Abstract

Background: Currently, there are no specific medical treatments for intracerebral haemorrhage (ICH), but the inflammatory response may provide a potential route to treatment. Given the known effects of acute brain injury on peripheral immunity, we hypothesised that inflammatory biomarkers in peripheral blood may be associated with clinical outcome following ICH, as well as perihæmatomal oedema (PHO), which is an imaging marker of the neuroinflammatory response.

Methods: We searched OVID Medline and EMBASE on 07 April 2021 for studies of humans with ICH measuring an inflammatory biomarker in peripheral blood and PHO or clinical outcome. Risk of bias was assessed using a scale comprising features of the Newcastle-Ottawa Assessment Scale, STROBE-ME and REMARK guidelines. We used random effects meta-analysis to pool standardised mean differences (SMD) if ≥ 1 study quantified the association between identical biomarkers and measures of PHO or functional outcome.

Results: Of 8,615 publications, 16 examined associations between 21 inflammatory biomarkers and PHO ($n=1,299$ participants), and 93 studies examined associations between ≥ 1 biomarker and clinical outcome ($n=17,702$ participants). Overall, 20 studies of nine biomarkers ($n=3,199$) met criteria for meta-analysis of associations between inflammatory biomarkers and clinical outcome. Death or dependency (modified Rankin Scale (mRS) 3–6) 90 days after ICH was

associated with higher levels of C-reactive protein (CRP) (SMD 0.80; 95%CI [0.44, 1.17]; $p < 0.0001$), fibrinogen (SMD 0.32; 95%CI [0.04, 0.61]; $p = 0.025$), white blood cell (WBC) count (SMD 0.27; 95%CI [0.11, 0.44]; $p = 0.001$) and high mobility group box protein 1 (HMGB1) (SMD 1.67; 95%CI [0.05, 3.30]; $p = 0.04$).

Conclusions: Higher circulating levels of WBC, CRP, fibrinogen and HMGB1 are associated with poorer outcomes after ICH. This study highlights the clinical importance of the inflammatory response to ICH and identifies additional research needs in determining if these associations are mediated *via* PHO and are potential therapeutic targets.

Introduction

Spontaneous intracerebral haemorrhage (ICH) accounts for 16–30% of all stroke cases¹. Overall, 40% of patients die within one month after ICH with only 12–39% living independently after six months². There are currently no specific medical treatments that have proven benefit to improve outcome³.

There is growing interest in the inflammatory reaction after ICH since it may be a therapeutic target⁴. Perihematomal oedema (PHO) is thought to be an imaging biomarker of the neuroinflammatory response⁵. Inflammatory biomarkers are highly expressed in human brain tissue following ICH⁶ and several ongoing clinical trials are targeting the immune system⁷. In animal models, local and recruited immune cells release inflammatory mediators (*e.g.*, cytokines, matrix-metalloproteinases (MMPs), and damage associated molecular patterns (DAMPs)) that contribute to brain damage and repair⁸. Various immunomodulatory treatments have been shown to improve outcome in preclinical models of ICH⁹. In humans, stroke-induced changes to the peripheral immune system are associated with the development of sequelae. Circulating immune cell characteristics are associated with trajectory of post-stroke cognitive impairment¹⁰ and fewer circulating leukocytes are associated with infection following ICH¹¹. Since PHO is an imaging marker of neuroinflammatory response, we hypothesised that circulating inflammatory biomarkers associated with clinical outcome should also be associated with measures of PHO.

We therefore conducted a systematic review and meta-analysis of associations between circulating inflammatory biomarkers and either PHO or functional outcome after ICH. We believe this is the first systematic review and meta-analysis that has assessed the relationship between inflammatory biomarkers and PHO and/or functional outcome after ICH without restriction based on pre-specified biomarkers. We aimed to (i) identify all studies examining associations between one or more blood-based biomarker and PHO or functional outcome after ICH, (ii) quantify pooled associations between individual biomarkers and PHO or outcome where possible, and (iii) determine whether study-level variables modified any of these associations.

Methods

We performed a systematic review and meta-analysis. The study protocol was pre-registered with the International prospective register of systematic reviews (PROSPERO; [CRD42019132628](https://doi.org/10.1186/1745-7246-28-28); 28 May 2019). This systematic review is reported in line with the PRISMA guidelines¹².

Search strategy and study selection

CK searched Ovid MEDLINE (1946) (RRID:SCR_002185) and Ovid EMBASE (1974) (RRID:SCR_001650) on 07 April 2021 using a prespecified search strategy that consisted of terms to identify studies that measured inflammatory markers in the blood of ICH patients and assessed functional outcome and/or PHO (Supplemental Information 1, available as *Extended data*¹³). The search was not limited by language or publication date. After de-duplication, three authors (CK, LS,

JB) independently screened titles and abstracts to identify potentially eligible studies and read the full text of articles that were potentially eligible for inclusion. Corresponding authors were contacted if full-text articles could not be obtained. A third independent reviewer (FHBMS, JL or NS) made the final decision over inclusion when conflicts arose at the abstract or full-text screening stage ([Figure 1](#)).

