ARTICLE INFO

Keywords: Biochar Pyrolyzed chitosan CO₂ capture Gas adsorption-separation

ABSTRACT

Sponge-like biochar sorbents were prepared from the dissolution of chitosan followed by freeze-drying methodology and pyrolysis at three different temperatures (400, 600, and 800 °C) to produce sustainable N-enriched carbon materials with enhanced CO2 uptake from CO2/CH4 and CO2/N2 gas mixtures. The pyrolysis process was reproduced by operando TGA-IR to study the gas evolved from the pyrolysis process. It was found that the pyrolysis temperature highly influences the textural properties of the chitosan sponge-like biochar materials, impacting mainly the amount and type of the N-species on the sample but also at the microporosity. XPS revealed the transformation of the amino groups from chitosan into pyridinic-N, pyrrolic-N, graphitic center-N, and graphitic valley-N or pyridine-N oxide species during the pyrolysis process. Increasing the pyrolysis temperature enhanced the quantity of the latter two N-type species. All sponge-like biochars adsorbed higher amounts of CO_2 compared with CH₄ and N₂ gases, with maximum CO₂ uptake (~1.6 mmol·g⁻¹) at 100 kPa and 25 °C for the sample pyrolyzed at 600 °C (named CTO_P600). Biochar produced at 800 °C showed no longer adsorption capacity for CH₄ and N₂, having the highest selectivity value for CO₂/N₂ separation under continuous flux conditions among all prepared biochar sorbents. Isobaric CO2 adsorption measurements on the CTO_P600 sorbent revealed that physisorption phenomena predominantly governed the CO2 adsorption process, which was confirmed by its consistent adsorption capacity after 10 consecutive adsorption-desorption cycles. Moreover, the biochar exhibited tolerance to water vapor adsorption, indicating its suitability to work under moisture-rich conditions.

1. Introduction

Carbon dioxide (CO_2) is one of the major greenhouse gases (GHG) that contributes to global warming and is significantly produced from anthropogenic sources [1-4]. To reduce GHG emissions, CO_2 capture, usage, and storage (CCUS) technologies have been pursued [2,4,5]. Currently, the most common commercial technology for CO_2 uptake is based on the absorption process by employing liquid amines like monoethanolamine (MEA) and diethanolamine (DEA) [1]. However, this method has significant negative human and environmental drawbacks, requiring a large amount of energy [1] and making amine scrubbing impractical for some CO_2 uptake applications, like biogas upgrading or

flue gas cleaning from the cement industry [1,2,6]. Therefore, it is essential to develop cost-effective sorbents from sustainable sources like biomass that can efficiently adsorb CO_2 and be used in large-scale post-combustion technologies or biogas upgrading. Among all sorbents, carbon materials are physical adsorbents with a high potential for CO_2 capture. They are less sensitive to moisture, have high adsorption capacity at ambient pressure, are more stable, easily regenerated, and require less power than conventional chemical processes [1,5,7]. However, most of these CO_2 adsorbents show low selectivity for CO_2/N_2 and CO_2/CH_4 separation processes or are relatively high priced.

Biochar, a carbon-based solid, can be obtained by pyrolysis of biomass. The unique features of biochar (namely thermal and chemical

stabilities) combined with a wide range of chemical compositions and surface properties (that can be obtained depending on the biomass source and synthesis conditions) are advantageous for CO_2 adsorption [8,9]. Still, there is a scarcity of studies using novel and optimized methods to enhance the biochar adsorption properties [10,11] and in understanding the solid–gas interfaces at the material surface as it occurs with porous silicas [12-16].

Perilla biochar [11], among other tested biochars (derived from soybean stover, Korean oak, and Japanese oak), showed the highest adsorption capacity and removal rate for H2S and CO2 gases from biogas due to the higher N amount, surface area, and mesoporosity. Yet, perilla leaf is used in Asian cuisine and Chinese medicine, and no selectivity and reusability were studied, essential for industrial application. Wang et al. [17] prepared algae-derived nitrogen-containing porous carbons for CO₂/CH₄ and CO₂/N₂ adsorption-separation. The materials showed good CO₂ adsorption capacity (maximum 3.9 mmol·g⁻¹) and CO₂/CH₄ and CO2/N2 selectivities at 100 kPa (with maximum values of 49 and 16.9, respectively). However, the synthesis process uses pulverized KOH before pyrolysis, and the study of the adsorption measurements considering pressures higher than 100 kPa and under humid conditions is missing. Duràn et al. [18] synthesized a lignocellulosic-based activated carbon for biogas upgrading. The authors carried out binary CO₂/ CH₄ breakthrough experiments at 30 °C under different gas compositions and adsorption pressures in a fixed-bed lab set-up to determine the competitive adsorption behavior of the activated carbon sample under dry and humid conditions. This material adsorbed 2 mmol·g⁻¹ of CO₂ at 120 kPa and 30 °C in a binary CO₂/CH₄ (50/50 vol.%) mixture, but the selectivity for CO2 over CH4 was only 5.23 under dry conditions. Under humid conditions, the CO2 adsorption capacity and the CO2/CH4 selectivity decreased to 1.39 and 3.36 mmol $\,\mathrm{g}^{-1}$, respectively. Lourenço et al. [10] prepared and tested biochar derived from chitosan with different surface areas, pore sizes, and N content and tested these sorbents on CO₂/CH₄ adsorption-separation. The authors observed that the drying method (supercritical CO₂, vacuum, or muffle under 40 °C) influenced the biochar microstructure and chemistry of the final material. Pyrolyzed chitosan spheres previously dried with supercritical CO₂ had the highest CO₂ adsorption capacity, selectivity, and easy regeneration compared with the samples dried using the other methods [10]. Nevertheless, the synthesis to prepare the chitosan alcohol beads is complicated and very time-consuming, and the adsorption kinetics of the obtained material is very slow, being relevant to enhance the method. Also, it is important to study the competitive adsorption of CO₂/N₂ and CO₂/H₂O gas mixtures and cyclic stability.

