Abstract

The structural complexity of crystalline silicon has inspired synthetic chemists to design cyclosilane building blocks for well-defined novel silicon materials with tunable optical properties. This dissertation describes synthetic strategies of constructing novel molecular and polymeric cyclosilane materials and their structure-property-relationships. Polycyclosilanes exhibit microstructure-dependent thermal properties and connectivity-dependent UV-vis absorption features. Novel hybrid σ,π -conjugated cyclosilane building blocks with pre-defined stereochemistry allow access to stereoregular polysilanes. Constitutional isomers of sulfur-incorporated π,n,σ -conjugated cyclosilanes can exhibit distinct conformations and delocalization patterns. Theoretical investigations through density functional theory calculations contribute to understanding the optical and electronic properties of these molecular and polymeric cyclosilane materials.

Advisor: Professor Rebekka S. Klausen

Reader: Professor J.D. Tovar

Reader: Professor Howard Fairbrother

Acknowledgements

First, I would like to thank my advisor, Professor Rebekka S. Klausen for her mentorship. Bekka welcomed me as a visiting undergraduate student purchasing summer research and then as a graduate student joining the group. She has not only led me to grow as a synthetic chemist but encouraged me to always explore more throughout graduate school. I could not get through the hard time during the pandemic without her care and support. What I learnt from Bekka, with no doubt, will be a priceless treasure of my life.

I want to thank my thesis committee members, Prof. J.D. Tovar and Prof. Howard Fairbrother, and my GBO committee member, Prof V. Sara Thoi, for their guidance of research and thoughtful advice on career development.

I would also like to thank all the staff in the chemistry department who supported my research in the past 5 years. I want to express my appreciation to Dr. Jonathan Catazaro, the NMR manager of the chemistry department. He has been a great mentor and a heartwarming friend during my time working with him as NMR TA.

Next, I would like to thank all the former and current members of the Klausen lab. I enjoyed the welcoming and inclusive lab culture in the Klausen group and will always miss the lab after graduation. They are already more than colleagues but personal friends of mine. In particular, I would like to thank Dr. Heidi van de Wouw and Dr Eric A. Marro for their mentorship which helped me develop experimental skills and grow as a scientific researcher. I would also like to thank my fantastic undergraduate, Ms. Sydnee Wong. I grew a lot as a mentor while working together with her for almost 3 years. I wish Sydnee the best for the future!

Then I would like to thank all my friends at Hopkins. Together we have been through a wonderful journey. I want to thank Dr. Yuyang Ji, my lab mate and also a friend from my first year. He is more than a close friend, a great collaborator, but a model polymer scientist to me. I learnt a lot about polymer science from him. I would also like to thank Bing Xu, my friend from undergraduate and roommate for 5 years. I will miss all these research discussions when I talk to you about material science and you try to convince me biochemistry is fun.

Last but not least, I would like to express my deepest appreciation to my family. They always encouraged me to chase my dreams. Even on the other side of the world, they supported me with their generous love for years. Without my family, none of my accomplishments can ever be possible. This dissertation is a gift to my family.

Chapter 1: Introduction

1.1 Forward

Silicon is the center of the modern world for its extensive usage in electronic devices. It is such a dominant material that the current period can be defined as the silicon age.¹ Its high abundance in the earth's crust¹ ensures silicon a relatively affordable and sustainable material for electronics industry and energy-related technology. Nanoscale silicon materials are particularly attractive for their optical and electronic properties with dimensional tunability.² They have found applications in high-speed transistors³, light-emitting devices⁴, lithium-ion battery anode⁵ and bioimaging.⁶

Top-down synthetic approaches are mostly employed in these applications mentioned above. However, to achieve a precise control of hierarchical structures and therefore understand the structure-property relationships, the bottom-up strategy is necessary. Design, synthesis and characterization of molecular silicon-based materials (e.g., silanes) lead towards unique electronic properties arising from silicon scaffolds. Their capability as molecular building blocks further motivates exploration of synthesizing polymeric materials with well-defined structures and tailored properties.

1.2 σ -Conjugation in silanes

Silanes exhibit unique optical properties compared to their group 14 relatives, saturated hydrocarbons.⁷ In 1964 when Sakurai and Kumada studied the ultraviolet spectra of oligosilanes, they found oligosilanes had strong absorption in the near ultraviolet region (210 to 260 nm) and the introduction of pentamethyldisilyl group into benzene caused an obvious red shift.⁸ This evidence suggests delocalization through Si-Si σ bonds, later known

as σ -conjugation. σ -Conjugation is extended across the oligosilanes with the increasing chain length similar to π -conjugated systems^{8,9}, but also found to be strongly dependent on the silane conformations.¹⁰⁻¹³

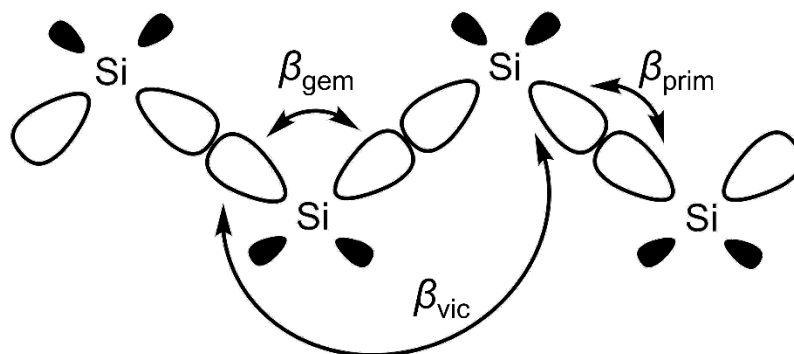

Figure 1.2.1 Ladder C model of σ -conjugation.

The Sandorfy C and H approximations were first applied to understand the delocalization across oligosilanes. However, they failed to interpret conformational effects of σ -conjugation.⁷ The ladder C model, developed and optimized by Michl^{14,15}, then was proved to fit experimental observation of linear oligosilanes better.

Three major types of orbital interactions are considered in oligosilanes: primary interaction – overlap of sp^3 orbitals on Si atoms oriented towards each other; geminal interaction – hyperconjugation between geminal σ orbitals on the same silicon atom; vicinal interaction - σ orbitals on the neighboring silicon atoms which are not oriented towards each other (Figure 1.2.1). The strength of these orbital interactions can be evaluated by the resonance integral β based on the degrees of orbital overlap.

While β_{prim} and β_{gem} are not sensitive to orbital geometries, β_{vic} is a function of the Si-Si-Si-Si dihedral angle ω of the silane chain (Figure 1.2.2a). During the free rotation of the Si-Si bond and change of dihedral angle ω , the strength of vicinal interaction increases significantly when the silane adopts to the *anti*-conformation ($\omega = 180^\circ$). Meanwhile, the

syn-conformation¹⁶ ($\omega = 0^\circ$) is not favored to maximize the vicinal interaction: β_{vic} is calculated to decrease by 1.4 eV.¹⁷ This dependence of β_{vic} on the dihedral angle ω results in the conformational effects on molecular orbital (MO) energies (Figure 1.2.2b). The HOMO energy increases and the LUMO energy decreases with larger β_{vic} , so that the all-*anti* conformation reduces the HOMO-LUMO gap allowing the most effective σ -conjugation (Figure 1.2.2b left). On the contrary the all-*cis* conformation minimizes β_{vic} , resulting in a larger HOMO-LUMO gap (Figure 1.2.2b right).

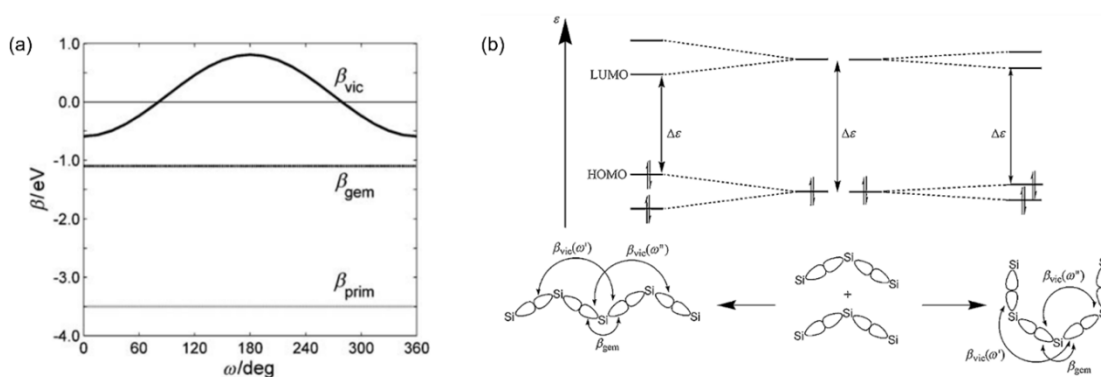

Figure 1.2.2 a) The resonance integrals β_{prim} , β_{gem} , and β_{vic} as a function of the dihedral angle ω . b) MO diagram describing schematically the effect of chain length doubling for the case of strong (left) and weak (right) σ -conjugation. Reprinted with permission from reference.¹⁷ Copyright 2009 Wiley.

These predictions on MO energy tendency are supported by experimental studies on photoelectron spectra of oligosilanes.^{10,11,18,19} West reported thermochromism of poly(di-*n*-hexylsilane) (PDHS) in hexane, where multiple absorption bands showed in the UV spectrum upon cooling of the fresh solution of PDHS (Figure 1.2.3).¹⁰ It indicated that PDHS existed in three different conformational forms in the solution, which was observed the first time in a polysilane. Band III was assigned as the absorption of *anti*- or near *anti*-conformation of the polysilane for its red shift from Band II (*transoid*-conformation)

(Figure 1.2.3c). Tamao is one of the pioneers of confirming the conformational dependence of σ -conjugation by conformationally constrained oligosilanes.^{11,18} *Syn*- and *anti*-disilane units were designed to construct tetrasilanes in which the dihedral angles are controlled to *syn(S)*, *anti(A)*, and *eclipsed (E)*. When ω increases from $7.1^\circ \rightarrow 117.5^\circ \rightarrow 180^\circ$ (conformation: *syn* \rightarrow *eclipsed* \rightarrow *anti*), λ_{\max} of UV absorption change from 210 nm to 238 nm¹⁸ (Figure 1.2.4a). Similar trend was also found in hexasilane compounds¹⁸ (Figure 1.2.4b). With more sterically constrained silane units, Tamao prepared *anti,cisoid*-alternating hexa- to decasilanes and obtained the first clear-cut experimental evidence that a small dihedral angle such as *cisoid* turn suppresses the σ -conjugation in polysilanes.¹¹ λ_{\max} remain around 240 nm regardless of the silicon chain length in all the *anti,cisoid*-alternating oligosilanes (Figure 1.2.5a), but increase with the chain length in *transoid*-oligosilanes (Figure 1.2.5b). More recently, Nuckolls designed bicyclo[2.2.2]octasilane, which has *cisoid* Si–Si–Si–Si dihedral angles ranging from 15° to 20° for its three silane bridges.¹⁹ These silanes were found to be of extremely low conductance due to destructive σ -interference using a scanning tunnelling microscope break junction (STM-BJ) technique.

1.3 Cyclosilanes inspired by crystalline silicon

Cyclosilanes have been widely studied for their unusual properties due to electron delocalization in the σ -frameworks and their reactivity pattern in the past 100 years.²⁰ The first synthesis of cyclosilanes can be dated back to 1921, when Kipping reported series of “saturated and unsaturated Si_4Ph_8 ”.²¹ Though some structure assignments were not

accurate initially, Gilman confirmed these compounds as perphenylated tetra, penta and hexacyclosilanes (Scheme 1.3.1).^{22,23} 30 years later, the first permethylated cyclosilane dodecamethylhexacyclosilane ($\text{Si}_6\text{Me}_{12}$) was discovered as a minor product (2% yield) in the synthesis of polydimethylsilane.²⁴ The synthesis was optimized by West using lithium in tetrahydrofuran as the reducing agent and the yield was increased to about 80%.²⁵

West, Hengge and Marschner contributed tremendously to this field for their efforts including mechanistic studies of cyclosilane reactivities, precise control of ring sizes and development of polycyclic silanes.^{26–30} Recently more examples are discovered on enriching functionality on the silicon scaffolds and the resulting unique properties.^{19,31}

Scheme 1.3.1 Cyclosilane structures.

In addition to the important electronic and optical properties of crystalline silicon, its structural complexity is also tempting and inspiring to synthetic chemists. Polycyclic fragments of chair cyclosilanes can be found in the structure of crystalline silicon lattice (Figure 1.3.1a), which brings a revealing insight on designing novel silicon materials with tunable optical properties.³² The Klausen lab has been extensively exploring the target-oriented synthesis of cyclosilanes inspired by crystalline silicon in the past few years (Figure 1.3.1b).³²⁻³⁶ The chemically inert Si-Me groups and reactive Si-H groups allow selective functionalization and polymerization of these cyclosilanes.

Figure 1.3.1 a) Polycyclic fragments highlighted in the crystalline silicon lattice. b) Cyclosilanes synthesized by the Klausen group.

The synthetic routes of cyclosilanes inspired by crystalline silicon are summarized in Scheme 1.3.2. The key intermediates for the synthesis of Si-H functionalized cyclosilanes are a class of oligosilyl dianions (Scheme 1.3.2a). Starting from di(TMS)diphenylsilane (**1.1**), TMS terminated oligosilanes (**1.2a-b**) were synthesized through salt metathesis as precursors, and treated with *tert*-butoxide/crown ether yielding

α,ω -dipotassiodisilanides (**1.3a-b**).³⁶ The chain length is tunable by using different dichlorooligosilanes. The cyclization of diaions and dichlorosilanes results in the isomeric tetraphenyl-functionalized cyclohexasilanes (**1.4** and **1.5**, Scheme 1.3.2b-c). The phenyl groups can be removed by treatment of trifluoromethanesulfonic acid (TfOH) giving silyl triflate intermediates, which are thereupon reduced by lithium aluminum hydride (LAH) leading to tetrahydrocyclohexasilanes, **1,4Si₆**³³ and **1,3Si₆**³⁴, which are of isomeric structures but different Si-H functional patterns. **1,4Si₆** is a white crystalline solid and the crystal structure suggests its chair-like conformation and high symmetry.³³ Meanwhile, **1,3Si₆** is a colorless oil at room temperature, but its precursor **1.5** is found to adapt a chair-like conformation in the solid state.³⁴

Scheme 1.3.2 Synthesis and polymerization of cyclohexasilanes.^{33,34,36}

Polycyclosilanes feature a structural pattern of a periodic alternation of methylated and hydrogenated silicon atoms. $\text{Cp}_2\text{ZrCl}_2/n\text{-BuLi}$ mediated dehydrocoupling polymerizations were performed on the bifunctional cyclosilane building blocks **1,4Si₆** and **1,3Si₆** yielding poly(cyclosilane)s of comparable molecular weights but different

microstructures (Scheme 1.3.2b-c). Polymerization of **1,4Si₆** resulted in a linear polymer **P1.1**, whereas **1,3Si₆** templated a macrocyclic architecture **P1.2**.

The cyclic polymer is distinct from the linear one by its high symmetry and the absence of SiH₂ end groups. This makes Si-H bonds diagnostic for spectroscopic characterization such as NMR spectroscopy and infrared spectroscopy. Comparison of experimental NMR spectra of the cyclosilane building blocks and their polymers reveals poly(cyclosilane) microstructures (Figure 1.3.2a).^{33,34} In the ¹H NMR spectrum of **P1.1**, several broad resonances are observed in the typical region of Si-H groups (3.5-3.0 ppm).³³ These signals are assigned as internal SiH groups and SiH₂ end groups arising from a linear structure. On the other hand, a broad singlet corresponding to internal SiH groups at 3.25 ppm dominates the Si-H region in the ¹H NMR spectrum of **P1.2**.³⁴ This indicates the high symmetry macrocyclic structure rather than a linear polymer structure.

Figure 1.3.2 Characterization of poly(cyclosilane) microstructures. (a) Cropped ¹H NMR spectra of (top to bottom) poly(**1,4Si₆**), **1,4Si₆**, poly(**1,3Si₆**), and **1,3Si₆**. Only the SiH region is shown. (b) Cropped ATR-FTIR spectra of **1,3Si₆** (dashed line) and poly(**1,3Si₆**) (solid line). Only the Si-H stretching frequencies are shown. Reprinted with permission from reference.³⁴ Copyright 2018 ACS.

The microstructure assignment can be further confirmed by IR spectroscopy (Figure 1.3.2b). Si-H bonds have characteristic stretching frequencies at $\sim 2100\text{ cm}^{-1}$ in IR spectroscopy and their exact values depend on the degree of silyl- substitution. The stretching frequency shifts towards lower wavenumber with silyl-substitution increasing.³⁷ The IR spectrum of polymerized **1,3Si₆** has a symmetric band in the Si-H region centered at lower frequency than before polymerization (Figure 1.3.2b).³⁴ This observation indicates a macrocyclic structure lacking SiH₂ end group.

Synthesis of siladecalin, the silicon analog of decalin, has been a long-standing challenge to synthetic chemists for decades. Although in 1972 West reported first reported its synthesis as a minor product (4 % yield) of dimethyldichlorosilane and trimethylchlorosilane reductive coupling²⁶, the structure was finally assigned via X-ray crystallography by Hengge in 1993.²⁷ Recently, Klausen reported stereocontrolled syntheses of functionalized *cis*- and *trans*-siladecalins via coupling of **Si₄** dianion and 1,2-dichlorohexacyclosilane (Scheme 1.3.3).³⁸ This approach allows control of relative stereochemistry and functional group interconversion.

Under optimized conditions, *cis*-**Si₁₀Ph₄** was synthesized with high diastereoselectivity (dr 10:90 *trans:cis*), and converted to *cis*-**Si₁₀H₄** (dr 15:85 *trans:cis*) in 65% yield via dearylation with TfOH and reduction with LAH. *cis*-**Si₁₀Ph₄** underwent epimerization when heated with excess **Si₄** dianion in toluene, yielding *trans*-**Si₁₀Ph₄** (dr 97:3 *trans:cis*) as the thermodynamically favorable product. Similar reaction conditions with *trans*-**Si₁₀Ph₄** (dr 97:3 *trans:cis*) provided 95:5 *trans*-**Si₁₀H₄** in 68% yield. Their structures were fully characterized and assigned by IR spectroscopy, NMR spectroscopies and X-ray crystallography. Si-H functional groups enable capabilities for future

functionalization and therefore make *trans*- and *cis*-**Si₁₀H₄** potential bicyclic silane building blocks for novel conjugated structures.

Scheme 1.3.3 Selective synthesis of functionalized *trans*- and *cis*-siladecalin.

1.4 Hydrosilylation reactions

Hydrosilylation, the addition of hydrosilanes across unsaturated bonds (Scheme 1.4.1a), serves as an essential method to synthesize and functionalize organosilicon materials. The study of hydrosilylation reactions can be dated to 1947 when Sommer reported the first hydrosilylation of 1-octene using trichlorosilane catalyzed by peroxide.³⁹ Later in 1957, Speier reported H_2PtCl_6 -catalyzed hydrosilylation of 1-pentene and cyclohexene leading to the industrial usage of transition metal catalysts in this field.⁴⁰ In 1973 Karstedt developed a platinum(0) catalyst (also known Karstedt's catalyst, Scheme 1.4.1b) showing high reactivity under ambient condition and it has been widely used in the industrial preparation of various silicone polymers.⁴¹ Nowadays, the collection of catalysts has been extended from Pt to other group VIII to X transition metals including Pd⁴², Co⁴³, Fe^{44,45}, Ni⁴⁶, Rh^{47–49} and Ru.^{50,51}

Chalk and Harrod proposed the first widely accepted mechanism of group VIII metal-catalyzed hydrosilylation of olefins⁵², which was then modified based on quantum chemical investigation.⁵³ The reaction typically undergoes the following catalytic pathway: oxidative addition of a hydrosilane to a transition metal center, olefin coordination, migratory insertion of the olefin forming a Si-C bond and reductive elimination through C-H bond formation (Scheme 1.4.1c).

Scheme 1.4.1 a) Generic scheme of hydrosilylation. b) Structure of Karstedt's catalyst. c) Modified Chalk-Harrod mechanism of hydrosilylation.

1.5 Polycarbosilane synthesis via hydrosilylation

Interest in synthesizing saturated polycarbosilanes has been greatly motivated since Yajima first reported polysilane and polycarbosilane pyrolysis to silicon carbide fibers at $>1000\text{ }^\circ\text{C}$ in the 1970's (Scheme 1.5.1).⁵⁴⁻⁵⁶

Scheme 1.5.1 SiC fibers synthesized from polycarbosilane.

Copolymerization of hydromonosilanes with alkenes through transition metal-catalyzed hydrosilylations has been extensively explored as a feasible synthetic approach

to saturated polycarbosilanes. Corriu reported the polymerization of dimethylvinylsilane catalyzed by H_2PtCl_6 yielding poly(dimethylsilylethylene) of low molecular weight ($M_n = 2740 \text{ g/mol}$) (Scheme 1.5.2a).⁵⁷ The reaction exhibits a low selectivity towards α addition (yielding n units) and β addition (yielding m units) on alkenes. Similar selectivity is also seen in the polymerization of dichlorovinylsilane catalyzed by Pt/C.⁵⁸ Increasing the steric hinderance on starting hydrosilanes and utilizing Karstedt's catalyst results in high ratio of β -addition units. Optically active (S)-1-phenyl-1-naphthyl-1-vinyl-3,3-dimethyl-1,3-disiloxane was polymerized in the presence of Karstedt's catalyst to yield an optically pure and highly stereoregular polycarbosiloxane with all β -addition units (Scheme 1.5.2b).⁵⁹ More recently, He reported the construction of polymers featuring Si-stereogenic heteroarylsilanes (Scheme 1.5.2c).⁶⁰ The Si steric centers are preserved in the hydrosilylation, opening up a new approach towards tailormade chiral polymers with a wide range of applications. To obtain polycarbosilanes of high molecular weights, Rh-based catalysts were used for intermolecular hydrosilylation of the vinylhydrosilane (Scheme 1.5.2d).⁴⁷ The resulting polymers exhibit wide molecular weight distribution featuring M_w up to 102000 g/mol in gel permeation chromatography.

Scheme 1.5.2 Synthesis of saturated polycarbosilanes through transition metal-catalyzed hydrosilylation.

Scheme 1.5.3 Synthesis of unsaturated polycarbosilanes through transition metal catalyzed hydrosilylation.

On the other hand, hydrosilylation between hydrosilane and alkynes leads to hybrid conjugated polymers with unique optical properties arising from mixing of σ and π orbitals (Scheme 1.5.3). Poly(silafluorene-phenylene-divinylene) was synthesized through hydrosilylation between 1,1-silafluorene and 1,4-diethynylbenzene (Scheme 1.5.3a).⁶¹ The photoluminescent polymer maintains a regioregular (*E*)-vinylene Si-C backbone allowing $\sigma^*-\pi/\pi^*$ conjugation. Serial photoluminescent silylene-arylene-vinylene polymers were obtained via addition of bis(silylhydrides) to 1,3-diynes (Scheme 1.5.3b).⁶² Although H_2PtCl_6 and Karstedt's catalyst find their ways in synthesizing novel σ , π -conjugated polymers, Rh-based catalysts have been attracting more attention to achieve better selectivity, higher efficiency and high molecular weights. $\text{RhI}(\text{PPh}_3)_3$ allows a highly selective synthesis of (*E*)- and (*Z*)-poly(silylene-1,4-phenylenevinylene)s controlled by temperature (Scheme 1.5.3c).⁴⁸ The formation of *trans* polymers favors reaction conditions at high temperature (up to 160 °C), whereas the ambient condition leads to the *cis* products.