Eligibility criteria

We included observational studies of ≥ 5 adults (≥ 16 years of age) with spontaneous ICH where inflammatory markers were measured in the blood, serum or plasma. We selected biomarkers if they were a marker (*e.g.*, C-reactive protein) or a mediator (*e.g.*, cytokines) of the inflammatory response and grouped the inflammatory biomarkers into six categories based on broad biological activity¹⁴: immune cells, acute phase reactants, cytokines/chemokines, damage-associated molecular patterns (DAMPs), tissue remodelling factors and adhesion molecules. We excluded: 1) studies of ICH due to an underlying macrovascular cause, traumatic ICH, ICH due to hereditary cerebral amyloid angiopathy or studies of ICH with mixed causes, 2) stroke cohorts where spontaneous ICH cases could not be separated from non-ICH cases, 3) studies including surgically treated patients that could not be separated from non-surgically treated cases, 4) conference abstracts, systematic or narrative reviews. Where studies had overlapping cohorts, the study with the largest cohort was included.

Data extraction

A minimum dataset (the biomarker, outcome definition, time point of biomarker and outcome measurement, measure of association between biomarker and outcome and risk of bias) was extracted from all included studies by one reviewer (CK, JB or NS) and is summarized in a narrative synthesis (Supplemental Table 1, *Extended data*¹³). Two authors (CK, JB, or NS) used a standardized proforma to independently extract data from all studies included in meta-analysis (Supplemental Information 2¹³). Conflicts were arbitrated by a third reviewer (JB, NS). As the included studies were mostly case series with no control group, risk of bias was assessed using an eight-item composite scale comprising features of the Newcastle-Ottawa Assessment Scale¹⁵ (case definition, representativeness of the cases), STROBE-ME¹⁶ and REMARK¹⁷ guidelines. The assessment assigned points for features indicating a high risk of bias, ranging from 0 (no risk of bias) to 8 (high risk of bias) (Supplemental Information 3 in *Extended data*¹³).

Meta-analysis

We undertook a meta-analysis of associations between a biomarker and outcome if (i) the same biomarker was assessed in ≥ 2 studies, (ii) means/medians (and errors) of biomarkers were reported and (iii) the same outcome measure was reported between studies at the same time point after ICH onset. We used the *metafor* (RRID:SCR_003450) (version 3.0-2) and *tidyverse* (RRID:SCR_019186) packages in R Project for Statistical Computing (RRID:SCR_001905) (version 3.6.3)¹⁸. Median and range were first converted to

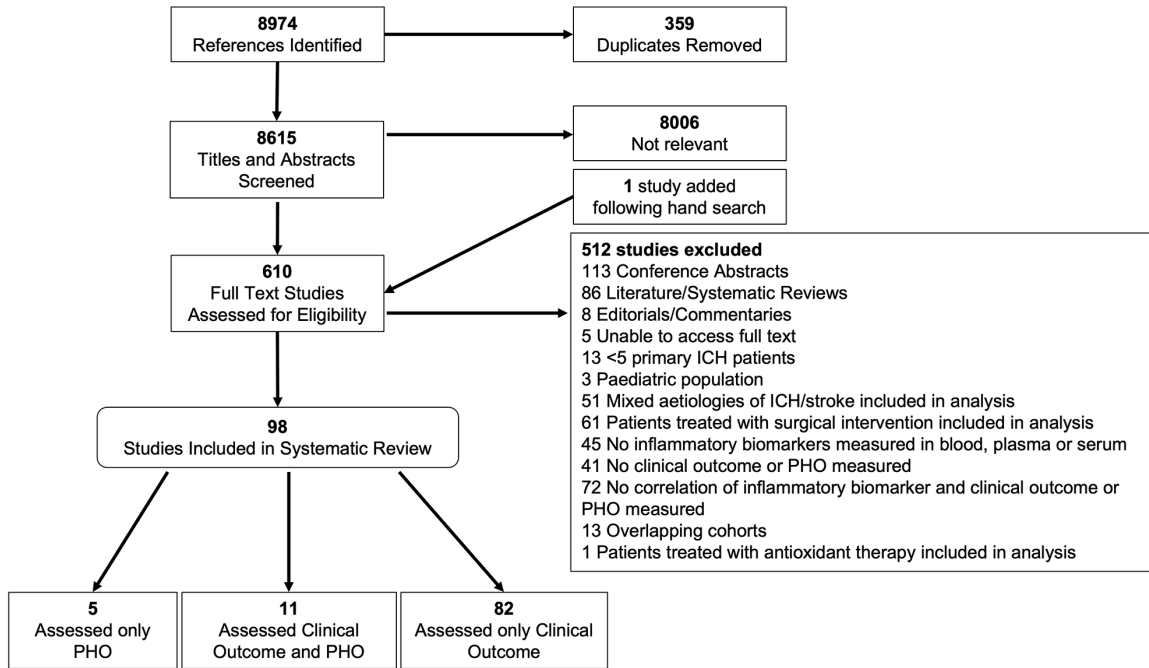

Figure 1. Flow diagram of study selection for inclusion in systematic review and meta-analysis including the rationale for exclusion. PHO, perihematoma oedema; ICH, intracerebral haemorrhage.