Here, we describe the preparation of sponge-like chitosan biochar sorbents for gas separation processes. Three biochar samples are prepared using a simple method by freeze-drying a chitosan solution followed by pyrolysis at different temperatures (400, 600, and 800 °C). Thermogravimetric analysis coupled with infrared spectroscopy (TGA-IR) is used to study the gases that evolve during the pyrolysis process at different temperatures, while X-ray photoelectron spectroscopy (XPS) provides information about the functional groups of the produced samples. Biochar materials are tested by measuring the pure CO₂, CH₄, and N_2 adsorption isotherms (at pressures up to 1000 kPa and 25 $^{\circ}$ C) to assess their potential for CO₂ separation from mixtures with N₂ and CH₄. The results are correlated with the materials' textural properties (specific surface area, pore volume, N content, and chemical species) to understand their relationship with CO2 adsorption and CO2/CH4 and CO₂/N₂ separation ability. The ability to capture CO₂ in a 20% mixture of CO₂/N₂ in a continuous flux process is determined for all biochar materials. Finally, the best-performing sample is tested for pure CO2 adsorption up to the atmospheric pressure and at different temperatures (30 – 80 °C), on water adsorption–desorption isotherm, on CO₂ adsorption isotherms under varied moisture conditions, and on 10 CO₂ adsorption-desorption cycles to study its sensitivity to temperature, humidity, and reusability, which are relevant aspects for industrial gas separation operation conditions.

2. Experimental details

2.1. Chemicals

Chitosan (medium molecular weight, 190,000-310000 Da, CAS number 9012-76-4) and acetic acid (glacial, 100%) were purchased from Sigma-Aldrich and used as received.

2.2. Pyrolyzed chitosan

Chitosan (CTO) based biochar was synthesized using a similar method described by Lourenço *et al.* [19]. Typically, chitosan (1.5 wt.%) was added to an acetic acid aqueous solution (268 mL, 0.1 M) and stirred overnight at room temperature. The chitosan solution was filtered-off, frozen overnight, and freeze-dried for 72 h. The obtained sponge-like chitosan aerogel was pyrolyzed under N_2 flux using the following heating procedure: i) $5 \, ^{\circ}$ C·min $^{-1}$, $200 \, ^{\circ}$ C, $2 \, h$ and ii) $5 \, ^{\circ}$ C·min $^{-1}$, final temperature, $2 \, h$, where the final temperature can be 400, 600 or $800 \, ^{\circ}$ C. Scheme S1, in the Supplementary Material (SM), shows a schematic representation of the synthesis of the biochar samples. The obtained pyrolyzed chitosan-based material was named CTO_Px, where x can be 400, 600, and 800, and the weight loss after the pyrolysis process is 68.26, 74.12 and $74.45 \, \%$, respectively.

2.3. Characterization

The materials prepared in this study were characterized by field emission scanning electronic microscopy (FESEM), 77 K (-196 °C) nitrogen adsorption-desorption isotherms, thermogravimetric analysis (TGA), operando TGA - infrared (IR) spectroscopy (TGA-IR), elemental analysis (EA), and X-ray photoelectron spectroscopy (XPS). Pure CO2, N2, and CH4 adsorption measurements on the biochar materials were performed using a lab-made stainless steel volumetric apparatus at 0, 25, and 35 °C up to 1000 kPa. Adsorption measurements of 20 vol.% of CO2 in a mixture of N2/CO2 were made in an operando TGA-IR apparatus at 35 °C and atmospheric pressure. A Dynamic Vapor Sorption (DVS) instrument was used to acquire pure CO₂ adsorption isotherm up to 89 kPa at 30 °C, pure CO₂ adsorption isobar up to 80 °C and 20 kPa, water vapor adsorption-desorption and CO2 adsorption-desorption isotherms under different moisture conditions at 30 °C, and reusability tests for the best-performing sample. The equipment and experimental parameters used are described in the SM.

3. Results and discussion

3.1. Characterization of materials

The assessment of the gases evolved from the biochar synthesis at various temperatures was performed using the *operando* TGA-IR technique (Fig. 1 and Figures S1 and S2, SM). The same initial sponge-like chitosan batch was used for the pyrolysis at 400, 600, and 800 °C under $\rm N_2$ flux to prevent any variability in the synthetic conditions arising from chitosan aerogel production. Fig. 1 reports the thermal treatment of the chitosan into TGA at 200 °C for 100 min and the behavior at further heating to 800 °C; the other treatment up to 400 °C and 600 °C are reported in the SM.