1.6 Functionalization of oligo- and polysilanes via hydrosilylation

Despite the numerous achievements on polycarbonsilane synthesis through hydrosilylation between hydromonosilane and alkenes/alkynes, the application of hydrosilylation to oligo- and polysilanes is very challenging due to the extensive Si-Si cleavage with the presence of transition metal catalysts.⁶³⁻⁶⁵ The mechanism was studied experimentally by the synthesis of bis(silylene)ruthenium complex from hydrodisilane.⁶⁴ The same as hydromonosilanes, hydrodisilanes react with the catalyst starting from transition metal insertion between the Si-H bond (oxidative addition). However, with existence of the weak Si-Si bonds the transition metal center prefers to further migrate

between Si atoms yielding metal-silylene complexes, which react with alkynes forming Si-Si bond cleaved products (Scheme 1.6.1).

Scheme 1.6.1 Mechanism of Si-Si bond cleavage in hydrosilylation of alkynes with hydrodisilane.

Scheme 1.6.2 a) $B(C_6F_5)_3$ catalyzed hydrosilylation of poly(phenylsilane). b) BH_3 catalyzed hydrosilylation of poly(cyclosilane). c) Ru-catalyzed hydrosilylation of hydrodisilane. d) Reaction mechanisms of hydrosilylation in the presence of $RuHCl(CO)(PPh_3)_3$.

Borane Lewis acids were used for hydrosilylation on polysilanes without skeletal fragmentation. Rosenberg reported functionalization of poly(phenylsilane) with $X=C$

groups catalyzed by tris(pentafluorophenyl)borane ($\text{B}(\text{C}_6\text{H}_5)_3$) (Scheme 1.6.2a).^{66,67} Klausen performed BH_3 catalyzed functionalization of poly(cyclosilane)s with electron-poor aryl alkynes (Scheme 1.6.2b).³³ Introduction of organic side chains containing dicyanovinyl electron acceptors results in novel well-defined silane donor–acceptor compounds.

Recently, Kyushin reported Ru catalyzed (*E*)- and (*Z*)- selective hydrosilylation of alkynes and hydrooligosilanes without Si–Si bond cleavage (Scheme 1.6.2c).^{50,51} The Si–Si bonds survive the reaction by avoiding formation of reactive metal-silylene intermediates (Scheme 1.6.2d). These studies enable the functionalization of oligo- and polysilanes to maintain diverse Si skeletons and give rise to novel organosilicon materials with desired thermal performance and unique optical properties.

1.7 Conclusion

The discussions above highlighted the progress of designing novel cyclosilanes building blocks and their polymerization. Investigating the effect of microstructures (linear vs cyclic) and connectivity patterns (1,3-linking vs 1,4 linking) on the thermal and optical properties of poly(cyclosilane)s led to further understanding the structure-property relationship of poly(cyclosilane)s as a new class of polymeric materials (Chapter 2&3). Hydrosilylation enabled novel cyclosilanes building blocks for constructing σ,π -conjugated hybrid polymers with stereoregularity (Chapter 4&6). Dehydrocoupling of hydrocyclosilanes and thiols allows access to $\sigma\text{-n-}\pi$ conjugated molecules and density functional theory calculations bring insights to understand electron transition behaviors (Chapter 5).

Chapter 2: Effect of poly(cyclosilane) microstructure on thermal properties

The work presented in this chapter has been published as: Jiang, Q.; Wong, S.; Klausen, R. S. *Polym. Chem.* **2021**, *12*, 4785–4794.

2.1 Introduction

Hydrocarbon-based elastomers, thermoplastics, and thermosets are distinguished by their thermal properties, such as the operating temperature (above or below the glass transition temperature, T_g) and physical behaviour above the phase transition (e.g. flow).¹ Models can quantitatively relate polymer T_g to structural phenomena (e.g. the Flory–Fox equation^{1,2} and the number-average molecular weight). In addition to reversible phenomena that occur at relatively low temperature like the phase transitions T_g or T_m , there is interest in the chemical reactivity of polymers at high temperature (pyrolysis).³ In contrast to hydrocarbon polymers, structure-based understanding of polysilane thermal property relationships^{4,5} is more limited and has focused on the influence of organic side chains.^{6,7} Two possible reasons for this issue are (1) the synthetic challenge of creating a structurally well-defined homologous series of polysilanes and (2) the propensity of some polysilanes to undergo skeletal rearrangement to polycarbosilanes at elevated temperatures.^{8,9} The polysilane to polycarbosilane rearrangement precedes the ultimate formation of silicon carbide (SiC) fibers.^{10–12}

We recently described the synthesis and Cp_2ZrCl_2/n -BuLi-mediated^{13,14} dehydrocoupling polymerization of the bifunctional cyclosilane monomers **1,4Si₆** and **1,3Si₆** (Figure 2.1.1a).^{15–20} These directional building blocks template distinct linear or cyclic polymeric architectures: polymers *lin*-poly(**1,4Si₆**) and *cyc*-poly(**1,3Si₆**) were

obtained in comparable molecular weights (M_n ca. 3000 g mol⁻¹), but *cyc*-poly(**1,3Si₆**) lacked spectroscopic signatures consistent with end groups. We considered these materials an opportunity to investigate the effect of polysilane backbone on thermal properties without variation of the side chain, which in all cases were methyl or hydro groups.

Figure 2.1.1 a) Prior work: $\text{Cp}_2\text{ZrCl}_2/n\text{-BuLi}$ -mediated dehydrocoupling polymerization of directional building blocks **1,4Si₆** and **1,3Si₆**. b) This work: Synthesis of new linear *lin*-poly(**1,3Si₆**) and analysis of relationships between microstructure and thermal decomposition.

We hypothesized that *lin*-poly(**1,4Si₆**) and *cyc*-poly(**1,3Si₆**) would exhibit distinct thermal behaviour and reactivity. Cyclic polymers, both experimentally and computationally, show markedly different properties from linear variants despite similar chemical compositions.^{21–28} For example, Roovers *et al.* reported that low molecular weight cyclic polystyrene ($M_w = 4,700$ g mol⁻¹) has a glass transition temperature 21 °C

higher than linear polystyrene of the same molecular weight.²⁷ In addition, the SiH₂ end groups present in *lin*-poly(**1,4Si₆**) are significantly stronger than SiH internal groups (Figure 2.1.1b) due to the weakening effect of silyl substitution on Si–H bonds,²⁹ which may perturb the sequence of chemical steps during thermolysis. To probe these differences, we also sought the synthesis of a linear polymer of **1,3Si₆** (*lin*-poly(**1,3Si₆**)) which would have the same relative connectivity of *cyc*-poly(**1,3Si₆**) but would possess SiH₂ end groups.

Herein, we report that replacement of the standard Cp₂ZrCl₂/*n*BuLi catalyst with Cp₂ZrMe₂ provided *lin*-poly(**1,3Si₆**), the desired linear polymer of **1,3Si₆**, a structural assignment supported by ¹H and ²⁹Si NMR spectroscopy. We investigate the influence of poly(cyclosilane) microstructure on thermal behavior and decomposition using a combined theoretical and experimental study. Thermal stability was investigated by differential scanning calorimetry (DSC) and thermogravimetric analysis (TGA) complemented by density functional theory (DFT) calculations. All three samples were glassy solids at room temperature. A glass transition was observed at 108 °C in *cyc*-poly(**1,3Si₆**), but no reversible phase transitions were found below 200 °C in *lin*-poly(**1,4Si₆**) and *lin*-poly(**1,3Si₆**). Above 250 °C, all three poly(cyclosilane)s showed significant thermal decomposition that proceeded in two phases. A generic thermolysis process of poly(cyclosilane)s is proposed based on this combined theoretical and experimental study. As a polymeric material combining cyclic subunits and mixed H- and Me- termination, poly(cyclosilane)s may find utility as ceramic precursors.

2.2 Dehydrocoupling of hydrosilanes catalyzed by Group 4 metallocene

Reductive Wurtz coupling of dichlorosilanes mediated by alkali metal has been the most popular method to access high molecular weight polysilanes (Scheme 2.2.1).³⁰ Alkyl

and aryl groups are mostly seen as side chains in the yielding polysilanes, such as poly(SiMe₂), poly(di-*n*-hexylsilane) and polymethylphenylsilane. However, strong reductive conditions and intolerance to functional groups limit its utilization of synthesizing more diverse polysilane structures.¹⁹

Scheme 2.2.1 Polymerization of dichlorodimethylsilane via Wurtz coupling.

Dehydrogenative polymerization of primary silanes (e.g. PhSiH₃) catalyzed by Group 4 metallocenes (Cp₂MX₂, M = Ti, Zr and Hf) serves as an intriguing alternative to Wurtz coupling polymerization. Harrod reported the first example of dehydrogenative polymerization making polyphenylsilane using Cp₂TiMe₂ in 1985 (Scheme 2.2.2a).³¹ A long induction period (hours to days) was observed in such reactions. Corey later reported Group 4 metallocene chlorides (Cp₂MCl₂, M = Ti, Zr and Hf) *in situ* activated by 2 equivalents of *n*-BuLi were also able to catalyze the polymerization of primary silanes (Scheme 2.2.2b).³² Once metallocene chlorides activated, no induction period was required for the polymerization. Notably, the same catalytic system led to dehydrocoupling of secondary silanes rather than polymerization, and showed no reactivity to tertiary silanes.³³

Scheme 2.2.2 Dehydrogenative polymerization of primary silanes.

Corey also proposed the mechanism of dehydrogenative coupling of hydrosilanes catalyzed by the $\text{Cp}_2\text{ZrCl}_2/n\text{-BuLi}$ system (Scheme 2.2.3).¹³ Although the mechanism of catalyst activation remained unclear, Corey hypothesized a highly reactive intermediate $[\text{Cp}_2\text{Zr}]$ was generated by treating Cp_2ZrCl_2 with 2 equivalents of $n\text{-BuLi}$. Through σ -bond metathesis first proposed by Tilley³⁴, the coupled silane product was formed and zirconocene hydride later turned to the initial reactive $[\text{Cp}_2\text{Zr}]$.

Scheme 2.2.3 Mechanism of dehydrogenative polymerization of primary silanes catalyzed by the $\text{Cp}_2\text{ZrCl}_2/n\text{-BuLi}$, proposed by Corey.³³

The Klausen group carried out a mechanistic study of dehydrocoupling polymerization of cyclosilane **1,4Si6**.³⁵ The polymerization is sensitive to the bulkiness of metallocene ligands. With Cp groups replaced by bulkier Cp* (permethylated cyclopentadiene), the reactivity of zirconocene catalysts decreased. Incomplete conversion and a modest decrease of molecular weight were observed with $\text{Cp}^*\text{CpZrCl}_2/n\text{-BuLi}$ system. The bulkiest $\text{Cp}^*_2\text{ZrCl}_2/n\text{-BuLi}$ did not catalyzed the polymerization.

Poly(**1,4Si6**) molecular weight characteristics were also affected by transition metal center. $\text{Cp}_2\text{ZrCl}_2/n\text{-BuLi}$ turned out to be the most effective system yielding polysilanes

with full consumption of starting **1,4Si₆**, highest molecular weight and best molecular weight distribution. Cp₂HfCl₂/*n*-BuLi exhibited lower reactivity for observation of starting cyclosilane after 24 hours and lower molecular weight of resulting poly(**1,4Si₆**). Although Cp₂TiCl₂/*n*-BuLi also gave full conversion of **1,4Si₆**, low molecular weight and dispersed molecular weight distribution were observed.

²⁹Si NMRs showed Cp₂TiCl₂/*n*-BuLi resulted in a significant structural rearrangement of the poly(cyclosilane) (Figure 2.2.1a). Identical SiH and SiH₂ resonances were found in ²⁹Si NMRs of Cp₂ZrCl₂/*n*-BuLi and Cp₂HfCl₂/*n*-BuLi catalyzed polymers. Such observation of internal tertiary silanes (SiH) and external secondary silane end groups (SiH₂) indicated a typical linear microstructure of poly(**1,4Si₆**). However, Cp₂TiCl₂/*n*-BuLi catalysis led to a significant structural difference: diminished intensity of SiH and SiH₂ resonances in ²⁹Si NMRs (Figure 2.2.1a). This suggests alkyl redistribution on poly(cyclosilane) yielding highly substituted species.^{32,35} The structural change of Ti-catalysis is also supported by UV-Vis spectroscopy (Figure 2.2.1b). An broader and less-well defined absorption band of Ti-derived poly(**1,4Si₆**) is consistent with the structural assignments above.

Figure 2.2.1 a) Cropped ^{29}Si $\{^1\text{H}\}$ DEPT NMR spectra of poly(**1,4Si₆**) in benzene-*d*₆ b) UV-vis spectra of poly(**1,4Si₆**) samples. Spectra recorded in THF at room temperature. Reprinted with permission from reference.³⁵ Copyright 2018 RSC.

2.3 Synthesis of *lin*-poly(**1,3Si₆**)

During our initial work on **1,3Si₆** polymerization with $\text{Cp}_2\text{ZrCl}_2/n\text{-BuLi}$, we identified two fractions by gel permeation chromatography (GPC): a dominant higher molecular weight fraction corresponding to *cyc*-poly(**1,3Si₆**) and a minor low molecular weight fraction attributed to linear oligomers too short to cyclize (Figure 2.3.1, dashed line).¹⁷ Spectroscopic support for this hypothesis arose from observation of minor signals consistent with SiH_2 end groups in ^1H NMR and ^{29}Si DEPT spectra.

Figure 2.3.1 GPC of *cyc*-poly(**1,3Si₆**) (dotted line) and *lin*-poly(**1,3Si₆**) (solid line). Determined relative to polystyrene standards at 254 nm (THF, [polymer] = 1 mg mL⁻¹, 40 °C, 0.35 mL min⁻¹, 10 μL injection).

Hypothesizing that at a lower average degree of polymerization, poly(**1,3Si₆**) might exist exclusively of linear oligomers we reinvestigated catalysis of **1,3Si₆** polymerization.

We found that Cp₂ZrMe₂-polymerization could provide either linear or cyclic samples depending on solvent. Bulk polymerization of **1,3Si₆** with Cp₂ZrMe₂ (Scheme 2.3.1) provided *lin*-poly(**1,3Si₆**) in 87% yield that subsequent NMR analysis indicated was consistent with structural assignment to a predominantly linear structure (*vide infra*). GPC analysis indicated *lin*-poly(**1,3Si₆**) consisted of a single fraction (Figure 2.3.1). Dilution of the **1,3Si₆**/Cp₂ZrMe₂ polymerization with toluene resulted in *cyc*-poly(**1,3Si₆**), which NMR characterization suggested was consistent with a predominantly cyclic architecture (Table 2.3.1). A 7-day reaction time was required for Cp₂ZrMe₂ catalysis in toluene, as this catalyst requires a 4-day induction period.^{36,37} Heating the reaction at 65 °C shortened the induction period to 24 hours.

Scheme 2.3.1 Synthesis of *lin*-poly(**1,3Si₆**), a linear polymer of **1,3Si₆**.

GPC analysis also indicated that *cyc*-poly(**1,3Si₆**) was obtained in higher molecular weight (ca. 3000 g mol⁻¹) than *lin*-poly(**1,3Si₆**) (ca. 1700 g mol⁻¹) which supports the hypothesis that cyclization is inhibited at lower degrees of polymerization presumably due to strain in forming smaller cycles. However, the known tendency of cyclic polymers to adopt more compact conformations that can lead to anomalous elution on GPC affects confidence in the GPC-estimated molecular weight characteristics of *cyc*-poly(**1,3Si₆**) and *lin*-poly(**1,3Si₆**). For example, Veige *et al.* showed that GPC overestimated the molecular weight of cyclic polystyrene by 10,000 g mol⁻¹, or approximately 100 degrees of polymerization.²⁶ For the cyclosilane system, however, GPC is unlikely to significantly

misestimate poly(cyclosilane) molecular weight as silane dehydropolymerization rarely exceeds 20 degrees of polymerization.³⁸

We suggest that linear oligomers were formed during bulk polymerization due to a change in physical properties. In the absence of solvent, the mixture of monomer and Cp₂ZrMe₂ gradually changes from a liquid to a glass. This may sequester oligomers from further reaction, providing a single fraction of low molecular weight oligomers too short to cyclize. This hypothesis is consistent with the observation that dilution with toluene actually increased molecular weight and lead to cyclized polymer. Dilution typically inhibits intermolecular reactions, such as chain extension.

Table 2.3.1 Molecular weight characteristics for metallocene-initiated dehydrocoupling polymerization of cyclosilane building blocks and resultant polymers.

Polymer	Monomer	Catalyst	Solvent	Reaction time	Structure	M _{n, GPC} (kg mol ⁻¹)	M _{w, GPC} (kg mol ⁻¹)	D ^b	\overline{DP}^c
<i>lin</i> -poly(1,4Si₆)	1,4Si₆	Cp ₂ ZrCl ₂ / <i>n</i> -BuLi	Toluene	24 h	Linear	2.59	3.29	1.27	9
<i>cyc</i> -poly(1,3Si₆)	1,3Si₆	Cp ₂ ZrCl ₂ / <i>n</i> -BuLi	Toluene	24 h	Cyclic	3.07	4.52	1.48	10
<i>lin</i> -poly(1,3Si₆)	1,3Si₆	Cp ₂ ZrMe ₂	none	24 h	Linear	1.77	2.39	1.35	6
<i>cyc</i> -poly(1,3Si₆)	1,3Si₆	Cp ₂ ZrMe ₂	Toluene	7 d	Cyclic	3.84	7.27	1.90	13

Mechanistic differences between the Cp₂ZrMe₂ and Cp₂ZrCl₂/*n*-BuLi catalysts may also play a role in the results. Group 4 metallocene derivatives are among the best-studied catalysts for hydrosilane dehydropolymerization and have long served an important role in understanding novel inorganic mechanisms.^{38,39} Corey *et al.* first reported that *in situ* activation of Cp₂ZrCl₂ in toluene with two equivalents of *n*-butyllithium yielded an effective catalyst for secondary silane polymerization.^{13,14} Chloride substitution by the alkyl lithium yields an intermediate dialkyl zirconocene, which further reacts via β-hydrogen abstraction to yield the active, undercoordinated catalyst, although the exact

catalyst structure remains ambiguous.⁴⁰ In contrast, dimethyl zirconocene (Cp_2ZrMe_2), first reported by Harrod *et al.*, does not require activation by an exogenous agent and can therefore be used either neat or with added solvent.^{36,41,42} However, reactions with Cp_2ZrMe_2 can show an induction period,⁴¹ presumably due to slow formation of the active undercoordinated catalyst in the absence of β -hydrogens.

2.4 Poly(cyclosilane) microstructure

Poly(cyclosilane)s feature a well-defined, periodic alternation of methylated and hydrogenated silicon atoms (Figure 2.1.1b). This structural pattern provides diagnostic features for spectroscopic characterization based on the unique signatures of tertiary (Si_3SiH), secondary (Si_2SiH_2), and primary (SiSiH_3) bonds. Variable silyl- and hydro-substitution strongly influences chemical shift in ^{29}Si NMR spectroscopy.^{43,44} The degree of silyl substitution has a marked weakening effect on Si–H bond strength,²⁹ which is reflected in a significant shift to lower-frequency FTIR resonances for the weaker Si_3SiH internal groups relative to stronger Si_2SiH_2 end groups.¹⁷

Figure 2.4.1 Cropped ^1H NMR spectra of *lin*-poly(**1,4Si₆**), *cyc*-poly(**1,3Si₆**) and *lin*-poly(**1,3Si₆**). Only the SiH region is shown.

^1H NMR spectra are shown in Figure 2.3.1. The spectrum of *cyc*-poly(**1,3Si₆**) is dominated by a single broad resonance at δ 3.25, consistent with its high symmetry macrocyclic structure.¹⁷ *lin*-Poly(**1,4Si₆**) has a series of resonances in the SiH_x region (δ 3.5-3.0), which were assigned to SiH₂ end groups or SiH internal sites by ^1H - ^{29}Si HSQC.¹⁷ The ^1H NMR spectrum of *lin*-poly(**1,3Si₆**) is strikingly similar to *lin*-poly(**1,4Si₆**) with several broad resonances from δ 3.45 to 3.10, even though each is a polymer of an isomeric cyclosilane. These spectral data are consistent with assignment of *lin*-poly(**1,3Si₆**) to a lower-symmetry linear structure rather than a macrocycle.

Figure 2.4.2 Cropped $^{29}\text{Si}\{^1\text{H}\}$ DEPT spectra of *lin*-poly(**1,4Si₆**), *cyc*-poly(**1,3Si₆**) and *lin*-poly(**1,3Si₆**). Only the SiH region is shown. DEPT = distortionless enhancement by polarization transfer.

Figure 2.4.3. ^{29}Si INEPT+ NMR spectrum (79 MHz, Benzene- d_6) of *lin*-poly(**1,3Si₆**).

Further support for assignment of *lin*-poly(**1,3Si₆**) to a predominantly linear structure comes from the ^{29}Si { ^1H } DEPT (Figure 2.3.2), ^{29}Si { ^1H } INEPT+ (Figure 2.3.3) and ^1H - ^{29}Si HSQC (Figure 2.3.4) spectra. Like *lin*-poly(**1,4Si₆**), the ^{29}Si { ^1H } DEPT spectrum of *lin*-poly(**1,3Si₆**) possesses two sets of strong resonances consistent with Si_3SiH tertiary silanes (internal sites, δ -115.3) and Si_2SiH_2 secondary silanes (end groups, δ -97.46). A proton-coupled ^{29}Si INEPT+ spectrum showed the expected multiplicities for the number of attached protons, confirming these assignments (Figure 2.3.3). The family of doublets (δ -109.8 to -117.0, $^1J_{\text{SiH}} = 160.1$ Hz) were assigned to *SiH* internal resonances. The triplet (δ -97.3, $^1J_{\text{SiH}} = 172.3$ Hz) was assigned to *SiH₂* end groups, consistent with assignment of *lin*-poly(**1,3Si₆**) to a linear polymer of **1,3Si₆**. The experimentally measured coupling constants were consistent with typical one-bond coupling constants between silicon and proton.

Figure 2.4.4 ^1H - ^{29}Si HSQC NMR spectrum of *lin*-poly(**1,3Si₆**). Crosspeaks are labelled. HSQC = heteronuclear single quantum coherence; DEPT = distortionless enhancement by polarization transfer.

In the ^1H - ^{29}Si HSQC spectrum of *lin*-poly(**1,3Si₆**), crosspeaks were observed between the ^1H resonances at δ 3.25 to 3.10 and ^{29}Si NMR resonances centered at δ -112 assigned to Si_3SiH sites (Figure 2.3.4). Meanwhile, ^1H resonances at δ 3.44 to 3.28 correlated with the ^{29}Si NMR resonances centered at δ -97 assigned to Si_2SiH_2 sites. The 2-D spectral correlations confirm the assignment of the *lin*-poly(**1,3Si₆**) structure to a linear structure containing both tertiary silane internal sites and secondary silane end groups.

