# Perturbations of Critical Fixed Points of Analytic Maps 

David Tischler

This paper has three parts. The first is concerned with an inequality relating the positions of the fixed point, the critical point, and the critical value obtained by a perturbation of an analytic function which has a critical point which is simultaneously a fixed point. The result is local in nature in that the analytic function need only be defined in a neighborhood of the fixed critical point. However, the motivation for this problem comes from a conjecture of Smale about polynomials, [4].

The conjecture states that, given a complex polynomial $f$ of degree $d$ and a non-critical point $z$, that for some critical point $\theta$

$$
\begin{equation*}
|f(z)-f(\theta)| /\left|(z-\theta) f^{\prime}(z)\right|<1 . \tag{1}
\end{equation*}
$$

Let $S(f, z, \theta)$ denote the left hand side of (1). For the polynomial $f(z)=$ $z^{d}+(d /(d-1)) z$, and the point $z=0$, for any choice of critical point $\theta$, $S(f, 0, \theta)=(d-1) / d$. This is possibly the worst case for the conjecture, which would mean that $(d-1) / d$ could replace 1 in (1). In [5], we showed that $(d-1) / d$ is an upper bound for any sufficiently small perturbation of $f(z)=z^{d}+(d /(d-1)) z$ and $z=0$. We also conjectured that the mean value conjecture might be strengthened to state that for any $f$ of degree $d$, and any $z$, for some $\theta$

$$
\begin{equation*}
|S(f, z, \theta)-1 / 2| \leq 1 / 2-1 / d . \tag{2}
\end{equation*}
$$

In the first part of this paper we will show that (2) is true for any sufficiently small perturbation of $f(z)=z^{d}+(d /(d-1)) z, z=0$.

In the second part of this paper we will consider a topological version of the mean value conjecture. That is, we will consider only critical points $\theta$ for which $f(\theta)$ is on the boundary of the largest disk centered at $f(z)$ on which a branch of $f^{-1}$ can be defined. For these critical points, by applying the Koebe $1 / 4$ theorem to $f^{-1}$, it was shown in [4] that $S(f, z, \theta) \leq 4$. The topological version of the mean value conjecture raises the question of whether there is a better version of the Koebe $1 / 4$ theorem for inverse branches of polynomials.

We will consider degrees $d=3,4$ where (2) is known to be true, [5]. We will show that the topological version of (2) is true for $d=3$ and is false for $d=4$. Whether the topological version of (1) is true is not known.

In the final section we will describe a quasi-conformal model for polynomials which will allow us to verify (2) for roots of polynomials whose critical values have norms that increase fast enough.
§1. Let $f(z)$ be a complex analytic function defined in a neighborhood of the point $\theta$. Suppose that $f(\theta)=\theta$ and that $f^{\prime}(\theta)=0$ and $f^{\prime \prime}(\theta) \neq 0$. Let $p$ be another point different than $\theta$, not necessarily in the domain of $f$. Since $\theta$ is a fixed point of $f,|\theta-p|=|f(\theta)-p|$. Let $h$ denote a complex analytic function which is a peturbation of $f$ in a neighborhood of $\theta$. For any sufficiently small perturbation $h$ of $f$ there will be a fixed point $q,(h(q)=q)$, and a critical point $\sigma,\left(h^{\prime}(\sigma)=0\right)$, near $\theta$. The following theorem gives a sufficient condition on perturbations of $f$ so that $|\sigma-p| \geq|h(\sigma)-p|$.

Theorem 1. Suppose that $\mathbf{R}\left((\theta-p)\left(f^{\prime \prime}(\theta)\right)<0\right.$. Suppose that $|\sigma-p|>$ $|q-p|$. Then if $h$ is sufficiently near $f,|h(\sigma)-p| \leq|\sigma-p|$.

Proof. Without loss of generality, for the purposes of this proof, we can assume that $p=0$. This follows because conjugating $f$ by a translation does not change the second derivative, and translations preserve lengths. Since $p=0$ and $p \neq \theta$, we can define an analytic function $g$ in a neighborhood of $\theta$ by the formula $f(z)=z g(z)$. We are interesterl in the level curves of $g$. That is the curves defined by $|g(z)|=$ constant.

Lemma 1. Let $f(z)=z g(z)$ and suppose $f^{\prime}(\theta)=0$ and $g^{\prime}(\theta) \neq 0$. Then, at $\theta$, the tangent vector $-\theta$ is orthogonal to the level curve of $g$.