For all pyrolyzed processes, the first heating step, up to 200 °C, promotes a weight loss of 20 – 22% which is mainly due to the evaporation of acetic acid that remains from the chitosan dissolution process (*cf.* IR information in Fig. 1b, and Figures S1 and S2). This behavior contrasts with the literature, where this weight loss corresponds to the evaporation of physically adsorbed and strongly hydrogen-bonded water on the commercial powdered chitosan [20], which was studied as received. Thus, the differences observed between both studies are related to the sample preparation differences. During the thermal treatment at 200 °C, the material continues releasing acetic acid. CO₂,

Fig. 1. a) schematic representation of the pyrolysis process at different temperatures and b) IR spectra of the developed gases at 134, 200, 200 (at 100 min), 299, and 800 °C under N₂ flow, obtained during the pyrolysis process to obtain CTO_P800 sample.

CO, NH₃, and H₂O start to develop in the pyrolysis process of the chitosan sponge-like material probably induced by the acidic conditions. Hetero-atomic rings containing the nitrogen not released at this stage during the random breaking of C - O - C skeletal bonds start to form, as reported in previous studies [21,22]. Finally, the last weight loss of $\it ca.$ 40 - 50 wt.% (depending on the final pyrolysis temperature) occurs mainly between 250 and 450 °C and continues to produce the following species: CO₂, CO, NH₃, H₂O, CH₃COOH, and CH₄. CH₄ probably derives mainly from the partial thermal degradation of residue acetic acid to CH₄ and CO₂ but also from the consequent formation of graphite-like structures via a dehydrogenation mechanism [20]. The other gases appear due to the thermal destruction/transformation of glucosamine and pyranose rings and the decomposition of residual carbon [20,23].

The remaining mass after pyrolysis is attributed to the resulting biochar at different temperatures. The weight loss observed in the operando TGA-IR measurements of the pyrolysis process matches the results obtained through experimental analysis in a conventional oven: 68.26, 74.12, and 74.45 wt·% for CTO_P400, CTO_P600, and CTO_P800, respectively.

Table S1 (SM) shows the N content obtained in the chitosan materials pyrolyzed at different temperatures determined by elemental analysis. All samples retain a substantial amount of nitrogen, indicating that the N groups of chitosan are present in the structure of the pyrolyzed chitosan samples. The sponge-like biochar material with the highest N content is CTO_P400 (9.9 wt.%), and this value decreases with increasing pyrolysis temperature, reaching 6.4 wt.% for the CTO_P800 sample. These results

agree with *operando* TGA-IR measurements, which showed that NH_3 (evolved from the degradation of chitosan) continues to be released up to 800 $^{\circ}$ C (Fig. 1).

The chemical features of the different biochar materials prepared in this study, as well as the pristine chitosan powder precursor and spongelike chitosan material, were assessed by XPS. The analysis of XPS allowed us to determine firstly the relative atomic concentration (at.%) of each element present on the samples' surfaces (as reported in Table 1), calculated from high-resolution (HR) spectra, to be much more precise in the peak area evaluation procedure. In Figure S3, survey spectra showed a clear trend in the oxygen peak evolution, having the highest intensity in the chitosan powder precursor and the lowest for the CTO P800 sample. The N content trend in the pyrolyzed samples is distinct since sample CTO P400 has the highest concentration (8.9 at. %), while the sponge-like chitosan aerogel has the lowest (3.4 at.%). The increase in the pyrolysis temperature promotes a reduction in the N content, which is in accordance with TGA and EA data. C1s core level peak has been first analyzed to establish the relative amount of graphitic species, together with bonds related to oxygen and/or nitrogen atoms. To perform the deconvolution procedure of the C1s peak (Fig. 2a), we have chosen as references some detailed works related to chitosan studies [24,25]. Apart from the well-known chemical shifts due to C -C/C-H (at 284.5 eV), there are chemical shifts due to C interactions with O and/or N at 286.2 eV (C - O/N), 287.5 eV (O - C - O/C = O), 288.5 eV (O - C = O) and the shake-up satellite due to π - π^* transition at binding energy (BE) > 291 eV, for carbon in aromatic compounds, coming from the ring excited by the exiting photoelectrons. The π bond is a characteristic feature of the sp² hybridization of carbon. The deconvolution procedures and chemical species relative percentages are displayed in Fig. 2a and Table 1.

There is a trend in reducing the components related to C-O/N bonds especially passing from chitosan precursor and polymer to pyrolyzed samples, which agrees with the reduction of O and N peaks intensity, as reported in the survey spectra (Figure S3) and Table 1. Moreover, the increase in the pyrolysis temperature (T) coincides with a reduction of the full width at half maximum (FWHM) of the C-C/H component (from 1.56 eV for CTO_P400 to 1.20 eV for CTO_P800),

Table 1XPS relative atomic concentration and C1s and N1s core level assignments evaluated from deconvolution procedures (reported in Figures 2 and S3, respectively).

