Abstract

The Buda-Lund hydro model describes an expanding ellipsoidal fireball, and fits the observed elliptic flow and oscillating HBT radii successfully. Due to fluctuations in energy depositions, the fireball shape however fluctuates on an event-by-event basis. The transverse plane asymmetry can be translated into a series of multipole anisotropy coefficients. These anisotropies then result in measurable momentum-space anisotropies, to be measured with respect to their respective symmetry planes. In this paper we detail an extension of the Buda-Lund model to multipole anisotropies and investigate the resulting flow coefficients and oscillations of HBT radii.

1 Introduction

Anisotropies in distributions of hadrons produced in ultrarelativistic heavy-ion collisions are the key observable in the quest for the transport properties of the hot strongly interacting matter. Through a careful comparison of measured data with theoretical predictions access is open to the values of shear and bulk viscosity, the equation of state, equilibration time, and other properties of the matter. Distributions of hadrons are formed at the very last moment of fireball history when all hadrons leave from the hot and strongly coupled system. It is therefore instructive to understand how the observed anisotropies of the momentum distribution are connected to the shape and the expansion pattern of the fireball at freeze-out. Helpful tools for this task are the hydrodynamically inspired models of hadron production which allow for easy simulation of different final states of the fireball. Here we will use a model that is in close connection to exact solutions of hydrodynamics as well—the Buda-Lund model [1, 2].

There are two kinds of source anisotropies which are translated into the anisotropy of hadron distributions. One is connected with the shape of the fireball and the other with the angular dependence of its expansion velocity. It has been investigated in the past how they both individually contribute to the second-order anisotropy of single-particle distributions and oscillations of correlation radii in femtoscopy [3, 4].

1

Unprecedented statistics collected in nuclear collisions at the LHC and at RHIC allow also detailed study of higher-order anisotropies and higher-order oscillations of Bose-Einstein correlation radii [5–8]. There is at present no sufficient theoretical understanding of the femtoscopic measurements.

To this end, we extend here the Buda-Lund model so that it includes the third-order anisotropy in shape and expansion velocity. Then we give an outlook at the extension to even higher orders. We further calculate the third-order angular dependence of the spectra and correlation radii and analyze how it is influenced by the different features of the model.

The model provides description of direct hadron production without the inclusion of resonance decays. Although resonances are not included in our current investigation, we note that the core-halo model was developed to correct the hydrodynamical and phenomenological calculations, similar to the ones presented here, to take into account the effects of decays from long-lived resonances [9]. Long lived resonances decay in a halo region, characterized by large length-scales (typically 20 fm or larger) that are outside the hydrodynamically evolving, hot and dense hadronic matter, that is referred to as the core region. Comparing the core-halo model calculations to experimental data, the main effects of resonances appear to be the modification of the single-particle spectra of pions, and the suppression of the strength of the two-pion Bose-Einstein correlations, however, their effects on the short range Bose-Einstein correlation or HBT radii and on the anisotropies of the single particle spectra are negligible, as indicated by the hydrodynamical scaling of these observables [2, 10, 11].

2   The Buda-Lund model

The Buda-Lund model is formulated in terms of the source function, which represents the (Wigner) probability density of particle creation at a space-time point $x = (t, r_x, r_y, r_z)$ and four-momentum $p = (E, p_x, p_y, p_z)$. It generally takes the form of a Jüttner-type statistical distribution:

$$S(x,k)d^4x = \frac{g}{(2\pi)^3}\frac{p^\mu d^4\Sigma_\mu(x)}{B(x,p) + s_q} \tag{1}$$

where g stands for degeneracy factor, $p^\mu d^4\Sigma_\mu$ is the Cooper-Frye factor [12], s_q is a quantum-statistical term, being -1 for Bose-Einstein, 1 for Fermi-Dirac statistics, and 0 for Maxwell-Boltzmann statistics, and the thermodynamic distribution $B(x,p)$ takes the form

$$B(x,p) = \exp\left[\frac{p_\mu u^\mu(x)}{T(x)} - \frac{\mu(x)}{T(x)}\right]. \tag{2}$$

The freeze-out in this model happens along the hypersurface perpendicular to the flow velocity and the Cooper-Frye factor is expressed as [2]:

$$p^\mu d^4\Sigma_\mu(x) = p^\mu u_\mu(x)H(\tau)d^4x \tag{3}$$

where $H(\tau)$ is the freeze-out probability density in proper time, with τ being the proper time in the local frame co-moving with the velocity u_μ. The smearing factor of the freeze-out time will be assumed to take the form of a delta function: $H(\tau) = \delta(\tau - \tau_0)$. This simplification corresponds to the approximation when the freeze-out happens suddenly at τ_0 freeze-out time.

The velocity field is calculated from a potential $\Phi(x)$:

$$u_\mu = \gamma(1, \mathbf{v}) = \gamma(1, \partial_x \Phi, \partial_y \Phi, \partial_z \Phi) \tag{4}$$

where $\gamma = 1/\sqrt{1 - (\partial_x \Phi)^2 - (\partial_y \Phi)^2 - (\partial_z \Phi)^2}$. With the potential field we shall be able to introduce azimuthal angle variations of the expansion velocity field.