mean and standard deviation based on previously published methods¹⁹. We then calculated individual standardized mean differences (SMDs) before estimating inter-study variability (τ^2) using a restricted maximum likelihood random-effects model, generating a summary standardized mean difference. We assessed heterogeneity using the Higgins' I^2 statistic and Q statistics. Where more than three studies were included in meta-analysis, we evaluated outliers both graphically²⁰ and *via* influence diagnostics²¹ and sensitivity was assessed by leave-one-out analysis. Publication bias was evaluated graphically with funnel plots and Egger's regression test²² where more than three studies were included in meta-analysis. If more than 10 studies were included in a meta-analysis, we used meta-regression to evaluate the influence of the pre-defined moderators ICH volume and age on the observed model variances. If more than 10 studies were included in meta-analysis, studies were stratified into high-quality (0–1 risk of bias score) and low quality (≥ 2 risk of bias score) and sub-group analysis performed to determine the impact of study quality on summary estimates. I^2 values of 0–39% were considered small, 40–69% moderate and 70–100% high. The code to reproduce the meta-analysis can be found at *Extended data*²³.

Results

Our search yielded 8,794 articles, of which 8,615 were unique. In total, 98 studies of 50 unique inflammatory biomarkers in 18,000 participants were included in our narrative synthesis, of which 93 ($n=17,702$ participants) examined the association between at least one biomarker and clinical outcome. Overall, 11 of these also examined PHO ($n=1,001$ participants). Five studies ($n=298$) examined an association between biomarkers and PHO alone (Figure 1).

From all 98 included studies, 85 (87%) studies reported biomarker levels on admission or within 24 hours from ICH onset, of which 13 (15%) also reported biomarkers at later time points. A total of 12 (12%) studies only reported biomarker levels at later time points ranging from <48 hours to 30 days after ICH onset, and one study did not report biomarker time point. Overall, 37 (38%) studies reported on a single biomarker, and the remainder reported on two biomarkers ($n=21$, 21%), three biomarkers ($n=14$, 14%) or four or more biomarkers ($n=26$, 27%).

Narrative synthesis of the associations between inflammatory biomarkers and perihematoma oedema

In total, 16 studies^{24–39} of 1,299 participants assessed the relationship between 21 inflammatory biomarkers and PHO (14 by CT, two by MRI) (Table 1; participant characteristics listed in Supplemental Table 2¹³). The median risk of bias was 2 [0–3]. Due to broad heterogeneity in the method and timing of PHO measurements between studies coupled with variation in the ways in which studies assessed the relationship between a given biomarker and PHO, we could not perform a meta-analysis of the association between inflammatory mediators and PHO. Therefore, what follows is a narrative synthesis of all published articles that analysed the association between one or more inflammatory biomarkers and PHO (Table 1).

The most frequently measured biomarker was MMP-9, which was assessed in five studies (CT $n=4^{31–34}$, MRI $n=1^{25}$; $n=225$), three^{32–34} of which found that MMP-9 levels were positively associated with PHO volume in univariate analyses only. MMP-2³⁴ and MMP-8³¹ were positively associated with absolute PHO volume. Comparisons of MMP-3

*Variables included in multivariate analysis:

*1: Abilleira (2003): ICH volume, MMP-9, Canadian stroke scale score, smoking, chronic alcoholism

*2: Bakhshayesh (2014): variables not stated

*3: Castillo (2002): admission Canadian stroke scale score, temperature, ICAM-1, IL-6, IL-10, glutamate

*4: Fonseca (2021): ICH volume, presence of infection

*5: Gusdon (2017): ICH Volume, intraventricular extension, EVD use, GCS

*6: Volbers (2018): ICH volume, age, haematoma location

*7 Li (2013): ICH volume, age, gender

** narrative only

and PHO were inconsistent with one study finding no association³¹ and one study showing a positive association²⁵. TIMP-1 was not associated with PHO in two studies^{32,34}, but had an inverse association with PHO volume in one³³.

Higher levels of ferritin were associated with PHO growth²⁹, relative³⁷, or absolute PHO volume²⁶. CRP had no association with midline shift and was not measured by any other method²⁸. White blood cell (WBC) count had no association with relative PHO volume^{36,37,39}, whereas neutrophil count and neutrophil-to-lymphocyte ratio (NLR) had a positive correlation with midline shift after adjusting for ICH volume and infection²⁸. NLR was positively correlated with PHO in three studies^{27,35,36}.

IL-4 and IL-10 were positively associated with absolute PHO in one of two studies³⁸. IL-6 was associated with absolute PHO volume in two studies^{30,38} and TNF α was associated with absolute volume in univariate but not multivariate analyses³⁰.

Adhesion molecules ICAM1 and VCAM1 were not associated with absolute PHO volume in multivariate analyses³⁰.