	Chitosan powder	Chitosan aerogel	CTO_P400	CTO_P600	CTO_P800

oxide								

which is a clear hint of a more ordered structure, due to the graphitization process induced. Also, the $\pi-\pi^*$ component (peak V) increases according to T, passing from 1.5 % (sample CTO_P400) to 4.8 % for the sample treated at 800 °C, representing a further indication of the graphitization process. The non-monotonic trends observed in this study (in Table 1-e.g., C - C/C - H) are not uncommon in the literature on biochar thermal treatments [26]. For example, grass-derived and wood-derived biochar [27] exhibit changes in electronic exchange capacity as the temperature increases, with an oscillating behavior in grass-derived samples (with a maximum at 400 °C) and a less oscillating trend with a peak shift (but with a maximum shift at 500 °C) in wood-derived samples. These peaks were associated with an abundance of quinoid group content measured by Near-edge X-ray absorption fine structure (NEXAFS).

From the N1s core level peaks, the different nitrogen species present in each sample were evaluated, as reported in Table 1 and Fig. 2b. Chitosan powder precursor and sponge-like aerogel showed only one type of nitrogen species, the amino group (named peak II), as expected from their chemical structure. The thermally treated samples have shown four more components assigned to: pyridinic-N (peak I), Pyrrolic-N (peak III), graphitic center-N (peak IV), and graphitic valley-N or pyridine-N oxide (peak V) [28-30]. There are three noticeable trends in the pyrolyzed biochar samples: following the temperature increase, there is a decrease in peak I intensity and an increase in peak IV and V. This is visible in Fig. 2b, in which the N1s peaks of the chitosan precursor and aerogel materials show only one component (amino group), while by increasing temperature there is a sort of splitting in the peak envelope, due to the increase of peak IV and V, due to graphitic components. In the case of the CTO biochar thermally treated at 800 °C for 2 h, the presence of pyridone-N species is more likely to occur than pyrrole-like N species, as the former is more stable at elevated temperatures [31]. This uncertainty to truly distinguish pyridone and pyrrole-like N species is due to peaks overlapping.

To ensure the effective degassing of the biochar samples without compromising their structural integrity, the thermal stability of the biochar samples under N_2 flux was investigated by TGA. Figure S4 shows that the thermal stability of the biochar samples under N_2 flow increases by rising the pyrolysis temperature, with CTO_P400 being the sample with the lowest thermal stability (up to 180 $^{\circ}$ C). Up to this temperature, just the adsorbed water and gases are released by all the biochar materials. As expected, thermal stability increases with the increase of the final pyrolysis temperature, with the CTO_P800 having the highest thermal stability, up to 750 $^{\circ}$ C.

The physical and textural properties of the biochar sorbents were studied by 77 K (-196 $^{\circ}$ C) N₂ adsorption-desorption isotherms and FESEM. In Figure S5, it is possible to observe that the chitosan samples pyrolyzed at different temperatures display a Type II curve (IUPAC classification) [32], usually observed for nonporous or macroporous materials. The specific surface area (S_{BET}) determined by applying the theory proposed by Brunauer-Emmett-Teller (BET), and pore volume of the pyrolyzed chitosan-based biochar materials are low, with values ranging between 11 and 18 m 2 ·g $^{-1}$ and 0.013 and 0.030 cm 3 ·g $^{-1}$), respectively, as expected. Biochar samples typically have low N₂ adsorption capacity at cryogenic temperatures, as the porous structure of these materials is almost entirely composed of ultra-micropores [33]. At 77 K (-196 °C), the diffusion rate of the N₂ molecules into ultramicropores is extremely slow [34], leading to very low values of $S_{\rm BET}$ for some biochars, which is the case of the present studied materials. According to P. Maziarka et al. [35], N2 adsorption-desorption isotherms can be unreliable determining conventional surface area and pore size distribution (PSD) curves of biochars. To address this, the authors proposed that a separate CO2 characterization should be conducted in conjunction with N₂ sorption isotherm to obtain information about narrow micropores, as demonstrated by A. Diéguez-Alonso et al. [36]. Additionally, an adjusted density functional theory (DFT) calculation can be applied to more accurately assess the microporosity of

Fig. 2. (a) C1s HR spectra for all the samples analyzed, with chemical shift peaks positions highlighted by dashed grey vertical lines: peak (I) for C - C/H, peak (II) for C - C/H, peak (II) for C - C/H, peak (III) for C - C/H for

biochars. Also, S. Dantas et al. [37] employed CO₂ adsorption to ascertain the pore size of micro-mesoporous carbons. The authors suggested a method to determine the PSD curves based on the reference theoretical isotherms, which employed Monte Carlo (MC) simulations in model pores of slit-shaped and cylindrical geometry. Similarly, P. I. Ravikovitch et al. [38] characterized various activated carbons using adsorption isotherms of different gases and models such as nonlocal density functional theory (NLDFT) and grand canonical Monte Carlo (GCMC). Multiple studies have shown that both NLDFT and GCMC methods can serve as a viable substitute for conventional phenomenological approaches, such as Dubinin-Radushkevich (DR), Horvath-Kawazoe (HK), and Barrett, Joyner, and Halenda (BJH) methods. Thus, we applied these methods in the CO_2 adsorption isotherms at 0 $^{\circ}C$ to determine the microporosity on chitosan-based biochar materials pyrolyzed at 400 and 600 °C (Figure S6, SM). A type I isotherm curve (IUPAC classification) [32] is observed for both samples. Interestingly, the S_{BET} increases from 400 to 600 °C, from 133 to 260 m²·g⁻¹, while a shrinkage of the pores is observed, Table S2 and Figure S6. The increase of the pyrolysis temperature to 800 °C led to a very slow adsorption kinetic process for CO₂ at 0 °C (not shown), which may be related to the continuous shrinkage of the pores to smaller ultra-micropores making difficult the accessibility of CO₂ molecules into the pores. By examining the pore size distribution curves of the CTO P600 sample, we can observe a significant number of pores with a size of approximately 0.35 nm. It is evident that if the pores continue to shrink as the pyrolysis temperature increases, CO2 molecules may face difficulty entering these pores due to their dimensions, which are approximately 0.33 nm. This effect is particularly noticeable when utilizing the NLDFT and MC models.