Proof. Let $w=g(z)$. The level curves of $g$ are the preimages of circles in the $w$ plane centered at 0 . The radial vector field $V(w)=w$ pulls back by $g$ to the vector field $g(z) / g^{\prime}(z)$. Since $g$ is conformal away from critical points we have that the vector field $g(z) / g^{\prime}(z)$ is orthogonal to the level curves of $g$. Since $f^{\prime}(z)=g(z)+z g^{\prime}(z)$ and $\theta$ is a critical point of $f$, we see that the vector $-\theta$ is orthogonal to the level curve of $g$ at $\theta$. Note that $g^{\prime}(\theta)$ is not zero because then $g(\theta)=0$ and then $f(\theta)=0$ which means that $\theta=0$ since $\theta$ is a fixed point for $f$, and we have assumed that $\theta \neq p=0$. Therefore the rays from 0 are transversal to the level curves of $g$ near $\theta$, and $|g(z)|$ increases in the direction of $-\theta$. Let us orient the level curves of $g$ so that at $\theta$ the orientation agrees with the direction $-(\sqrt{-1}) \theta$. Let $k$ denote the curvature of the level curves of $g$ with the given orientation. A calculation shows that

$$
k=\left|g^{\prime}(z) / g(z)\right| \mathbf{R}\left(1-\left(g(z) g^{\prime \prime}(z) /\left(g^{\prime}(z)^{2}\right), \text { see }[2, \mathrm{p} .359]\right.\right.
$$

If we express this formula for $k$ in terms of $f$ and use that $\theta$ is both a fixed point and a critical point for $f$ we obtain the formula

$$
k=|1 / \theta| \mathbf{R}\left(-1-\theta f^{\prime \prime}(\theta)\right) .
$$

By hypothesis, $\mathbf{R}\left(\theta f^{\prime \prime}(\theta)\right)<0$. Therefore, $k>-1 /|\theta|$, which is the curvature of the circle $C_{\theta}$ with center 0 and which passes through $\theta$. Since $-\theta$ is orthogonal to the $g$ level curve at $\theta$ and $-\theta$ is also orthogonal to $C_{\theta}$ at $\theta$, it follows that the $g$ level curve is tangent to $C_{\theta}$ at $\theta$. We conclude that in a small enough neighborhood of $\theta$ the level curve of $g$ passing through $\theta$ is outside $C_{\theta}$.

Suppose $h$ is a perturbation of $f$. Define $j(z)=h(z) / z$. For sufficiently small perturbations $h$ of $f$ the level curves of $j$ are transversal to the rays from 0 , the level curve of $j$ through $\sigma$ is outside the circle $C_{\sigma}$ which passes through $\sigma$ with center 0 . Let $b$ denote the intersection of the ray through $q$ and the
level curve of $j$ through $\sigma$. Let $c$ denote the intersection of the ray through $q$ and the circle $C_{\sigma}$. Note that $|j(z)|$ increases along the rays in the direction towards 0 . Therefore $|j(c)| \geq|j(b)|$. By hypothesis, $|\sigma-0| \geq|q-0|$, so $|j(c)| \leq|j(q)|$. Since $b$ and $\sigma$ are on the same level curve of $j$, we conclude that $|j(\sigma)| \leq|j(q)|$. Since $q$ is a fixed point for $h$ we obtain $1>|h(\sigma) / \sigma|$ or $|\sigma-0|>|h(\sigma)-0|$. Since we have assumed $p=0$, this completes the proof of Theorem 1.

Remark. Theorem 1 is also true if all three inequality signs are reversed. The proof is analogous to the one given above.

Let us apply Theorem 1, and more particularly, the method of proof to the case of $f(z)=z^{d}+(d /(d-1)) z$ and $p=0$, which was the case discussed in the introduction. The critical points $\theta$ of $f$ satisfy $\theta^{d-1}=-1 /(d-1)$. For this polynomial $f(z)$ we find that $g(z)=z^{d-1}+d /(d-1)$ and $f^{\prime \prime}(\theta)=d(d-1) \theta^{d-2}$ which implies $\mathbf{R}\left(\theta f^{\prime \prime}(\theta)\right)<0$. Without loss of generality we can restrict our attention to perturbations $h$ of $f$ which are degree $d$ polynomials which satisfy $h(0)=0$ and $h^{\prime}(0)=d /(d-1)$. As was shown in [5], for any such perturbation $h$ there is a critical point $\sigma$ and a fixed point $q$ near one of the critical points $\theta$ of $f$ so that $|\sigma-0| \geq|q-0|$. From Thm. 1, we conclude that $|\sigma|>|h(\sigma)|$ and $S(h, 0, \sigma)<(d-1) / d$. This was already shown in [5]. Here we want to show in addition that

Theorem 2. The stronger mean value conjecture (2) is true for any sufficiently small perturbation $h$ of the above $f$ with $z=0$ and some critical point $\sigma$ of $h$.