Meta-analysis of the association between inflammatory biomarkers and clinical outcome

From 93 studies examining the association between inflammatory biomarkers and clinical outcome after ICH, the median risk of bias was two [1–3]. The most commonly reported outcome measure was the modified Rankin scale (mRS) (n=59, 63%) and the most frequent time point for outcome ascertainment was 90 days (n=41, 44%) (Supplemental Figure 1A and 1B¹³). Therefore, studies reporting mRS at 90 days were selected for meta-analysis with poor outcome defined as death or dependency (mRS 3–6). Overall,

20 studies of nine biomarkers were included in meta-analysis (Table 2). Of these 20 studies, only one study reported steroid use at the time of ICH⁴⁰ and no studies reported on the use of osmotic agents, NSAIDs, or other immunomodulatory drugs at the time of ICH. No studies reported the number of febrile patients on admission, but 13 reported the presence of intercurrent infection with 10 using it as an exclusion criterion. Seven studies reported the use of antiplatelet agents and nine studies reported anticoagulant medication at the time of ICH (Supplemental Table 3, available as *Extended data*¹³). All 93 studies examining the association between inflammatory biomarkers and clinical outcome have been included in a narrative synthesis (Supplemental Table 1, available as *Extended data*¹³).

Immune cells. A total of 53 studies reported WBC count^{24–26,41–90} in relation to clinical outcome after ICH. Of these, 13^{24,26,46,52,55,56,61,75,79,81,83,88,90} studies of 2,453 participants were meta-analysed. Overall, 10 (77%) studies reported WBC at admission, the remainder reporting it within 48 hours after ICH onset. Higher WBC was associated with death or dependency at 90 days (pooled SMD 0.27; 95% CI [0.11, 0.44]; p=0.001) (Figure 2). Pooled associations were not influenced by median cohort ICH volume (p=0.14) or age (p=0.68). Study quality did not influence pooled associations (p=0.07) (Supplemental Figure 2A¹³). There was no evidence of publication bias (Supplemental Figure 2B¹³, Egger's regression: p=0.23) and no outliers were identified. There was a high level of statistical heterogeneity between studies (Figure 2).

In total, 18 studies^{27,28,40,41,49,52,58,60,61,65,66,68,71,72,80,87,91,92} examined the association between neutrophil count and clinical outcome. Three studies^{40,52,61} of 629 participants measuring neutrophil count at admission were meta-analysed. There was no association between neutrophil count and death

Table 2. WBC and 90-day mRS

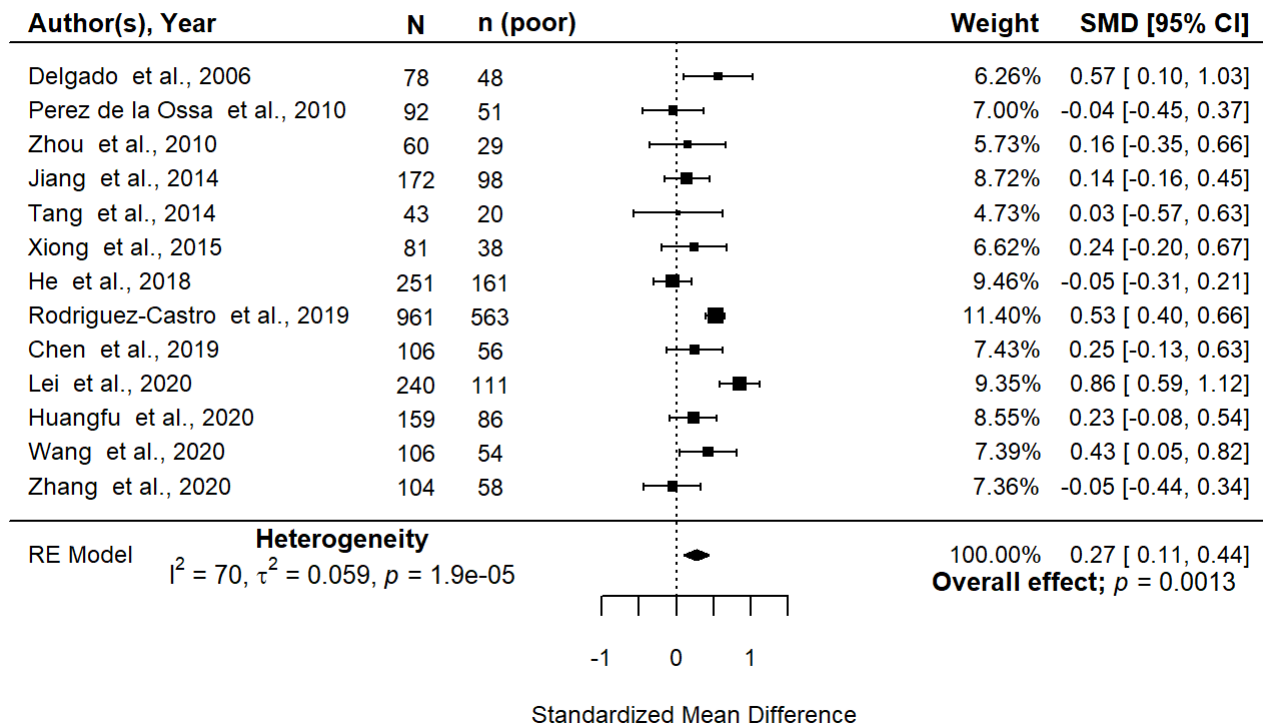

Figure 2. Forest plot of pooled associations of WBC with death or dependency 90 days after ICH. Pooled association of circulating WBC with death or dependency at 90 days. Poor outcome defined as mRS 3–6. WBC, white blood cell; ICH, intracerebral haemorrhage; mRS, modified Rankin Scale; SMD, standardised mean difference.