Figure S7 shows the FESEM images of the different synthesized biochars. The sponge-like structure of the chitosan aerogel (Scheme S1) is retained after pyrolysis, even at higher temperatures (800 °C), and the open-hole structure can be observed at low magnification (500x). At higher magnification (50000x), the morphological characteristics of the pyrolyzed freeze-dried chitosan at different temperatures show a compact surface, almost without evidenced porosity, explaining the results obtained from the N_2 -sorption isotherms. The inner regions of the particles seem to be dense, showing just some cracks, macro-, and mesoporosity. The latter case is more noticeable in the samples pyrolyzed at a higher temperature (cf. inset of Fig. S7c). The dense external surface of the chitosan-based biochar samples restricts N_2 diffusion to the interior only through narrow, unseen micropores at FESEM, which corresponds

to a very slow process at 77 K (-196 °C) N₂ adsorption.

3.2. CO₂ adsorption-separation performance on biochar sorbents

3.2.1. Pure-component adsorption isotherms of CO₂, CH₄ and N₂

Pure CO_2 , CH_4 , and N_2 adsorption isotherms at 25 °C of the pyrolyzed chitosan-based samples are displayed in Fig. 3, while the determined Virial coefficients and Henry constants (K) for the adsorption are presented in Table 2. In all samples, CO_2 adsorption is significantly higher than the other two gases, which suggests that the materials have good potential for separating CO_2 from CH_4 and N_2 . In more detail, increasing the pyrolysis temperature from 400 °C to 600 °C (samples CTO_2P400 and CTO_2P600) led to higher adsorption of the pure gases. The sample pyrolyzed at 800 °C had a slightly lower adsorption capacity for CO_2 than the sample pyrolyzed at 600 °C. The observed behavior can be attributed to the ongoing reduction in pore size resulting from the increase in pyrolysis temperature. This decrease in pore size could hinder the adsorption of CO_2 molecules within the pores.

Additionally, lower N content in the CTO P800 sample, which, combined with a higher amount of graphitic center-N species (cf. Tables 1 and S1), can lead to a reduction in CO2 adsorption when compared with the CTO P600 adsorbent. Previous studies have shown that pyridone, pyridine, and pyrrole species enhanced CO₂ adsorption due to the Lewis acid-base and H-bonding interactions, which was corroborated by DFT [39] and XPS [28]. Despite the slightly reduced CO₂ adsorption for the CTO P800 compared to the sample pyrolyzed at 600 °C, this sample still seems to be one of the most effective in this study for separating CO₂ from CH₄ and N₂, as the adsorbed amounts of CH₄ and N₂ are below the sensitivity of the method, while CTO_P600 shows the highest CH4 and N2 adsorption performance from the overall samples. The reason for the preferential adsorption of CO2 over CH4 and N2 can be explained by the following factors: i) the molecular diameter of CO₂ (0.33 nm) is smaller than both CH₄ (0.38 nm) and N₂ (0.36 nm) molecules [28], making it easier for CO2 to enter the ultra-micropores that are likely present in higher amount in the sample pyrolyzed at higher temperature [40,41]; ii) the adsorption process in these materials is primarily due to physisorption, which is an exothermic process. Hence, the higher the critical temperature of a gas, the easier it is to be adsorbed. The critical temperature of CO₂ (31.2 $^{\circ}$ C) is higher than of both CH₄ (-82.6 $^{\circ}$ C) and N₂ (-147 °C), thus CO₂ should be easier to adsorb [42-44]; iii) as stated above, CO2 adsorption on biochar may be influenced by distinct interactions, including H-bonding, van der Waals attractions, and Lewis

 $^{^{*}}$ The third virial coefficient (C_3) was neglected for all fitted adsorption isotherms.

acid-base interactions with N- and O- containing functional groups [45]. The CO_2 molecule has a higher quadrupolar moment than the CH_4 and N_2 molecules [46], thus being able to interact strongly with the functional groups of the biochar samples.

The pure gases adsorption isotherms at 35 °C for the pyrolyzed sample at 400 °C (Fig. S8a) show an expected behavior, *i.e.*, a slight decrease of the amount of gas adsorbed comparatively to the adsorption isotherms at 25 °C. However, the pyrolyzed samples at 600 and 800 °C (namely CTO_P600 (Fig. S8b) and CTO_P800 (not shown), respectively) show at 35 °C much lower adsorption capacities for all studied pure gases. The Henry constants and the Virial coefficients determined at 35 °C for each sample and gas studied are displayed in Table S3.