The model includes gradients in temperature profile:

$$\frac{1}{T(x)} = \frac{1}{T_0}\left(1 + a^2 s\right) \tag{5}$$

where a parametrizes the gradient and s is a scaling variable which depends on spatial coordinates and will be specified later. The parameter a^2 can also be expressed as

$$a^2 = \frac{T_0 - T_s}{T_s} \tag{6}$$

where T_0 is the central temperature and T_s is the temperature at the surface of the fireball. The scaling variable s is important when the parametrization is identified as a solution of a certain class of hydrodynamic models [13, 14]. In such a case, its co-moving derivative must vanish

$$u^\mu \partial_\mu s = 0 \,. \tag{7}$$

The fugacity term is defined similarly

$$\frac{\mu(x)}{T(x)} = \frac{\mu_0}{T_0} - bs \tag{8}$$

i.e. the parameter b is the density gradient. (Note that $b = 1$ was assumed in earlier versions of the Buda-Lund model.)

Next we extend the previous formulation of the Buda-Lund model so that anisotropy in azimuthal angle up to third order is included.

There are two kinds of asymmetries which we investigate in this paper: the spatial asymmetry and the velocity field asymmetry. The former can be described by the scale variable s. For completeness and for the sake of example let us review that the perfectly symmetric case (not investigated here) would be that of spherical symmetry with

$$s = \frac{r_x^2 + r_y^2 + r_z^2}{R_\circ^2} \tag{9}$$

and the spheroidal symmetry with distinguished longitudinal direction

$$s = \frac{r^2}{R^2} + \frac{r_z^2}{Z^2} \,, \tag{10}$$

with $r^2 = r_x^2 + r_y^2$. Depending on the model, $R_\circ$ and/or R is the radial scale and Z is the longitudinal scale. Ellipsoidal symmetry would be then represented by

$$s = \frac{r_x^2}{X^2} + \frac{r_y^2}{Y^2} + \frac{r_z^2}{Z^2} \,. \tag{11}$$

3

The anisotropy in transverse shape can be introduced for the elliptic deformation (second order) also like

$$s = \frac{r^2}{R^2}\left(1 + \epsilon_2 \cos(2\alpha)\right) + \frac{r_z^2}{Z^2},$$ (12)

with $\cos\alpha = r_x/r$, and a connection to the transverse principal axes of the ellipsoid (X, Y) can be established via $X = R/\sqrt{1 + \epsilon_2}$ and $Y = R/\sqrt{1 - \epsilon_2}$. A triangular deformation (third order) can also be introduced as

$$s = \frac{r^2}{R^2}\left(1 + \epsilon_3 \cos(3\alpha)\right) + \frac{r_z^2}{Z^2}.$$ (13)

The extension to asymmetry of arbitrary order is straightforward

$$s = \frac{r^2}{R^2}\left(1 + \sum_n \epsilon_n \cos\left(n(\alpha - \alpha_n)\right)\right) + \frac{r_z^2}{Z^2},$$ (14)

similarly to Ref. [14]. The phase factors α_n must generally be included to reflect the different orientation of the nth order event planes. Their influence will be investigated in more detail in Section 4.

The expansion velocity field is obtained via eq. (4) from the potential $\Phi(x)$. We generalize now the parametrization for $\Phi(x)$ in a similar way as we did for the scaling variable. Let us connect with previous works by recalling that for the spherically symmetric case one chooses

$$\Phi(x) = \frac{H_\circ}{2}r^2, \quad \mathbf{v} = (H_\circ r_x, H_\circ r_y, H_\circ r_z)$$ (15)

where $H_\circ$ is the radial Hubble-parameter, and eq. (7) with s from (9) can be fulfilled via the choice of $H_\circ = \frac{\dot{R}_\circ}{2R_\circ}$. The velocity profile with ellipsoidal expansion symmetry has so far been parametrized via [2]

$$\Phi(x) = \frac{H_x}{2}r_x^2 + \frac{H_y}{2}r_y^2 + \frac{H_z}{2}r_z^2,$$ (16)

$$\mathbf{v} = (H_x r_x, H_y r_y, H_z r_z),$$ (17)

where $H_{x,y,z}$ are the directional Hubble-parameters, and eq. (7) with s from (11) can be fulfilled via the choice of $H_x = \frac{\dot{X}}{2X}$ and similarly for y and z. Here X, Y, Z are the length scales in three perpendicular directions and $\dot{X}$, $\dot{Y}$, $\dot{Z}$ their proper time derivatives. Here we shall use a form that is more straightforwardly generalized to anisotropies of higher orders. The elliptic anisotropy is then parametrized as

$$\Phi(x) = \frac{H}{2}r^2\left(1 + \chi_2 \cos(2\alpha)\right) + \frac{H_z}{2}r_z^2$$ (18)

where H is the radial Hubble-parameter, while H_z is the one describing longitudinal expansion. This form fulfills eq. (7) with s from eq. (12), if

$$\dot{\epsilon}_2 = -2H\chi_2(1 - \epsilon_2^2), \quad \frac{\dot{R}}{R} = H(1 - \epsilon_2\chi_2), \quad \frac{\dot{Z}}{Z} = H_z.$$ (19)

4

For arbitrary-order asymmetries, Φ can be introduced via a general form

$$\Phi(x) = \frac{H}{2}r^2\left(1 + \sum_{n=2}^{\infty}\chi_n\cos(n(\alpha - \alpha_n))\right) + \frac{\dot{Z}}{2Z}r_z^2. \tag{20}$$

With this choice of u^μ and s from eq. (14), eq. (7) can be satisfied if one requires $\chi_n = 0$ and the time derivative of ϵ_n to vanish. This yields a Hubble-like expansion without the change in the asymmetries.