or dependency at 90 days (pooled SMD 0.36; 95% CI [0.03, 0.75]; $p=0.07$; Supplemental Figure 3¹³). There was high statistical heterogeneity between studies.

Lymphocyte count was measured in 12^{27,28,49,58,60,65,66,68,71,72,87,91} studies and NLR was measured in 10^{27,49,60,65,66,68,71,72,93,94}, but neither were meta-analysed because less than two studies reported mean/medians at 90-day mRS. Six (50%) studies found that lower lymphocyte counts were associated with worse outcome. Eight (80%) studies found an association between higher NLR and poor outcome by univariate analysis, which remained significant by multivariate analysis in six (75%) studies.

Acute phase reactants. The most frequently measured acute phase protein was CRP in 31 studies^{28,40,42,45,46,48,51,52,54–56,61,62,67,69,70,73–75,77,81,88,89,92,95–101}, including three that measured hypersensitive CRP^{51,52,92}. Of these, 11 studies of 2,622 participants were eligible for meta-analysis. Nine (82%) studies reported CRP at admission, the other two within 72 hours of ICH onset. Higher CRP was associated with death or dependency at 90 days (pooled SMD 0.80; 95% CI [0.44, 1.17]; $p<0.0001$) (Figure 3A). Pooled associations were not influenced by median cohort ICH volume

($p=0.43$). However, increasing median cohort age significantly reduced the association between high levels of CRP and worse outcome (beta -0.0841; $p<0.001$) (Figure 3B). Study quality did not influence pooled associations ($p=0.09$) (Supplemental Figure 4A¹³). There was no evidence of publication bias (Supplemental Figure 4B¹³, Egger's regression: $p=0.84$). Influence diagnostics identified one potential outlier⁶¹, however summary effect sizes were similar when this study was removed and remained statistically significant (pooled SMD 0.67; 95% CI [0.39, 0.95]; $p<0.001$). We thus retained this study in the remaining analysis. There was a high level of statistical heterogeneity between studies.

A total of 16 studies^{21,24,27,35,37–39,45,46,48,56,60,67,74,75,89} reported on fibrinogen and clinical outcome. Seven studies of 1,833 participants measuring fibrinogen upon admission were meta-analysed^{26,40,52,55,56,75,90}. Higher fibrinogen levels were associated with death and dependency at 90 days (pooled SMD 0.32; 95% CI [0.04, 0.61]; $p=0.025$) (Supplemental Figure 5A¹³). There was no evidence of publication bias (Supplemental Figure 5B¹³, Egger's regression: $p=0.126$) and no outliers were identified by influence diagnostics, thus, sensitivity analysis was not required. There was a high level of statistical heterogeneity between studies.

