t=1}^n$ , the DFA method, proposed by Peng *et al.* [20], has the objective of evaluating the statistical fluctuation  $F(l)$ , in order to obtain a set of measures, where  $l$  represents the window length. By varying the length  $l$ , the fluctuation can be characterized by the scaling exponent, that is, the slope of the line obtained by regressing  $\ln(F(l))$  on  $\ln(l)$ .

The estimator  $\hat{d}_{DFA}$  is given by

$$\hat{d}_{DFA} = \frac{\sum_{j=1}^m (x_j - \bar{x})y_j}{\sum_{j=1}^m (x_j - \bar{x})^2} - \frac{1}{2}, \tag{7}$$

where  $y_j = \ln(F(j+3))$ ,  $x_j = \ln(j+3)$ ,  $\bar{x} = 1/m \sum_{j=1}^m x_j$  and  $m = [g(n) - 3]$ . The function  $F(l)$ , for each block of size  $l$ , is the *root mean square fluctuation* given by

$$F^2(l) = \frac{1}{\tilde{n}} \sum_{t=1}^{\tilde{n}} Z_t^2, \tag{8}$$

with  $Z_t = Y_t - Y_t^l$ , where  $Y_t = \sum_{j=1}^t X_j$ , for each  $t \in \{1, 2, \dots, n\}$ ,  $Y_t^l$  is the adjusted fit on each block and  $\tilde{n} = [M \cdot l] \leq n$ , with  $M = [n/l]$ .

For technical details on the estimator  $\hat{d}_{DFA}$  we refer the reader to Crato *et al.* [6].

## 3. Transformations

A nucleotide sequence is composed by the basis A (adenine), C (cytosine), T (thymine) and G (guanine). In order to apply numerical methods to a nucleotide sequence, it is necessary to transform it into a numerical sequence.

From the biological point of view, it is common to apply the SW (strong-weak pairing) rule, which maps C and G to 1 and A and T to 0. We could also try scaling according to the purine-pyrimidine alphabet (RY rule), that is  $A = G = 1$  and  $C = T = -1$ . This rule

describes how purines (A and G) and pyrimidines (C and T) are distributed along the sequence. Another interesting scaling (real rule) is the one that assigns  $A = -1.5$ ,  $C = 0.5$ ,  $G = -0.5$  and  $T = 1.5$  [5].

Guharay *et al.* [13] symmetrically assign a four-dimensional vector to each of the four bases A, C, G and T, which are equidistant from each other, and their sum is equal to zero, that is, maps A to  $(0.75, -0.25, -0.25, -0.25)$ , C to  $(-0.25, 0.75, -0.25, -0.25)$ , G to  $(-0.25, -0.25, 0.75, -0.25)$  and T to  $(-0.25, -0.25, -0.25, 0.75)$ .

Cristea [7] proposes a tetrahedral representation of the nucleotides: four vectors in three dimensions, symmetrically placed with respect to each other, i.e. oriented towards the corners of a tetrahedron, are placed in correspondence with the nucleotides, in which it is emphasized that the vertices of a regular tetrahedron are a subset of the vertices of a cube. Thus, this rule maps A to  $(1, 1, 1)$ , C to  $(-1, 1, -1)$ , G to  $(-1, -1, -1)$  and T to  $(1, -1, -1)$ .

Rather than choose values arbitrarily, the spectral envelope approach [25] selects scales that help to emphasize any periodic feature that may exist in a categorical time series. This approach can be used for any categorical time series in a quick and automated fashion.

If we consider the naive approach of arbitrarily assigning numerical values (scales) to the categories and then proceeding with a spectral analysis, the result will depend on the particular assignment of the numerical values. Here we consider the estimation of the fractional parameter  $d$ , based on the four methods given in Section 2, relatively to all possible transformations  $f : \{A, C, G, T\} \rightarrow \{0, 1, 2, 3\}$ . To analyze the long-range dependence, we consider the AL163202 nucleotide sequence, corresponding to a part of the *H. sapiens* chromosome 21 (with 340,000 bp).