Proof. Observe that the image by $g$ of the level curve through $\theta$ is a circle centered at the origin. Since $\theta$ is fixed by $f, g(\theta)=1$. Using the same notation as in the proof of Thm. $1, g\left(C_{0 \theta}\right)$ is the circle of radius $1 /(d-1)$ centered at $d /(d-1)$. For a perturbation $h$ close to $f, j$ will be a polynomial approximately the same as $g$. Therefore, $j\left(C_{\sigma}\right)$ is approximately a circle of radius $1 /(d-1)$. So the curvature of $j\left(C_{\sigma}\right)$ is approximately $1 /(d-1)$. Furthermore, $j\left(C_{\sigma}\right)$ is
tangent at $j(\sigma)$ to the circle centered at 0 passing through $\sigma$. Let $C_{q}$ be the circle centered at 0 passing through $q$. Like $j\left(C_{\sigma}\right), j\left(C_{q}\right)$ is also approximately a circle with radius $1 /(d-1)$. By hypothesis, $C_{\sigma}$ is outside $C_{q}$ and so $j\left(C_{\sigma}\right)$ is outside $j\left(C_{q}\right)$.

Since $h(q)=q, j(q)=1$. As a first estimate, we suppose that $j\left(C_{\sigma}\right)$, is actually a circle of radius $1 /(d-1)$ passing through 1 , with center at a point $e$ approximately equal to $d /(d-1)$. Denote any such circle by $C$. Let $s$ denote the point where $C$ is tangent to a circle centered at 0 . So $s, 0$, and $e$ are collinear. Let $\phi$ be the central angle at $e$ between $s$ and 1. Let $u=(1+1 /(d-1)) / 2$.

Lemma 2. For $d \geq 4$, there is a positive constant $M$, independent of $\phi$, such that $|u-s|<1-u-M \phi^{2}$.

Proof. Let $A$ be the angle between the rays $0 s$ and 01 . Let $r$ be the point in the interval $[0,1]$ which is equidistant from 1 and $s$. So $|s-r|=1-r$. In triangle $0 r s$, the interior angle at $s$ is $A+\phi$. By the law of sines, $(1-r) / r=$ $\sin (A) / \sin (A+\phi)$. In triangle $0,1, e$, the interior angle at 1 is $\pi-(A+\phi)$. By the law of sines in this triangle $\sin (A) / \sin (\pi-(A+\phi))=(1 /(d-1)) /|e|<$ $1 /(d-1)$. Since $\sin (A+\phi)=\sin (\pi-(A+\phi))$ we conclude that $r>(d-1) / d$. For $d \geq 4, u<(d-1) / d$ so that $u<r$. In triangle $u, r, s$ the interior angle at $r$ is $\pi-(2 A+\phi)$. Note that $A=0(\phi)$ and that $\phi$ is near 0 since $\phi=0$ for the uperturbed function $f$. Using the law of cosines in triangle $u, r, s$ and the fact that $|1-u|=|1-r|+|r-u|$ we find that $|u-s|<|1-u|$ and $|u-s|^{2}-|1-u|^{2}=0\left(\phi^{2}\right)$. Therefore, $|u-s|<|1-u|-M \phi^{2}$ for some positive number $M$. This proves the lemma for $d \geq 4$.

Remark. The cases of $d=3,4$ of Thm. 2 are treated in [5].

Suppose that the curvature $k$ of $j\left(C_{\sigma}\right)$, and that of $j\left(C_{q}\right)$, satisfy $|k-1 /(d-1)|<\varepsilon$. Let $A_{\sigma}$ be the angle between the rays 01 and $0 j(\sigma)$ and let $A_{q}$ be the angle between 01 and $0 t$, where $t$ is an element of $j\left(C_{q}\right)$, with
$0, t, e$ collinear. Then $\left|A-A_{\sigma}\right|$ and $\left|A-A_{q}\right|$ are both less than $\pi \varepsilon$. Furthermore, the distance from 1 to $t$ along $j\left(C_{q}\right)$ is $0(\phi)$. Therefore, $|s-t|<L \varepsilon \phi^{2}$, for some constant $L$, independent of $\phi$ and $\varepsilon$. Therefore, for small enough $\phi$ and $\varepsilon,|u-t| \leq|1-u|-M \phi^{2}+L \varepsilon \phi^{2}<|1-u|$. Since $j\left(C_{\sigma}\right)$ is outside of $j\left(C_{q}\right)$ we can make a similar estimate to show $|u-j(\sigma)|<|u-t|+N \varepsilon \phi^{2}$ for some $N$ independent of $\phi$ and $\varepsilon$. This shows that for a sufficiently small perturbation $h$ of $f$ that $|j(\sigma)-u|<|1-u|$.

In order to complete the proof of Theorem 2 we recall the normalization discussed just before the statement of Thm. 2 to obtain

$$
S(h, 0, \sigma)=h(\sigma) /\left(\sigma h^{\prime}(0)\right)=j(\sigma){ }^{\prime}(d-1) / d .
$$

Therefore, $((d-1) / d)|j(\sigma)-u|=|S(h, 0, \sigma)-1 / 2|$. Also, $((d-1) / d)|1-u|=$ $1 / 2-1 / d$. Therefore $|S(h, 0, \sigma)-1 / 2|<1 / 2-1 / d$ and the proof of Theorem 2 is complete.
§2. If $A$ and $B$ are first degree polynomials, then it is easy to check that

$$
S(A \circ f \circ B, z, \theta)=S(f, B(z), B(\theta)) .
$$

Suppose $f$ is a degree three polynomial that has two distinct critical points. Choose $B$ so that the critical points are at $z=1 / 2$ and $z=-1 / 2$, and choose $A$ so that $f(1 / 2)=1 / 2$ and $f(-1 / 2)=-1 / 2$. Then $f(z)=-2 z^{3}+(3 / 2) z$. In [5], we gave a topological description of polynomials, all of whose critical points are also fixed points. We will use that description to show that $f$ satisfies the topological version of (2).