A) CRP and 90-day mRS

B) CRP and 90-day mRS summary SMDs across median cohort age

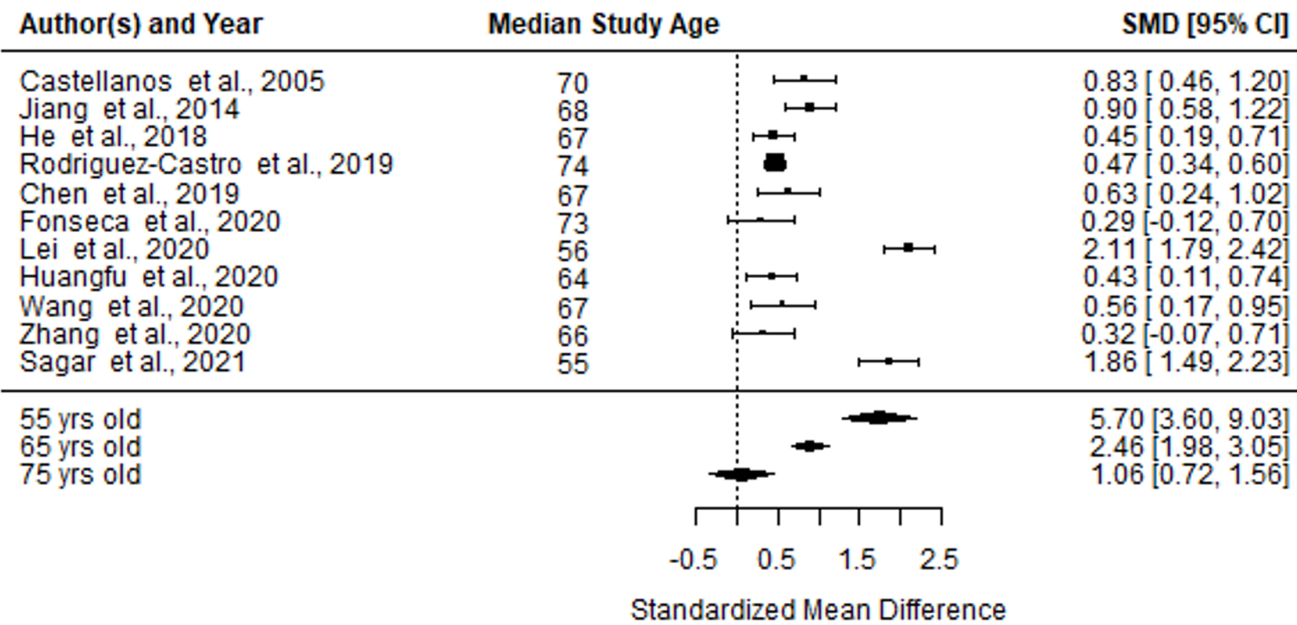

Figure 3. Pooled associations of CRP with death or dependency at 90 days after ICH. **A)** Forest plot of pooled associations of circulating CRP with death or dependency at 90 days. Poor outcome defined as mRS 3–6. **B)** Influence of age on the association of CRP with death or dependency at 90 days after ICH. Study cohorts with lower median cohort age have larger standardized mean differences between CRP and death or dependency at 90 days after ICH. CRP, C-reactive protein; ICH, intracerebral haemorrhage; mRS, modified Rankin Scale; SMD, standardised mean difference.

From three studies reporting on ferritin and clinical outcome^{26,29,102}, two studies of 155 participants measuring ferritin upon admission were included in a meta-analysis^{26,29}. There was no association between ferritin and death or dependency at 90 days (pooled SMD 1.59; 95% CI [-0.94, 4.13]; $p=0.22$) (Supplemental Figure 6¹³). There was a high level of statistical heterogeneity between studies.

Cytokines/chemokines. Two proinflammatory cytokines were included in meta-analyses; IL-6^{26,30,69,83,90,98,103} and TNF α ^{26,30,83,90,98,104}. Four studies^{26,69,83,90} of 303 participants reporting on IL-6 and 90-day mRS were meta-analysed. There was no association between IL-6 and death or dependency at 90 days (pooled SMD 0.72; 95% CI [-0.23, 1.66]; $p=0.14$) (Figure 4A). There was evidence of publication bias (Supplemental Figure 7¹³, Egger's regression: $p=0.025$) and influence diagnostics identified one potential outlier⁹⁰. However, pooled estimates were similar when this study was removed (pooled SMD 0.27; 95% CI [-0.03, 0.57]; $p=0.08$). There was a high level of statistical heterogeneity between studies. Three studies of 233 participants reporting on TNF α ^{26,83,90} and 90-day mRS were meta-analysed. There was no association between TNF α and death or dependency at 90 days (pooled SMD 0.87; 95% CI [-0.59, 2.33]; $p=0.24$) (Figure 4B). There was a high level of statistical heterogeneity between studies.

Overall, 11 other cytokines were measured in 10 studies^{30,31,69,98,99,101,105–108} where high levels of seven cytokines were associated with worse clinical outcome, and this association was sustained in multi-variate analysis in four studies.

Damage associated molecular patterns. Nine studies reported on S100B^{24,69,103,109–114} and functional outcome. Four studies including 238 participants reporting on S100B upon admission and 90-day mRS were meta-analysed^{24,69,110,114}. There was no association between S100B and death or dependency at 90 days (pooled SMD 0.55; 95% CI [-0.23, 1.32]; $p=0.17$) (Supplemental Figure 8A¹³). There was no evidence of publication bias (Supplemental Figure 8B¹³, Egger's regression: $p=0.20$) and influence diagnostics identified one potential outlier¹¹⁴. However, summary effect sizes were similar when this study was removed (pooled SMD 0.20; 95% CI [-0.09, 0.50]; $p=0.18$). There was a high level of statistical heterogeneity between studies.

Two studies^{61,90} of 300 participants reporting on HMGB1 upon admission and outcome were meta-analysed. Higher HMGB1 levels were associated with death or dependency at 90 days (pooled SMD 1.67; 95% CI [0.05, 3.30]; $p=0.04$) (Figure 5). There was a high level of heterogeneity between studies.

Tissue remodelling factors. Nine studies^{25,31–34,69,100,115,116} reported on MMP-9 and clinical outcome, six of which found no association with outcome^{31,33,34,69,101,116}. An additional six MMPs

and two TIMPs were also reported by five of these studies^{25,31,33,34,116} and no consistent association with clinical outcome was found. Meta-analysis was not performed because only single studies reported both biomarker concentrations and mRS at 90-days for each analyte.