Finally, *lin*-poly(**1,3Si₆**)'s Fourier transform infrared (FTIR) spectrum showed two resonances in the SiH_x region consistent with stronger Si_2SiH_2 and weaker Si_3SiH bonds (Figure 2.3.5). *cyc*-Poly(**1,3Si₆**) lacking Si_2SiH_2 end groups has a more symmetric band in this region centered at a lower frequency. The spectroscopic studies described here support assignment of *lin*-poly(**1,3Si₆**) to a largely linear structure.

Figure 2.4.5 Cropped ATR-FTIR spectra of *cyc*-poly(**1,3Si**₆) and *lin*-poly(**1,3Si**₆) highlighting the Si–H and Si–Me regions.

2.5 Differential Scanning Calorimetry

While the thermal properties of Si–O polymers are well-characterized, and cyclic and linear polydimethylsiloxane (PDMS) were foundational models for understanding the effect of architecture on the T_g ,²³ systematic investigation of polysilane thermal properties has been largely limited to understanding the role of organic side chains in influencing backbone conformation and optical properties. Polysilanes with longer side chains (hexyl, heptyl, octyl) exhibit solid-state thermochromism,^{45,46} while polysilanes with shorter side chains (butyl, pentyl) do not.⁴⁷ Significant experimentation supports the following model: (1) Polysilanes with short side chains adopt a helical Si–Si conformation at room temperature that absorbs higher energy light ($\lambda = 317$ nm). (2) In contrast, polysilanes with longer side chains adopt an all-*anti* conformation at room temperature that maximizes σ -conjugation and results in a bathochromically shifted absorption band ($\lambda = 375$ nm). This is attributed to side chain crystallization that locks the Si–Si backbone into the *anti*-

conformation. At elevated temperatures, side chain melting results in a backbone disordering that shifts the absorption band back to higher energies ($\lambda = 317$ nm).

Rabolt *et al.* found by differential scanning calorimetry (DSC) a reversible first-order transition at ca. 40 °C in poly(di-*n*-hexylsilane) that was assigned to the side-chain melting.⁴⁶ Schilling *et al.* reported that DSC analysis of poly(di-*n*-butylsilane) and poly(di-*n*-pentylsilane) yielded significantly different results, including the lack of a transition comparable to side-chain melting (a weaker transition to a more disordered phase was found above ca. 80 °C).⁴⁷ In addition, Schilling *et al.* reported a very weak second-order transition at 36 °C (only apparent in poly(di-*n*-butylsilane) during slow DSC runs) and an intense second-order transition at -40 °C. On the basis of solid-state NMR experiments (¹³C CP-MAS), all phase transitions were attributed to side chains.

The poly(di-*n*-alkylsilanes) studied by Miller,⁴⁶ Schilling,⁴⁷ and others were prepared by Wurtz polymerization of the corresponding dichlorodialkylsilane. Wurtz polymerization typically results in higher molecular weight materials than those prepared by dehydropolymerization and the products also differ in possessing two alkyl side chains rather than one (e.g. poly(SiR₂) vs. poly(SiHR)). While monoalkyl polysilanes surely possess different thermal properties than dialkyl, we have identified only one report of thermal analysis of a polysilane prepared by dehydropolymerization. Corey *et al.* reported dehydropolymerization of *p*-tolylsilane and that DSC analysis of poly(SiH(*p*-tol)) (degree of polymerization ca. 20) revealed no phase transitions over the temperature range 25 to 200 °C.⁴⁸ Some insight into the influence of hydro side chains arises from comparison of the copolymer poly(SiPh₂-*co*-SiMeH) to poly(SiMePh).⁴⁹ Both poly(SiMePh) and poly(SiPh₂-*co*-SiMeH) exhibited a single glass transition, but the poly(SiPh₂-*co*-SiMeH)

T_g decreased with increasing methylhydro composition ($T_g = 64$ to 85 °C vs. 88 °C for poly(SiMePh)). These data were interpreted as showing greater flexibility and mobility in hydro-substituted polysilanes.

While prior work has provided insight into side chain effects, little is understood about how the silane architecture might influence thermal properties. We therefore performed DSC analysis of the three poly(cyclosilane)s in the temperature range 35 to 200 °C as thermogravimetric analysis (TGA, vide infra) indicated polymer decomposition above 200 °C. Heating rates between 3 and 20 °C min^{-1} were tested.

For the two linear systems *lin*-poly(**1,4Si₆**) and *lin*-poly(**1,3Si₆**), no reversible phase transition was observed below 200 °C at any heating rate (Figure 2.4.1a,c). In contrast, for *cyc*-poly(**1,3Si₆**) we observed an apparent second-order phase transition at 108 °C (Figure 2.4.1b). The transition was only observed with a heating rate of 20 °C min^{-1} and a cooling rate of 3 °C min^{-1} ; no transition was apparent at slower heating rates. The reversibility of the 108 °C transition is unclear: no transition is seen on cooling (Figure 2.4.2) but the transition observed on heating is reproducible (second and third heating cycles overlay, Figure 2.4.3), which is inconsistent with a change in chemical structure. The 108 °C transition was apparent in all samples of *cyc*-poly(**1,3Si₆**) evaluated, regardless of preparative method.

Figure 2.5.1 DSC curves of a) *lin-poly(1,4Si₆)*, b) *cyc-poly(1,3Si₆)*, and c) and *lin-poly(1,3Si₆)*. The second cycle is shown. Heating rate: 3 °C min⁻¹ for *lin-poly(1,4Si₆)*, 20 °C min⁻¹ for *cyc-poly(1,3Si₆)* and *lin-poly(1,3Si₆)*.

Figure 2.5.2. The second cooling cycle of DSC measurement of *lin-poly(1,3Si₆)*. Cooling rate: 3 °C min⁻¹. No phase transition was observed.

Figure 2.5.3. The overlay of the second (solid line) and third (dotted line) heating cycle of DSC measurement of *lin*-poly(**1,3Si₆**). Heating rate: 20 °C min⁻¹.

The DSC analysis of *lin*-poly(**1,4Si₆**) and *lin*-poly(**1,3Si₆**) is similar to that reported by Corey *et al.* for linear poly(SiH(*p*-tol)).⁴⁸ The comparatively high mobility of monoalkyl segments in linear polysilanes may complicate observation of the T_g in polymers with the general formula poly(SiHR). The observation of a 108 °C phase transition is unprecedented. We suggest assignment to a glass transition. While the T_g is not apparent on cooling, this may arise from crystallization during the heating phase. Assignment to a glass transition is also consistent with the known tendency of cyclic polymers to exhibit anomalous glass transitions relative to linear polymers.

2.6 Thermal stability of poly(cyclosilane)s

Polymers based on main group elements find application as solution-processable precursors to ceramics (polymer-derived ceramics, PDCs).^{8,11} Yajima *et al.* discovered pyrolysis of polydimethylsilane ([SiMe₂]_n) yielding silicon carbide (SiC) fibers.^{50,51} Polysilazane pyrolysis yields silicon nitride (Si₃N₄) or Si/C/N ceramics depending on the

precursor and thermolysis conditions.^{8,52,53} Several studies have demonstrated the influence of precursor structure on PDC structure and properties. Schilling *et al.* demonstrated the positive influence of backbone branching on SiC ceramic yield using polycarbosilanes prepared by potassium reduction of vinylmethylchlorosilane.⁵⁴ Polysilanes bearing both hydrogen and alkyl substituents⁵⁵ are particularly attractive to circumvent carbon formation during pyrolysis, as shown by Laine *et al.* in the decomposition of polymethylsilane ($-\text{[MeSiH]}_x-$).⁵⁶

The thermal decomposition of poly(cyclosilane)s was studied by thermogravimetric analysis (Figure 2.5.1). The three polymers showed overall similar thermal decomposition behavior. A minor mass loss at 65 °C in *lin*-poly(**1,4Si₆**) was attributed to residual catalyst (Figure 2.5.1a), which was easier to remove from the more soluble *cyc*-poly(**1,3Si₆**) and *lin*-poly(**1,3Si₆**) samples. TGA curves of derivative weight change reveal two main phases of weight loss when samples are heated from 40 to 600 °C in argon flow. When the temperature increased to 500 °C, about 50% weight loss is observed in all three samples. Then, the weight became constant above 550 °C. A black solid residue remained in the sample pan after the TGA measurement. These observations are consistent with ceramization,⁸ although the product was not characterized in this study.

Figure 2.6.1 TGA curves of a) *lin*-poly(**1,4Si₆**), b) *cyc*-poly(**1,3Si₆**) and c) *lin*-poly(**1,3Si₆**). Solid lines: derivative weight change; dotted lines: percentage weight change.

Some differences between the polymer systems were also apparent between 200 to 400 °C. The linear polymers both showed similar derivative weight change in this region, with a peak value greater than 0.6, while for *cyc*-poly(**1,3Si₆**) the peak value was lower than 0.5 (Figure 2.5.1b). Both linear polymers lost approximately 45% of their weight in this phase, while only 33% for *cyc*-poly(**1,3Si₆**). This indicates that linear poly(cyclosilane)s decomposed more rapidly than *cyc*-poly(**1,3Si₆**) in this temperature range. In addition, multiple features (e.g. peaks and shoulders) appeared in the derivative weight change curve of *lin*-poly(**1,4Si₆**), while smoother curves were obtained in the measurements of *cyc*-poly(**1,3Si₆**) and *lin*-poly(**1,3Si₆**).

These observations point to microstructure-dependent differences in early stage poly(cyclosilane) pyrolysis. The first phase of polysilane pyrolysis to SiC is skeletal rearrangement from a polysilane to a polycarbosilane;⁵⁷ in poly(SiMeH) pyrolysis, this rearrangement occurs at 400 °C.⁵⁶ The pyrolysis of hexamethyldisilane is a model system for polysilane thermolysis and several reactive intermediates have been proposed, including radical,^{57,58} silylene (R₂Si),⁵⁹ and silene (C=Si) species.⁵⁸ In all cases, homolysis of a weak bond (e.g. Me₃Si–SiMe₃ to 2Me₃Si•) initiates skeletal rearrangement. The different poly(cyclosilane) microstructures, especially with respect to Si–H bond strengths, may influence the relative rates of processes implicated in poly(cyclosilane) thermolysis.

2.7 Bond dissociation energy calculations

To understand the influence of poly(cyclosilane) microstructure on thermolysis, we carried out density functional theory (DFT) calculations of bond dissociation energy on monomers and model molecules. As a compromise between computational ease and experimental relevance, the monomer **1,4Si₆** and its linear trimer were selected for study.

Geometries were fully optimized without symmetry restrictions using B3LYP hybrid exchange-correlation functional with the 6-31G(d) basis set. The basis set was utilized to investigate structures and expected characteristics of linear and cyclic forms of poly(**1,3Si₆**).¹⁷ To ensure optimized geometries were local minima on their potential energy surfaces, the same level of theory was utilized to perform frequency calculations and showed no imaginary frequencies. The optimized geometry of **1,4Si₆** is a chair conformation (consistent with a prior X-ray crystallographic study),¹⁶ whereas in the linear trimer rings were slightly twisted. Table 2.6.1 summarizes calculated homolytic bond dissociation energies (BDEs) of **1,4Si₆** and its trimer.

Table 2.7.1. Calculated bond dissociation energy of **1,4Si₆** and *lin*-(**1,4Si₆**)₃.

1,4Si₆		<i>lin</i> -(1,4Si₆) ₃	
Bond	BDE (kcal mol ⁻¹)	Bond	BDE (kcal mol ⁻¹)
Si(1)-H ^a	88.0	Si(1)-H ^a	88.4
Si(1)-H ^e	86.5	Si(1)-H ^e	86.7
Si(2)-Me ^a	80.0	Si(4)-H	85.6
Si(2)-Me ^e	78.9	Si(6)-Me ^a	73.4
Si(1)-Si(2)	68.1	Si(6)-Me ^e	73.3
Si(2)-Si(2)	68.4	Si(2)-Si(3)	63.0
		Si(3)-Si(4)	59.6
		Si(4)-Si(5)	54.9

In **1,4Si₆**, Si–Si bonds were significantly weaker than Si–Me and Si–H bonds by 12-18 kcal mol⁻¹. A similar trend in relative bond strengths (from high to low: Si–H, Si–Me, and Si–Si) was observed in *lin*-(**1,4Si₆**)₃. The Si–Si bond between repeat units was notably weaker than endocyclic Si–Si bonds by 5 to 8 kcal mol⁻¹. These data suggest that the Si–Si bonds between monomers are most likely to homolyse first in poly(cyclosilane) thermolysis. Small, volatile silanes generated from homolysis near an end group in linear poly(cyclosilane)s would result in a significant weight decrease, which is consistent with the major weight loss observed between 200 to 400 °C in TGA measurements. In *cyc*-poly(**1,3Si₆**), fewer volatile products may form as at least two Si–Si bond rupture events would be required to form a volatile byproduct. This may account for the slower mass loss observed in *cyc*-poly(**1,3Si₆**) relative to linear poly(cyclosilane)s.

At higher temperatures, organic side groups and hydrogen atoms start to detach from silicon leading to the second phase of weight loss. Combining experimental measurements and BDE calculations, the thermolysis process of poly(cyclosilane)s is proposed as shown in Figure 2.6.1.

Figure 2.7.1 Proposed poly(cyclosilane) pyrolysis.

2.8 Conclusion

Herein, we investigated the microstructure-dependent thermal properties of poly(cyclosilane)s. We prepared a known linear polymer of **1,4Si₆** (*lin*-poly(**1,4Si₆**)) and a predominantly cyclic polymer of **1,3Si₆** (*cyc*-poly(**1,3Si₆**)). In the course of these efforts, we also synthesized a new, linear oligomer of cyclosilane **1,3Si₆** (*lin*-poly(**1,3Si₆**)). Thermal analysis by DSC found no phase transitions for linear poly(cyclosilane)s below the decomposition temperature, but a phase transition at 108 °C was found for *cyc*-poly(**1,3Si₆**). We suggested assignment to a glass transition temperature. Poly(cyclosilane) thermolysis was investigated by TGA and investigated by density functional theory calculations. Lower rates of mass loss were found for *cyc*-poly(**1,3Si₆**), which was attributed to the need for two bond homolysis events to form volatile byproducts. These studies provide insights into how synthetic control of polysilane microstructure can predictably influence thermal properties.

Chapter 3: Poly(cyclosilane) connectivity tunes optical absorbance

The work presented in this chapter has been published as: Fang, F.; Jiang, Q.; Klausen, R. S. *J. Am. Chem. Soc.* **2022**, 144, 17, 7834–7843

3.1 Introduction

Polysilanes are a class of organometallic polymers with a backbone comprised of Si–Si atoms^{1–5} that have long attracted interest for their longer-wavelength optical transitions relative to organic polyolefins.⁶ Polysilane absorption spectra are conformation-dependent,^{7,8} giving rise to thermochromism in the solid- and solution-state^{9–11} and conformation-dependent molecular conductance.^{12–16} Efforts to control conformation, with corresponding bathochromic shifts in absorption spectra, have focused on modifying the organic backbone of the molecular^{17–20} or polymeric silane.^{9,10}

We now demonstrate tailoring of polysilane optical properties via changes in the silicon skeleton. The connectivity of isomeric cyclosilanes introduces distinct conformations and σ -conjugated pathways: 1,3-linkages achieve extended zigzag pathways not available to 1,4-linked cyclosilanes, resulting in a 20-nm difference in λ_{max} (Figure 1). Critically, this insight enables a connection between structural design and tunable absorption spectra. We show that copolymerization of the cyclosilane monomers **1,3Si₆** and **1,4Si₆**, results in systematic increases in λ_{max} with higher compositions of **1,3Si₆**.

Skeletal control of polysilane optical absorbance requires complex monomers. The earliest polysilanes were prepared by sodium-mediated Wurtz polymerization, which is limited to simple diorganodichlorosilanes (e.g. Cl₂SiMe₂)²¹ due to the strongly reducing conditions and results in disperse mixtures of oligomeric and polymeric species.^{22,23} Our

group, inspired by crystalline silicon's diamond lattice structure, sought to synthesize polymeric silanes with cyclic repeat units.²⁴ The metal-catalyzed dehydrogenative coupling of hydrosilanes promised greater functional group tolerance than Wurtz polymerization,^{25,26} leading to the design and synthesis of the bifunctional cyclosilane monomers **1,4Si₆** and **1,3Si₆** (Scheme 3.1.1). In earlier reports, we described the structural characterization of the linear and cyclic poly(cyclosilane)s arising from **1,4Si₆** and **1,3Si₆** dehydropolymerization,^{27–30} as well as the effect of poly(cyclosilane) microstructure on thermal properties.³¹

Figure 3.1.1. Connectivity, conformation, and optical properties in poly(cyclosilane)s.

Herein, we report solution-phase UV-vis absorbance spectra of three cyclosilane homopolymers differing in connectivity (1,3- or 1,4-) and architecture (linear or cyclic). We found that *lin*-poly(**1,3Si₆**) was bathochromically shifted by 20-nm relative to *lin*-poly(**1,4Si₆**). Time-dependent density functional theory (TD-DFT) calculations provided a structure-based hypothesis for this observation. In hexameric model systems, 1,3-linkages led to extended *transoid*-conformation ($|\omega|=165^\circ$)³² σ -conjugated pathways and low-energy HOMO–LUMO vertical transitions, while 1,4-linkages could not access all *transoid*-conformations. TD-DFT calculations suggested that the HOMO–LUMO transition in 1,4-linked cyclosilanes is symmetry-forbidden, resulting in a shift to higher-energy UV-vis absorption spectra. Based on these design principles, we hypothesized that

statistical copolymers should show vertical transitions intermediate between the homopolymers. Indeed, as the composition of **1,3Si₆** increased in statistical copolymers, λ_{\max} increased systematically. TD-DFT provides additional insight into the influence of sequence and composition on predicted absorbance spectra.

Scheme 3.1.1. Prior work: The structural isomers **1,3Si₆** and **1,4Si₆** template linear and cyclic poly(cyclosilane) architectures. This work: Cyclosilane copolymerization raises questions of reactivity, sequence, architecture, and physical properties.

Our results establish a conceptual framework for skeletal-based control of polysilane optical properties. An advantage of skeletal control is that in principle every Si atom could contribute to optical activity. An additional key advance in the current work is the coupling of experiment to theory, which provides deeper insights to the relationship between structure and photophysical properties. While the conventional wisdom that σ -conjugation is conformation-dependent implies that non-ideal conformations result in more localized bonds and changes in molecular orbital energies, our finding is that conformation

affects orbital symmetry and the identity of allowed transitions. We hope that the combined impact of these two advances is facilitate the rational design of polymeric silanes with defined optical properties.

3.2 UV-vis spectroscopy: homopolymers

A systematic comparison of poly(cyclosilane) UV-vis absorbance spectra has not previously been reported. Prior work has shown that *lin*-poly(**1,4Si₆**) and *cyc*-poly(**1,3Si₆**) were bathochromically shifted relative to their respective monomers (Table 3.2.1), but experimental and computational comparison of the homopolymers was not reported. The optical properties of *lin*-poly(**1,3Si₆**) have not previously been described in any form.³¹

Figure 3.2.1. UV-vis absorbance spectra of homopolymers. [polymer] = 0.012 mg mL⁻¹, THF, room temperature.

A more complete understanding of poly(cyclosilane) UV-vis absorbance spectroscopy was therefore necessary. Solution phase spectra (solvent = THF) of the three distinct homopolymers were collected at room temperature (Figure 3.2.1) and data are summarized in Table 3.2.1. The spectra of the two **1,3Si₆** homopolymers, linear and cyclic,

were nearly identical and both were bathochromically shifted relative to poly(**1,4Si₆**) by over 20 nm. All three homopolymers absorbed at significantly longer wavelengths (ca. 100 nm) than their respective monomers, which have characteristic sharp absorptions around 190 nm in pentane. These results pointed to skeletal connectivity having a marked effect on the extent of σ -conjugation relative to monomer.

Table 3.2.1. UV-vis spectroscopic properties of cyclosilane monomers and homopolymers.

Polysilanes	λ_{\max} (nm)	λ_{onset} (nm)
1,3Si₆ ^a	<190	230
<i>cyc</i> -poly(1,3Si₆)	296	311
<i>lin</i> -poly(1,3Si₆)	292	308
<i>lin</i> -poly(1,4Si₆)	271	291
1,4Si₆ ^a	194	232

Conditions: [*lin*-poly(**1,3Si₆**)] = 0.005 mg mL⁻¹, [*lin*-poly(**1,4Si₆**)] = 0.012 mg mL⁻¹, [*cyc*-poly(**1,3Si₆**)] = 0.010 mg mL⁻¹, [monomer] = 3.0 × 10⁻⁵ M, THF, rt. ^a solvent = pentane.

3.3 Calculated electronic transitions: homopolymers.

The bathochromic shift of *lin*-poly(**1,3Si₆**) relative to *lin*-poly(**1,4Si₆**) suggested distinct σ -conjugation pathways. That *lin*-poly(**1,3Si₆**) appeared to have a longer effective conjugation length despite a lower degree of polymerization was particularly striking (M_n = 1770 g mol⁻¹ vs. 2770 g mol⁻¹).

We hypothesized that computational characterization including time-dependent density functional theory (TD-DFT) could shed light on the unique σ -conjugation pathways in each macromolecule. We therefore sought to identify reasonable molecular analogs of each structure. The poly(cyclosilane) absorption bands were similar in position to those of molecular silanes with 8-10 Si atoms. In linear silanes with the general formula

$\text{Me}(\text{SiMe}_2)_n\text{Me}$ ($n = 2-8$), each additional SiMe_2 unit results in a bathochromic shift of ca. 15 nm; the *lin*-poly(**1,4Si₆**) transition ($\lambda_{\text{max}} = 279$ nm) is comparable to the molecular octasilane $\text{Me}(\text{SiMe}_2)_8\text{Me}$ ($\lambda_{\text{max}} = 272.5$ nm). With degrees of polymerization of ca. 10-20 monomers indicated by size exclusion chromatography (SEC) and solid-state nuclear magnetic resonance (ssNMR) spectroscopy,^{27,30} the experimentally observed optical transitions point to an effective conjugation length much shorter than the length of the macromolecule.

Figure 3.3.1 Geometry-optimized conformations of linear and cyclic hexamers of the cyclosilanes **1,3Si₆** and **1,4Si₆**. Adapted with permission from *J. Am. Chem. Soc.* **2018**, *140*, 5976, copyright 2018 American Chemical Society. Methyl groups omitted for clarity. B3LYP/6-31G(d).

We therefore chose cyclic and linear hexamers of **1,3Si₆** and **1,4Si₆** to model σ -conjugation and predict vertical transitions. Diastereomers with *trans* linkages were chosen for *lin*-(**1,4Si₆**)₆ as ssNMR spectroscopy has indicated this is the major diastereomer.³⁰ Lower-energy *cis*-linkages were chosen for **1,3Si₆** oligomers by analogy. We previously used hexamers to predict distinct infrared (IR) spectra for *lin*- and *cyc*-poly(**1,3Si₆**),²⁹ indicating that hexamers could be computationally tractable. The same functional and basis set were chosen for geometry optimization of a linear hexamer of **1,4Si₆** (*lin*-(**1,4Si₆**)₆) and low energy conformations of all three cyclosilane hexamers are shown in Figure 3.3.1.