The topological description of $f(z)=-2 z^{3}+(3 / 2) z$ is as follows. There are two closed topological disks, one around $z=-1 / 2$ and one around $z=1 / 2$ on each of which $f$ is topologically conjugate to $z \rightarrow z^{2}$. In the interior of each disk the conjugation is analytic. The two disks have the point $z=0$ as their intersection, and it is a repelling fixed point for $f$. The imaginary axis is invariant by $f$. Denote the positive imaginary axis by $J_{1}$ and the negative imaginary axis by $J_{4}$. The points $z=+(\sqrt{3}) / 2$ and $-(\sqrt{3}) / 2$ are the two
other preimages of $z=0$. See Fig. 1 as reference for the following part of the description of $f$. The curves $J_{2}, J_{6}$ are preimages of $J_{4}$ whereas, $J_{3}, J_{5}$ are preimages of $J_{1}$. The region between $J_{1}$ and $J_{2}$ and outside of the disk around $z=1 / 2$ is mapped by $f$ onto the part of the right half plane which lies outside the disk around $z=1 / 2$. The region between $J_{2}$ and $J_{3}$ is mapped onto the half plane $\mathbf{R}(z)<0$, sending $[(\sqrt{3}) / 2, \infty)$ onto $(-\infty, 0]$. Each of these maps is a homeomorphism. There are similar homeomorphisms of the regions outside the union of the two disks and between the curves $J_{i}$ and $J_{i+1}, i=1$ to 6 , (note that $J_{7}$ means $J_{1}$ ).

Figure 1
In studying the topological mean value conjecture, we make a choice of a non- critical point $p$. There are three points $p_{i}, i=1,2,3$ with the same output $f(p)$. We draw a straight segment $c$ from $f(p)$ to whichever critical value is closest to $f(p)$. Let us assume that $\mathbf{R}(f(p))<0$ so that $z=-1 / 2$ is the closest critical value. The preimage of $c$ consists of three $\operatorname{arcs} I_{i}, i=1,2,3$. $I_{1}$ and $I_{2}$ have an endpoint at $-1 / 2$ and $I_{3}$ has an endpoint at the other preimage of $z=-1 / 2$ which $z=1$. Since the segment $c$ does not intersect $J_{1}$ and $J_{4}$ neither does any $I_{i}$ intersect any $J_{j}$. The other endpoints of the $I_{i}$ are the $p_{i}$. Then $\theta_{-}=-1 / 2$ is the critical point topologically related to $p_{1}$ and $p_{2}$, whereas $\theta_{+}=1 / 2$ is topologically related to $p_{3}$.

We can describe this correspondence in terms of the level curves $|f(z)-f(p)|=$ constant, which are preimages by $f$ of circles centered at $f(p) .\{z:|f(z)-f(p)|=$ $|f(p)+1 / 2|\}$ is the preimage of the circle passing through $\theta_{-}$and it has a component which is a topological figure-eight which contains both $I_{1}$ and $I_{2}$, one arc inside each loop of the figure-eight. The other component is a loop around $p_{3}$ which contains $I_{3}$.

The preimage of the circle through $\theta_{+}$is also a figure-eight. Each loop of this figure-eight contains one of the components of the preimage of the circle through $\theta_{-}$, see Fig. 2.

Figure 2
From the Fig. 2, we see that a branch of $f^{-1}$ which sends $f(p)$ to $p_{3}$ can be defined on the disk centered at $f(p)$ and which has $\theta_{+}$on its boundary. Similarly, for $p_{1}$ and $p_{2}$, with $\theta_{-}$. So we see that $\theta_{j}$ is topologically related to $p_{i}$, if $\left|\theta_{j}-p_{i}\right| \leq\left|\theta_{-j}-p_{i}\right|$.

From [5], we have that $S\left(f, p_{i}, \theta_{j}\right)-1 / 2=-(1 / 6)\left(\theta_{j}-p_{i}\right) /\left(\theta_{-j}-p_{i}\right)$, for $i=1,2,3$, and for $j=+,-$. Therefore, if $\left.\left|\theta_{j}-p_{i}\right| \leq \mid \theta_{-j}-p_{i}\right) \mid$, $\left|S\left(f, p_{i}, \theta_{j}\right)-1 / 2\right| \leq 1 / 6=1 / 2-1 / 3$. This proves the topological version of (2) when $d=3$.