More generally, eq. (7) can also be fulfilled, if ϵ_n and χ_n are so small that their bilinear and quadratic terms can be neglected. In this case,

$$\frac{\dot{R}}{R} = H \quad \text{and} \quad \dot{\epsilon}_n = -2\frac{\dot{R}}{R}\chi_n \tag{21}$$

are required to fulfill eq. (7). The complete set of conditions that are derived from eq. (7) for the $\alpha_n = 0$ case includes:

$$\frac{\dot{R}}{R} = H\left(1 + \frac{1}{2}\sum_{n=1}^{\infty}\epsilon_n\chi_n\left(1 + \frac{n^2}{4}\right)\right), \tag{22}$$

as well as for any $k > 0$

$$\dot{\epsilon}_k = 2H\chi_k - 2\left(\frac{\dot{R}}{R} - H\right)\epsilon_k + H\sum_{n=1}^{\infty}\epsilon_n\chi_{n+k}\left(1 + \frac{n(n+k)}{4}\right) \tag{23}$$

$$+ H\sum_{\substack{n=1 \\ n\neq k}}^{\infty}\epsilon_n\chi_{|n-k|}\left(1 + \frac{n(n-k)}{4}\right).$$

If only a subset of ϵ_n and χ_n values are nonzero, then this set of equations can be solved successively. Let us recall that since the co-moving derivative of s vanishes in all the above cases, the Buda-Lund profile described above can be taken as a result of a hydrodynamic calculation, and may form the basis of exact hydrodynamic solutions. Note, however, that this will *not* be required in the present study. For an illustration of the density and flow fields defined above, see Fig. 1.

3   Single particle distributions

Observable quantities, like invariant momentum distributions or the correlation radii, are generally obtained by integrating and calculating the space-time moments of the source function, eq. (1). If this cannot be accomplished analytically then numeric methods have to be resorted to.

The invariant momentum distribution is obtained as

$$E\frac{d^3N}{dp^3} = N_1(p) = \int d^4x\, S(x,p). \tag{24}$$

In this paper we shall concentrate on midrapidity, as is appropriate for the description of the experiments at RHIC and the LHC. Furthermore, when looking at azimuthally integrated
Figure 1: Example flow (left) and density (right) fields with example values of $\epsilon_2 = \chi_2 = 0.3$ and $\epsilon_3 = \chi_3 = 0.1$ for the asymmetry coefficients.

distributions we shall have to integrate over the azimuthal angle of the emitted hadrons (which we denote by ϕ here)

$$\frac{d^2N}{p_t \, dp_t \, dy} = \int_0^{2\pi} d\phi \, N_1(p) \,. \tag{25}$$

The anisotropies of the transverse momentum distribution are denoted by v_n. These observables drew much experimental as well as theoretical interest recently, and are defined as n-th order Fourier coefficients with respect to the angle of the n-th order event plane ψ_n:

$$\frac{\frac{d^3N}{p_t \, dp_t \, dy \, d\phi}}{\frac{d^2N}{2\pi p_t \, dp_t \, dy}} = 1 + 2 \sum_{n=1}^{\infty} v_n \cos(n(\phi - \psi_n)). \tag{26}$$

The anisotropy coefficients v_n can be obtained from

$$v_n e^{in\psi_n} = \frac{\int_0^{2\pi} d\phi \, e^{in\phi} \, N_1(p)}{\int_0^{2\pi} d\phi \, N_1(p)} \,. \tag{27}$$

Usually, v_2 is referred to as elliptic flow and v_3 as triangular flow.

In our calculations we chose the values of parameters that are motivated by earlier fits to data [4, 15]. They are listed in Table 1.

Generally, one expects that the azimuthal anisotropy has no influence on the azimuthally integrated spectrum. However, the space and flow anisotropies in the present model modify the effective volume, particularly at high p_t where the anisotropy is more pronounced. This is illustrated in Fig. 2. Thus there is a slight flattening of the single-particle p_t spectra connected with the increase of the anisotropy parameters ϵ_i and/or χ_i. Note that in the figure we only show the dependence on ϵ_2 but this is qualitatively similar to the dependences on other parameters.

It has been calculated in [3] how the elliptic flow coefficient v_2 depends on the second order anisotropy in shape and expansion. Here, in Fig. 3 we again plot this dependence together with the dependence of v_3 on ϵ_3 and χ_3. Similarly to the second order, also here we have an ambiguity: same values of v_i can be obtained from various combinations of ϵ_i and χ_i. Note that ϵ_2 and χ_2 do not influence v_3, and vice versa.

Particle mass	m	140 MeV
Freeze-out time	τ_0	7 fm/c
Central freeze-out temperature	T_0	170 MeV
Temperature-asymmetry parameter	a^2	0.3
Spatial slope parameter	b	−0.1
Transverse size of the source	R	10 fm
Longitudinal size of the source	Z	15 fm
Transverse expansion	$\dot{R}$	1
Longitudinal expansion	$\dot{Z}$	0.94

Table 1: Default values of the model parameters (at the freeze-out). Anisotropy parameters are not listed here because they are varied in the different studies reported here.
Figure 2: Azimuthally integrated single-particle p_t spectra for various values of the second-order anisotropy parameter ϵ_2.

Figure 3: The effect of various anisotropy parameters on the flow coefficients. at $p_t = 300$ MeV/c.