We have a total of  $4^4$  different maps. Some of these  $4^4$  transformations are equivalent for the estimations results. For instance, the transformations  $(1, 0, 0, 0)$ ,  $(2, 0, 0, 0)$ ,  $(3, 0, 0, 0)$ , and  $(4, 0, 0, 0)$  lead necessarily to the same correlation and spectral estimates. In this regard, they constitute a class of equivalent transformations. In Table 1, we chose one mapping representative for each of such classes. This is what we call the set of the relevant transformations. Although each map brings out a different property of the sequence, note that all of them display long-range dependence. For each sequence, we test the hypothesis  $H_0 : d = 0$  versus  $H_1 : d \neq 0$ , based on the long-range dependence parameter, at 95% confidence level, for all estimators proposed.

The value for the spectral envelope estimator is  $\hat{d}_{WS} = 0.0722$ , calculated for all transformations together, applied to the AL163202 nucleotide sequence. Since it is a single value, we do not report

Table 1. Estimators for the parameter  $d$ , with their respective 95% confidence levels for the AL163202 nucleotide sequence, using 30 different transformations.

Note: \*The rejection of  $H_0$  hypothesis at 5% significance level.

it in Table 1. From Table 1, one observes that the  $\hat{d}_{\text{GPH}}$  estimator always gives higher estimates for the parameter  $d$  among all four methods. The estimators  $\hat{d}_W$ ,  $\hat{d}_{\text{WS}}$  and also  $\hat{d}_{\text{DFA}}$  are in the same order of magnitude. What is important is that all estimators are significantly pointing to the direction of long memory.

**4. Long-range dependence and the tail index estimator**

The most important parameter to estimate on the heavy-tailed data is the tail rate of decay  $\alpha$  which determines the probability of occurrence of extreme values of the underlying distribution. That is,  $\alpha$  is the parameter such that

$$\mathbb{P}(|X| > x) \sim Cx^{-\alpha}, \quad \text{for } x \in \mathbb{R},$$

where  $C$  is a positive constant. Our interest here lies on the probabilistic modeling and on the inference statistics for the extreme part of the tail of the distribution of  $X_t$  for coding (cds), and  $Y_t$  for noncoding (ndcs) regions, of some DNA sequences (see Definition 5.1) by estimating the parameter  $\alpha$ .

Let  $X_1, X_2, \dots$  be i.i.d. random variables representing risks or losses with an unknown cumulative distribution function (CDF)  $F(x) = \mathbb{P}(X_i \leq x)$ . A loss is treated as a positive number and extreme events occur when losses take values in the right tail of the loss distribution  $F(\cdot)$ . Define  $M_n = \max(X_1, \dots, X_n)$  as the worst-case loss in a sample of  $n$  losses. An important part of the extreme value theory focuses on the distribution of  $M_n$ . From the i.i.d. assumption, the CDF of  $M_n$  is given by

$$\mathbb{P}(M_n \leq x) = \mathbb{P}(X_1 \leq x, \dots, X_n \leq x) = \prod_{i=1}^n F(x) = F^n(x).$$

Since  $F^n(\cdot)$  is assumed to be unknown and the empirical distribution function is often a very poor estimator for  $F^n(\cdot)$ , an asymptotic approximation to  $F^n(\cdot)$  based on the *Fisher–Tippett Theorem* [9] is used to make inferences on  $M_n$ . Furthermore, since  $F^n(x) \rightarrow 0$  or  $1$ , as  $n \rightarrow \infty$  and  $x$  is fixed, the asymptotic approximation is based on the standardized maximum value

$$Z_n = \frac{M_n - \mu_n}{\sigma_n}, \tag{9}$$

where  $\sigma_n$  and  $\mu_n$  are sequences of real numbers such that  $\sigma_n > 0$  is interpreted as a scale measure and  $\mu_n$  as a location measure.

A natural measure of extreme events are values of the  $X_i$  that exceed a high threshold  $u$ . Define the *excess distribution* above the threshold  $u$  as the conditional probability

$$F_u(y) = \mathbb{P}(X - u \leq y | X > u) = \frac{F(y + u) - F(u)}{1 - F(u)}, \quad y > 0. \tag{10}$$

It can be shown [8] that for a large enough  $u$  there exists a positive function  $\beta(u)$  such that the excess distribution (10) is well approximated by the *generalized Pareto distribution* (GPD)

$$G_{\xi, \beta(u)}(y) = \begin{cases} 1 - (1 + \xi y / \beta(u)), & \text{if } \xi \neq 0 \\ 1 - \exp(-y / \beta(u)), & \text{if } \xi = 0, \end{cases} \tag{11}$$

defined for  $y > 0$ , when  $\xi \geq 0$ , and for  $0 \leq y \leq -\beta(u) / \xi$ , when  $\xi < 0$ , where  $\beta(u) > 0$ .