For the case of $d=4$, we will describe a case where the topological version of (2) is false. Consider $f(z)=-3 z^{4}+4 z^{3}$. Note that $z=0$ and $z=1$ are the only critical points and they are each fixed points for $f$. Since all the critical points are fixed we can describe a topological model for $f$. There are topological disks around $z=0$ and $z=1$ on which $f$ is topologically conjugate to $z \rightarrow z^{3}$ and $z \rightarrow z^{2}$ respectively. The two disks have one point $q$ in common, that is, $q=(-1+\sqrt{13}) / 6$. This is a repelling fixed point as is $(-1-\sqrt{13}) / 6$. There are three invariant expanding curves $J_{i}, i=1,2,3$, see Fig. 3. Extend $J_{3}$ to $q$ by adding on the invariant segment $[p, q]$. These curves bound three regions of the plane denoted by $R_{i}, i=1,2,3$, where $R_{i}$ is the region not bordered by $J_{i}$. The preimages of the region $R_{i}$ will be denoted by $R_{i}^{-1}$. Let $z$ be of the form $1+t \sqrt{(-1)}$. With $t$ a sufficiently large negative real number, one can check that $z \in R_{1}^{-1}$ since as $t \rightarrow-\infty,|f(z)| \rightarrow \infty$, and $\arg (f(z)) \rightarrow \pi^{-}$. In particular, the component of $R_{1}^{-1}$ which contains $z$, also contains 0 in its boundary. Take a straight segment $c$ joining the critical point 0 to $f(z)$. The segment $c$ will have four preimage arcs $I_{i}$, three of which, say for $i=1,2,3$, emanate from 0 and lie inside the three components of $R_{1}^{-1}$, respectively which have 0 in their boundary. We denote the other endpoint of $I_{i}$ by $z_{i}$, for $i=1,2,3$. The other component $I_{4}$, lies in the other component of $R_{1}^{-1}$ which has as one boundary component a part of the positive real axis. One endpoint of $I_{4}$ is $z=4 / 3$ and we will denote the other endpoint by $z_{4}$. We see that the critical point $z=1$ is topologically related to $z_{4}$, whereas the critical point $z=0$ is topologically related to the other three preimages of $f(z)$.

In [5], it is shown that

$$
S\left(f, z, \theta_{j}\right)-1 / 2=(-1 / 4)\left\{\left(\theta_{j}-z\right)\left(\theta_{j}^{\prime}-z\right)\right\} /\left\{\left(\theta_{j+1}-z\right)\left(\theta_{j+2}-z\right)\right\}
$$

where $\theta_{j}^{\prime}=2 G-\theta_{j}, G=(1 / 3) \sum_{1}^{3}\left(\theta_{k}\right)$. We can use this formula to calculate which critical points satisfy (2) for a given $z$. In our case, $\theta_{1}=0, \theta_{2}=0$, $\theta_{3}=1, G=1 / 3, \theta_{1}^{\prime}=\theta_{2}^{\prime}=2 / 3$ and $\theta_{3}^{\prime}=-1 / 3$.

If $j=1$ then $\left.\left\{\left(\theta_{1}-z\right)\left(\theta_{1}^{\prime}-z\right)\right\} /\left\{\left(\theta_{2}-z\right)\left(\theta_{3}-z\right)\right\}=((2 / 3)-z)\right) /(1-z)$. Therefore, if $\mathbf{R}(z)>5 / 6, S\left(f, z, \theta_{1}\right)$ does not satisfy (2).

So, for $z=1+t \sqrt{(-1)}$ for $t$ sufficiently negative, $\left|S\left(f, z, \theta_{1}\right)-1 / 2\right|>$ $1 / 2-1 / 4$. However, $\theta_{1}$ is the only critical point topologically related to $z$, and so the topological version of (2) is false for $d=4$.
§3. Given a polynomial $f$ of degree $d$, let $\theta_{1}, \ldots, \theta_{d-1}$, denote the critical points of $f$. Assume that $\left|f\left(\theta_{1}\right)\right|<\left|f\left(\theta_{2}\right)\right|<\cdots<\left|f\left(\theta_{d-1}\right)\right|$. We will decompose the domain of $f$ into $d-1$ pieces and describe a simple model for each piece. The $d-1$ pieces are defined as the connected components of the complement of a set of $d-2$ loops $C_{i}, i=1, \ldots, d-2$.

The loops $C_{i}$ are defined as follows. Choose $u_{i}, i=1, \ldots, d-2$, so that $\left|f\left(\theta_{i}\right)\right|<u_{i}<\left|f\left(\theta_{i+1}\right)\right|$. Denote the connected component of the level curve of $f$ passing through each $\theta_{i}$ by $\ell_{1}$. For each $i, 1 \leq i \leq d-1, \ell_{i}$ is a figure-eight. For each $u_{i}$, the level curve at level $u_{i}$ has a connected component $C_{i}$ which is a loop which together with the figure-eight through $\theta_{i}$ bounds an annulus.