In general, all prepared pyrolyzed chitosan-based materials adsorb higher amounts of CO_2 than CH_4 and N_2 (Table 2). Considering the low N_2 adsorption capacity and Henry constants for N_2 for all the pyrolyzed materials, it is possible to generalize that these materials are weak N_2 adsorbents.

The mean selectivity for separation and equilibrium phase diagrams for the adsorbed phase can be calculated using a method proposed by Myers [47], with implementations described in previous works [48,49], using the Viral equation fitted to the adsorption data at 25 °C (Table 2) and the Ideal Adsorbed Solution Theory (IAST) [50]. Fig. 4 shows that the CTO_P600 has the highest selectivity values, presenting a three times

Fig. 4. Comparative mean selectivity, at 25 $^{\circ}$ C, of CTO_P400 (orange) and CTO_P600 (yellow), for the CO₂/CH₄ separation (square symbols) and for the CO₂/N₂ separation (circle symbols). (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

higher selectivity value in the CO₂/N₂ separation, comparatively to CTO_P400. The high amounts of nitrogen species (between 6 and 10 wt. %) and the presence of ultramicroporosity (Figure S6) can contribute to the preferential adsorption of CO2 over the CH4 and N2 [10]. No significant microporosity is observed with the low-temperature N2 adsorption (less than 0.015 cm³·g⁻¹). This suggests that the CO₂ uptake observed in the pyrolyzed samples may be adsorbed in very narrow micropores (ultramicropores) that are more selective for CO₂ [10], which were only detected by 0 °C CO2 adsorption-desorption isotherms (Figure S6). Based on the PSD curves obtained using NLDFT and MC models (Fig. S6c-d), it can be observed that the CTO_P600 sample has a bimodal distribution of ultramicropores, with the peak centered at 0.35 and 0.50 nm. In contrast, the PSD curve of the CTO_P400 sample is wider and also shows the presence of micropores centered at 0.82 nm. The pores centered at 0.35 nm can physically separate CO₂ (0.33 nm) from CH_4 (0.38 nm) and N_2 (0.36 nm), and they exist in higher amounts in the CTO P600 sample. However, other adsorption phenomena, for instance, chemical interactions, can be present in these samples as CTO P400 and CTO_P600 samples have similar selectivity for CO2/CH4 separation (less than 20 at 500 kPa).

The evolution of the composition of the gas phase as a function of the composition of the adsorbed phase for two possible binary mixtures, CH₄/CO₂ and N₂/CO₂, are shown in Fig. 5. Each plot shows the variation in x (which is the molar fraction of the component gas in the adsorbed phase) with the variation in y (which is the molar fraction of the component gas in the gaseous phase at equilibrium conditions) at 500 kPa. For the binary mixture of CH₄ and CO₂ (Fig. 5a), at a molar fraction of about 0.5 (composition of a typical biogas feed) in the gas phase (yCH₄), the molar fraction of CH₄ in the adsorbed phase (xCH₄) is 0.080 on CTO_P400 and 0.061 on CTO_P600, at 500 kPa and 25 °C. This means that the adsorbed phase is richer in carbon dioxide than in methane for both materials. Moreover, CTO_P600 absorbs a higher amount of pure carbon dioxide (0.939 M composition) under these conditions. However, for the binary mixture of N2 and CO2 (Fig. 5b), at a molar fraction of N2 of 0.8 (in the gas phase), the x(N₂) on CTO_P400 and CTO_P600 are 0.02 and 0.03, respectively, which means that the adsorbed phase is almost pure carbon dioxide for both materials. The complete phase diagrams, presented in Figure S9, confirm the better performance of CTO P600 material in terms of selectivity and adsorption capacity of CO₂.

The isosteric heats of adsorption for CO_2 were determined using the Clausius-Clapeyron equation, and the viral isotherms fitted to the CO_2 adsorption isotherms at 25 and 35 °C (Figure S10). According to the values estimated, CTO_P600 has the highest heat of adsorption for CO_2 among the tested sorbents. This implies that CTO_P600 has a stronger affinity for CO_2 molecules, resulting in a stronger dependence on the temperature, and the high value indicates that the adsorption of CO_2 is

probably associated with a strong chemical interaction with the materials' surface that may be originated from a combination of narrow pores and the presence of N functional groups. Following CTO_P600, CTO_P800 exhibits a lower heat of adsorption, while CTO_P400 displays the lowest heat of adsorption for CO_2 .

3.2.2. Continuous flux N_2 and CO_2 adsorption-separation isotherms

The CO_2 selectivity over N_2 under continuous flux conditions and atmospheric pressure was measured at 35 °C on the different biochars prepared in this study, and the weight increase is presented in Fig. 6a. All samples show a weight increase when the CO_2 gas (20 vol.%) is added to the system, exhibiting selectivity for CO_2 over N_2 even under gas mixture conditions.