For more details see Embrechts *et al.* [8] and Samorodnitsky and Taqqu [23].

#### 4.1 Long-range dependence

We can define the *long-range dependence* in the *symmetric  $\alpha$ -stable (s $\alpha$ s)* case [8], but certainly not via the covariance function since the second moments for the marginal distributions do not exist. An example of *s $\alpha$ s  $H$ -selfsimilar process* is given by the integral

$$X_t^{(H)} = \int_{\mathbb{R}} [((t-x)^+)^{H-1/\alpha} - ((-x)^+)^{H-1/\alpha}] dM(x), \quad t \in \mathbb{R}, \quad (12)$$

where  $H \in (0, 1)$  is the *Hurst's effect* parameter for estimating the long-range dependence. In the above expression,  $M$  is an *s $\alpha$ s* random measure with Lebesgue control measure. For  $H = 1/\alpha$  the process is formally interpreted as an *s $\alpha$ s* motion. The *s $\alpha$ s* process so defined in expression (12) is called *linear fractional stable motion*. It is a process with stationary increments, but the subclass of selfsimilar processes does not consist only of these fractional motions. The corresponding *fractional s $\alpha$ s noise* can be defined as

$$Y_t^{(H)} = X_{t+1}^{(H)} - X_t^{(H)}, \quad t \in \mathbb{Z}. \quad (13)$$

When  $H = 1/\alpha$ , in expression (13), the process is formally interpreted as a *symmetric  $\alpha$ -stable (s $\alpha$ s) noise*, whereas for  $H \in (1/\alpha, 1)$  and  $1 < \alpha < 2$ , it is considered as a process with *long-range dependence*, in analogy to the fractional Brownian noise.

*Remark 4.1* The Hurst parameter  $H$ , in expression (12), is related to the fractional parameter  $d$  [1] by the equation

$$d = H - \frac{1}{2}. \quad (14)$$

Since  $H = 1/\alpha$ , from expression (14) we obtain

$$d = \frac{1}{\alpha} - \frac{1}{2} \iff \alpha = \frac{2}{2d + 1}, \quad (15)$$

that is, one has the relationship between the fractional parameter  $d$  and the tail index  $\alpha$ .

#### 4.2 Hill estimator for the tail index

For the GPD, the shape  $\alpha$  may be estimated nonparametrically in quite different ways. A popular method due to Hill [14] applies to the case where  $\alpha > 0$  so that the data are generated by some fat-tailed distribution in the domain of attraction of Fréchet family or GPD distribution. To describe the Hill estimator, let us consider a sample of losses  $X_1, \dots, X_n$  and define the order statistics as

$$X_{(1)} \geq X_{(2)} \geq \dots \geq X_{(n)}.$$

For a positive integer  $k$ , the *Hill estimator* for  $\alpha$  is defined as

$$\hat{\alpha}(k) = \left( k^{-1} \sum_{j=1}^k \ln(X_{(j)}) - \ln(X_{(k)}) \right)^{-1}. \quad (16)$$

The Hill estimators for  $\alpha$  depend on the integer  $k$ . It can be shown that if  $F(\cdot)$  is in the domain of attraction of a GPD distribution, then  $\hat{\alpha}(k)$  is asymptotically normally distributed with asymptotic variance given by  $\text{avar}(\hat{\alpha}(k)) = k^{-1}\alpha^2$ .

### 5. Length distribution analysis in DNA sequences

In this section, we analyze the coding and noncoding length distribution by considering the Hill estimator. This analysis will help us to identify differences between these distributions and the existence of long memory for noncoding regions of DNA sequences.

A common problem in analyzing long nucleotide sequence data is how to identify coding regions (cds) dispersed throughout the sequence and separated by noncoding regions (ncds). Distinguishing the distribution for each one of these regions can help to locate both coding and noncoding regions in DNA sequences.

**DEFINITION 5.1** Let  $\{n_i\}_{i=1}^n$  be any nucleotide sequence. By ordering all lengths of coding (or noncoding) segments, according to their order in the complete genome, the obtained integer sequence is called a coding (or noncoding) length sequence.