While *lin*-(**1,4Si₆**)₆ was predicted to be linear, **1,3Si₆** introduces curvature and bending, as reflected in an almost helical structure for *lin*-(**1,3Si₆**)₆ and the macrocyclic structure of *cyc*-(**1,3Si₆**)₆. In all oligomers, individual cyclosilane rings adopted a chair conformation, with some twisting between rings. Prior work has demonstrated that the lowest energy conformation of a cyclohexasilane is chair-like, albeit with lower barriers to inversion than in cyclohexanes.^{33–36}

Figure 3.3.2 a) TD-DFT calculated absorbance spectra of *lin*-(**1,3Si**)₆, *cyc*-(**1,3Si**)₆, and *lin*-(**1,4Si**)₆ relative to TD-DFT calculated absorbance spectra of the monomers showed bathochromic shifts and absolute values consistent with experiment. b) Calculated molecular orbital distributions of HOMOs. TD-PBE0/6-311G(d)//B3YLP/6-31G(d). Adapted with permission from *J. Am. Chem. Soc.* **2018**, *140*, 5976. Copyright 2018 American Chemical Society.

From geometry optimized ground state structures, vertical transitions were calculated (TD-PBE0/6-311G(d)//B3YLP/6-31G(d)). This combination was previously reported for simulation of linear hexasilane electronic transitions.¹⁹ The calculated spectral shapes for all three model oligomers (Figure 3.3.1) accurately depicted a sharp transition ca. 190 nm for the monomers, as well as an approximately 100-nm bathochromic shift upon oligomerization. The experimental observation that *lin*-poly(**1,4Si**)₆ has a higher energy λ_{max} than **1,3Si**₆ oligomers (265 vs. 299 nm) was also reproduced by the calculations.

The calculated transition wavelengths and oscillator strengths (Table 3.3.1 and Table 3.3.2) showed that *lin*-(**1,4Si**)₆ is distinct from the linear and cyclic hexamers of **1,3Si**₆. The most intense vertical transition, with respect to oscillator strength, for *lin*-poly(**1,4Si**)₆ corresponds to the HOMO→LUMO+4 and was found at 265.5 nm, 35-nm lower than the strong HOMO→LUMO transition of *lin*-(**1,3Si**)₆. In all three oligomers, not all Si atoms contributed to conjugation (Figure 3.3.1), but the extent of HOMO delocalization in *lin*-(**1,4Si**)₆ was clearly less extensive than in *lin*-(**1,3Si**)₆ (e.g., no orbital density on the terminal cyclosilanes).

Table 3.3.1. Calculated vertical electronic transitions in cyclosilane hexamers. TD-PBE0/6-311G(d)//B3YLP/6-31G(d). Relative contributions given in percentages, where H=HOMO and L=LUMO.

HOMO-4	-6.48	-6.45	-6.38
HOMO-5	-6.56	-6.52	-6.44

Our calculations point to two explanations for the experimental observation of poly(**1,4Si₆**)’s higher energy absorption band: reduced σ -conjugation in the ground state HOMO and symmetry-forbidden electronic transitions. Both phenomena are fundamentally conformation dependent. In describing silane conformations, especially torsion angles, we used the nomenclature proposed by Michl and West:³² *anti*, $\omega = 180^\circ$; *transoid*, $|\omega| = 165^\circ$; *deviant*, $|\omega| = 150^\circ$; *ortho*, $|\omega| = 90^\circ$; *gauche*, $|\omega| = 60^\circ$, and *cisoid*, $|\omega| = 40^\circ$. σ -Conjugation is suppressed by small torsion angles (e.g., *cisoid*)²⁰ while torsion angles close to 180° (e.g., *transoid/anti*) extend σ -conjugation by maximizing the interaction of vicinal sp^3 orbitals.⁸ We found a *transoid*-pathway across multiple cyclosilanes in *lin*-(**1,3Si₆**)₆ (Figure 3.3.3a). At the central bond (indicated with green arrow), a 130.6° torsion angle is the smallest angle along the conjugation pathway highlighted in pink. In contrast, because the Si–Si chain in *lin*-(**1,4Si₆**)₆ must pass through a chair cyclohexasilane, small torsion angles (ca. 60° , *gauche*) cannot be avoided (Figure 3.3.3b). These conformational differences interrupt σ -conjugation in the *lin*-(**1,4Si₆**)₆ HOMO and also result in changes in symmetry that affect the probability of vertical transitions.

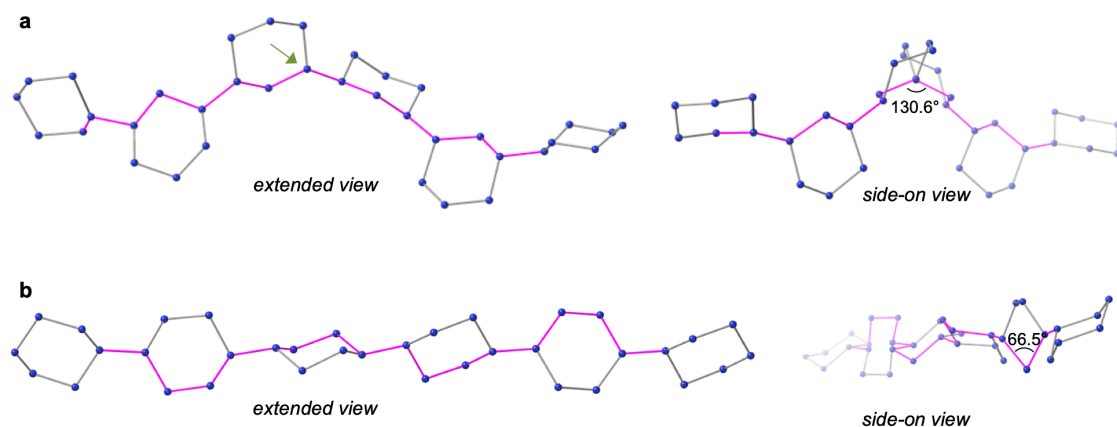

Figure 3.3.3 σ -Conjugation pathways and selected torsion angles in a) *lin*-(**1,3Si**₆)₆ and b) *lin*-(**1,4Si**₆)₆. Methyl groups and hydrogens omitted for clarity. Extended Si-Si pathways highlighted in magenta. B3YLP/6-31G(d).

We note that a shortcoming of the calculations reported herein is that they only consider electronic transitions from a single conformation of the ground state oligomer, while the experimental sample at room temperature is an ensemble of different oligomer lengths, conformations, and tacticities. Additionally, these calculations were performed in the gas phase and do not account for the influence of solvent on conformation or vertical transition energies. Nonetheless, the reasonable agreement with experimental UV-vis absorption data bolsters confidence in the general conclusions.

The insight that 1,3-linkages maximize extended conformations inspired interest in statistical copolymers of **1,3Si**₆ and **1,4Si**₆. We hypothesized that a chain with both 1,3- and 1,4-linked cyclosilanes might exhibit properties intermediate between the homopolymers. To test this hypothesis, we sought to prepare the desired statistical copolymers, verify a linear structure with tunable composition, and obtain solution-phase UV-vis spectroscopy. We also pursued TD-DFT calculations to support the experimental observations.

3.4 Copolymer synthesis and microstructure characterization

While statistical copolymerization is broadly used in organic polymers to tune properties such as solubility,³⁷ self-assembly,³⁸ glass transition temperature (T_g),³⁹ and mechanical strength,⁴⁰ silane copolymerization has been largely limited to Wurtz polymerization of dichloroorganosilanes.⁴¹ West demonstrated reductive copolymerization of $\text{Cl}_2\text{SiMe}_2/\text{Cl}_2\text{SiMePh}$,^{42,43} while Fujiki demonstrated Wurtz copolymerization of alkyl and fluoroalkyl comonomers.⁴⁴ These studies have typically yielded blocky copolymers. Dehydrocopolymerization of hydrosilanes is limited to phenylsilane with substituted arylsilanes (Waymouth)²⁶ or methylsilanes (Hengge, Marschner).^{45,46} Rieger investigated the copolymerization of *n*-hexylsilane and phenylsilane by Lewis acid catalysis.⁴⁷ Given the dearth of prior investigation of zirconocene-catalyzed hydrosilane copolymerization, we identified several critical questions to address through our studies including the relative comonomer reactivity (is a copolymer obtained or a blend of homopolymers?) as well as microstructural characterization (statistical or blocky sequence; linear or cyclic?).

The synthesis of cyclosilane copolymers were investigated by Fan Fang in the Klausen group. The full structural characterization has been performed and published in the following reference: Fang, F.; Jiang, Q.; Klausen, R. S. *J. Am. Chem. Soc.* **2022**, 144, 17, 7834–7843.

Several different comonomer ratios were evaluated for copolymerization upon exposure to $\text{Cp}_2\text{ZrCl}_2/n\text{-BuLi}$ in toluene. This system was first identified by Corey as an effective dehydrocoupling catalyst for primary and secondary silanes^{48–50} and we have previously demonstrated its effectiveness for homopolymerization of **1,3Si₆** and **1,4Si₆**.^{27–}

A *linear* architecture of copolymers was assigned by NMR analysis and further supported by differential scanning calorimetry (DSC). This assessment of copolymer microstructure in solution points to a linear copolymer with composition proportional to the comonomer feed ratio. We suggest a statistical sequence is most likely based on the similar structure and reactivity of **1,3Si₆** and **1,4Si₆**. An alternating A-B copolymer would have resulted in identical compositions of each comonomer in all three copolymerizations. A blocky structure is unlikely as consecutive runs of **1,3Si₆** monomers would favor macrocyclization.

Scheme 3.4.1. Synthesis of cyclosilane copolymers.

3.5 UV-vis spectroscopy: copolymers

UV-vis spectroscopy of the three copolymers under similar conditions (THF, room temperature, Figure 3.5.1) showed a single transition intermediate between the homopolymers, consistent with the overall incorporation of each monomer. The onset of absorption also varied with composition (Table 3.5.1). These results lend support to the conclusion based on DOSY and SEC that binary copolymerization yielded a single copolymer, rather than a blend of homopolymers: a blend of homopolymers would show two optical transitions at 279 and 296 nm at intensities consistent with the concentration of each homopolymer. The observations were also more consistent with a statistical

copolymer, rather than an alternating A-B copolymer as A-B alternating copolymers would have identical connectivities and identical absorption spectra.

Figure 3.5.1. UV-vis absorbance spectra of copolymers. [copolymer] = 0.012 mg mL⁻¹, THF, room temperature.

The variation of the copolymer optical transition with comonomer composition validated our hypothesis that increasing the probability of consecutive 1,3-linkages increased the wavelength of maximum absorption. We next described TD-DFT calculations that provide additional support for our experimental observations.

Table 3.5.1. UV-vis spectroscopic properties of cyclosilane homopolymers and copolymers.

Polysilanes	λ_{\max} (nm)	λ_{onset} (nm)
<i>lin</i> -poly(1,3Si₆)	<190	230

3.6 Calculated electronic transitions: copolymers

We considered tetramers with different compositions and sequences as models for the copolymers. The 4-digit numbers used herein abbreviate **1,3Si₆** and **1,4Si₆** to 3 and 4, respectively. Geometry-optimized ground state conformations are shown in Figure 3.6.1. Vertical transitions were calculated in the same manner as for homopolymer models (TD-PBE0/6-311G(d)//B3YLP/6-31G(d)) and transition wavelengths, oscillator strengths, and assignments are summarized in Table 3.6.1 and Table 3.6.2. The range of predicted wavelengths (262–285 nm) compared favorably to the experimentally observed range (Table 3.6.1, 279–292 nm), suggesting that tetramers were valid models for poly(cyclosilane)s.

We found that both composition and sequence affected vertical transitions. In general, the energy of a vertical transition decreased with increasing **1,3Si₆**, but also depended on the position of **1,3Si₆** within the tetramer (chain end or interior). Evidence for these trends is summarized below:

1. An interior **1,3Si₆** residue increased λ_{max} relative to a chain end **1,3Si₆**. For example, 4443 and 4434 have the same composition (25% **1,3Si₆**) but the predicted 4434 λ_{max} was bathochromically shifted 14-nm relative to 4443 (Table 3.5.1).
2. When controlled for position, λ_{max} increased with increasing *consecutive* **1,3Si₆** residues. Each additional **1,3Si₆** residue in the series 4443 to 4433 to 4333 resulted in a bathochromic shift from 262.3 to 278.8 to 283.9 nm. Figure 3.6.2 plots the energy

of a vertical transition versus the number of consecutive **1,3Si₆** residues, showing a general trend of increasing λ_{max} .

Figure 3.6.1. Ground state conformations of cyclosilane tetramers of different compositions and sequences. Methyl groups omitted for clarity. B3YLP/6-31G(d).

Figure 3.6.2. The predicted λ_{\max} versus the number of consecutive $1,3\text{Si}_6$ residues. Squares indicate interior $1,3\text{Si}_6$ residues and circles indicate chain ends $1,3\text{Si}_6$ residues.

HOMO-3	-6.56	-6.54	-6.53	-6.60	-6.58	-6.49	-6.56	-6.58	-6.48	-6.61
HOMO-4	-6.70	-6.68	-6.64	-6.66	-6.60	-6.63	-6.70	-6.60	-6.66	-6.67
HOMO-5	-6.72	-6.76	-6.80	-6.77	-6.80	-6.81	-6.71	-6.77	-6.76	-6.72

The tetramers 3443 and 4334 illustrate the combined effect of consecutive **1,3Si₆** monomers and interior positioning. The tetramers have the same overall composition but in 3443 both **1,3Si₆** residues were located at chain ends and were not consecutive, while in 4334 two consecutive **1,3Si₆** residues were found only in the interior. 4334 was predicted to have a longer λ_{\max} by almost 22 nm (262.4 vs. 284.8 nm).

We noted that the tetramers predicted to have the *shortest* wavelength λ_{\max} (3443 and 4443, ca. 262 nm) both had **1,3Si₆** residues only at chain ends and were anomalous in the assignment of the most intense vertical transition, which corresponded to the HOMO→LUMO+2 instead of the HOMO→LUMO transition for other tetramers (Table

3.6.1). A shift in the terminating orbital to a LUMO+n was also observed in *lin*-poly(**1,4Si₆**) (Table 3.2.2). We expect that this is likely general for segments of consecutive **1,4Si₆** residues.

Figure 3.6.3. Impact of **1,3Si₆** position on backbone conformation: interior sites increase consecutive *trans* torsion angles. Methyl groups and hydrogens omitted for clarity. B3YLP/6-31G(d).

We attribute the observed trends in vertical transition energies to changes in conformation with increasing consecutive **1,3Si₆** residues. Figure 3.6.3 highlights 4344 and 4443, which had the same overall composition but different sequences. We found that the interior **1,3Si₆** residue in 4344 allowed for consecutive torsion angles close to 180° in the vicinity of the **1,3Si₆** residue (Figure 3.6.3, blue highlight in Table). This was not possible for 4443. The σ -conjugated pathway (pink) for 4443 resembled *lin*-(**1,4Si₆**)₆ in having small torsion angles (0–60°, eclipsing and *gauche*) alternate with larger torsion angles. Increasing the number of consecutive **1,3Si₆** residues extends this trend.

These computational models validate the experimental observation that increasing the **1,3Si₆** concentration in the feed ratio results in bathochromically shifted experimental λ_{\max} in the copolymers. Increasing the [**1,3Si₆**] in the feed from 25 to 75% during a statistical copolymerization would necessarily result in more consecutive **1,3Si₆** residues in the interior of a chain. The longer length of experimental chains relative to tetramers

likely dilutes the strong effect of chain end versus interior position observed computationally. We expect that the experimental observation of increasing λ_{\max} with increasing [1,3Si₆] is tied to 1,3Si₆-enriched interior segments that have symmetry-allowed HOMO-LUMO transitions. In contrast, consecutive runs of 1,4Si₆ comonomers effect a change in LUMO symmetry, resulting in a symmetry-forbidden HOMO-LUMO transition and a shift to lower wavelength λ_{\max} .¹⁹

3.7 Conclusion

Herein, we investigated the effect of connectivity on the optical properties of poly(cyclosilane)s. Using the isomeric monomers 1,3Si₆ and 1,4Si₆, we prepared a homologous set of linear (co)polymers that were structurally characterized by a suite of NMR spectroscopies. We observed experimentally that across the set of linear polymers possessing from 0 to 100% 1,3Si₆ comonomers, λ_{\max} and λ_{onset} increased systematically from 271 to 292 nm.

Computational studies provided structural insight into the role of skeletal connectivity in influencing optical properties. We found that oligomeric model systems of 4 or 6 cyclosilanes accurately reproduced polymeric properties. These model systems demonstrated that 1,3-linked cyclosilanes can access extended *transoid* conformations with predicted lower-energy HOMO→LUMO transitions. In contrast, 1,4-connectivity requires endocyclic *gauche* conformations that are associated with a change in LUMO symmetry. As a result of the change in terminating orbital symmetry, the most intense electronic transitions in 1,4-linked cyclosilanes correspond to higher energy HOMO→LUMO+n transitions. Copolymers achieve optical properties intermediate between homopolymers by

increasing the probability of consecutive **1,3Si₆** monomers and *transoid*-conformation pathways.

This is the first demonstration of *main chain* control of polysilane optical properties. Prior work focused on the role of alkyl side chains in constraining polysilane conformation and conformation-dependent absorbance spectra. Skeletal control could result in materials in which every Si atom contributes to optical activity. We also report computational insights into the role of conformation in affecting orbital symmetry and photophysical properties. The studies herein point to the potential for structurally complex silane building blocks to define structure-optical property relationships.

Chapter 4: Highly selective addition of cyclosilanes to alkynes enabling new conjugated materials

The work presented in this chapter has been published as: Jiang, Q.; Gittens, A. F.; Wong, S.; Siegler, M. A.; Klausen, R. S. *Chem. Sci.* **2022**, *13*, 7587–7593.

4.1 Introduction

We report the synthesis of visible-light absorbing organocyclosilanes via Ru-catalyzed chemoselective, regioselective, and diastereoselective hydrosilylation. While extraordinary progress in predicting and controlling selectivity in organic reactions has been made, the development of similar insights for main group molecules is in its infancy. This lack of synthetic control limits the discovery of structure-property relationships in main group materials. For example, while linear oligosilanes (e.g., Ar(SiMe)_nAr) capped with aromatic end groups have been extensively studied for molecular electronics^{1,2}, metal-organic framework (MOF) secondary building units,³ charge transport,⁴ photoinduced charge transfer,^{5–7} and nonlinear optical properties,^{8–10} there has been very limited investigation of cyclic σ,π -conjugation,¹¹ as cyclosilanes are typically synthesized by methods^{12–14} that restrict functional group diversity on an organic fragment. Nonetheless, the well-established conformation-dependence of σ -conjugation¹⁵ strongly suggests that the restricted degrees of freedom in cyclosilanes should give rise to properties distinct from linear oligosilanes.

Our group is interested in the synthesis and properties of (macro)molecular mimics of crystalline silicon and we have described new approaches to the selective synthesis of materials based on cyclohexasilanes. We reported the five-step synthesis and

chemoselective polymerization of the cyclohexasilane building blocks **1,4Si₆** and **1,3Si₆**,^{16–21} as well as the seven-step stereocontrolled synthesis of *cis*- and *trans*-**Si₁₀H₄** (Figure 4.2.1).²² These works have led to new insights, such as the discovery that the diastereomeric siladecalins have vastly different absorption spectra arising from configuration- and conformation-dependent σ -conjugation.

We envisioned an alternative approach to functionalized cyclosilanes via derivatization of the Si–H bond of our building blocks,²³ but confronted several challenges. First, the Me₃Si–SiMe₃ bond is weaker than a H₃C–CH₃ bond (BDE: 79 vs 90 kcal mol⁻¹)²⁴ and cross-reactive with reagents for Si–H functionalization; Pd- and Pt-complexes like Karstedt’s catalyst fragment Si–Si bonds.^{25–27} Second, while the targeted cyclosilanes exhibit *cis/trans* diastereoisomerism, Si–C bonds are longer than C–C bonds,²⁸ potentially diminishing the steric factors often implicated in asymmetric stereoinduction. Third, the tetrafunctional cyclosilanes pose a significant selectivity challenge: the reaction of **1,4Si₆** and phenylacetylene could provide more than 40 distinct products arising from mono-, di-, tri-, or tetra-functionalization, (*E*)/(*Z*)-geometric isomers, α/β -addition, or *cis/trans* diastereoisomerism.

We report herein the extraordinarily selective outcome of the RuHCl(CO)(PPh₃)₃-catalyzed²⁹ reaction between cyclosilanes and aryl acetylenes. We observed perfect regioselectivity for 1,4-difunctionalization and β -addition and perfect (*E*)-selectivity. Products were isolated as a single diastereomer or as a mixture (ca. 2:1) favoring the thermodynamic isomer. The hydrosilylation is highly functional group tolerant: no Si–Si bond cleavage occurred, and functional group tolerance was high. These syntheses enabled a broad probe of the influence of substituent effects, structural isomerism, and

configuration on conjugation in organocyclosilanes, which revealed bathochromic shifts relative to starting materials. We also expect the work herein to expand additional frontiers for the study of conjugated materials. As an initial example, we report the synthesis of a novel thienyl-silane conjugated polymer derived from a *trans*-1,4-bis(thienylvinyl)cyclosilane, which not only absorbs visible light, but is also an entry to stereoregular polysilanes, a class of materials where control of tacticity has been a long-standing challenge.

Figure 4.1.1 Highly selective reactions between cyclosilane building blocks and functionalized acetylenes.

4.2 Investigation of regio- and diastereoselectivity

Hydrosilylation is widely used in the industrial preparation of silicones (*e.g.*, Si–O polymers).^{30–33} The application of hydrosilylation to oligo- and polysilanes (*e.g.*, Si–Si polymers) has been of interest since at least the 1960's,³⁴ but as documented by Rosenberg,³⁵ free-radical^{36–38} and many transition-metal catalyzed^{34,39} hydrosilylations are accompanied by partial to extensive Si–Si cleavage. Borane Lewis acids are useful for Si–H/X–H dehydrocoupling and Si–H/X=C hydrosilylation without skeletal

fragmentation.^{23,40,41} Recently, Kyushin reported Ru-catalyzed (*E*)- or (*Z*)-selective hydrosilylation of alkynes and hydrooligosilanes without Si–Si bond cleavage.^{29,42}

Table 4.2.1 Optimization of the RuHCl(CO)(PPh₃)₃-catalyzed reaction between phenylacetylene and **1,4Si₆**.^a

entry	[catalyst] ^b	solvent	time	conversion ^c		
				mono-4.1a	4.1a	4.1a*
1	5 mol%	toluene	7 d	22%	9%	0%
2 ^d	10 mol%	toluene	24 h	42%	50%	0%
3	5 mol%	DCM	24 h	61%	39%	0%
4	10 mol%	DCM	24 h	17%	83%	0%
5 ^e	10 mol%	DCM	24 h	45%	25%	0%
6	20 mol%	DCM	2 h	0%	100%	0%
7 ^f	20 mol%	DCM	2 h	0%	100%	0%

^a The reactions were carried out with 0.171 mmol of **1,4Si₆** and 0.428 mmol of phenylacetylene in 1 mL of solvent at room temperature under nitrogen protection unless noted. ^b RuHCl(CO)(PPh₃)₃ loading was relative to **1,4Si₆**. ^c The conversion was determined by ¹H NMR spectra of reaction aliquots. ^d The reaction was carried out at 60 °C. ^e The reactions were carried out with 0.171 mmol of **1,4Si₆** and 0.171 mmol of phenylacetylene. ^f The reactions were carried out with 0.171 mmol of **1,4Si₆** and 1.026 mmol of phenylacetylene.