The complement of $C=U C_{i}$ consists of $d-1$ connected components $K_{i}$. Each $K_{i}$ contains exactly one critical point $\theta_{i}$. There are only a small number of topological types for the $K_{i}$, which we will now catalog. Let $D_{i}$ denote the open disk bounded by $C_{i}$.

The region $\bar{K}_{1}$ is a closed disk since it is the closure of the disk bounded by $C_{1}$. For $1<i<d-1$, there are three possible topological types for $\bar{K}_{i}$, namely, a disk, a disk minus one disk, or a disk minus two disks. One boundary component of $\bar{K}_{i}$ is $C_{i}$. We will call it the outer boundary since $|f(z)|$ restricted to $\bar{K}_{i}$ is maximal along $C_{i}$. The level curve $\ell_{i}$ passing through $\theta_{i}$ consists of two loops. Inside each loop there may or may not be any critical points of $f$. If there are none in either loop then $\bar{K}_{i}$ is a closed disk. If there are critical points inside only one loop, then $\bar{K}_{i}$ is the closed annulus bounded by $C_{i}$ and $C_{j}$, where $\theta_{j}$ is the critical point of largest critical value inside one loop of $\ell_{i}$. If $\ell_{i}$ has critical points inside each of its loops then $\bar{K}_{i}=\bar{D}_{i}-\left\{D_{j} \cup D_{k}\right\}$ where $\theta_{j}, \theta_{k}$ are the critical points inside each loop of largest critical value inside their respective loops.

Finally, the region $\bar{K}_{d-1}$ differs from the last cases, only in that, there is no outer boundary $C_{d-1}$. That is, $\bar{\Gamma}_{d-1}=\mathbf{C}$, for $d=2$, or $\bar{K}_{d-1}=\mathbf{C}-D_{j}$ or $\bar{K}_{d-1}=\mathbf{C}-D_{j}-D_{k}$.

Suppose that for some $i, \bar{K}_{i}$ has three boundary loops $C_{i}, C_{j}$, and $C_{k}$. We will describe a set $K_{i}^{*} \subset \mathbf{C}$ and a polynomial function $f_{i}$ defined on $K_{i}^{*}$ so that
there is a conformal map $h_{i}: K_{i}^{*} \rightarrow \bar{K}_{i}$ satisfying $f_{i}=f \circ h_{i}$. Let $m_{r}=$ degree of $f$ restricted to $C_{r}$, for $r=1, \ldots, d-1$. The degree $m_{r}$ is the number of roots of $f$ which lie inside $C_{r}$. Define $f_{i}(z)=\lambda_{i} z^{m_{j}}(z-1)^{m_{k}}$, where $\lambda_{i}$ is a constant chosen so that, at the critical point $\sigma_{i}=m_{j} /\left(m_{j}+m_{k}\right)$ of $f_{i}$, the critical value $f_{i}\left(\sigma_{i}\right)=f_{i}\left(\theta_{i}\right)$.

The level curve of $f_{i}$ corresponding to $u_{j}$, i.e., $\left\{z:\left|f_{i}(z)\right|=u_{j}\right\}$ consists of two loops, one around $z=0$ and one around $z=1$.

Recall, $u_{j}<\left|f_{i}\left(\theta_{i}\right)\right|$ and that all the roots of $f_{i}$ lie at $z=0$ and $z=1$. The loop around $z=0$, denoted by $C_{j}^{*}$, will be one boundary component of $K_{i}^{*}$. Similarly, for the $u_{k}$ level of $f_{i}$, there is a loop around $z=1$, denoted by $C_{k}^{*}$, which will be another boundary component of $K_{i}^{*}$.

The outside boundary of $K_{i}^{*}$ is defined to be the level curve of $f_{i}$ at the level $u_{i}$, denoted by $C_{i}^{*}$, which is a single loop inside of which is the critical point $\sigma_{i}$.
$K_{i}^{*}$ is the union of three annuli bounded by four curves: the level curve through $\sigma_{i}, C_{i}^{*}, C_{j}^{*}$, and $C_{k}^{*}$. Similarly $\bar{K}_{i}$ is the union of three annuli bounded by $\ell_{i}, C_{i}, C_{j}$, and $C_{k}$. Both $f_{i} \mid K_{i}^{*}$ and $f_{i} \mid \bar{K}_{i}$ are branched mappings with the same critical value. On each pair of corresponding annuli, $f_{i}$ and $f$ are covering maps with the same image. Note that the degrees of $f_{i}$ and $f$ are the same on each pair of corresponding annuli. Define $h_{i}: K_{i}^{*} \rightarrow \bar{K}_{i}$, on each of the three closed annuli, as a mapping between covering spaces which satisfies $h_{i}\left(\sigma_{i}\right)=\theta_{i}$.

Therefore, $f_{i} \mid K_{i}^{*}=f \circ h_{i}$ is conformal since it is conformal on each of the three annuli and is well defined on the level curve passing through $\sigma_{i}$.