4   Correlation radii

The correlation radii are very important quantities for the exploration of the space-time structure of the source. Generally, the two particle momentum correlation function is defined as

$$C_2(p_1, p_2) = \frac{N_2(p_1, p_2)}{N_1(p_1)N_1(p_2)}. \tag{28}$$

The denominator which provides the two-particle distribution with no correlations is experimentally obtained by means of event mixing. Usually one introduces the momentum difference q and the average pair momentum K

$$q = p_1 - p_2 \ \text{ and } \ K = \frac{p_1 + p_2}{2}. \tag{29}$$

Then the correlation function can be determined (within reasonable approximation) from the source function

$$C_2(q, K) = 1 + \frac{\left| \int d^4x \, e^{iqx} S(x, K) \right|^2}{\left(\int d^4x S(x, K) \right)^2}. \tag{30}$$

If the shape of the correlation function is reasonably close to a Gaussian, then the correlation function can be parametrized by a Gaussian

$$C(q, K) = 1 + \lambda \exp\left(-\sum_{i,j} R_{ij}^2 \, q_i \, q_j \right) \tag{31}$$

run over the spatial directions, and where the parameter λ stands for the (in general, mean momentum dependent) intercept parameter, that measures the strength of two-particle Bose-Einstein correlation functions. When particle identification errors are negligibly small, this parameter λ can be interpreted in the core-halo picture as the (momentum dependent) squared fraction of particles coming from the hydrodynamically evolving core [9].

The temporal component of q is suppressed via the on-shell constraint

$$q \cdot K = 0 \Rightarrow q^0 = \frac{\vec{q} \cdot \vec{K}}{K^0} = \vec{q} \cdot \vec{\beta}. \tag{32}$$

For nearly Gaussian, for example hydrodynamically evolving sources, the correlation radii R_{ij}^2 can be expressed through spatio-temporal (co)variances of the hydrodynamically evolving, core part of the source function. The temporal admixture in these radii is due to the on-shell constraint (32). Note, however, that long lived resonances typically dominate the variances of the source distribution even if their decay products are present in a small relative fraction. Due to this reason, the evaluation of the correlation radii has to be restricted to the core or the hydrodynamically evolving part of the source [10].

When studying the azimuthal dependence of the correlation radii, meticulous bookkeeping of the angular variables is requested. Recall that we denote that

ϕ is the azimuthal angle of the emitted particles

ψ_n is the n-th order event plane determined for the distribution of produced hadrons according to eq. (27)

α is the spatial coordinate azimuthal angle

α_n is the phase of the spatial azimuthal dependence of the source function.

It is also useful to notice that ϕ and ψ_n are measurable while α and α_n only appear in the calculations and cannot be directly accessed by measurement.

In general, the correlation radii measure the lengths of homogeneity [16]. These are sizes of the homogeneity regions from which particles with given momentum are produced. For hydrodynamically expanding fireballs, these homogeneity regions are typically smaller than the whole volume of the fireball, if the fireball has gradients in the flow velocity distribution, that lead to variations in the local flow velocities that are larger than what can be overcompensated by the locally thermalized velocity distribution of the emitted particles.

The spatio-temporal distribution of the particle emitting source is frequenty analyzed in the Bertsch-Pratt side-out-longitudinal decomposition, as measured in the Longitudinal Center of Mass System of the particle pair (LCMS). LCMS is the frame where the longitudinal component of a given particle pair has vanishing mean momentum along the beam direction, the transverse momentum components being the same as in the laboratory. In this frame, the direction of the mean momentum of a given particle pair defines the outwards or *out* direction, which is perpendicular to the beam direction, which in turn is referred to as the longitudinal or *long* direction. The sidewards or *side* direction is perpendicular to both the *out* and the *long* direction, so that the (*side,out,long*) directions form a right-handed coordinate system.

When analyzing the correlations of particles emitted under different azimuthal angles, one looks at the fireball from those angles. This change of the viewpoint introduces the *explicit* azimuthal angle dependence of the correlation radii.

The homogeneity regions change for particles emitted under different azimuthal angles. This introduces the *implicit* azimuthal angle dependence of the correlation radii.

It is instructional to write out the outward and sideward coordinates as

$$r_{\text{out}} = r \cos(\alpha - \phi) \tag{33a}$$
$$r_{\text{side}} = r \sin(\alpha - \phi) \tag{33b}$$

where ϕ is defined by the direction of the particle. With this notation we obtain

$$R_{\text{out}}^2(K) = \left\langle (r_{\text{out}} - \beta_t t)^2 \right\rangle_c - \left\langle r_{\text{out}} - \beta_t t \right\rangle^2 \tag{34a}$$
$$R_{\text{side}}^2(K) = \left\langle r_{\text{side}}^2 \right\rangle_c - \left\langle r_{\text{side}} \right\rangle_c^2 . \tag{34b}$$

where β_t is the transverse component of β introduced in eq. (32), and we have introduced averaging over the source function of the hydrodynamically evolving core

$$\langle f(x) \rangle_c = \frac{\int d^4x \, f(x) \, S_c(x, K)}{\int d^4x \, S_c(x, K)} , \tag{35}$$

similarly to e.g. the notation of eqs. (106)-(110) of ref. [10]). Using this method, we have evaluated the correlation radii numerically as functions of ϕ for various azimuthal anisotropy parameters.
Figure 4: The ϕ-dependence of R^2_{out} for sources with $\chi_2 = 0.2$, $\chi_3 = 0.3$, and $\epsilon_2 = \epsilon_3 = 0$. Sources are oriented so that $\alpha_2 = 0$ (top) and $\alpha_3 = 0$ (bottom). Different curves correspond to different values of $\Delta\alpha_{23} = \alpha_2 - \alpha_3$.