We envisioned that (*E*)-selective addition of cyclosilanes to alkynes could yield σ,π -conjugated cyclosilanes. As Kyushin's study focused on linear monohydrosilanes like H–SiMe₂SiMe₂Ph, our initial focus was regioselectivity with tetrafunctional **1,4Si₆** (Table 4.2.1 and Scheme 4.2.1). It was unclear if replacement of one Si–H bond with a vinyl group

would be *activating* (1,1'-functionalization), *deactivating* (1,4-difunctionalization), or *neutral* (mixture). The success of monohydrosilanes suggested the feasibility of fully alkylated Si centers, such as **4.1a***. A first attempt with 2.50 equivalents of phenylacetylene and 5 mol% RuHCl(CO)(PPh₃)₃ resulted in mono-**4.1a** (22%) and 1,4-difunctionalized **4.1a** (9%), as determined by ¹H NMR spectroscopy. No 1,1'-difunctionalized **4.1a*** was observed. Further optimization of solvent and catalyst loading led to increased conversion to **4.1a** without residual mono-**4.1a** (entry 6). 1,1'-Difunctionalization was not observed even with excess phenylacetylene (entry 7). The mechanistic origin of the selectivity for monofunctionalization, be it steric, electronic, or a combination of factors, is not yet clear. In all cases, the ¹H NMR spectra were consistent with Si-addition to the phenylacetylene β-position, as α-addition would result in a 1,1-disubstituted alkene.

Scheme 4.2.1 Synthesis of *trans* and *cis*-**4.1a** via hydrosilylation of phenylacetylene with **1,4Si₆** catalyzed by RuHCl(CO)(PPh₃)₃.

Having established regioselectivity, we investigated (*E*)-selectivity and diastereoselectivity under the optimized conditions. **4.1a** was isolated in 89% yield as a 65:35 mixture of two isomeric products, assigned to the *trans* and *cis* diastereomers (Scheme 4.2.1). The isomers were not separable by silica gel chromatography, but recrystallization afforded pure *trans*-**1a** (X-ray crystal structure, Figure 4.2.1), which was confirmed as the major diastereomer. The X-ray crystal structure also confirmed that

hydrosilylation proceeded *without skeletal rearrangement* and with (*E*)- and β -selectivity. In the solid state, *trans*-**1a** adopted a chair conformation with both styryl groups at equatorial positions. This was the expected thermodynamic isomer, in which 1,3-diaxial interactions were minimized. The recrystallization filtrate was enriched in the minor product, which was assigned to *cis*-**1a** based on symmetry consistent with 1,4-difunctionalization. The ca. 1:3 *trans*:*cis* ratio was stable over time but could not be further increased by silica gel column chromatography. The ^1H and ^{29}Si NMR spectra of *trans*, *cis* and mixture of diastereomers are shown in Figure 4.2.2.

Figure 4.2.1 Displacement ellipsoid plot (30% probability level) of *trans*-**4.1a** at 110(2) K. Blue = Si, Black = C, Pink = H. Hydrogens on methyl and phenyl groups were omitted for clarity.

Figure 4.2.2 (a) Cropped ^1H NMR spectra (400 MHz, C_6D_6) comparing (top to bottom) *cis*-**4.1a** (dr 25:75 *trans:cis*), *trans*-**4.1a**, and the as-isolated mixture of isomers. (b) Cropped ^{29}Si $\{^1\text{H}\}$ DEPT spectra (79 MHz, C_6D_6) comparing (top to bottom) *cis*-**4.1a** (dr 25:75 *trans:cis*), *trans*-**4.1a**, and the as-isolated mixture of isomers. DEPT = distortionless enhancement by polarization transfer. The methyl groups are omitted for clarity.

^1H - ^{29}Si HSQC and ^{29}Si INEPT+ spectroscopy (Figure 4.2.3 and Figure 4.2.4) allowed assignment of the *SiMe*₂ and *SiH* resonances (Figure 4.2.2b). In the ^1H - ^{29}Si HSQC spectrum of the diastereomer mixture, the *SiH* resonances only correlated with Si peaks at ca. -63.0 ppm and -64.9 ppm, which indicated these Si resonances resulted from *SiH* groups, rather than *SiMe*₂. The ^{29}Si INEPT+ spectrum supported assigning the doublet (δ -64.8, $^1J_{\text{SiH}} = 169.8$ Hz) to the *SiH* resonance. The experimentally measured coupling constant was consistent with typical one-bond coupling constants between silicon and proton.⁴³

Figure 4.2.3 ^1H - ^{29}Si HSQC NMR spectrum (400 MHz, C_6D_6) of **4.1a**. $^1J_{\text{Si-H}} = 120$ Hz.

Figure 4.2.4 ^{29}Si INEPT+ NMR spectrum (79 MHz, C_6D_6) of *trans*-**4.1a**.

Figure 4.2.5 The coupling constant analysis of ^1H NMR spectra of **4.1a**.

The coupling constant analysis of ^1H NMR spectra further supported the structure assignment: (*E*)-alkene attached to a tertiary silane (Figure 4.2.5). The coupling constants

of the vinylic peak a (d, $J = 18.7$ Hz) and b (dd, $J = 5.2, 18.7$ Hz) were consistent with an (*E*)-alkene (Figure 4.2.5a). Peak c, the doublet assigned as SiH resonance (d, $J = 5.2$ Hz), exhibited the same coupling constant as peak b, the vinylic proton on the neighboring carbon (dd, $J = 5.2, 18.7$ Hz) (Figure 4.2.5b).

4.3 Substrate scope

Having established selectivity with **1,4Si₆**, we investigated substrate scope (Figure 4.3.1). With a variety of 4-substituted phenylacetylenes, 1,4-bis(styryl)cyclohexasilanes were obtained in >80% yield and without erosion in regio- or diastereoselectivity, as shown by X-ray crystallography (Figure 4.3.2). This provided σ,π -hybrids functionalized with halogens (**4.1b-c**), electron donating groups (**4.1d-f**) and moderately electron withdrawing groups (**4.1g-h**).

The functional groups selected for investigation in Figure 4.3.1 were chosen on the basis of potential applications. Sulfur was tolerated in thiomethyl **4.1d** and thienyl **4.1i-j**, of relevance to molecular electronics.⁴⁴ Functional groups that would not be tolerated by the reductive coupling methods traditionally used to prepare cyclosilanes from dihalosilanes were also successfully incorporated, such as methyl ester **4.1h**. Benzoate esters are useful intermediates to a variety of other oxygenated functionality, such as carboxylic acids that have been employed as MOF ligands.³ In addition, halogenated products (e.g., **4.1b** and **4.1j**) are suitable for catalytic cross-coupling (*vide infra*). Low conversion was observed with strongly electron-withdrawing substituents (e.g., 4-nitro and 4-cyanophenylacetylene) and an electron-poor heterocycle (4-ethynylpyridine).

We also explored the cyclosilane scope. Regioselectivity was maintained (Figure 4.3.1), yielding 1,3- or 1,4-difunctionalized products instead of 1,1'-difunctionalized

cyclosilanes. No skeletal decomposition was observed and perfect (*E*)- and β -selectivities were retained. Interestingly, *cis*-**Si₁₀H₄ underwent a slow reaction with phenylacetylene. Low conversion (<5%) was observed in 24 hours.**

Figure 4.3.1 Substrate scope of hydrosilylation of alkynes with cyclosilanes. For **1,4Si₆**, major diastereomers are shown. ^a dr determined by ¹H NMR spectroscopy. Isolated yields are reported. ^b Only the *trans* diastereomer was detected.

Figure 4.3.2 X-ray crystal structure of (a) *trans*-**4.1e** and (b) *trans*-**4.1j**. Blue = Si, black = C, pink = H, red = O, yellow = S, brown = Br. Hydrogens on methyl and aromatic groups are omitted for clarity.

Figure 4.3.3 Cropped ¹H NMR spectra (400 MHz, C₆D₆) comparing SiH resonances of (top) **4.3a** and *trans*-**Si₁₀H₄** (bottom).

Figure 4.3.4 Displacement ellipsoid plot (30% probability level) of **4.3a** at 173(2) K. Blue = Si, Black = C, Pink = H. Hydrogens on methyl and phenyl groups were omitted for clarity.

Figure 4.3.5 Model for stereoselection.

The cyclosilane exerted a striking effect on diastereoselectivity. While diastereomeric ratios (dr) ca. 2:1 were observed for all **1,4Si₆**-derived products, the dr decreased to ca. 1:1 for **1,3Si₆** and increased dramatically for *trans*-**Si₁₀H₄**, where only one diastereomer could be detected by ¹H NMR spectroscopy (Figure 4.3.3). A relatively complicated SiH resonance was found in the ¹H NMR spectrum of *trans*-**Si₁₀H₄**, as the equatorial (H_{eq}) and axial (H_{ax}) protons showed difference splitting patterns.²² Only the

axial proton undergoes W-coupling with the neighboring methyl group (H-Si-Si-C-H), leading to a multiplet. The equatorial proton meanwhile exhibits a doublet ($J = 2.1$ Hz) resulting from geminal coupling to the axial Si-H proton. After the reaction, however, only a single SiH resonance (doublet) was observed for **4.3a**, indicating exclusive formation of a single diastereomer. The coupling constant was found to be 5.2 Hz, the same as SiH resonance of **4.1a**. The NMR evidence supports full conversion of the starting *trans*-**Si₁₀H₄** in the hydrosilylation reaction.

An X-ray crystal structure of **4.3a** confirmed assignment to the *trans* diastereomer (Figure 4.3.4) with diequatorial styryl groups. Like *trans*-decalin, *trans*-**Si₁₀H₄** is conformationally locked,²² suggesting that hydrosilylation is selective for the equatorial Si-H bond. The reduced diastereoselectivity with **1,3Si₆** and **1,4Si₆** was attributed to rapid ring inversion⁴⁵⁻⁴⁷ in a mono-functionalized intermediate (Figure 4.3.5). Hydrosilylation is highly selective for the equatorial proton (blue circle). Interconversion of axial and equatorial conformers (substituent labelled with orange circle) of a mono-functionalized intermediate determines the *trans*:*cis* ratio of difunctionalized products. Therefore, we expect that the equilibrium between equatorial and axial conformers in mono-functionalized intermediates should determine the dr in difunctionalized products.

4.4 UV-vis absorbance spectra

Finally, we investigated the UV-vis spectroscopic properties of the (bis)styrylcyclosilanes in pentane solution at room temperature. Comparison of *trans*-**4.1a** to **1,4Si₆** and phenylacetylene showed that the hybrid material was red-shifted 100-nm compared to purely σ -conjugated and 50-nm relative to purely π -conjugated starting materials (Figure 4.4.1a). DFT calculations showed that the HOMO and LUMO of *trans*-

4.1a is fully delocalized across the entire molecule including both σ (cyclosilane) and π -conjugated (aromatic) moieties (Figure 4.4.2). We also compared the UV-vis spectrum of *trans*-**4.1a** to *cis*-**4.1a** (dr 25:75 *trans*:*cis*) and found that relative configuration did not strongly influence optical absorbance in solution (Figure 4.4.1b). This observation facilitated comparison of all three cyclosilanes to each other (Figure 4.4.1c), given the different outcomes with respect to dr in the hydrosilylation. While 1,4-difunctionalized **4.1a** and 1,3-difunctionalized **4.2a** were quite similar in the onset of absorption, the onset of absorbance for *trans*-siladecalin **4.3a** was red-shifted by ca. 30 nm relative to monocyclic silanes. Finally, we note the bathochromic influence of thienyl substitution relative to aryl substitution comparing *trans*-**4.1j** to *trans*-**4.1a** (Figure 4.4.1d).

Figure 4.4.1 UV-vis spectra with normalized absorbance ($[\text{compound}] = 10^{-5} \text{ M}$, in *n*-pentane). (a) Comparison to starting material. Red: *trans*-**4.1a**; black: **1,4Si₆**; blue: styrene. (b) Influence of configuration. Red: *trans*-**4.1a**; blue: *cis*-**4.1a** (dr 25:75 *trans*:*cis*). (c) Cyclosilane comparison. Red: *trans*-**4.1a**; blue: **4.2a** (dr 55:45 *trans*:*cis*); orange: **4.3a**. (d) Heterocycle effect. Red: *trans*-**4.1a**; blue: *trans*-**4.1j** (dr 90:10 *trans*:*cis*).

Figure 4.4.2 Calculated HOMO and LUMO of *trans*-**4.1a**. B3YLP/6-31G(d).

4.5 Stereoregular conjugated polymer synthesis

The extended conjugation observed in hybrid molecules suggested a new conjugated polymer design: *stereoregular* copolymers alternating in σ - and π -conjugated motifs could be prepared via copolymerization of a dibrominated building block (e.g., *trans*-**4.1b** or *trans*-**4.1j**) with an appropriate comonomer. Polymers containing Si–Si bonds can be largely divided into two types: polysilanes (e.g., poly(SiR₂))^{48,49} and σ,π -copolymers (e.g., poly(Ar(SiMe₂)_nAr)).^{50,51} Polysilanes in which the alkyl substituents are not the same (e.g., poly(SiR'R''), R' \neq R'') are stereogenic at each Si atom, but assignment and control of polysilane tacticity is a long-standing problem with no general solution.^{52–}

⁵⁷ Use of a stereochemically pre-defined monomer appeals to avoid issues of control of relative configuration during polymerization.

We found that treatment of dibromo *trans*-**4.1j** (dr 90:10 *trans*:*cis*) with stoichiometric *i*-PrMgCl resulted in quantitative Mg-halogen exchange.⁵⁸ The intermediate α,ω -dimagnesiocyclosilane underwent Kumada cross-coupling with 2-bromothiophene, yielding *trans*-**4.1k** in 100% conversion (86% isolated yield) and without cyclosilane skeletal rearrangement or erosion of relative configuration (Scheme 4.5.1a).

Scheme 4.5.1 a) Model reaction: Kumada cross-coupling of *trans*-**4.1j** and 2-bromothiophene. (b) Kumada polycondensation synthesis of **P4.1**. c) Kumada polycondensation synthesis of **P4.2**.

The novel polymer **P4.1** ($M_n = 6706 \text{ g/mol}$, $M_w/M_n = 2.63$, Figure 4.5.1) was prepared by Kumada polycondensation of 2,5-dibromothiophene with the α,ω -dimagnesiocyclosilane derived from *trans*-**4.1j** (Scheme 4.5.1b and Figure 4.5.1). The dibromo building blocks could in principle serve as either a precursor to a nucleophile for Kumada polymerization, as showed above in the synthesis of **P4.1**, but also as the electrophile. We therefore also synthesized copolymer **P4.2** in which Mg-halogen

exchange of *trans*-**4.1j** was followed by Kumada polycondensation with dibromo *trans*-**4.1b** ($M_n = 5075 \text{ g mol}^{-1}$, $M_w/M_n = 2.43$, Scheme 4.5.1c and Figure 4.5.1).

Figure 4.5.1 Size exclusion chromatograms of **P4.1** and **P4.2** at 254 nm (solid line) and 350 nm (dotted line). Molecular weight determined relative to polystyrene standards at 254 nm (THF, [**P4.1**] or [**P4.2**] = 0.5 mg mL^{-1} , $40 \text{ }^\circ\text{C}$, 0.35 mL min^{-1} , $10 \text{ } \mu\text{L}$ injection)

Figure 4.5.2 Comparison of UV-vis spectra of *trans*-**4.1j** (blue), *trans*-**4.1k** (orange), **P4.1** (red) and **P4.2** (purple) in THF. [*trans*-**4.1j**] = 10^{-5} M , [*trans*-**4.1k**] = 10^{-5} M , [**P4.1**] = 0.03 g/L , [**P4.2**] = 0.03 g/L .

The **P4.1** onset of absorption (510 nm) was 140 nm red-shifted from *trans*-**4.1j** itself and 50 nm from *trans*-**4.1k** (Figure 4.5.2), validating the hypothesis that σ,π -mixing

could be extended across a conjugated polymer chain. Comparison of the UV-vis spectra showed that **P4.1** was red-shifted relative to **P4.2**. This was attributed to the difference between dithienyl and phenyl-thienyl units, as we showed (Figure 4.5.2) that molecular thienyl cyclosilanes were red-shifted relative to phenylsilanes. The all-organic conjugated polymer PTVT (poly(thienylenevinyleneethienyl)) exhibited a similar absorbance spectrum relative to **P4.1** despite a much longer degree of polymerization (PTVT: $\lambda_{\max} = 430$ nm, $\lambda_{\text{onset}} = 550$ nm, $M_n = 21,000$ g mol⁻¹).⁵⁹

These initial studies on conjugated polymer synthesis highlight the utility of stereodefined σ,π -hybrid materials, as well as the stability of relative configuration to subsequent chemical functionalization. Future work will examine the impact of stereoregularity on physical properties, as tactic polymers can demonstrate enhanced mechanical, thermal, and other properties relative to atactic.⁶⁰

4.6 Conclusion

We demonstrated that Ru-catalyzed addition of tetrafunctional cyclosilanes to functionalized alkynes proceeded with high selectivity across several parameters: chemoselectivity for Si-H over Si-Si bonds, regioselectivity with respect to both cyclosilane and alkyne, and high (*E*)/(*Z*) and *cis/trans* diastereoselectivity. Broad functional group tolerance was exhibited, providing a complex organocyclosilanes bearing reactive functional groups challenging to incorporate by other means. The diverse functional groups incorporated open up several new possible directions, from MOF synthesis to molecular electronics. We also demonstrated that these synthetic achievements enabled the first broad investigation of structure-property relationships in σ,π -hybrid cyclosilanes, which revealed visible light absorption dependent on both the cyclosilane and

arene identity. As exemplified by the Kumada polycondensation herein, we expect the results of this study to inspire new approaches to stereoregular conjugated materials combining σ - and π -conjugated motifs. We believe this contribution will continue to expand possibilities for the selective synthesis of complex materials from the main group.

Chapter 5: Conjugation in isomeric cyclosilane thioethers

The work presented in this chapter has been published as: Gittens, A. F.; Jiang, Q.; Siegler, M. A.; Klausen, R. S. *Organometallics* **2022**, 41, 23, 3762–3769.

5.1 Introduction

Since the discovery in the 1960's that permethylcyclosilanes exhibit longer-wavelength absorption spectra¹ than cycloalkanes and form stable radical anions,² interest in the synthesis of increasingly complex cyclosilanes has only grown.³ Prismatic solids^{4,5} and polycyclic silanes⁶ have shed light on the impact of strain and curvature on σ -conjugation, while we have investigated the synthesis of stereochemically defined cyclosilanes.⁷⁻⁹ An interest in the influence of heteroatomic substitution on optoelectronic properties has inspired work on boron-¹⁰⁻¹² and nitrogen-containing cyclosilanes (Scheme 5.1.1).^{13,14} Herein, we report the synthesis of cyclosilane thioethers via chemoselective dehydrocoupling of partially hydrogenated cyclosilanes and arylthiols and examine the effect of structural isomerism on conjugation. Density functional theory (DFT) calculations were used to elucidate potential mechanisms underlying experimental observations.

In recent work, we found that isomeric silanes, both molecular and polymeric, can exhibit strongly different absorbance spectra due to differences in conformation. We have previously reported the synthesis of the partially hydrogenated cyclosilanes **1,3Si₆** and **1,4Si₆** as monomers for dehydrocoupling polymerization¹⁵⁻²⁰ and found that linear polymers of **1,3Si₆** were red-shifted by 22-nm relative to linear polymers of **1,4Si₆** (Scheme 5.1.2),²⁰ while *cis*-siladecalin is optically inactive compared to *trans*-siladecalin.⁷

Scheme 5.1.1 Heteroatomic substitution of cyclosilanes.

Scheme 5.1.2 Isomeric oligo- and polysilanes with distinct absorption spectra.

Curious about the effect of isomerism on π, n, σ -conjugation, we sought to synthesize two sets of isomeric cyclosilanes bearing exocyclic heteroatoms (Scheme 5.1.2). Based on the high degrees of conversion and chemoselectivity identified by Rosenberg et al. in dehydrocoupling of thiols and linear oligosilanes,²¹ we report a combined experimental and computational study probing the effects of sulfur incorporation on the optical properties of isomeric cyclosilanes. Our study demonstrates that the reduced conformational degrees of freedom in cyclosilanes results in a compelling platform to study the effects of isomerism on optical and electronic properties, resulting in the discovery that

changes in skeletal connectivity can have competing effects on conformation and delocalization.

Scheme 5.1.3 Structural isomers of cyclosilane-sulfur hybrids investigated herein. Isomer **5.3** was not synthesized, but computationally evaluated.

5.2 Synthesis of isomeric cyclosilane thioethers

Identification of methods for the functionalization of Si–H bonds in the presence of Si–Si bonds has been a problem of long-standing interest.^{22,23} A consistent challenge has been chemoselectivity, given the susceptibility of Si–Si bonds to cleavage by strong nucleophiles,^{24,25} Lewis acids,^{26,27} and late transition metals including Rh and Pt.^{28,29} In recent years, tris(pentafluorophenyl)borane (B(C₆F₅)₃) has been reported as a versatile catalyst for the chemoselective activation of Si–H bonds in linear oligosilanes and polysilanes,^{21,30,31} with particularly high yields observed for the dehydrocoupling of thiols

with H-functionalized oligosilanes (Scheme 5.2.1). Therefore, we selected $B(C_6F_5)_3$ as the catalyst for cyclosilane thiolation.

Scheme 5.2.1 Catalytic dehydrocoupling of disilane and propylthiol.

The synthesis of cyclosilane thioethers were investigated by Alex Gittens in the Klausen group. The full structural characterization has been performed and published in the following reference: Gittens, A. F.; Jiang, Q.; Siegler, M. A.; Klausen, R. S. *Organometallics* **2022**, 41, 23, 3762–3769.

Scheme 5.2.2 Catalytic dehydrocoupling of **1,4Si₆** and arylthiols.

In an initial survey of reaction scope, we found that exposing **1,4Si₆** to $B(C_6F_5)_3$ and a slight excess of thiophenol resulted in the immediate evolution of hydrogen. A white solid precipitate formed, which was isolated by filtration and proved to be clean tetrafunctionalized cyclosilane thioether **5.1a** (57% yield, Scheme 5.2.2). Full substitution

of all Si–H bonds was notable in comparison to the Ru-catalyzed hydrosilylation reaction between **1,4Si₆** and alkynes, which yielded the difunctionalized product exclusively.⁹ Several other arylthiols were also examined (Scheme 5.2.2). X-ray crystal structures confirmed the structural assignments (Figure 5.2.1).

Figure 5.2.1 Displacement ellipsoid plots (50% probability level) of cyclosilane thioethers **5.1a-c** at 110(2) K (**5.1a** and **5.1c**) or at 294(2) K (**5.1b**). Hydrogens omitted for clarity. Blue = silicon, black = carbon, yellow = sulfur, burgundy = bromine.

Scheme 5.2.3 Catalytic dehydrocoupling of **1,3Si₆** and phenylthiols.