There is an oriented tree $T$ associated to the pieces $\bar{K}_{i}$ by associating a vertex $v_{i}$ to each $\bar{K}_{i}$ and an edge $e_{i m}$, oriented from $v_{i}$ to $v_{m}$ provided that the outer boundary $C_{i}$ of $\bar{K}_{i}$ is an inner boundary of the piece $\bar{K}_{m}$.

We can choose complex affine mappings $A_{i}, 1 \leq i \leq d-1$, of $\mathbf{C}$ with the following property. The subsets $A_{i}\left(\Lambda_{i}^{*}\right)$ are deployed in such a way that, for
each edge $e_{i m}$ of $T, A_{i}\left(K_{i}^{*}\right)$ is inside the loop $A_{m}\left(\left(h_{m}\right)^{-1}\left(C_{i}\right)\right)$, see Fig. 4.

Figure 4

In general $A_{i}\left(\left(h_{i}^{-1}\left(C_{i}\right)\right)\right.$ is not the same affine shape as $A_{m}\left(\left(h_{m}^{-1}\left(C_{i}\right)\right)\right.$. However there is an analytic homeomorphism $\varepsilon_{i m}: A_{i}\left(\left(h_{i}\right)^{-1}\left(C_{i}\right)\right) \rightarrow$ $A_{m}\left(\left(h_{m}\right)^{-1}\left(C_{i}\right)\right)$ defined by $\varepsilon_{i m}=A_{m} \circ\left(h_{m}\right)^{-1} \circ h_{i} \circ\left(A_{i}\right)^{-1}$.

Suppose $C$ is a boundary component of some $K_{i}^{*}$, corresponding to an $f$ level curve at level $u$. For $\varepsilon>0$, if $\varepsilon<\left\|u|-| f\left(\sigma_{i}\right)\right\|$ then there is an $\varepsilon$-collar neighborhood of $C$ in $K_{i}^{*}$ defined by all level curves in $K_{i}^{*}$ whose level is within $\varepsilon$ of $u$. There is a product structure on the collar given by the level curves and the orthogonal trajectories to the level curves. For small enough $\varepsilon$, define $J_{i}^{*}=K_{i}^{*}$ minus an $\varepsilon$-collar around each boundary component of $K_{i}^{*}$. The region between the outer boundary of $A_{i}\left(\cdot J_{i}^{*}\right)$ and the inner boundary of $A_{m}\left(J_{m}^{*}\right)$ is topologically an annulus denoted by $E_{i m}$. On one of the boundary components of $E_{i m}, f_{m} \circ\left(A_{m}\right)^{-1}$ is defined and is a covering map of degree $m_{i}$ onto the circle of radius $u_{i}+\varepsilon$, centered at 0 . On the other boundary component of $E_{i m}, f_{i} \circ\left(A_{i}\right)^{-1}$ is defined and it is a covering map of degree $m_{i}$ onto the circle of radius $u_{i}-\varepsilon$, centered at 0 . Therefore, there is a covering
$\operatorname{map} f_{i m}$ of degree $m_{i}$ from $E_{i m}$ onto the annulus between the circles of radii $u_{i}-\varepsilon$ and $u_{i}+\varepsilon$ which restricts to $f_{i} \circ\left(A_{i}\right)^{-1}$ and $f_{m} \circ\left(A_{m}\right)^{-1}$ on the two boundary components respectively. This covering map can be chosen in many ways.

Suppose that for each $E_{i m}$ a covering map $f_{i m}$ has been chosen. Then we can define a branched covering $f^{*}$ from $\mathbf{C}$ to $\mathbf{C}$ as follows. If $z$ is in $J_{r}^{*}$, let $f^{*}(z)=f_{r} \circ\left(A_{r}\right)^{-1}$. If $z$ is in $E_{i m}$ let $f^{*}(z)=f_{i m}$. There is a complex structure on the domain of $f^{*}$ which makes $f^{*}$ holomorphic as follows. On each $J_{r}^{*}$ one has the usual complex structure of $\mathbf{C}$ and on each $E_{i m}$ define the complex structure as the pullback of the usual one by $f_{i m}$.

The Beltrami coefficient determined by this map is given by $\mu=0$ on each $J_{r}^{*}$ and $\mu=\left(\partial f_{i m} / \partial \bar{z}\right) /\left(\partial f_{i m} / \partial z\right)$ otherwise. By the measurable riemann mapping theorem, there is a quasi-conformal homeomorphism $\phi: \mathbf{C} \rightarrow \mathbf{C}$ so that $f^{*} \circ \phi$ is holomorphic in the usual complex strucutre on C. Since $f^{*} \circ \phi$ has the branching structure of a polynomial, it is a polynomial. Furthermore $f^{*} \circ \phi$ has the same critical values as $f$ and the same critical level curve combinatorics as recorded by $T$. Therefore, there is a homeomorphism $A: \mathbf{C} \rightarrow \mathbf{C}$ so that $f=f^{*} \circ \phi \circ A$. Since $f^{*} \circ \phi$ and $f$ are polynomials of degree $d, A$ is a degree one polynomial. By the Ahlfors- Bers theorem, $\phi$ will be close to the identity if $\mu$ is sufficiently close to 0 .