In the real experiment the shape and expansion pattern of the fireball fluctuate from event to event. Even if we fix the average transverse size and the anisotropy parameters ϵ_n and χ_n there still remain the phases α_n which are unlikely to be correlated for the second and the third order. In an experimental analysis one usually rotates all events so that they are aligned according to ψ_2 or ψ_3. By rotating and summing up a large number of events only oscillations of the same order (and its multiplicatives) remain as that of the angle of the reaction plane.

In order to see both the second-order and the third-order oscillations in data one would have to refrain from averaging over a large number of events which all have different $\Delta\psi_{23} = \psi_2 - \psi_3$. Perhaps a way to select events for such an analysis can be provided by the recently proposed Event Shape Sorting [17]. Here we want to investigate what is actually the effect of averaging on the ϕ-dependence of the correlation radii. To this end, we fix the anisotropy parameters and perform several calculations where we always set the difference of α_2 and α_3 at a different value. Note that in the calculation we rotate the source by choosing α_2 and α_3, while the experimental data analysis is done with the event planes ψ_2 and ψ_3. In a soft particles emitting source without resonance decays—like here—those two kinds of directions actually must agree.

The results for R^2_{side} vs. ϕ with different $\Delta\alpha_{23} = \alpha_2 - \alpha_3$ values are plotted in Fig. 4. We clearly see that the gross shape of the dependence is set by the choice of the alignment angle. This behavior is best understood qualitatively if we write out the velocity field for both cases. If we rotate the source to the second-order event-plane, i.e. $\alpha_2 = 0$, then the transverse

10

velocity field derived from Eq. (4) with $\Phi(x)$ given by Eq. (20) becomes

$$v_x = r\frac{\dot{R}}{R}\left(\cos\alpha + \chi_2\cos\alpha + \frac{\chi_3}{4}(5\cos(2\alpha - \Delta\alpha_{23}) - \cos(4\alpha - \Delta\alpha_{23}))\right) \tag{36a}$$

$$v_y = r\frac{\dot{R}}{R}\left(\sin\alpha - \chi_2\sin\alpha - \frac{\chi_3}{4}(5\sin(2\alpha - \Delta\alpha_{23}) + \sin(4\alpha - \Delta\alpha_{23}))\right). \tag{36b}$$

The scaling variable for non-vanishing ϵ_2 and ϵ_3 would be

$$s = \frac{r^2}{R^2}(1 + \epsilon_2\cos(2\alpha) + \epsilon_3\cos(3\alpha - \Delta\alpha_{23})) + \frac{r_z^2}{Z^2}. \tag{37}$$

If, on the other hand, we choose $\alpha_3 = 0$, then the velocity field becomes

$$v_x = r\frac{\dot{R}}{R}\left(\cos(\alpha) + \chi_2\cos(\alpha + \Delta\alpha_{23}) + \frac{\chi_3}{4}(5\cos(2\alpha) - \cos(4\alpha))\right) \tag{38a}$$

$$v_y = r\frac{\dot{R}}{R}\left(\sin(\alpha) - \chi_2\sin(\alpha + \Delta\alpha_{23}) - \frac{\chi_3}{4}(5\sin(2\alpha) + \sin(4\alpha))\right), \tag{38b}$$

and the scaling variable

$$s = \frac{r^2}{R^2}(1 + \epsilon_2\cos(2\alpha + \Delta\alpha_{23}) + \epsilon_3\cos(3\alpha)) + \frac{r_z^2}{Z^2}. \tag{39}$$

Due to the mechanism of how the flow velocity is set by Eq. (4) the angle difference $\Delta\alpha_{23}$ is combined in the two cases with different orders of harmonic oscillations and there is no simple shift from one alignment to the other.

When summing up over a large number of events the various curves are all being averaged into one. We want to see the influence of such averaging. To this end, we set $\alpha_2 = 0$ and calculate $R_{\mathrm{side}}^2(\phi)$ in two different ways. First, calculation via Eq. (34b) is performed with $\chi_2 = 0.2$ and $\chi_3 = 0.3$ at multiple values of $\Delta\alpha_{23}$ and then the results are averaged over $\Delta\alpha_{23}$. Second, χ_3 is set to 0 and the calculation with only the second-order parameter $\chi_2 = 0.2$ is performed. Both results are plotted in Fig. 5. We observe that the averaging basically preserves the shape of the dependence but it increases its absolute size by a relatively small amount. Qualitatively, similar results are observed for averaging over any of ϵ_2, ϵ_3, χ_2, χ_3.

This is best understood qualitatively by means of a very simplified model in which, however, we keep both the second and the third order variation. Let us write the emission function as

$$S_{\mathrm{toy}}(x) = e^{-s} = \exp\left[-\frac{r^2}{R^2}(1 + \epsilon_2\cos 2\alpha + \epsilon_3\cos 3(\alpha - \Delta\alpha_{23}))\right]. \tag{40}$$

Then if we average over $\Delta\alpha_{23}$, we get

$$S_{\mathrm{toy,av}}(x) = \langle S_{\mathrm{toy}}(x)\rangle_{\Delta\alpha_{23}} = \exp\left[-\frac{r^2}{R^2}(1 + \epsilon_2\cos 2\alpha)\right]I_0\left(\epsilon_3\frac{r^2}{R^2}\right) \tag{41}$$

with I_0 denoting the zeroth order modified Bessel function. If we then integrate over α, we get

$$\int d\alpha S_{\mathrm{toy,av}}(x) = 2\pi e^{-\frac{r^2}{R^2}}I_0\left(\epsilon_2\frac{r^2}{R^2}\right)I_0\left(\epsilon_3\frac{r^2}{R^2}\right). \tag{42}$$
11

Figure 5: The ϕ-dependence of R^2_{side} for $\chi_2 = 0.2$, $\epsilon_2 = \epsilon_3 = 0$. Solid: $\chi_3 = 0.3$ and the curve is averaged over $\Delta\alpha_{23}$; dashed: $\chi_3 = 0$ and no averaging.