Adhesion molecules. Eight adhesion molecules were reported alongside clinical outcome in seven studies^{25,30,62,63,100,117,118}. However, as no single molecule was reported with 90-day mRS more than once, meta-analysis was not performed. Higher levels of four adhesion molecules; sCD40L, ICAM1, Selectin-E, Selectin-P, were associated with worse outcome in three studies^{30,62,100}. Three molecules; VCAM1, VEGF, Tim-3, showed no association in four studies^{25,30,63,118}. Lower amounts of CD163 were associated with poor outcome in one study¹¹⁷.

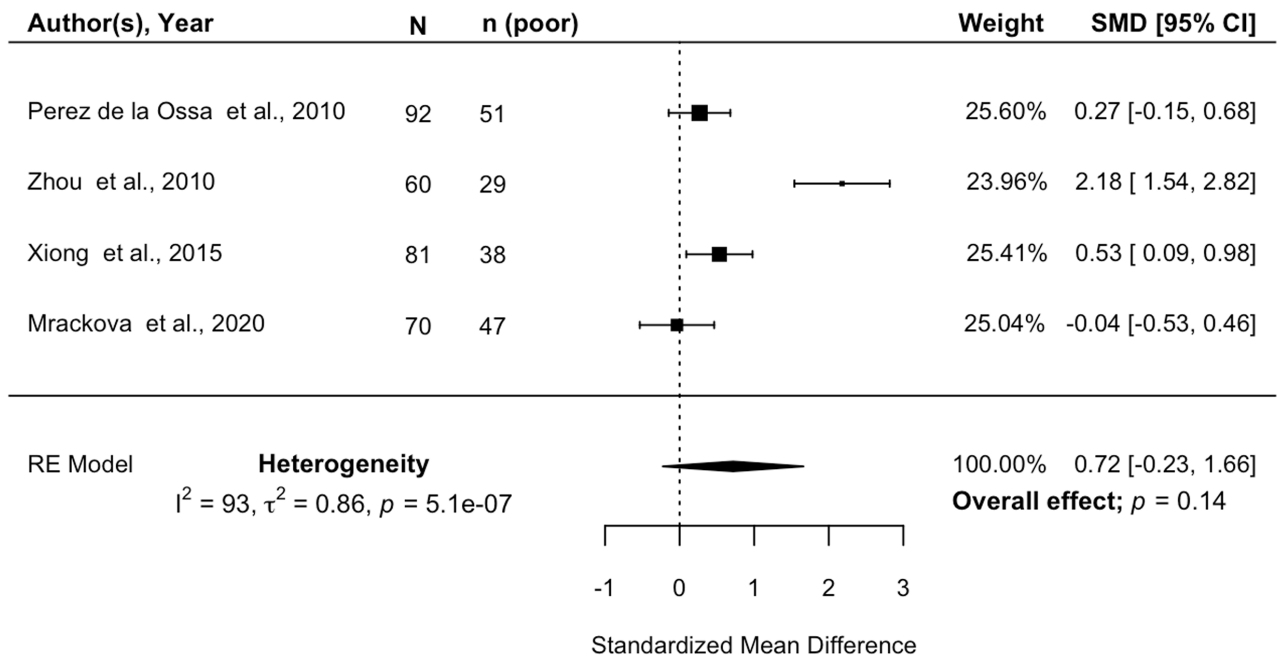

Narrative synthesis of the association between inflammatory biomarkers and both PHO and outcome
Overall, 11 studies of 1,001 participants measured both PHO and clinical outcome. We did not find any biomarker that was consistently associated with both PHO and clinical outcome in more than one study and thus no meta-analysis could be performed. In one study of 116 participants, higher levels of IL-6, TNF α and ICAM1 were associated with larger PHO volumes and worse clinical outcomes in univariable analyses³⁰. In individual studies, S100B²⁴ and ferritin²⁶ were positively associated with both PHO and outcome in univariable analyses only. In one study ($n=57$) higher levels of MMP-9 were associated with larger PHO volumes in adults with supratentorial deep ICH and worse clinical outcomes at days 3–6 after ICH onset in univariable analyses³². Studies of lymphocyte counts and NLR and their associations with PHO and outcome reported inconsistent findings^{27,28}.

Discussion

This systematic review and meta-analysis is the first to assess the relationship between all inflammatory biomarkers and both PHO and outcome following ICH. From 93 studies examining the relationship between 50 biomarkers and functional outcome after ICH, we found that higher circulating levels of four biomarkers; WBC count, CRP, fibrinogen and HMGB1, were associated with death or dependency at 90 days after ICH. We did not find an association between neutrophil count, ferritin, IL-6, TNF α or S100B and clinical outcome. We did not find any biomarker that was associated with both PHO and outcome in more than one study. The methodological heterogeneity between studies of inflammatory biomarkers and PHO precluded meta-analysis. However, we have narratively synthesised the findings from all published studies investigating the relationship between circulating inflammatory mediators and PHO

MMP-9 was the most frequently assessed biomarker in studies of PHO. It may be associated with PHO after ICH, but studies have been small with inconsistent findings and rarely controlled for important covariates such as ICH

A) IL6 and 90-day mRS

B) TNFα and 90-day mRS

Figure 4. Forest plot of pooled associations of IL-6 and TNFα with death or dependency 90 days after ICH. A) Pooled association of circulating IL-6 levels with death or dependency at 90 days. **B)** Pooled association of circulating TNFα levels with death or dependency at 90 days. Poor outcome defined as mRS 3–6. ICH, intracerebral haemorrhage; mRS, modified Rankin Scale; SMD, standardised mean difference.