Theorem 3. Given $f$, if $\phi$ is sufficiently $C^{0}$ close to the identity then the topological version of (2) is true for $S(f, z, \theta)$ where $z$ is a root of $f$.

Proof. We can assume that $A=$ identity since $S(f \circ A, z, \theta)=S(f, A(z), A(\theta))$. Note that $\phi$ is automatically conformal in the interior of the pieces $J_{r}^{*}$, so that if $\phi$ is uniformly near the identity then $\phi^{\prime}(z)$ is near one. Consider a piece $K_{i}^{*}$ where $f_{i}(z)=\lambda_{i} z^{m_{j}}(z-1)^{m_{k}}$ and where $m_{j}=1$. For $f_{i}$, the critical point $\sigma_{i}=1 /\left(1+m_{k}\right)$ is topologically related to $z=0$ which is a root of $f_{i}$. For ease of notation denote $m_{k}$ simply by $m$. Then $S\left(f_{i}, 0, \sigma_{i}\right)=$ $(m /(1+m))^{m}$. For all $m,(m /(1+m))^{m}$ is contained in the interval $(1 / e, 1 / 2]$, so $\left|S\left(f_{i}, 0, \sigma_{i}\right)-1 / 2\right|<1 / 2-1 / d$, for $d \geq 3$. On the piece $K_{i}, f=f_{i} \circ \phi$.

Let $z=\phi^{-1}(0)$ and $\theta_{i}=\phi^{-1}\left(\sigma_{i}\right)$. Then $z$ is a root of $f$ and $\theta_{i}$ is a critical point of $f$ topologically related to $z$. A calculation shows that $S\left(f, z, \theta_{i}\right)=$ $\left\{\left(0-\sigma_{i}\right) /\left(\left(z-\theta_{i}\right) \phi^{\prime}(z)\right)\right\} S\left(f_{i}, 0, \sigma_{i}\right)$. For $\phi$ sufficiently near the identity $\phi^{\prime}(z)$ is near 1 and we conclude that $\left|S\left(f_{i}, 0, \sigma_{i}\right)-1 / 2\right|<1 / 2-1 / d$, for $d \geq 3$.

Proposition 1. For a polynomial $f$ of degree $d$, if $\left|f\left(\theta_{i+1}\right) / f\left(\theta_{i}\right)\right|$ is sufficiently large for all $i$ then the topological version of (2) is true for $S(f, z, \theta)$ where $z$ is a root of $f$.

Proof. This is a corollary of Thm. 3 if we show that in the construction above that we can make the Beltrami coefficient sufficiently close to zero.

Let $f(z)=\lambda z^{a}(z-1)^{b}$. For $\delta>0$ there is a degree one polynomial $A$ so that $f \circ A(z)=z^{a}(\varphi(z))$, with $|\varphi(z)-1|<\delta$ for all $z$ in some neighborhood of $z=0$. Furthermore there is a degree one polynomial $B$ so that $f \circ B(z)=$ $z^{a+b}(\psi(z))$, with $|\psi(z)-1|<\delta$, for all $z$ in some neighborhood of $z=\infty$. Suppose that for $|z|<R, f_{m} \circ A(z)=z^{n}(\varphi(z))$ and for $|z|>r, f_{i} \circ B(z)=$ $z^{n}(\psi(z))$. One shows that $\varphi$ and $\psi$ can be made $C^{1}$ close to 1 near $|z|=R, r$ respectively by the Cauchy inequalities. If $\left|f\left(\theta_{i+1}\right) / f\left(\theta_{i}\right)\right|$ is sufficiently large then we can choose $u_{i}$, so that $\left|f\left(\theta_{i}\right)\right|<u_{i}<\left|f\left(\theta_{i+1}\right)\right|<\left|f\left(\theta_{m}\right)\right|$, and so that $A_{m}\left(C_{i}\right) \subset\{z:|z|<R\}$ and $A_{i}\left(C_{i}\right) \subset\{z:|z|>r\}$. With these choices the covering map $f_{i m}$ must agree on the respective components of the boundary of $E_{i m}$ with $z^{n}(\varphi(z))$ and $z^{n}(\psi(z))$. Since both are $C^{1}$ close to the constant function $1, f_{i m}$ can be chosen so that $f_{i m}=z^{n}(H(z))$ where $H(z)$ is $C^{1}$ close to 1 and hence the Beltrami coefficient $\mu$ on $E_{i m}$ is close to zero. For a fixed degree $d$, there are only a finite number of polynomials $z^{a}(z-1)^{b}$ with $a+b \leq d$. Therefore, there is a constant $L$ so that if $\left|f\left(\theta_{i+1}\right) / f\left(\theta_{i}\right)\right|>L$ for all $i$, the proposition is true.