The lowest CO₂ adsorption capacity over N₂ is found for the sample pyrolyzed at a lower temperature (CTO P400), with a weight increase of only 0.42 mmol·g⁻¹ (1.87 wt.%). The selectivity towards CO₂ under continuous flux conditions is enhanced by increasing the pyrolysis temperature, obtaining the highest adsorption for CO2 over N2 for the CTO_P800 samples (3.82 wt.% of weight increase, 0.87 mmol·g⁻¹). This means that increasing the pyrolysis temperature to double allows the adsorption of twice the amount of CO2 adsorbed in these conditions without significant differences in the weight loss of the sample during the pyrolysis process (section 2.2). Curiously, the increase in adsorption capacity/selectivity towards CO2 is inversely proportional to the N content found on the samples (Tables 1 and S1, SM). This behavior can be related to the concomitant effect of higher amounts of ultramicropores (Table S2 and Figure S6), which usually appear at higher pyrolysis temperatures [40,41], allowing to physically separate these two gases more efficiently [43]. Also, the higher amount of graphitic valley-N or pyridine-N oxide species can play a relevant role as these species present favorable CO₂ adsorption [28,39]. The findings in Fig. 6b highlight the adsorption and desorption characteristics of different sorbents, specifically CTO_P800, CTO_P600, and CTO_P400, in the given experiment. Regarding the adsorption kinetics, CTO_P800 and CTO P600 exhibit similar behavior by reaching approximately 70% of the total CO₂ adsorption within a 10 min period. This suggests that these sorbents have a rapid and efficient adsorption capacity. On the other hand, CTO_P400 displays a slower adsorption behavior, indicating a longer time is required to achieve the same level of CO2 adsorption. During the desorption process, which was carried out under a pure N2 flux at the same temperature as the adsorption measurement (35 °C), the results demonstrate the desorption efficiency of the sorbents. CTO P800 exhibits the highest desorption efficiency, releasing 89% of the adsorbed CO2 gas in less than 10 min. CTO_P600 follows closely with 79% desorption, while CTO_P400 shows a relatively lower desorption efficiency of 71%. These findings have promising implications for the

Fig. 5. Isothermal (at 25 °C), isobaric (at 500 kPa) xy diagrams of a) CO_2/CH_4 and b) CO_2/N_2 mixtures on the CTO_P400 (orange solid line) and CTO_P600 (yellow solid line) based materials. $y(CH_4)$, $y(CH_4)$, $y(N_2)$ and $x(N_2)$ are the molar fractions of methane and nitrogen in the gas and in the adsorbed phases, respectively. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

(For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

potential use of CTO_P800 and CTO_P600 in cyclic adsorption—desorption measurements under industrial operating conditions. The efficient adsorption and high desorption efficiency make them suitable candidates for applications where repeated adsorption and regeneration cycles are required, such as in carbon capture and storage systems.

3.2.3. CO₂ and water adsorption isotherms

Pure CO_2 adsorption isotherms at 30 °C and up to 89 kPa and isobar at 20 kPa and up to 80 °C were performed on the CTO_P600 sample using a gravimetric apparatus, and the results are presented in Fig. 7. At the maximum pressure acquired in this measurement, CTO_P600 was able to adsorb 1.32 mmol·g⁻¹ (~6 wt.%, Fig. 7a), which agrees with the

Fig. 8. Cyclic regenerability of the CTO_P600 biochar up to 10 consecutive adsorption (30 $^{\circ}\text{C})$ – desorption (80 $^{\circ}\text{C})$ cycles at 20 kPa using a dm/dt criterium of 0.01 $\%\text{-min}^{-1}$.

values obtained in the previous section 3.2.1 by using the volumetric apparatus. After exposing the CTO_P600 sample to the CO₂ adsorption process at 30 °C and 89 kPa, it showed a decrease in the CO₂ amount adsorbed with the increase of the temperature (Fig. 7b) [51,52]. This means that physisorption is the dominant process in this sample [53]. The isobar equilibrium criterion (dm/dt) is 0.01 %·min $^{-1}$, 10 times lower than the equilibrium criterium used in the isotherm measurement, explaining the differences obtained in both methods regarding the CO₂ adsorption capacity at 30 °C. The reversibility of the process was evaluated by lowering the temperature, and the results showed that the same amount of desorbed CO₂ molecules were re-adsorbed by the CTO_P600 biochar.

Fig. 7c presents the H₂O vapor adsorption for the CTO_P600 sample, which can adsorb 0.66 mmol·g⁻¹ (\sim 1.2 wt.% of H₂O) at 4 kPa. This process takes 8.5 h to reach the maximum of adsorption, which is nearly 4 times lower than the water vapor uptake observed in our previous study for an amine-functionalized multiwalled carbon nanotube sample (CNT_SD_DETASi) [7]. An increase of the H₂O quantities adsorbed is observed when the H2O vapor pressure increases, showing a type Ib isotherm (IUPAC classification) [32]. However, the desorption process, by reducing the humidity, is much slower than the adsorption process, resulting in hysteresis [54]. This behavior can be associated with the capillary condensation of the adsorbed water [55]. At the same operating conditions (pressure and temperature), this sample revealed a CO₂ adsorption capacity of 0.34 mmol g^{-1} (~1.5 wt.%), which is half of the water vapor uptake and three times higher when compared with the adsorption capacity observed for the CNT_SD_DETASi sorbent [7]. Fig. 7 e-f depicts the adsorption behavior under H_2O/CO_2 mixtures, up to 3.8 kPa. CTO_P600 biochar displays a marked preference for CO2 adsorption, especially at lower water vapor pressure, which is evident from the observed increase in weight after addition of CO₂ gas. As the H₂O pressure is increased from 1.06 kPa to 3.8 kPa, the amount of CO₂ adsorbed decreases from 1.03 wt.% to 0.08 wt.%, respectively. Thus, considering our previous work, CTO_P600 sorbent appears to be more interesting from the economic and sustainable material preparation point of view, but also regarding the performance in the CO₂ adsorption separation process even when moisture is present.