We also examined the reaction of **1,3Si₆** with thiophenol. In general, 1,3-functionalized cyclosilanes are more soluble than 1,4-functionalized.¹⁶ No product precipitation was observed from benzene. Instead, reaction progress was monitored by ¹H NMR spectroscopy. We found that an increased reaction temperature and longer reaction time were necessary for complete consumption of **1,3Si₆**, but ultimately compound **5.2a** could be isolated in 66% yield (Scheme 5.2.3). The observation of complete substitution

of Si–H bonds with minimal byproducts across two sets of cyclosilanes and three distinct thiophenols suggests a promising level of generality and may be appropriate for the synthesis of extended solids.

Figure 5.2.2 Displacement ellipsoid plots (50% probability level) of **5.2a** at 110(2) K a) Top down and b) side-on views. Hydrogens omitted for clarity. Black = carbon, blue = silicon, yellow = sulfur.

The crystal structure of **5.2a** was determined (Figure 5.2.2). The central cyclosilane ring adopted a twist-boat conformation in the solid state (Figure 5.2.2). This is distinct both from the 1,4-functionalized cyclosilane thioethers **5.1a-c** and from the crystal structure of a 1,3-tetraarylcyclosilane we previously reported.¹⁶ As it has long been appreciated that oligosilanes have both lower barriers to conformational change than alkanes, we considered two hypotheses for the change in conformation: (1) the twist-boat conformation is lower energy than a chair conformation for **5.2a** or (2) the twist-boat conformation is not the lowest energy conformation, but attractive intermolecular aromatic interactions in the solid-state are maximized in the twist-boat conformation. To investigate these possibilities, we obtained gas-phase conformational data for isomeric **5.1a** and **5.2a**.

5.3 Conformational study via DFT calculations

To understand the conformational differences between **5.1a** and **5.2a** in their crystal structures, we used density functional theory (DFT) calculations to compare the energies of the chair and twist-boat conformers for both **5.1a** and **5.2a**. Geometries were fully

optimized starting from chair or twist-boat conformations respectively without symmetry restrictions using B3LYP hybrid exchange–correlation functional with the 6-311G(d) basis set. Crystal structures were used as starting geometries if applicable. Frequency calculations were performed with the same level of theory, to ensure optimized geometries were local minima on their potential energy surfaces. The calculation indicates that the chair conformation of **5.1a** is of lower energy than the twist-boat conformation by 2.43 kcal mol⁻¹ (Table 5.3.1). However, for **5.2a**, the twist-boat conformer is lower energy by 3.06 kcal mol⁻¹ compared to the chair conformer. These calculations suggest that the difference in cyclosilane conformation in the crystal structures of **5.1a** and **5.2a** should also be reflected in the gas-phase or solution where intermolecular attractions might be minimized. We hypothesize that 1,3-diaxial interactions between pseudoaxial thiophenol substituents are minimized in the twist-boat conformation.

Table 5.3.1 Calculated energies of conformers **5.1a** and **5.2a**.

Structures	Energies (E _h)		$\Delta E_{\text{chair-twist}}$ (E _h)	$\Delta E_{\text{chair-twist}}$ (kcal mol ⁻¹)
	chair	twist		
5.1a	-4576.377926	-4576.374056	-0.00387	-2.43
5.2a	-4576.370076	-4576.374962	0.00489	3.07

5.4 Time dependent DFT (TD-DFT) calculations

As oligosilane optical properties are conformation-dependent, these observations suggested that the structural isomers **5.1a** and **5.2a** could have distinct optical properties. Quantum chemical calculations would allow us to directly compare the twist-boat and chair conformers in **5.1a** and **5.2a**, while experimental spectra would reflect different populations of conformers.

Different combinations of functionals and levels of theory were examined by comparing the simulated UV-vis spectra of **5.1a** to the experimental results (Figure 5.4.1). The PBE0 functionals with the 6-311G(d) basis set was selected for its best match of onset and λ_{max} absorption compared to the experimental spectrum (Figure 5.4.1). This combination was previously reported for studying electronic transitions in linear hexasilanes and poly(cyclosilane)s.^{20,32} The number of states of TD-DFT calculations was set as 50, as the simulated spectra with higher number of states better matched the broad absorption band from 220 nm to 320 nm in the experimental results (Figure 5.4.2).

Figure 5.4.1 Comparison of experimental UV-vis spectra and simulated spectra with different functionals and levels of theory.

Figure 5.4.2 Comparison of experimental UV-vis spectra and simulated spectra with different numbers of states (N). TD-PBE0/6-311G(d)//B3YLP/6-311G(d).

Figure 5.4.3 Calculated frontier orbitals of chair and twist-boat conformers of **5.1a** and **5.2a**. H atoms omitted for clarity. TD-PBE0/6-311G(d)//B3YLP/6-311G(d). Isovalue=0.02.

Conformation-dependent π, n, σ -conjugation in the cyclosilane thioethers was investigated by TD-DFT calculations for both **1,4Si₆** and **1,3Si₆**-derived compounds. The calculated frontier orbitals of chair cyclosilane thioethers are shown in Figure 5.4.3. The HOMO of chair-**5.1a** delocalizes across the silane ring and all four thioethers. In chair-

5.2a, the electron density on the phenyl groups decreased and the HOMO was predominantly observed on one of the equatorial phenyl groups. LUMOs of chair-**5.1a** and chair-**5.2a** are mostly situated on the silicon frameworks and the equatorial thioethers.

The frontier orbitals of the twist-boat conformers were also studied (Figure 5.4.3). Both HOMOs and LUMOs delocalize across silicon frameworks, sulfur atoms and the equatorial phenyl groups. Interestingly, pseudo π^* orbitals were observed for the LUMO+1 of all four conformers (Figure 5.4.4). These orbitals are assembled by in-phase interaction of $\sigma^*(\text{Si-C/S})$, similar to the LUMOs of decasilahydrotriquinacene and decasilaisotwistane reported by Kyushin.⁶ We note that such pseudo π^* orbitals were found partially broken in twist-**5.1a** and chair-**5.2a** (Figure 5.4.4).

Figure 5.4.4 The LUMO+1 orbital of **5.1a** and **5.2a**. H atoms omitted for clarity. Discontinued pseudo π^* orbitals were found on twist-**5.1a** and chair-**5.2a**. TD-PBE0/6-311G(d)//B3YLP/6-311G(d). Isovalue=0.02.

Table 5.4.1. Calculated vertical electronic transitions in cyclosilane thioethers. Only transitions of wavelength above 230 nm and oscillator strength above 0.05 are shown. Relative contributions given in percentages, where H = HOMO and L = LUMO. Assignments are shown if the relative contribution is higher than 10%.

Electronic transitions in the cyclosilane thioethers are affected by both conformation and connectivity. In the twist and chair **1,4Si₆**-derived thioethers, the HOMO \rightarrow LUMO transition is symmetry forbidden (Table 5.4.1). For chair-**5.1a**, the HOMO \rightarrow LUMO+1 transition is dominant. However, for twist-1a, the HOMO-2 and HOMO-1 \rightarrow

LUMO both contribute to the predicted lowest-energy vertical transition. Chair-**5.1a** also shows a more pronounced absorption feature at 260 nm compared to twist-**5.1a** in the simulated UV-vis spectra (Figure 5.4.5a).

Figure 5.4.5 Simulated UV-vis spectra of (a) **5.1a** and (b) **5.2a**. Solid lines: chair conformations. Dotted lines: twist-boat conformations. TD-PBE0/6-311G(d)//B3YLP/6-311G(d).

Table 5.4.2. Calculated vertical electronic transitions in cyclosilane thioethers. H = HOMO and L = LUMO.

Transition	chair- 5.1a	twist- 5.1a	chair- 5.2a	twist- 5.2a
H → L	5.48 eV	5.41 eV	5.20 eV	5.28 eV
H → L+1	5.52 eV	5.47 eV	5.51 eV	5.37 eV

In contrast, in chair and twist **1,3Si₆**-derived thioethers the HOMO → LUMO transition is allowed (Table 5.4.2), as well as other higher-energy transitions. Twist-**5.2a** has a stronger absorption at 275 nm than chair-**5.2a** (Figure 5.4.5b), resulting from a wider HOMO → LUMO+1 gap in chair-**5.2a** (Table 5.4.3). The LUMO+1 of chair-**5.2a** is found to be a partially broken pseudo π^* orbital (Figure 5.4.4). The discontinued conjugation

raises its energy level, requiring higher energy for HOMO \rightarrow LUMO+1 transition in chair-**5.2a**.

TD-DFT calculations also facilitated the study of isomeric compounds that have not yet been synthesized. We probed the influence of sulfur connectivity by comparing Ar-S-Si in **5.1b** and MeS-Ar-Si in **5.3** (Figure 5.4.6). In structure **5.3**, sulfur atoms are substituents on the phenyl rings, rather than inserted between the cyclosilane and aromatic groups. Cyclosilane thioether **5.1b** has frontier orbitals similar to **5.1a** (Figure 5.4.6).

Figure 5.4.6 Comparison of calculated HOMO and LUMO of **5.1b** to its isomeric structure **5.3**. Hydrogen atoms omitted for clarity. TD-PBE0/6-311G(d)//B3YLP/6-311G(d). Isovalue=0.02.

Tetraaryl cyclosilane **5.3** however has a HOMO mainly localized on the equatorial aromatics and the LUMO at the axial aromatics. No pseudo π^* orbital delocalizing through the silicon framework was found in **5.3**. Its LUMO+1 is majorly formed by the π^* orbitals of axial phenyl groups (Figure 5.4.7). These results suggest sulfur incorporation (n-electron

donors) facilitates the delocalization between silicon frameworks (σ -conjugation) and aromatic rings (π -conjugation).

Figure 5.4.7 The LUMO+1 orbital of **5.3**. No pseudo π^* orbital delocalizing through the silicon framework was found. Hydrogen atoms omitted for clarity. TD-PBE0/6-311G(d)//B3YLP/6-311G(d). Isovalue=0.02.

5.5 UV-vis spectroscopy

Experimental UV-vis spectra were obtained to evaluate the computational predictions. We first compared the solution-phase UV-vis spectrum of **5.1a** to thiophenol and **1,4Si₆**. The cyclosilane thioether exhibited a broad absorption band at 258 nm, which was red-shifted relative to both thiophenol and **1,4Si₆** (Figure 5.5.1a). The experimentally observed transition is consistent with the TD-DFT calculated spectrum, which predicted λ_{max} of 260 nm (Figure 5.5.1a). Compared to non-sulfur-incorporated cyclosilane **1,4Si₆Ph₄**, **5.1a** also exhibited a red-shifted absorption band (Figure 5.5.1b). This observation agrees with the prediction made by TD-DFT calculations that sulfur incorporation facilitates delocalization between the π - and σ -fragments. The cyclosilane thioethers **5.1b** and **5.1c** had very similar UV-vis spectra to **5.1a** with respect to the onset of absorption and overall peak shape (Figure 5.5.1c), consistent with the frontier orbital

calculations (Figure 5.5.2 and Table 5.5.1). These observations suggest delocalization of the π - and σ -conjugated systems through the sulfur lone pair and that moderately electron-donating or withdrawing aromatic substituents do not strongly impact that delocalization.

Figure 5.5.1 Solution-phase UV-vis spectra ([compound] = 0.01 mM, THF). a) Comparison of thioether **5.1a** to thiophenol and **1,4Si₆** demonstrates red-shift in absorbance. b) Comparison of thioether **5.1a** to **1,4Si₆Ph₄** demonstrates delocalization between the π - and σ -fragments. c) Comparison of cyclosilane thioethers **5.1a-c**. c) Comparison of isomer cyclosilane thioethers **5.1a** and **5.2a**.

Comparison of the UV-vis spectra of **5.1a** and **5.2a** validated the predictions made by TD-DFT calculations. We predicted similar absorption features for chair-**5.1a** and twist-**5.2a**, the lowest-energy conformers of each cyclosilane thioether (Figure 5.4.5). Despite

stronger absorbance at 230 nm, **5.2a** exhibits similar absorption bands compared to **5.1a** in the experimental UV-vis spectra (Figure 5.5.1d), which agrees with computational studies as we discussed above.

Figure 5.5.2 Simulated UV-vis spectra of chair-**5.1a** (black), **5.1b** (blue) and **5.1c** (red). TD-PBE0/6-311G(d)//B3YLP/6-311G(d).

Table 5.5.1. Calculated band gaps in chair-**5.1a**, **5.1b** and **5.1c**. H = HOMO and L = LUMO. TD-PBE0/6-311G(d)//B3YLP/6-311G(d).

Transition	chair- 5.1a	5.1b	5.1c
H → L	5.48 eV	5.42 eV	5.36 eV
H → L+1	5.52 eV	5.46 eV	5.38 eV

5.6 Conclusion

We investigated the effect of conformation and connectivity on conjugation of isomeric cyclosilane thioethers. We prepared thioethers **5.1a-c** and **5.2a** through the $B(C_6F_5)_3$ -catalyzed dehydrocoupling of various thioethers and partially hydrogenated

cyclohexasilanes **1,4Si₆** and **1,3Si₆**. These reactions run with high chemoselectivity for Si-H bonds in the presence of Si-Si bonds, preserving the σ -framework. Their structures were confirmed using ¹H and ²⁹Si NMR spectroscopy and single crystal X-ray crystallography. X-ray crystal structures, as well as gas phase calculations, showed that cyclosilanes adopt different conformations depending on skeletal connectivity.

Computational studies were used to probe the factors that influence the photophysical properties of our π, n, σ -conjugated molecules. By comparing isomers **5.1b** and **5.3** using TD-DFT calculations, we see a lack of pseudo π^* orbital delocalizing through the silicon framework when sulfur is not connected to both the cyclosilane and phenyl rings. Thus, the insertion of sulfur between the σ -conjugated and π -conjugated systems extends electron delocalization across the whole system.

We demonstrated the important influence of heteroatom substitution in facilitating π - and σ -conjugation in cyclosilane thioethers and observed that constitutional isomers can exhibit distinct conformations and patterns of delocalization. We expanded upon our prior work in building complex silicon building blocks and their precise functionalization. We described their photophysical activity through the use of computational and experimental data. The studies herein provide insight into the potential use of sulfur-influenced conjugated materials.

Chapter 6: Impact of stereoregularity on hybrid conjugated polymers

6.1 Introduction

Stereoregularity in the polymer results in pronounced differences in thermal, mechanical and optical properties, and thus well-defined stereoregular polymers are of great interest in both synthesis and applications for decades.¹ In 1927, Staudinger predicted that the main-chain stereochemistry of a polymer would lead to the change of its physical properties², and Schildknecht reported the synthesis of the first stereoregular polymer, polyvinyl alkyl ether.³ The stereoregular polyolefin synthesis catalyzed by transition-metal catalysts has been extensively studied.^{4,5}

Scheme 6.1.1 Stereoregular polymeric structures containing cyclic units. (a) Stereoregular hydrocarbon polymers. (b) β -Cyclodextrin.

The synthesis of organic polymers with cyclic repeating units in the main chain is an emerging field for their unique physical properties compared to linear polyolefins, including higher melting (T_m) or glass-transition temperatures (T_g), control of polymer rigidity and optical transparency.⁶⁻⁸ Promotion of stereoregularity of these polymers further improves the beneficial properties. Takeuchi reported a precise isomerization

polymerization of alkenylcyclohexanes yielding stereoregular polymers containing six-membered rings in the polymer backbone (Scheme 6.1.1a).⁷ Higher T_g were observed when the ratio of cyclohexyl units increased. More recently, Hou demonstrated the synthesis of functionalized cyclic polyolefins with high isotacticity through the scandium-catalyzed cyclopolymerization of functionalized α,ω -dienes (Scheme 6.1.1a).⁸

The macromolecular structures with stereoregularity can also be constructed with pre-defined stereoregular building blocks. β -Cyclodextrin is an example of highly regulated structures in nature and has found its way in industrial utilization (Scheme 6.1.1b).⁹ It is assembled by glucopyranosides, six-membered carbohydrate rings with multiple stereogenic centers.

Scheme 6.1.2 Anionic ROP of amino-functionalized masked disilene.

Control of polysilane main-chain stereoregularity, however, has been a long-term challenge to synthetic chemists. The difficulties are from both synthetic methods and characterization of the structures.¹⁰ Though Wurtz polymerization and dehydrocoupling polymerization generated the atactic polysilanes, anionic ring-opening polymerization (ROP) gave some success in the field.¹⁰ Matyjaszewski reported the ROP of all-*trans* cyclotetrasilane resulting in an isotactic polysilane.¹¹ More recently, polymerization of the amino-functionalized masked disilene was reported by Sakurai and the resulting polysilane was found to be predominately syndiotactic (Scheme 6.1.2).¹² On the other hand, a lack of stereoisomerically pure small molecule model compounds makes the tacticity assignment

of polysilanes complicated through NMR.¹⁰ Conflicting identifications of tacticity were reported in the case of poly(SiMePh) from references.^{11,13–15}

This Work

- Stereoregular polysilane
- Conformational-dependent thermal and optical properties

Scheme 6.1.3 (a) Prior work: hybrid conjugated polymer containing linear silane units. (b) Stereoregular polysilane synthesized with cyclosilane building blocks.

The organosilicon materials containing hybrid σ,π -conjugated structures have raised broad interest for their unique optoelectronic properties and potential applications in photoresists, emitting polymers and semiconductive materials.¹⁶ Plenty of study in this field has pursued to increase the structural diversity of π -conjugated units.^{17–20} However, the σ fragments in these materials were largely limited to linear oligosilanes²¹ (Scheme 6.1.2) due to the limited suitable silane building blocks and synthetic methods.²² The Klausen lab has extensively explored the design, synthesis, and polymerization of cyclosilanes.^{23–26} We recently described a highly selective synthesis of σ,π -conjugated cyclosilanes through RuHCl(CO)(PPh₃)₃-catalyzed hydrosilylation.²⁷ As initial examples,

the copolymerization of the *trans*-bis(thienylvinyl)cyclosilane with dibromo building blocks was also demonstrated.

Herein, we report the synthesis of hybrid conjugated stereoregular polysilanes using *trans* and *cis* cyclosilane building blocks as stereochemically pre-defined monomers. The stereochemistry on cyclosilanes was preserved in the polymerization, enabling well-defined stereoregularity. We observed that stereoregular polysilanes exhibited more pronounced phase transition behaviors in DSC measurements and had more distinct absorption bands in the UV-vis spectra compared to atactic polysilanes. Influence of silane structures (cyclic *versus* linear) and vinyl group incorporation on the polysilane properties was also examined.

6.2 Stereoregular hybrid σ,π -conjugated polymers

We have reported the copolymerization of the building block *trans*-**6.1** and 2,5-dibromothiophene (Table 6.2.1, Entry 1).²⁷ The building block *trans*-**6.1**, isolated in high diastereomeric purity after recrystallization, can be elaborated to conjugated polymer **P6.1** by Mg/Br exchange^{28,29} followed by NiCl₂dppp-catalyzed Kumada polycondensation in the presence of PPh₃ ligands (Table 6.2.1, Entry 1). Herein, the reaction conditions were further investigated by varying catalyst and ligand species (Table 6.2.1). At this time, the focus continued to be on Ni-catalyzed Kumada polycondensation as Ni does not cleave Si–Si bonds, whereas the Pd catalysts employed in Stille or Suzuki polycondensation are known to cleave Si–Si bonds.^{30–32}

Under the NiCl₂dppp-catalyzed conditions, low conversions of starting materials were observed with no additional ligands (Table 6.2.1, Entry 2). Although excess ligands are not usually required in the Kumada catalyst-transfer polycondensation (KCTP) making

poly(3-hexylthiophene)³³, the similar low yield was reported in Kumada couplings of heteroaryl chlorides and lithium tri(quinolyl)magnesates catalyzed by Ni(acac)₂ and dppp.³⁴ The low conversions might arise from a different copolymerization mechanism rather than KCTP. The cyclosilane silane building blocks lacked a continuous π -conjugated backbone, and prevented the Ni catalyst from “walking” along the polymer chain.³³ Therefore, the catalyst required regeneration after a growth of each unit. PPh₃ ligand might improve catalyst recovery and therefore result in a higher conversion of monomers.

Table 6.2.1. Variation of **P6.1** molecular weight characteristics with Ni catalysts and ligands. The relative configuration was maintained in the polymerization (highlighted in red).

Entry	Catalyst	Ligand	M_n (g mol ⁻¹) ^a	M_w/M_n ^a	Yield
1 ^b	NiCl ₂ dppp	PPh ₃	6.70k	2.63	78%
2	NiCl ₂ dppp	n/a	-	-	Low conversion
3	NiCl ₂ dppp	dppp	-	-	Low conversion
4	NiCl ₂ (PPh ₃) ₂	PPh ₃	4.77k	2.05	63%
5	NiCl ₂ (PPh ₃) ₂	n/a	4.94k	2.08	65%
6	NiCl ₂ (PPh ₃) ₂	dppp	4.32k	2.02	55%

^a Determined by size exclusion chromatography relative to polystyrene standards at 254 nm (THF, [copolymer] = 1 mg mL⁻¹, 40 °C, 0.35 mL min⁻¹, 10 μ L injection). ^b Previously reported in reference.²⁷

Further experimental exploration supported the above hypothesis. Additional dppp ligands did not improve the polymerization (Table 6.2.1, Entry 3). However, reasonable starting material conversion and molecular weight characteristics of products were

observed in $\text{NiCl}_2(\text{PPh}_3)_2$ -catalyzed polymerizations regardless of the ligand species and amount (Table 6.2.1, Entry 4-6). The reaction condition described in Table 6.2.1, Entry 1 was chosen as the general polymerization condition because of the relatively high molecular weight of products.

Scheme 6.2.1. Synthesis of hybrid conjugated polymers **P6.2** (predominately *cis*) and **P6.3** (atactic). The relative configuration was maintained in the polymerization (highlighted in red).

Under the optimized polymerization condition, we have now synthesized the stereoisomers of **P6.1** (Table 6.2.1) by variation of the diastereomeric ratio in the starting monomer **6.1**, yielding **P6.2** (predominantly *cis*) and **P6.3** (atactic). We note that *cis*-**6.1** (dr 20:80 *trans:cis*) was enriched in the filtrate of **6.1** recrystallization. Similar molecular weight characteristics were determined for all three macromolecules by size exclusion chromatography (Table 6.2.2). However, solubilities of these polymers in CDCl_3 were found to be dependent on the degree of stereoregularity (Figure 6.2.1). The atactic **P6.3** formed a clear solution in CDCl_3 at room temperature, whereas the stereoregular **P6.1** and **P6.2** both made orange suspension in CDCl_3 at the same concentration. The observation

was consistent with polymers of higher crystallinity exhibiting lower solubility in the solution.

Table 6.2.2. Molecular weight characteristics of hybrid conjugated polysilanes.

Cyclosilane	dr (<i>trans:cis</i>)	Polymer	M_n (g mol ⁻¹) ^a	M_w/M_n ^a	Yield (%)
<i>trans</i> - 6.1 ^b	90:10	P6.1	6706	2.63	78
<i>cis</i> - 6.1	20:80	P6.2	6382	2.66	73
6.1	63:37	P6.3	6883	2.59	63

^a Determined by size exclusion chromatography relative to polystyrene standards at 254 nm (THF, [copolymer] = 1 mg mL⁻¹, 40 °C, 0.35 mL min⁻¹, 10 µL injection). ^b Previously reported in reference.²⁷

P6.1 P6.3 P6.2

Figure 6.2.1 Solubility characteristics of (left to right) **P6.1**, **P6.3**, and **P6.2** (25 mg polymer in 0.7 mL CDCl₃).