However, if we had set $\epsilon_3 = 0$ and then integrated over α, we would have obtained

$$\int d\alpha S_{\text{toy}}(x; \epsilon_3 = 0) = 2\pi \exp\left[-\frac{r^2}{R^2}\right] I_0\left(\epsilon_2 \frac{r^2}{R^2}\right). \tag{43}$$

The two results differ by a factor of $I_0\left(\epsilon_3 r^2/R^2\right)$, even in this very simple case, and in the more complicated case of Fig. 5. It is also clear from this that averaging over random variations between the difference of the third order and second order event planes, or assuming that there are no third order variations in the density profile leads to very similar results for $\epsilon_3 \ll 1$, with corrections of the order of ϵ_3^2. It also turns out, that the same is true for third order oscillations: event-plane averaged second order anisotropies have an effect of the size $I_0\left(\epsilon_2 r^2/R^2\right)$.

A numerical investigation of the effects of third order variations of the velocity profile is indicated in Fig. 5, that suggests that the relative error that comes from the averaging over the random orientation of the third order event plane modifies the amplitude of HBT oscillations slightly, and the modification increases with increasing χ_3, the coefficient of third order variations of the velocity profile.

In order to describe the azimuthal oscillations of Bose-Einstein or HBT radii, a blast-wave model was also developed in ref. [18]. It was applied to study the second order oscillations of pion and kaon HBT radii in ref. [19]. However, in these models, third order anisotropies as well as the possible difference between the second order and third order event planes have not been considered. Based on Fig. 5, such an approximation may be valid if ξ_3, the amplitude of third order oscillations in the local valocity distribution does not exceed the relative error of the experimental determination of the HBT radii, corresponding to 5-10 % in the case of a recently published measurement of pion and kaon correlations [19].

This shows that if one needs to speed up the calculation then the easier way by setting some anisotropies to 0 is viable. We have checked that this gives good results for the $\alpha_2 = 0$ leading Fourier order of the ϕ-dependence and some deviations may appear (though not always) in
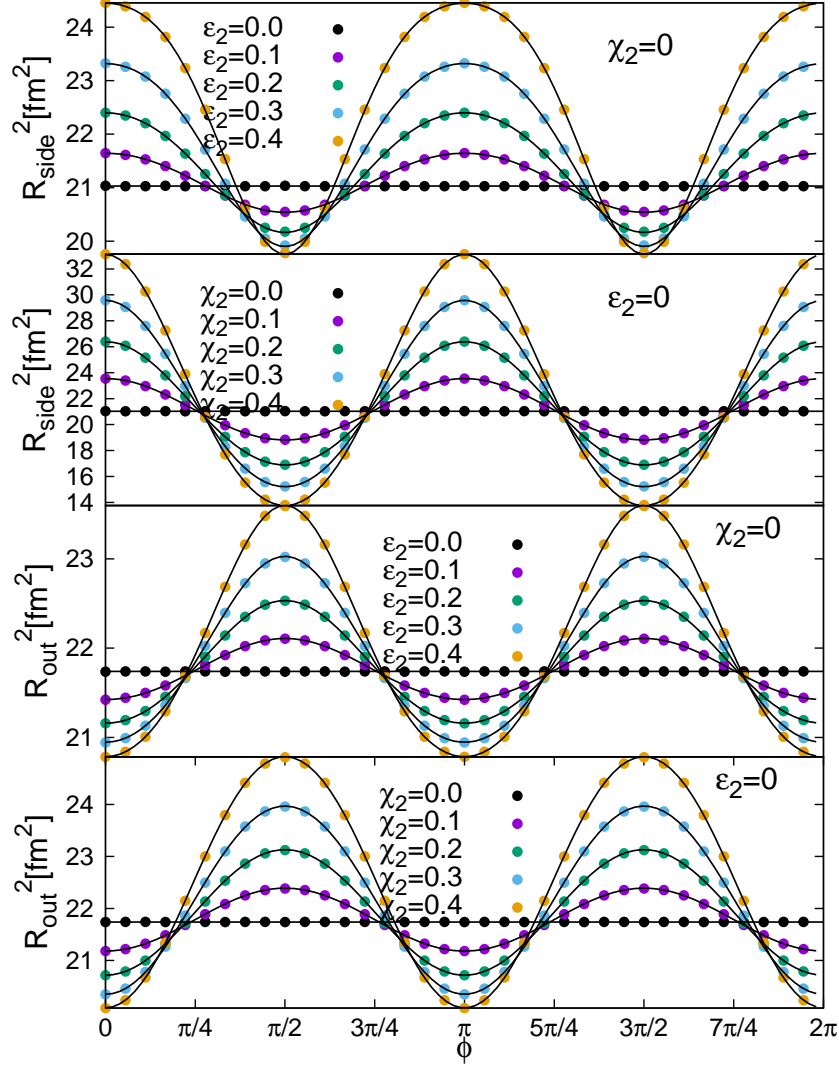

12

Figure 6: The ϕ-dependence of R_{out}^2 and R_{side}^2 after setting $\psi_2 = \alpha_2 = 0$ and averaging over $\Delta\alpha_{23}$. Values of parameters are indicated in the panels. Points are results of calculations, lines are fits with Eq. (44).
Figure 7: The ϕ-dependence of R_{out}^2 and R_{side}^2 after setting $\psi_3 = \alpha_3 = 0$ and averaging over $\Delta\alpha_{23}$. Values of parameters are indicated in the panels. Points are results of calculations, lines are fits with Eq. (45).

the sub-leading terms. There are differences between the results of the two schemes for the case $\alpha_3 = 0$. The results presented here are obtained by conscientious averaging over $\Delta\alpha_{23}$.