HMGB1 and 90-day mRS

Figure 5. Forest plot of pooled association of HMGB1 with death or dependency at 90 days after ICH. Pooled association of circulating HMGB1 with death or dependency at 90 days. Poor outcome defined as mRS 3–6. HMGB1, high mobility group box protein 1; ICH, intracerebral haemorrhage; mRS, modified Rankin Scale; SMD, standardised mean difference.

volume, which may act as confounders. As MMPs have a role in the breakdown of the blood brain barrier, and contribute to vasogenic and cytotoxic PHO^{119,120}, we believe this merits further investigation. Currently, these results are hypothesis generating and require replication in larger studies using a prespecified scanning protocol for the measurement of PHO.

A key finding from this study is the association between higher circulating HMGB1 levels and poorer outcome after ICH. HMGB1 is released from necrotic and inflammatory cells and stimulates DAMP receptors to amplify release of pro-inflammatory cytokines and recruit peripheral immune cells^{121,122}. Its activity is increased after ICH in humans and is associated with the development of PHO¹²³. Since inhibiting HMGB1 improves outcome in animal models of ICH^{124,125} it may be a potential therapeutic target that merits further investigation.

Additionally we observed that higher levels of CRP, WBC and fibrinogen are associated with poor outcome and this is consistent with studies of ischemic stroke that have found similar associations^{126,127}. These findings support the role of inflammation in ICH but do not provide information on the exact inflammatory pathways engaged or lead

to potential therapeutic targets. Unlike HMGB1, which has been shown in preclinical studies to be specifically neutralised by anti-HMGB1 monoclonal antibodies¹²⁵, CRP and WBC are non-specific markers of inflammation. For example, CRP is produced in the acute phase of most forms of inflammation and is thus non-specific to the inflammatory response to ICH. We believe that the analysis of more specific inflammatory mediators is required in order to gain a deeper understanding of the immune response to ICH and identify potential therapeutic targets. Of note however, the association of CRP with poor outcome is stronger as the median age of the cohort decreases. Whilst this could be explained by CRP biology as background serum levels of CRP increase during ageing¹²⁸, it could also be linked to confounders such as patient selection, since studies with lower median cohort ages had higher risk of bias scores.

Our meta-analysis did not find an association between circulating levels of either IL-6 or TNF α with death or dependency at 90 days. These cytokines stimulate the expression of acute phase proteins, such as CRP, and are thought to play detrimental roles in the pathogenesis of ICH^{8,129}. Several factors may explain why we did not find an association: only four studies were included in these meta-analyses, the time point of biomarker measurement in relation to ICH onset

varied, and peripheral circulating levels of these cytokines may not be comparable to concentrations in the brain. Moreover, the majority of studies only reported biomarker measurements upon admission or within 24hr. It is thus difficult to establish if these biomarker levels are reflective of the baseline physiology of individuals at risk of developing worse outcome or are directly caused by the onset of ICH itself. Longitudinal, serial blood sampling would assist in measuring the effect of ICH on systemic inflammatory levels independently of baseline levels.

We did not find any biomarker that was associated with both PHO and outcome in more than one study. Future studies should aim to identify if any biomarker is associated with both, since such an inflammatory mediator would be more likely to be a potential therapeutic target.

Our review is strengthened by a comprehensive search strategy of historic and contemporary literature without language or publication date restrictions. We did not limit our search strategy based on *a priori* knowledge of pre-specified biomarkers, and we identified many studies that were not considered in a recent review of the association between biomarkers and prognosis after ICH¹³⁰. We believe this is the first systematic review to assess the relationship between inflammatory biomarkers and both PHO and functional outcome after ICH. Critical appraisal of studies was determined by two independent reviewers and most meta-analyses were not affected by publication bias.

This study has some limitations. Our risk of bias assessment used a summed score, which may not fully reflect the degree of bias in certain studies. We encountered a high level of heterogeneity between studies in relation to biomarker measurement and PHO assessment, which precluded meta-analyses of some biomarkers. Given the heterogeneity and small numbers of studies of some biomarkers, we were unable to use meta-regression to determine the influence of variables such as ICH volume¹³¹ on the association of all biomarkers with clinical outcome.

Conclusions

Higher levels of WBC, CRP, fibrinogen and HMGB1 were associated with worse outcome after ICH. Future prospective studies should prioritise the investigation of specific inflammatory mediators (such as HMGB1, cytokines, DAMPs and adhesion molecules) and adjust for key covariates such as ICH severity to better understand the pathophysiology of PHO and inflammation after ICH. This may reveal novel biomarkers, identify potential therapeutic targets and give better insights into certain immune-related post-ICH sequelae, such as infection.