3.2.4. Adsorbent regeneration capacity

The regeneration ability of adsorbents is a relevant characteristic for understanding how they will behave under long-time operation processes. Thus, a fast-cycle adsorption/desorption study of 10 cycles on the CTO_P600 sample was performed after the adsorption isotherm (Fig. 8). The adsorption process was carried out at \sim 20 kPa (0.2 bar) and 30 $^{\circ}\text{C}$ while the desorption process was done at 80 $^{\circ}\text{C}$ under vacuum. The obtained data indicate that CTO_P600 biochar performs well under cyclic adsorption—desorption processes retaining the same CO_2 adsorption capacity after each cycle.

3.3. Comparison with other materials

The capacities for CO_2 , N_2 , and CH_4 adsorption of the best-performing biochar (CTO_P600) for the CO_2/N_2 and CO_2/CH_4 separation are compared with other carbonaceous sorbents in Table 3.

All biochar and activated carbon compiled in this Table can adsorb CO₂ in the temperature range of 0 – 35 °C, with the highest CO₂ uptake values observed for the activated carbon materials (AC-KOH-D-5-700 [33], Cell-UK [56], and BC800K [57]) typically obtained by a secondstep of thermal activation (at temperatures of 700 or 800 °C) under the presence of high amounts of KOH. Despite these materials having high CO₂ adsorption capacity (between 2.3 and 4.4 mmol·g⁻¹) at 20 – 25 °C and 100 kPa and seemingly showing high CO₂ selectivity over N₂, both CH₄ and N₂ adsorption capacities were not measured or provided on most of the cases, as well as CO2 selectivity over CH4. Moreover, in the only activated carbon, where the N₂ adsorption capacity is provided (Cell-UK), the obtained value is much higher than the one obtained for the biochar studied in this work. Additionally, all these carbonaceous sorbents are not sustainable from a preparation standpoint, as they require high amounts of KOH for activation and are obtained in powder form, which requires further processing for industrial use, e.g., pelletization, to avoid pressure drop issues. Some biochars reported in the literature (BC-CO₂-0.1-800 [33] and C-Char_800 [58]) seem to be promising for CO₂ uptake, showing high CO₂ adsorption capacities (2.2 and 4.0 mmol·g $^{-1}$, respectively) and selectivity over N₂ (55) in the case of the BC-CO₂-0.1-800 sorbent [33]. However, the preparation of these biochar sorbents is made under a CO₂ atmosphere, and in the latter case, activation is necessary. These materials are also prepared in powdered

All biochar sorbents prepared in this study perform better than CNT_COOH_DETASi sorbent [7], which had the highest CO₂ adsorption capacity and selectivity towards CO₂ among multi-walled carbon nanotubes in our previous study. Additionally, CTO_P600 showed lower water vapor uptake when compared with the CNT_SD_DETASi sorbent [7] (not compared in Table 3, *cf.* reference [7]), thus being a highly promising CO₂ adsorbent even under moisture conditions. CTO_P600 biochar and Chit_supCO₂_P800 sorbent [10] showed similar CO₂ uptake and CO₂/CH₄ selectivity under the same operating conditions. Both sorbents have the potential for industrial application due to their shape. However, Chit_supCO₂_P800 has a much more complex synthesis procedure involving chitosan beads production, followed by a solvent-switch method (from water to ethanol) and supercritical CO₂ drying technology (which is more expensive to perform than freeze-drying), and a higher pyrolysis temperature.

4. Conclusions

A sponge-like chitosan freeze-dried aerogel was successfully pyrolyzed at different temperatures to create sponge-like biochars with varying textural properties. XPS data revealed that the amino groups in the sponge-like chitosan aerogel underwent degradation and transformations during the pyrolysis process, resulting in various types and levels of N-species, such as pyridinic-N, pyrrolic-N or pyridone, graphitic center-N and graphitic valley-N or pyridine-N oxide species. The resulting biochars were tested for their ability to adsorb CO2, CH4, and N2 at different temperatures and pressures. In general, the increase in pyrolysis temperature enhanced the CO₂ adsorption capacity and selectivity for CO2/CH4 and CO2/N2 separation. CO2 isobar measurements up to 80 °C showed that physisorption was the dominant adsorption process in CTO_P600 sorbent. The CTO_P600 biochar showed tolerance to moisture and retained its CO2 adsorption capacity after being reused for 10 cycles in pure CO₂ adsorption-desorption conditions, suggesting potential for surface regeneration and application in cyclic separation processes at the industrial level. The sustainable production of these biochars without requiring extra activation or functionalization procedures, coupled with their sponge-like aerogel shape, renders them