In Fig. 6 we present the ϕ-dependence of R^2_{out} and R^2_{side} with $\psi_2 = \alpha_2 = 0$, for various values of ϵ_2 and χ_2 (while $\epsilon_3 = 0$, $\chi_3 = 0$). Similarly, in Fig. 7 the third-order oscillation is presented with $\psi_3 = \alpha_3 = 0$ and second-order parameters set to $\epsilon_2 = 0$, and $\chi_2 = 0$. The common observation of these dependencies clearly shows that there are important next-to-leading order contributions in the Fourier expansions of $R^2_{\text{out}}(\phi)$ and $R^2_{\text{side}}(\phi)$.

To analyze this, the calculated values (data points) were fitted with Fourier series. For $\psi_2 = 0$ this reads

$$R^2_i(\phi) = R^2_{i,2,0} + R^2_{i,2,2}\cos(2\phi) + R^2_{i,2,4}\cos(4\phi) + R^2_{i,2,6}\cos(6\phi), \tag{44}$$

where i stands for 'out' or 'side'. Higher-order terms have been neglected. For $\phi_3 = 0$ we have an expansion with terms of order 3 and its multiples

$$R^2_i(\phi) = R^2_{i,3,0} + R^2_{i,3,3}\cos(3\phi) + R^2_{i,3,6}\cos(6\phi) + R^2_{i,3,9}\cos(9\phi). \tag{45}$$

Note that in general $R^2_{i,3,6} \neq R^2_{i,2,6}$. Therefore we have to introduce the cumbersome indexing of the Fourier terms which indicates the order of the event-plane set to 0 and the order of the term.

The dependence of scaled amplitudes $R^2_{i,2,2}/R^2_{i,2,0}$ has been studied in Ref [3]. Here we show it for completeness in Fig. 8 together with the average radii and the scaled amplitudes for the fourth order, $R^2_{i,2,4}/R^2_{i,2,0}$. Note the symmetry of the results with respect to the change $(\epsilon_2, \chi_2) \to (-\epsilon_2, -\chi_2)$. In fact, such a change is equivalent to a mere shift of the phase α_2 by $\pi/2$. An interesting saddle-like dependence is discovered for the fourth-order scaled amplitudes. While $R^2_{i,2,4}/R^2_{i,2,0}$ seems to vanish very roughly along the diagonals $\chi_2 = \pm\epsilon_2$, an important fourth order contribution shows up when one of the parameters is close to 0.

For the $\alpha_3 = \psi_3 = 0$ case we plot the average and the third and sixth-order scaled amplitudes as functions of χ_3 and ϵ_3 ($\epsilon_2 = 0$, $\chi_2 = 0$) in Fig. 9. Although we have kept the same R in all calculations, the change in $R^2_{i,3,0}$ can be as large as 30% for the investigated interval of ϵ_3 and χ_3. Smallest values are obtained roughly along $\epsilon_3 = -\chi_3$ which actually means that spatial and flow anisotropies have phases shifted by the maximum value of $\pi/6$. The largest radii are obtained for large values of $\epsilon_3 = \chi_3$.

The third-order scaled amplitude of $R^2_{\text{side}}(\phi)$ shows an interesting dependence on χ_3 and ϵ_3. It seems to mainly depend on spatial anisotropy ϵ_3, so in first approximation $R^2_{\text{side},3,3}/R^2_{\text{side},3,0}$ could be used for the determination of ϵ_3. However, we also observe a wavy structure if it is considered as a function of χ_3, as indicated by the second panel of Fig. 7, so the statement holds only approximately. Nevertheless, we observe that the correlation between χ_3 and ϵ_3 which leads to the same value of $R^2_{\text{out},3,3}/R^2_{\text{out},3,0}$ is almost perpendicular to that which yields the same v_3 (cf. Fig. 3). Thus from the combination of the two measurements one should be able to determine both third-order anisotropy parameters of this model.

The contribution from the sixth-order Fourier coefficient has its gradient roughly along the line $\chi_3 = -\epsilon_3$. This is the same direction as the one along which we observe the smallest average values of the correlation radii.

The most important observation is however, that with the contours of Fig. 3 and Figs. 8-9, indeed the spatial and flow-field anisotropies can be disentangled. For illustration, in Fig. 10 we show how the particular values of the oscillation of the correlation radii and of the flows let one determine the contribution from ϵ_2, χ_2, ϵ_3, and ξ_3.
15