The Si-H bonds are known to be diagnostic for NMR spectroscopy²³⁻²⁵, and the comparison of ²⁹Si NMR spectra of cyclosilane monomers to polysilanes identified the preserved stereochemistry of cyclosilane units in the copolymerization. The SiH resonances of cyclosilane conformers had distinct chemical shifts in ²⁹Si NMR spectra:

64.5 ppm for *trans*-**6.1** and 63.0 ppm for *cis*-**6.1** (Figure 6.2.2). Polysilane **P6.1-3** had similar SiH resonances to the monomers. Distinct peaks were found at 63.0 and/or 64.8 ppm depending on the diastereomer ratio of their starting cyclosilanes. These features confirmed the remained stereochemistry of the cyclosilane rings and no Si-Si bond cleavage in presence of the Ni catalyst in the polycondensation.

Figure 6.2.2 Cropped $^{29}\text{Si} \{^1\text{H}\}$ DEPT spectra (79 MHz, CDCl_3) comparing (top to bottom) *trans*-**6.1** (dr 90:10 *trans:cis*), **P6.1**, **P6.2**, **P6.3** and *cis*-**6.1** (dr 20:80 *trans:cis*). $^1J_{\text{Si-H}} = 120$ Hz. DEPT = distortionless enhancement by polarization transfer. The methyl groups are omitted for clarity.

6.3 Synthesis of hybrid conjugated polymers containing linear silane units

To address the effect of cyclosilane units on the conjugated polymer properties, a linear silane building block **6.2** was synthesized through $\text{RuHCl}(\text{CO})(\text{PPh}_3)_3$ -catalyzed hydrosilylation using dihydrodisilane and bromoethynylthiophene (Figure 6.3.1a).

Figure 6.3.1. (a) Synthesis of linear silane building block **6.2** and its polycondensation with dibromothiophene yielding **P6.4**. (b) ^1H NMR spectra (400 MHz, CDCl_3) of **6.2** (top) and **P6.4** (bottom).

The ^1H NMR spectrum confirmed a depletion of Si-H groups for the absence of resonances in 3.0-4.0 ppm, where SiH resonances were usually identified (Figure 6.3.1). The coupling constant analysis of alkenyl resonances indicated the selective formation of (*E*)-alkene, which was consistent with literatures.^{27,35} The building block **6.2** was then copolymerized with 2,5-dibromothiophene producing the linear silane analog of σ,π -conjugated polysilane (Scheme 6.3.1). The resulting polysilane **P6.4** ($M_n = 5051 \text{ g mol}^{-1}$, $M_w/M_n = 2.08$) was a red powder which was fully soluble in CDCl_3 . The Si-Me, alkenyl

and thienyl resonances in the ^1H NMR spectrum broadened after the copolymerization also indicating the formation of polymeric structures (Figure 6.3.1).

Scheme 6.3.1. Synthesis of linear silane building block **6.3** and its polycondensation with dibromothiophene yielding **P6.5**. Adapted from known procedure.²⁰

Known polysilane **P6.5** was synthesized as a comparison to **P6.4** to investigate the influence of vinyl fragments on the thermal and optical properties. The stoichiometrical Mg/Br exchange on one side of 2,5-dibromothiophene was conducted at -78°C in diethyl ether. Then the bromothieryl magnesium chloride was coupled to dichlorodisilane, affording **6.3**. The linear silane **6.3** was copolymerized with 2,5-dibromothiophene following the standard procedure (Table 6.2.1, Entry 1), resulting in **P6.5**.

6.4 Thermal property study with differential scanning calorimetry

The glass transition temperature of polymers is known to be strongly tacticity-dependent.³⁶ By achieving control of both relative configuration and molecular weight, it is possible to study the impact of tacticity on polymer properties in isolation. As an example of stereoregularity impact on bulk properties, we found that the three macromolecules exhibited distinct glass transition (T_g) temperatures. The atactic **P6.3** showed a minimal transition, but both *trans* **P6.1** and *cis* **P6.2** showed more pronounced T_g at distinct

temperatures (Figure 6.4.1). The thermal property of atactic **P6.3** is consistent with the absence of phase transition between 40 °C to 200 °C for atactic linear poly(cyclosilane)s.²⁶

Figure 6.4.1 Cropped DSC curves of **P6.1-5**. The second cycle is shown. Heating rate: 20 °C min⁻¹, cooling rate: 20 °C min⁻¹.

Linear silane-embedded **P6.4** and **P6.5** did not undergo remarkable phase transition between 40 to 180 °C. Based on these comparisons, we attributed the glass transition that **P6.1** and **P6.2** exhibited at 68-74 °C to the ring inversion of cyclohexasilane units. The free-energy profile of cyclohexasilane ring inversion is known to be much lower than cyclohexane.³⁷ While the temperature increased, the ring inversion would promote mobility of polymer backbones, enhancing glass transition behaviors. We note that **P6.5** was the only polymer that showed melting temperature (T_m) at 203 °C. No T_m was detected

for the other polysilanes before they degraded above 250 °C. This indicated that the incorporation of vinyl groups in the backbone built up polymer rigidity and raised their T_m .

6.5 UV-vis absorbance spectra

We obtained UV-vis spectra of the stereoregular polysilane thin films. The polysilanes were dissolved in THF (2.0 mg/mL), drop-casted on quartz substrates and fully dried under vacuum at room temperature overnight (Figure 6.5.1, blue curves). All three polymers were similar in UV-vis absorption: $\lambda_{\max} = ca.$ 420 nm and $\lambda_{\text{onset}} = ca.$ 570 nm. No notable difference was identified, which agreed with the similar UV-vis absorption of *trans*- and *cis*-**6.1**.²⁷

Figure 6.5.1 Comparison of film UV-vis spectra of (a) **P6.1**, (b) **P6.4** and (c) **P6.5**. Before annealing: Blue. After annealing: Red.

The films were then annealed by being heated at 80 °C for 8 hours under vacuum and slowly cooled to room temperature overnight. Compared to UV-vis spectra obtained before annealing, all three annealed polymers showed similar onset (λ_{onset}) and maximum (λ_{\max}) absorption, whereas the absorption bands became narrower only in spectra of

annealed **P6.1** and **P6.2**. This is consistent with the DSC results that glass transition were observed in stereoregular **P6.1** and **P6.2** but not atactic **P6.3**. Annealing the stereoregular polymers at temperature above T_g helped form more ordered arrangement of neighboring polymer chains, resulting in more distinct absorption bands.

Figure 6.5.2 Comparison of solution UV-vis spectra of **P6.1** (Red), **P6.4** (Blue), and **P6.5** (Prussian) in THF. [polymer] = 0.03 g/L.

The influence of silane and vinyl units embedded in conjugated polymer chains was also investigated through UV-vis spectroscopy (Figure 6.6.2). Despite higher degree of polymerization, λ_{\max} of both linear silane-derived polymers were blue-shifted compared to **P6.1**, by *ca.* 10 nm for **P6.4**, and *ca.* 55 nm for **P6.5**. This indicated that cyclosilane units better extended conjugation than their linear analogs. We also note the bathochromic influence of vinyl incorporation as the result of enlarging π -conjugated fragments (**P6.4** versus **P6.5**).

6.6 Expanded scope of hybrid conjugated polymers

To further address the impact of stereoregularity on the polysilane optical properties in addition to bulk characteristics, we replaced the comonomer 2,5-dibromothiophene with more sterically hindered **6.4** (Table 6.6.1). The long alkyl side substituents on **6.4** were expected to amplify the influence of cyclosilane stereoregularity on the polymer chain geometry by increasing stereo effects. The standard copolymerization condition (Table 6.2.1, Entry 1) was used. Conjugated polymers **P6.6-8** were synthesized by variation of diastereomer ratio of **6.1** (Table 6.6.1).

Table 6.6.1. Molecular weight characteristics of hybrid conjugated polysilanes. ^a

Cyclosilane	dr (<i>trans</i> : <i>cis</i>)	Polymer	M _n (g mol ⁻¹) ^a	M _w /M _n ^a	Yield (%)
<i>trans-6.1</i>	90:10	P6.6	4163	2.52	72
<i>cis-6.1</i>	20:80	P6.7	4051	2.24	68
6.1	63:37	P6.8	4468	2.02	56

^a Determined by size exclusion chromatography relative to polystyrene standards at 254 nm (THF, [copolymer] = 1 mg mL⁻¹, 40 °C, 0.35 mL min⁻¹, 10 μL injection).

As the *trans*:*cis* ratio in **6.1** tuned from 90:10 to 63:37 to 20:80, the molecular weight characteristics of the copolymer stayed constant (Table 6.6.1), but significantly different absorbance spectra were recorded (Figure 6.6.1). Increasing the ratio of certain diastereomer of cyclosilanes led to a more pronounced transition at ca. 320 nm and a more notable shoulder at 370 nm (Figure 6.6.1).

Figure 6.6.1 Comparison of UV-vis spectra of **P6.6** (red), **P6.7** (blue), and **P6.8** (purple) in THF solution. [polymer] = 0.03 g/L.

6.7 Conclusion and future

We demonstrated that stereoregularity showed substantial influence on the thermal and optical properties of hybrid conjugated polymers. A series of stereoregular and atactic σ,π -conjugated polymers derived from sterically pre-defined cyclosilane building blocks were synthesized. Compared to the atactic polymer, the stereoregular polysilanes exhibited notable phase transitions and their optical characteristics better benefitted from annealing. Using blocky aromatic comonomers, the impact of stereoregularity on the optical properties was amplified and the absorption features were more distance in the solution phase. We also demonstrated that the incorporation of cyclosilane and vinyl units into the polymer chain extended conjugation.

Future study of the demonstrated hybrid conjugated polymers will include examining the semicrystallinity by film X-ray diffraction (XRD) and fluorescence

emission properties by fluorescence spectroscopy. More synthetic exploration will be done, including achieving higher stereochemical purity in the building blocks by further purifying cyclosilane monomers with recycling gel permeation chromatography, and altering the electron donor/acceptor profile of aromatic comonomers.

Chapter 7: Experimental details

7.1 General information

General Experimental Procedures

All experiments were performed under protection of dry nitrogen or argon with the rigid exclusion of air and moisture using standard Schlenk techniques or in a nitrogen glovebox. All glassware was oven-dried overnight in a 175 °C oven.

Materials

Unless otherwise specified, all chemicals were used as purchased without further purification. Solvents DCM (Fisher, HPLC grade), THF (Fisher, HPLC grade), pentane (Fisher, certified ACS), and toluene (Fisher, certified ACS) were dried on a J. C. Meyer Solvent Dispensing System (SDS) using stainless steel columns packed with neutral alumina (except for toluene which is dried with neutral alumina and Q5 reactant, a copper(II) oxide oxygen scavenger), following the manufacturer's recommendations for solvent preparation and dispensation unless otherwise noted. Acetylenes (4-ethynylthioanisole¹, 4-ethynylbromobenzene² and 2-bromo-5-ethynylthiophene³) and 1,4-dibromo-2,5-((2-ethylhexyl)oxy)benzene⁴ were prepared by adaptation of literature procedures.

Instrumentation

¹H NMR, ¹³C {¹H} NMR, ¹⁹F {¹H} NMR and ²⁹Si {¹H} NMR spectra were recorded on either a Bruker Avance 300, 400 or III HD 400 MHz Spectrometer and chemical shifts are reported in parts per million (ppm). Spectra were recorded in benzene-d₆ or chloroform-d₁ with the residual solvent peak as the internal standard (¹H NMR: C₆H₆

$\delta = 7.16$; $\text{CHCl}_3 \delta = 7.26$, ^{13}C NMR: $\text{C}_6\text{H}_6 \delta 128.06$; $\text{CHCl}_3 \delta = 77.16$). Chemical shifts of ^{19}F $\{^1\text{H}\}$ NMR spectra were calibrated by 0.05% trifluorotoluene in C_6D_6 . Chemical shifts of ^{29}Si $\{^1\text{H}\}$ NMR spectra were calibrated by tris(Me_3Si)methane in CDCl_3 . The temperature was room temperature unless otherwise specified. Multiplicities are as indicated: s (singlet), d (doublet), dd (doublet of doublets), m (multiplet) and br (broad). Coupling constants, J, are reported in Hertz, and integration is provided.

Solid-state $^1\text{H} \rightarrow ^{29}\text{Si}$ and ^{13}C CPMAS spectra were recorded on a Bruker Ascend spectrometer (500 MHz) and chemical shifts were reported in parts per million (ppm). Chemical shifts of $^1\text{H} \rightarrow ^{29}\text{Si}$ CPMAS spectra were calibrated by silicone rubber. Chemical shifts of $^1\text{H} \rightarrow ^{13}\text{C}$ CPMAS spectra were calibrated by adamantane. In a glove box, 14 mg of polymer samples were packed into a sample rotor compatible with a 3.2 mm Phoenix HX probe. Spectral data was acquired at a spinning speed of 20 kHz.

All column chromatography was performed on a Teledyne ISCO Combiflash Rf+ using Redisep Rf silica columns. Fourier transformed infrared (FTIR) spectroscopy was performed on a Thermo NicoletNexus 670 FTIR spectrometer. Mass spectrometry and high-resolution mass spectrometry were performed in the Department of Chemistry at Johns Hopkins University using a VG Instruments VG70S/E magnetic sector mass spectrometer with electron ionization (EI) (70 eV). The samples for UV-vis spectroscopy were all prepared in the glove box and packed in sealed quartz cuvettes. UV-vis spectroscopy was performed on a Shimadzu UV-1800 UV-vis spectrophotometer. Molecular weights of polymers were measured by gel permeation chromatography (GPC) on a Tosoh Bioscience EcoSEC GPC workstation with UV detection at 254 nm using butylated hydroxytoluene stabilized tetrahydrofuran (THF) as the eluent (0.35 mL min^{-1}),

40 °C) through TSKgel SuperMultipore HZ-M guard column (4.6 mm ID x 2.0 cm, 4 µm, Tosoh Bioscience) and a TSKgel SuperMultipore HZ-M column (4.6 mm ID x 15 cm, 4 µm, Tosoh Bioscience). Polystyrene standards (EasiVial PS-M, Agilent) were used to build a calibration curve. Processing was performed using EcoSEC Data Analysis software (Version 1.14, Tosoh Bioscience). The samples were dissolved in THF (0.5 mg mL⁻¹), filtered through syringe filters (Millex-FG Syringe Filter Unit, 0.20 µm, PTFE, EMD Millipore), and injected by an auto-sampler (10 µL). Differential scanning calorimetry (DSC) was conducted using a TA Instruments DSC Q20 V24.11 Build 124 and processing was performed using Universal V4.5A (TA Instruments). Thermogravimetric analysis (TGA) was conducted using a TA Instruments SDT Q600 under flowing Ar at a heating rate of 5.0 °C min⁻¹ from 40 to 600 °C.

7.2 Effect of poly(cyclosilane) microstructure on thermal properties

Cp₂ZrMe₂ Synthesis of *lin*-poly(1,3Si₆)

In a nitrogen atmosphere glove box, Cp₂ZrMe₂ (0.056 equiv., 0.019 mmol, 4.8 mg) was added to an oven-dried 2-dram vial equipped with a stir bar. **1,3Si₆** (1.0 equiv., 0.34 mmol, 0.100 g) was added by syringe. The vial was sealed with a septum cap equipped with a vent needle. The mixture was stirred at room temperature in the glove box. After 24 hours, the stir bar was trapped in a dark red glass in the vial. The solid was dissolved in 10 mL of pentane and 0.5 grams of Celite was added. The solution was stirred for 2 hours. The Celite was filtered through a fritted funnel and washed with 5 mL of pentane. The filtrate was then concentrated to a yellow solid under vacuum. The procedure was repeated until a white solid was yielded, which indicated that the catalyst had been fully removed. The solid was further dried under vacuum at 60°C for 3 hours (85.8 mg, 87%).

Cp₂ZrMe₂ Synthesis of *cyc*-poly(1,3Si₆)

In a nitrogen atmosphere glove box, Cp₂ZrMe₂ (0.056 equiv., 0.019 mmol, 4.8 mg) was added to an oven-dried 2-dram vial equipped with a stir bar and dissolved by 0.5 mL of toluene. **1,3Si₆** (1.0 equiv., 0.34 mmol, 0.100 g) was weighed in a 1-dram vial and diluted by 0.5 mL of toluene. The solution of **1,3Si₆** was added dropwise to the 2-dram vial by syringe. 0.25 mL of toluene was used to rinse the vial and syringe, then added to the 2-dram vial as well. The 2-dram vial was sealed with a septum cap equipped with a vent needle. The mixture was stirred at room temperature in the glove box. After 24 hours, the reaction mixture turned yellow, and deep orange after 4 days. 7 days later, volatile materials were removed under vacuum and the residual solid was dissolved in 10 mL of pentane. 0.5 grams of Celite was added and the solution was stirred for 2 hours. The Celite was filtered

through a fritted funnel and washed with 5 mL of pentane. The filtrate was then concentrated to a yellow solid under vacuum. The procedure was repeated until a white solid was yielded, which indicated that the catalyst had been fully removed. The solid was further dried under vacuum at 60°C for 3 hours (83.4 mg, 85%).

NMR Spectra

Differential scanning calorimetry

Differential scanning calorimetry (DSC) was conducted using a TA Instruments DSC Q20 V24.11 Build 124 and processing was performed using Universal V4.5A (TA Instruments). Samples were sealed in hermetic aluminum pans, heated from 35 to 200 °C (3 °C min⁻¹ for *lin*-poly(**1,4Si₆**) and 20 °C min⁻¹ for *cyc*-poly(**1,3Si₆**) and *lin*-poly(**1,3Si₆**)), and cooled from 200 to 35 °C (3 °C min⁻¹), for three cycles under a purge gas of nitrogen (25 mL min⁻¹). Phase transition temperature were calculated from the second heating cycle. The second heating and cooling cycles are shown.

Computational Methods

All the DFT calculations are performed with the Gaussian 09 package.⁵ Geometries were optimized using the B3LYP functional with the 6-31G(d) basis. No symmetry restrictions were applied to geometry optimization. Homolytic bond dissociation energies (BDEs) are calculated as follows: $BDE = \sum E_{rs} - E_{cs}$, where $\sum E_{rs}$ is the sum of energy of all radical species, and E_{cs} is the energy of the closed shell species. Hydrogens in optimized structures are omitted for clarity.

7.3 Poly(cyclosilane) connectivity tunes optical absorbance

The synthesis of cyclosilane copolymers were investigated by Fan Fang in the Klausen group. The full structural characterization has been performed and published in the following reference: Fang, F.; Jiang, Q.; Klausen, R. S. *J. Am. Chem. Soc.* **2022**, 144, 17, 7834–7843.

All DFT calculations were performed using the Gaussian 09 package.⁵ Geometries were optimized using the B3LYP functional with the 6-31G(d) basis set employing tight optimization parameters and an ultrafine integration grid. No symmetry restrictions were applied to geometry optimizations. All optimized structures possess zero imaginary frequencies. TD-DFT calculations were performed using the PBE0 functional with the 6-311G(d) basis set on geometries optimized with the B3LYP functional. Coordinates of optimized structures can be found in the following reference: Fang, F.; Jiang, Q.; Klausen, R. S. *J. Am. Chem. Soc.* **2022**, 144, 17, 7834–7843.

7.4 Highly selective addition of cyclosilanes to alkynes enabling new conjugated materials

Hydrosilation of acetylenes with 1,4Si₆

Synthesis of 4.1a

In a glove box, an oven-dried scintillation vial with stir bar was charged with **1,4Si₆** (1.0 equiv., 1.71 mmol, 0.500 g) and RuHCl(CO)(PPh₃)₃ (0.2 equiv., 0.342 mmol, 0.325 g). DCM (10 mL) was added to dissolve the reagents. Phenylacetylene (2.5 equiv., 4.27 mmol, 0.47 mL) was added dropwise by syringe. After the addition was complete, the reaction mixture turned dark red and was stirred for 2 hours at room temperature. The solution was concentrated under vacuum, transferred to a silica gel cartridge, and then dried on it under vacuum. The cartridge was subjected to automated column chromatography with 100% hexanes to yield **4.1a** (dr 65:35 *trans*:*cis*) as a white solid (0.756 g, 89%).

Isolation of *trans*-**4.1a**: In a scintillation vial, 0.500 g of **4.1a** (dr 65:35 *trans*:*cis*) was dissolved in 3 mL of DCM and layered with 17 mL of dry methanol. The solution was allowed to sit overnight in a glove box and colorless crystals were found at the bottom. The mixture was filtered through a fritted funnel, washed with 5 mL of dry methanol and dried under vacuum. *trans*-**4.1a** (0.249 g, 77%) was collected as a colorless crystal. X-ray quality crystals were grown by liquid-liquid diffusion using THF as the solvent and methanol as the antisolvent.

Enrichment of *cis*-**1a**: The filtrate was dried under vacuum yielding a white solid. The solid was determined as enriched *cis*-**4.1a** (dr 25:75 *trans*:*cis*) through ¹H NMR spectroscopy.

Tabulated Characterization Data for 1a

Synthesis of **4.1b**

In a glove box, an oven-dried 2-dram vial with stir bar was charged with **1,4Si₆** (1.0 equiv., 0.342 mmol, 0.100 g) and RuHCl(CO)(PPh₃)₃ (0.2 equiv., 0.068 mmol, 0.0651 g). DCM (1 mL) was added to dissolve the reagents. 4-ethynylbromobenzene (2.5 equiv., 0.854 mmol, 0.155 g) was dissolved by 0.5 mL of DCM in a 1-dram vial and added dropwise into the reaction mixture by pipette. The vial was rinsed by 0.5 mL of DCM and the solution was added to the reaction as well. After the addition was complete, the reaction mixture turned dark red and was stirred for 2 hours at room temperature. The solution was transferred to a silica gel cartridge, and then dried on it under vacuum. The cartridge was subjected to automated column chromatography with 100% hexanes to yield **4.1b** (dr 65:35 *trans:cis*) as a white solid (0.179 g, 80%).

Isolation of *trans*-**4.1b**: In a scintillation vial, 0.500 g of **4.1b** (dr 65:35 *trans:cis*) was dissolved in 3 mL of DCM and layered with 17 mL of dry methanol. The solution was allowed to sit overnight in a glove box and colorless crystals were found at the bottom. The

mixture was filtered through a fritted funnel, washed with 5 mL of dry methanol and dried under vacuum. *trans*-**4.1b** (0.233 g, 72%) was collected as a colorless crystal.

Synthesis of **4.1h**

In a glove box, an oven-dried scintillation vial with stir bar was charged with **1,4Si₆** (1.0 equiv., 0.342 mmol, 0.100 g) and RuHCl(CO)(PPh₃)₃ (0.2 equiv., 0.068 mmol, 0.0651 g). DCM (1 mL) was added to dissolve the reagents. Methyl 4-ethynylbenzoate (2.5 equiv., 0.854 mmol, 0.137 g) was dissolved by 0.5 mL of DCM in a 1-dram vial and added dropwise into the reaction mixture by pipette. The vial was rinsed by 0.5 mL of DCM and the solution was added to the reaction as well. After the addition was complete, the reaction mixture turned dark red and was stirred for 2 hours at room temperature. The solution was transferred to a silica gel cartridge, and then dried on it under vacuum. The cartridge was

subjected to automated column chromatography with 85% hexanes/15% ethyl acetate to yield **4.1h** (dr 60:40 *trans:cis*) as a white solid (0.168 g, 80%).