**Remark 5.1** From Definition 5.1, one obtains the time series  $\{X_t\}_{t=1}^n$  (analogously, the time series  $\{Y_t\}_{t=1}^n$ ) derived from the coding (or noncoding) length sequence given by

$$X_t = \text{the length of the coding segment at position } t$$

$$Y_t = \text{the length of the noncoding segment at position } t,$$

where the length of a coding (or noncoding) segment means the number of its bases in the segment.

Figure 1 shows the histograms of the coding and noncoding length sequences, respectively, for the *H. sapiens* chromosome 21. The observed long tail in Figure 1 illustrates how difficult it can be to attribute probabilities to extreme events using all data sets. One can note that there is a difference between coding and noncoding length sequence histograms.

Our interest is to analyze the distribution of coding and noncoding regions, by considering, respectively, the coding and noncoding length sequences (see Definition 5.1). Table 2 presents,

Figure 1. Histogram for Coding and Noncoding Length Sequences for the *H. sapiens* chromosome 21.

Table 2. Hill estimator  $\hat{\alpha}_{\text{cds}}$  ( $\hat{\alpha}_{\text{ncds}}$ ) for coding (noncoding) length sequences for *H. sapiens* chromosomes, with  $k = n^{0.5}$ .

<i>H. sapiens</i> Chr.	Sequence	Coding's size	$\hat{\alpha}_{\text{cds}}$	Noncoding's size	$\hat{\alpha}_{\text{ncds}}$
1	CM000252	45119	2.6216	45118	1.8538

20	CM000271	13203	2.4240	13202	1.6034
21	CM000272	5243	2.1805	5242	1.6884
22	CM000273	5243	2.1805	5242	1.6884
X	CM000274	15604	2.3963	15603	1.5784
Y	CM000275	361	2.1131	360	2.0556

respectively, the Hill estimator  $\hat{\alpha}_{\text{cds}}$  for the *coding* and  $\hat{\alpha}_{\text{ncds}}$  for the *noncoding length sequences* for all *H. sapiens* chromosomes. This set of data is available from the EBI (<http://www.ebi.ac.uk/>). Since each set of sequences begins and ends with a coding segment, we always have one more segment for coding (column 3) than for noncoding (column 5).

The  $\alpha$  parameter evaluates the tail rate of decay, which determines the probability of occurrence of extreme events and the existence of moments for the underlying distribution. Here  $k$  is given by  $n^{0.5}$ , where  $n$  is the sample size.

From Table 2, one observes that coding regions present  $\alpha$  estimates usually larger than those from noncoding regions. This happens both on average and within the same chromosome. Only in two cases (chromosomes 15 and 18) it does not happen that the first estimate is larger than the corresponding second one. Although this needs further investigation, one may suspect that the  $\alpha$  parameters are generally above the  $\alpha = 2$  mark for coding segments and below this mark for noncoding segments.

## 6. Conclusions

In this paper, we analyze the performance of the estimator  $\hat{d}_{\text{WS}}$ , obtained by replacing the periodogram in expression (4) by the spectral envelope. Considering several different transformations, we compare the  $\hat{d}_{\text{GPH}}$  estimator with  $\hat{d}_{\text{W}}$ ,  $\hat{d}_{\text{WS}}$  and  $\hat{d}_{\text{DFA}}$ , where the first one is the well-known estimator based on the linear regression equation, the second one is the approximated maximum likelihood method, and the last one is the estimator obtained from the DFA method. For the AL163202 nucleotide sequence applied to these different transformations, the estimators for the fractional parameter  $d$  considered in Section 2 are statistically different from zero. This indicates the existence of long-range dependence for the considered sequence when the four bases are

numerically assigned by these maps. This type of dependence cannot be induced by the scaling; it is a property of the sequence.

We also performed an analysis of the tail rate decay of coding and noncoding regions' distribution, for all considered *Homo sapiens* chromosomes. We applied the  $\hat{\alpha}$  estimator to both *coding* and *noncoding length sequences*. Although this needs further investigation, results seem to indicate that for most *noncoding regions* the length distributions tend to have finite first and second moments ( $\alpha \geq 2$ ), while for *coding regions* the length distributions tend to have no finite second moments, being in the domain of attraction of an  $\alpha$ -stable law, with  $\alpha < 2$ .