Figure 8: Average radius and scaled amplitudes with $\psi_2 = \alpha_2 = 0$ for R^2_{side} (left column) and R^2_{out} (right column) average (top row), second (middle), and fourth (bottom) scaled amplitude, as functions of ϵ_2 and χ_2.
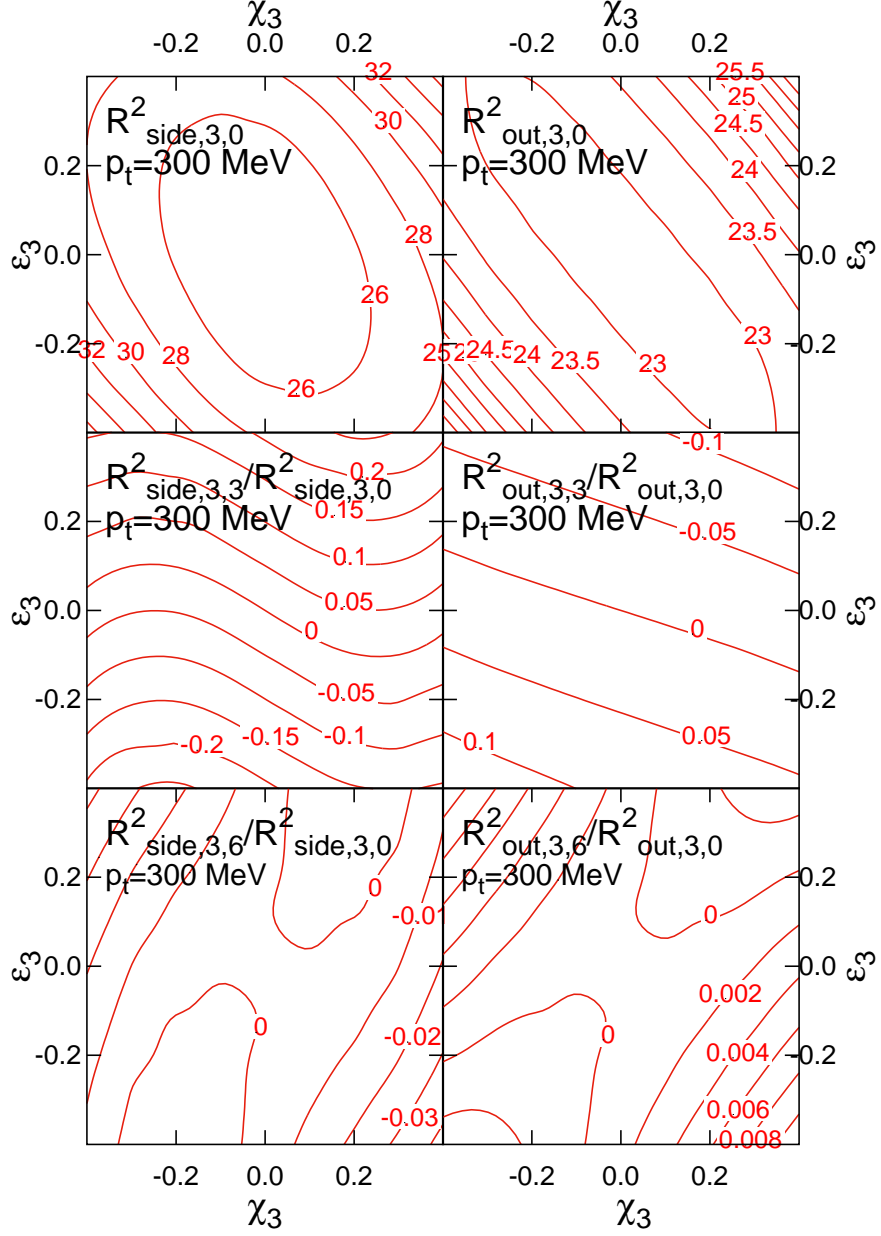

Figure 9: Average radius and scaled amplitudes with $\psi_3 = \alpha_3 = 0$ for R^2_{side} (left column) and R^2_{out} (right column) average (top row), third (middle), and sixth (bottom) scaled amplitude, as functions of ϵ_2 and χ_2.
Figure 10: Flow coefficients and scaled amplitudes from Figs. 3,8-9 superimposed, as functions of ϵ_2, χ_2, ϵ_3, and ξ_3. The upper panels show the second order scaled HBT amplitudes as well as the elliptic flow, while the lower panels show the third order scaled HBT amplitudes as well as the triangular flow. The lines that go through the point (0,0) in the ϵ, χ plane correspond to the 0 value of the given observable. The values of the consecutive contours can be read out from Figs. 8-9.

5   Conclusions

We have extended the Buda-Lund hydro model with higher-order anisotropies in transverse shape and expansion velocity profile. In a special case, this model can be identified with a solution of a certain hydrodynamic model.

With the extended model we pushed further the study that has been started in [3]. There, the influences of second-order anisotropies in space and expansion on the observable v_2 and the elliptic modulation of the correlation radii were investigated. It was deduced, how to disentangle them with the help of the following observations: to consider both the elliptic flow and the second order HBT oscillations. In a similar manner, here we showed that the third-order anisotropies in space and expansion velocity can be disentangled if v_3 and $R^3_{i,3,3}/R^2_{i,3,0}$ are studied experimentally.

Within the Buda-Lund model we investigated how the mean value of the correlation radii and the absolute normalization of single particle p_t spectra increase if we average over the azimuthal angle.

The conclusions drawn here were deduced from the results obtained with the extended Buda-Lund model. There are other analogical parameterizations of the freeze-out state of the fireball on the market, however. Examples are the Blast-wave model [18, 20] and/or the Cracow single freeze-out model [21]. In the next future we therefore plan to implement higher-order anisotropies also in the Blast-wave model and perform a similar study. This will show which features of the results obtained here are robust and which are rather an artifact of the specific model.

Future analytic investigations of solutions with small density and velocity perturbations along the lines of ref. [22] on the top of those exact hydrodynamical solutions that form the basis of the Buda-Lund hydro model (for example refs. [2, 11]) are also among the future research directions that we consider important to pursue.