Synthesis of **4.1j**

In a glove box, an oven-dried scintillation vial with stir bar was charged with **1,4Si₆** (1.0 equiv., 1.708 mmol, 0.500 g) and RuHCl(CO)(PPh₃)₃ (0.2 equiv., 0.342 mmol, 0.325 g). DCM (8 mL) was added to dissolve the reagents. 2-bromo-5-ethynylthiophene (2.5 equiv., 4.269 mmol, 0.799 g) was diluted by 1 mL of DCM in a 1-dram vial and added dropwise into the reaction mixture by pipette. The vial was rinsed by 1 mL of DCM and the solution was added to the reaction as well. After the addition was complete, the reaction mixture turned dark red and was stirred for 30 minutes at room temperature. The solution was concentrated under vacuum, transferred to a silica gel cartridge, and then dried on it under vacuum. The cartridge was subjected to automated column chromatography with 100% hexanes to yield **4.1j** (dr 63:37 *trans:cis*) as a white solid (0.849 g, 75%).

Isolation of *trans*-4.1j: In a scintillation vial, 0.500 g of **4.1j** (dr 63:37 *trans:cis*) was dissolved in 2 mL of DCM and layered with 18 mL of dry methanol. The solution was allowed to sit overnight in a glove box and colorless crystals were found at the bottom. The mixture was filtered through a fritted funnel, washed with 5 mL of dry methanol and dried under vacuum. *trans*-**4.1j** (dr 90:10 *trans:cis*) (0.270 g, 83%) was collected as a colorless crystal. X-ray quality crystals were grown by liquid-liquid diffusion using THF as the solvent and methanol as the antisolvent.

Model reaction: Kumada cross-coupling of 4.1j and 2-bromothiophene

In a glove box, an oven-dried 2-dram vial with stir bar was charged with *trans*-**4.1j** (dr 90:10 *trans:cis*) (1.0 equiv., 0.075 mmol, 50.0 mg) and THF (1.0 mL). *i*-PrMgCl (2.0 M in THF) (75 μ L) was added by micro syringe. The solution was stirred at room

temperature for 30 minutes, yielding a di-Grignard intermediate. NidpppCl₂ (0.1 equiv., 0.007 mmol, 4.1 mg), triphenylphosphine (0.2 equiv., 0.014 mmol, 3.9 mg) and 2-bromothiophene (2.5 equiv., 0.187 mmol, 30.6 mg) were weighed in a 2-dram vial with stir bar and dissolved in THF (1.0 mL). The di-Grignard solution was quickly added to the reaction mixture by pipette, yielding a dark red solution. 0.5 mL of THF was used to rinse the vial and combined with the reaction mixture. The reaction was heated to 40 °C and allowed to stir for 24 hours in a glove box. The solution turned bright orange after 16 hours.

The reaction was cooled to room temperature and quenched by 0.1 mL of dry methanol. The solution was transferred to a silica gel cartridge, and then dried on it under vacuum. The cartridge was subjected to automated column chromatography with 100% hexanes to yield *trans*-**4.1k** (dr 90:10 *trans:cis*) as a yellow solid (43.5 mg, 86%).

Tabulated Characterization Data for trans-4.1k

δ_{H} (400 MHz, C ₆ D ₆)	7.21 (d, J = 18.3 Hz, 2H, vinyl), 6.98 (d, J = 3.6 Hz, 2H, thienyl), 6.84 (d, J = 3.7 Hz, 2H, thienyl), 6.69 (d, J = 5.2 Hz, 2H, thienyl), 6.65 – 6.58 (m, 2H, thienyl), 6.55 (d, J = 3.8 Hz, 2H, thienyl), 6.42 (dd, J = 18.4, 5.5 Hz, 2H, vinyl), 4.12 (d, J = 5.6 Hz, 2H, SiH), 0.39 (s, 12H, -CH ₃), 0.38 (s, 12H, (thienyl)H ₃).

Synthesis of P4.1 via Kumada Polycondensation

In a glove box, an oven-dried 2-dram vial with stir bar was charged with **4.1j** (dr 90:10 *trans:cis*) (1.0 equiv., 0.075 mmol, 50.0 mg) and THF (1.0 mL). *i*-PrMgCl (2.0 M in THF) (75 μ L) was added by micro syringe. The solution was stirred at room temperature for 30 minutes, yielding a di-Grignard intermediate. 0.1 mL of reaction mixture was taken as an aliquot, quenched by methanol and dried under vacuum. The clean ^1H NMR spectrum of the quenched intermediate showed a full conversion of the starting cyclosilane. Ni(dppp)Cl_2 (0.1 equiv., 0.007 mmol, 4.1 mg), triphenylphosphine (0.2 equiv., 0.014 mmol, 3.9 mg) and 2,5-dibromothiophene (1.5 equiv., 0.112 mmol, 27.2 mg) were weighed in a 2-dram vial with stir bar and dissolved in THF (1.0 mL). The di-Grignard solution was quickly added to the reaction mixture by pipette, yielding a dark red solution. 0.5 mL of THF was used to rinse the vial and combined with the reaction mixture. The reaction was heated to 40 $^\circ\text{C}$ and allowed to stir for 24 hours in a glove box. The solution turned bright orange after 16 hours.

After 24 hours, the reaction was quenched by adding the orange solution dropwise to 15 mL of dry methanol in a scintillation vial. Formation of orange precipitates was observed. The suspension was allowed to sit overnight, and the top clear yellow solution was removed. 10 mL of methanol were added, and precipitates were washed sufficiently by shaking the vial. The suspension was allowed to sit until the precipitates settled at the bottom. The above washing procedure was repeated 2 more times. Then the suspension

was filtered through a Buchner funnel and the solid was dried under vacuum, yielding an orange powder (36.8 mg, 80%).

Tabulated Characterization Data for **P4.1**

δ_{H} (400 MHz, CDCl_3)	7.03 (br, 4H, vinyl and thienyl), 6.82 (br, 2H, thienyl), 6.14 (br, 2H, vinyl), 3.77 (br, 2H, SiH), 0.31 (br, 24H, $-\text{CH}_3$).

Synthesis of **P4.2** via Kumada Polycondensation

In a glove box, an oven-dried 2-dram vial with stir bar was charged with **4.1j** (dr 90:10 *trans:cis*) (1.0 equiv., 0.075 mmol, 50.0 mg) and THF (1.0 mL). *i*-PrMgCl (2.0 M in THF) (75 μL) was added by micro syringe. The solution was stirred at room temperature for 30 minutes, yielding a di-Grignard intermediate. NidpppCl_2 (0.1 equiv., 0.007 mmol, 4.1 mg), triphenylphosphine (0.2 equiv., 0.014 mmol, 3.9 mg) and *trans*-**4.1b** (1.1 equiv., 0.082 mmol, 54.0 mg) were weighed in a 2-dram vial with stir bar and dissolved in THF (1.0 mL). The di-Grignard solution was quickly added to the reaction mixture by pipette,

yielding a dark red solution. 0.5 mL of THF was used to rinse the vial and combined with the reaction mixture. The reaction was heated to 40 °C and allowed to stir for 24 hours in a glove box. The solution turned dark red after 16 hours.

After 24 hours, the reaction was quenched by adding the orange solution dropwise to 15 mL of dry methanol in a scintillation vial. Formation of orange precipitates was observed. The suspension was allowed to sit overnight, and the top clear yellow solution was removed. 10 mL of methanol were added, and precipitates were washed sufficiently by shaking the vial. The suspension was allowed to sit until the precipitates settled at the bottom. The above washing procedure was repeated 2 more times. Then the suspension was filtered through a Buchner funnel and the solid was dried under vacuum, yielding a yellow powder (46.7 mg, 60%). Solid-state $^1\text{H}\rightarrow^{29}\text{Si}$ and ^{13}C CPMAS spectra were recorded for its low solubility in CDCl_3 . The broadness of peaks arises from the residual Ni catalyst.

Tabulated Characterization Data for P4.2

Single Crystal X-Ray Crystallography

All reflection intensities were measured either at 110(2) K for **4.1a**, **4.1e** and **4.1j** or at 173 K for **4.3a** using a SuperNova diffractometer (equipped with Atlas detector) either with Mo $K\alpha$ radiation ($\lambda = 0.71073 \text{ \AA}$) for **4.1a** and **4.1j** or with Cu $K\alpha$ radiation ($\lambda = 1.54178 \text{ \AA}$) for **4.1e** and **4.3a** under the program CrysAlisPro (Version CrysAlisPro 1.171.39.29c, Rigaku OD, 2017). The same program was used to refine the cell dimensions and for data reduction. The structure was solved with the program SHELXS-2018/3 (Sheldrick, 2018) and was refined on F^2 with SHELXL-2018/3 (Sheldrick, 2018). Numerical absorption correction based on gaussian integration over a multifaceted crystal model was applied using CrysAlisPro for **4.1a** and **4.1j**. Analytical numeric absorption correction using a multifaceted crystal was applied using CrysAlisPro for **4.1e** and **4.3a**. The temperature of the data collection was controlled using the system Cryojet (manufactured by Oxford Instruments). The H atoms were placed at calculated positions (unless otherwise specified) using the instructions AFIX 43 or AFIX 137 with isotropic displacement parameters having values 1.2 or 1.5 U_{eq} of the attached C atoms.

4.1a: The H atoms attached to Si1, Si4 and Si7 were found from difference Fourier maps, and their coordinates were refined freely. The structure is ordered. The asymmetric unit contains $1 + \frac{1}{2}$ crystallographically independent molecules. One of the two molecules is found at one site of inversion symmetry, and thus only one half is crystallographically independent.

4.1e/4.1j: The H atom attached to Si1 was found from difference Fourier map, and its coordinates were refined freely. The structure is ordered. The asymmetric unit contains ½ crystallographically independent molecule as it is found at one site of inversion symmetry.

4.3a: Some crystals were initially flashcooled from room temperature to 110 K, but these crystals cracked and the diffraction pattern was not of great quality. Another crystal was flashcooled from room temperature to 173 K, and the diffraction pattern was consistent with that of a single crystal. The H atoms attached to Si1, Si8, Si11 and Si18 were found from difference Fourier maps, and their coordinates were refined pseudofreely using the DFIX instruction in order to keep the Si–H within an acceptable range. The asymmetric unit contains two crystallographically independent molecules of the target compound. The C1A→C8A fragment is disordered over two orientations, and the occupancy factor of the major component of the disorder refines to 0.836(7).

Computational methods

All DFT calculations were performed using the Gaussian 09 package.⁵ Geometries were optimized using the B3LYP functional with the 6-31G(d) basis set starting from the crystal structure employing tight optimization parameters and an ultrafine integration grid. No symmetry restrictions were applied to geometry optimizations. Frequency calculations carried out at the same level of theory on fully optimized geometries showed no imaginary frequencies, confirming optimized geometries as local minima on their potential surfaces. Energy calculations carried out at the same level of theory and visualization of optimized geometries and molecular orbitals were performed using GaussView 5.0.9. Coordinates of the optimized structure can be found in the following reference: Jiang, Q.; Gittens, A. F.; Wong, S.; Siegler, M. A.; Klausen, R. S. *Chem. Sci.* **2022**, *13*, 7587–7593.

7.5 Conjugation in isomeric cyclosilane thioethers

The synthesis of cyclosilane thioethers were investigated by Alex Gittens in the Klausen group. The full structural characterization has been performed and published in the following reference: Gittens, A. F.; Jiang, Q.; Siegler, M. A.; Klausen, R. S. *Organometallics* **2022**, 41, 23, 3762–3769.

All the DFT calculations are performed with the Gaussian 16 package.⁶ Geometry optimizations and energy calculations were carried out using the B3LYP functional with the 6-311G(d) basis. No symmetry restrictions were applied to geometry optimization. Crystal structures were used as starting geometries on chair-**5.1a** and twist-**5.2a**. All optimized structures possess zero imaginary frequencies. TD-DFT calculations were carried out with the PBE0 function with the 6-311G(d) basis. Numbers of states were set as 50. Molecular orbitals were visualized in GaussView 5.0. with isovalue=0.02. Coordinates of optimized structures can be found in the following reference: Gittens, A. F.; Jiang, Q.; Siegler, M. A.; Klausen, R. S. *Organometallics* **2022**, 41, 23, 3762–3769.

Excitation energies and oscillator strengths:

Excited state symmetry could not be determined.

Excited State 1: Singlet-?Sym 4.5987 eV 269.61 nm f=0.0000 <S**2>=0.000
 205 -> 211 0.11877
 207 -> 210 -0.15702
 207 -> 211 0.12911
 208 -> 209 0.63262

This state for optimization and/or second-order correction.

Total Energy, E(TD-HF/TD-DFT) = -4730.34793303

Copying the excited state density for this state as the 1-particle RhoCI density.

Excited state symmetry could not be determined.

Excited State 2: Singlet-?Sym 4.6173 eV 268.52 nm f=0.2817 <S**2>=0.000
 205 -> 209 -0.33976
 206 -> 211 0.10991
 207 -> 209 -0.12981
 207 -> 212 -0.10948
 208 -> 210 0.54472

Excited state symmetry could not be determined.

Excited State 3: Singlet-?Sym 4.6681 eV 265.60 nm f=0.1088 <S**2>=0.000
 207 -> 209 0.60888
 207 -> 212 -0.11943
 208 -> 210 0.10276
 208 -> 211 0.23154

Excited state symmetry could not be determined.

Excited State 4: Singlet-?Sym 4.6961 eV 264.02 nm f=0.0000 <S**2>=0.000
 205 -> 210 0.36089

205 -> 211 -0.12405
206 -> 209 0.45815
207 -> 210 0.14853
207 -> 211 0.14714
208 -> 209 0.13322
208 -> 212 -0.17530

Excited state symmetry could not be determined.

Excited State 5: Singlet-?Sym 4.7163 eV 262.89 nm f=0.0000 <S**2>=0.000

204 -> 210 0.13179
205 -> 210 -0.36273
206 -> 212 -0.16582
207 -> 210 0.50611
208 -> 212 -0.11838

Excited state symmetry could not be determined.

Excited State 6: Singlet-?Sym 4.7692 eV 259.97 nm f=0.1781 <S**2>=0.000

203 -> 210 0.11812
205 -> 209 0.33782
205 -> 212 0.11657
206 -> 210 0.46117
207 -> 212 -0.12263
208 -> 210 0.28054

Excited state symmetry could not be determined.

Excited State 7: Singlet-?Sym 4.8022 eV 258.18 nm f=0.0553 <S**2>=0.000

205 -> 209 0.40850
205 -> 212 -0.21964
206 -> 210 -0.38048
206 -> 211 -0.15719
208 -> 210 0.21358

Excited state symmetry could not be determined.

Excited State 8: Singlet-?Sym 4.8209 eV 257.18 nm f=0.0000 <S**2>=0.000

205 -> 210 -0.32620
205 -> 211 -0.10600

7.6 Impact of stereoregularity on hybrid conjugated polymers

Isolation of *trans*-6.1 and *cis*-6.1

In a scintillation vial, 0.500 g of **6.1** (dr 63:37 *trans*:*cis*) was dissolved in 2 mL of DCM and layered with 18 mL of dry methanol. The solution was allowed to sit overnight in a glove box and colorless crystals were found at the bottom. The mixture was filtered through a fritted funnel, washed with 5 mL of dry methanol and dried under vacuum. *trans*-**6.1** (dr 90:10 *trans*:*cis*) (0.270 g) was collected as a colorless crystal. The filtrate was collected and dried under vacuum, yielding a white powder *cis*-**6.1** (dr 20:80 *trans*:*cis*) (0.178 g).

Synthesis of **6.2**

In a glove box, an oven-dried 2-dram vial with stir bar was charged with 1,1,2,2-tetramethyldisilane (1.0 equiv., 0.845 mmol, 0.100 g) and $\text{RuHCl(CO)(PPh}_3)_3$ (0.2 equiv., 0.169 mmol, 0.161 g). Toluene (2.5 mL) was added to dissolve the reagents. 2-bromo-5-ethynylthiophene (4 equiv., 3.38 mmol, 0.632 g) was diluted by 1 mL of toluene in a 1-dram vial and added dropwise into the reaction mixture by pipette. The vial was rinsed by 0.5 mL of toluene and the solution was added to the reaction as well. After the addition was complete, the reaction mixture turned dark red and was stirred for 24 hours at room temperature. The solution was concentrated under vacuum, transferred to a silica gel cartridge, and then dried on it under vacuum. The cartridge was subjected to automated

column chromatography with 100% hexanes to yield **6.2** as a pale-yellow oil (0.272 g, 65%).

Tabulated Characterization Data for 6.2

δ_{H} (400 MHz, CDCl_3)	6.93 (d, $J = 3.8$ Hz, 2H, thienyl), 6.78 (d, $J = 18.7$ Hz, 2H, vinyl), 6.68 ($J = 3.8$ Hz, 2H, thienyl), 6.14 (d, $J = 18.7$, 2H, vinyl), 0.22 (s, 12H, $-\text{CH}_3$).
δ_{C} (101 MHz, CDCl_3)	147.02 (vinyl), 136.01 (thienyl), 130.50 (thienyl), 128.67 (thienyl), 125.64 (thienyl), 111.92 (vinyl), -3.99 ($-\text{CH}_3$).
δ_{Si} (79 MHz, CDCl_3)	-23.80 (SiMe_2)

Synthesis of 6.3

The procedure was adapted for literature.⁷ On the Schlenk line, an oven-dried 100 mL Schlenk flask with a stir bar was charged with 2,5-dibromothiophene (1.0 equiv., 8.27 mmol, 2.00 g). Diethyl ether (50 mL) was added and the solution was cooled to $-78\text{ }^\circ\text{C}$ in an acetone/dry ice bath. With syringe pump, $i\text{-PrMgCl}$ (2 M in THF, 4.13 mL) was slowly added in 30 minutes, and the reaction mixture was stirred for another 30 minutes. White precipitates were observed during the addition. 1,2-dichloro-1,1,2,2-tetramethyldisilane (0.5 equiv., 4.13 mmol, 0.774 g) was then added through syringe. The reaction mixture was allowed to warm up to room temperature and stirred for 24 hours. The reaction was quenched with 50 mL of DI water. The aqueous layer was separated with the organic layer and washed with diethyl ether (50 mL x 3). All the organic layers were combined, dried over anhydrous magnesium sulfate, concentrated under vacuum and purified by silica column with 100 % hexanes. A white solid was isolated as **6.3** (3.25 g, 89%). NMR spectra were consistent with the literature.

General procedure of Kumada polycondensation using di(bromothieryl)silane and aryl dibromide building blocks

In a glove box, an oven-dried 2-dram vial with stir bar was charged with di(bromothieryl)silane (1.0 equiv) and THF (2 mL). *i*-PrMgCl (2.0 M in THF, 2.0 equiv.) was added by micro syringe. The solution was stirred at room temperature for 30 minutes, yielding a di-Grignard intermediate. Ni(dppp)Cl₂ (0.1 equiv.), triphenylphosphine (0.2 equiv) and aryl dibromide (1.5 equiv.) were weighed in a 2-dram vial with stir bar and dissolved in THF. The di-Grignard solution was quickly added to the reaction mixture by pipette, yielding a dark red solution. 0.5 mL of THF was used to rinse the vial and combined with the reaction mixture. The reaction was heated to 40 °C and allowed to stir for 24 hours in a glove box.

After 24 hours, the reaction was quenched by adding the orange solution dropwise to 15 mL of dry methanol, which was stirred fast in a round bottom flask. Formation of precipitates was observed. The suspension was allowed to sit overnight, and the top clear yellow solution was removed. 10 mL of methanol were added, and precipitates were washed sufficiently by stirring vigorously for 30 minutes. The suspension was allowed to sit until the precipitates settled at the bottom. The above washing procedure was repeated 2 more times. Then the suspension was filtered through a Buchner funnel. The solid was washed with methanol and dried under vacuum, yielding hybrid polysilane products.

Synthesis of P6.2: The polycondensation was set up at the scale of 0.150 mmol with *cis*-**6.1** (dr 20:80 *trans*:*cis*) and 2,5-dibromothiophene. Yield: 67.2 mg, 73%.

Synthesis of P6.3: The polycondensation was set up at the scale of 0.150 mmol with **6.1** (dr 65:35 *trans:cis*) and 2,5-dibromothiophene. Yield: 57.9 mg, 63%.

Synthesis of P6.4: The polycondensation was set up at the scale of 0.203 mmol with **6.2** and 2,5-dibromothiophene. Yield: 50.5 mg, 61%.

Synthesis of P6.5: The polycondensation was set up at the scale of 0.227 mmol with **6.3** and 2,5-dibromothiophene. Yield: 59.2 mg, 70%.

Synthesis of P6.6: The polycondensation was set up at the scale of 0.150 mmol with *trans*-**6.1** (dr 90:10 *trans:cis*) and 1,4-dibromo-2,5-((2-ethylhexyl)oxy)benzene. Yield: 90.9 mg, 72%.

Synthesis of P6.7: The polycondensation was set up at the scale of 0.150 mmol with *cis*-**6.1** (dr 20:80 *trans:cis*) and 1,4-dibromo-2,5-((2-ethylhexyl)oxy)benzene. Yield: 85.8 mg, 68%.

Synthesis of P6.8: The polycondensation was set up at the scale of 0.510 mmol with **6.1** (dr 65:35 *trans:cis*) and 1,4-dibromo-2,5-((2-ethylhexyl)oxy)benzene. Yield: 70.7 mg, 56%.

Chapter 8: Curriculum vitae

Education

- 2017 to 2023 **Johns Hopkins University, Baltimore, MD**
Department of Chemistry
Ph.D. in Chemistry, with Prof. Rebekka S. Klausen
- 2013 to 2017 **Nanjing University, Nanjing, P.R. China**
School of Chemistry & Chemical Engineering
B.S. in Chemistry, research with Prof. Qun-dong Shen

Honors & Awards

- 2022, Outstanding Poster Award of TPC2022, Second Place.
- 2022, Harry and Cleio Greer Fellowship, awarded to an outstanding advanced-year graduate student.
- 2022, Dissertation Completion Fellowship of Johns Hopkins University.
- 2017, Excellent Undergraduate Thesis of Nanjing University, 3 awardees from School of Chemistry & Chemical Engineering per year.
Thesis Title: New Bionic and Implantable Electronic Devices Based on Ferroelectric Polymer
- 2017, Chemistry Experiment Award in School of Chemistry & Chemical Engineering of Nanjing University, 3 awardees per year.

Teaching & Mentoring Experience

- *NMR Teaching Assistant*, Department of Chemistry, Johns Hopkins University, 2021 to 2023
- *Teaching Assistant*, Department of Chemistry, Johns Hopkins University
 - Advanced Organic Synthesis I (030.677), Fall 2019
 - Organic Chemistry II (030.206), Spring 2019
 - The Science of Color (030.118), Fall 2018
 - Introductory Chemistry (Lecture and Lab) II (030.102), Spring 2018
 - Introductory Chemistry (Lecture and Lab) I (030.101), Fall 2017
- *Mentoring Undergraduate Researchers*
 - First-generation Undergraduate Research Experience (FiGURE), Intersession 2022
 - Provost’s Undergraduate Research Award (Summer PURA program), Summer 2021
