PREAMBLE

This is a cumulative thesis consisting of two studies I was the first author on. The first *Epigenome-wide Association Study of Alcohol Use Disorder in Five Brain Regions* was published in *Neuropsychopharmacology* and is presented in chapter 2 of this thesis. The second study *Multi-omics Signatures of Alcohol Use Disorder in the Dorsal and Ventral Striatum* was published in *Translational Psychiatry* and can be found in chapter 3. I was involved in the conception of both studies. I performed the literature research, developed the analysis plan and performed all bioinformatic analyses independently and under the supervision of the co-authors. I wrote both manuscripts and revised them according to the co-authors and the reviewer's input.

1 INTRODUCTION

1.1 Alcohol Use Disorder, Alcohol Dependence, and Alcohol Consumption

1.1.1 Defining the Constructs

Alcohol Use Disorder (AUD) is defined in the Diagnostic and Statistical Manual of Mental Disorders (DSM) 5 by a set of co-occurring symptoms, such as loss of control over alcohol intake, craving, development of tolerance, and withdrawal symptoms when alcohol consumption ceases (American Psychiatric Association, 2013).

In the history of the DSM, the diagnostic criteria and name of AUD have been changed repeatedly, reflecting both the heterogeneity as well as the societal view on of the disorder. In the DSM-5, AUD is a dimensional construct and can be mild, moderate, or severe, depending on the number of symptoms an affected person experiences. In the previous version, the DSM-IV, one of two categorical diagnoses, alcohol abuse and alcohol dependence, were given. Alcohol abuse is characterized by symptoms such as continued consumption despite negative social consequences or an increased likelihood of getting hurt when drinking. In alcohol dependence, additional symptoms such as withdrawal and tolerance are observed (American Psychiatric Association, 1994). Both diagnostic manuals observe symptoms over in a 12-month period.

Alcohol consumption is a continuous construct and is most commonly assessed by the first three items of the alcohol use disorder identification test (AUDIT), the so-called consumption scale (AUDIT-C) (Babor et al., 2001). It consists of questions regarding the frequency of alcohol consumption, the amount of alcohol consumed at a drinking event, and the frequency of binge drinking. The remaining AUDIT items form the problem scale (AUDIT-P) and inquire about problematic consequences that arrive from drinking. The problem scale is often used as a proxy for AUD. Another commonly used measure is drinks per week, which is the number of standard drinks individuals consume in a typical week.

1.1.2 Prevalence and Relevance to Global Health

The lifetime prevalence of AUD varies worldwide. The lowest prevalence is observed in North African and Middle Eastern countries (0.59%) and the highest in Eastern European countries (4.25%). This also corresponds to the prevalence of alcohol consumption in different regions of the world, which differ due to varying religious, cultural, and policy aspects (World Health Organization, 2019). Globally, AUD has a lifetime prevalence of 1.32% (Degenhardt et al., 2018). AUD contributes significantly to the global burden of disease with 5.3% of all deaths and more than 230 diseases being attributable to harmful alcohol consumption (World Health Organization, 2019). Although many individuals are affected by AUD, the current FDA-approved treatment options are limited. Currently, there are only a few medications available for the treatment of AUD. In the US, naltrexone and acamprosate can be prescribed to treat AUD, and both medications have been shown to reduce the number of drinking days

in the first few months after treatment, compared to a placebo (Donoghue et al., 2015). At the same time, not all patients benefit from these treatments, and relapse rates remain high. To offer the best possible care to patients with AUD, it is necessary to gain a deeper understanding of pathomechanisms to facilitate personalized medicine as a novel treatment option for AUD in the future (Litten et al., 2016).

1.2 Neurocircuitry of Addiction

This section presents the neurobiological perspective on the mechanisms underlying AUD. While alcohol consumption has toxic effects on the entire organism, dependence or use disorders are thought to develop in the brain (Volkow et al., 2016). The current understanding of the development of substance use disorders and AUD in particular relies on a neurocircuitry of addiction that is associated with three stages of addiction. These stages and the corresponding circuits are depicted in Figure 1.1.

Figure 1.1. The three stages of addiction and the associated neurocircuitry, published in Koob and Volkow (2010), *The Lancet Psychiatry* (3) 8, 760-773, reprinted with permission from Elsevier.

1.2.1 The Three Stages of Addiction

The neurocircuitry of addiction describes signaling pathways within functionally connected brain regions that are thought to be involved in the development and maintenance of substance use disorders. According to Koob and Volkow (2010), there are three stages of addiction. The binge/intoxication stage is mainly characterized by the rewarding effects of substances, which are associated with an increase of dopamine in the mesolimbic dopamine system, in particular in the ventral tegmental area. The time course of dopamine signaling is thought to be especially important for how a reward is perceived and has an important impact on behavior (Schultz, 2007). In the second stage, the negative effect/withdrawal stage, reward thresholds are elevated, which might be due to dopamine systems being compromised from extended drug intake (Koob & Volkow, 2010). The preoccupation/anticipation stage is closely related to relapsing behavior and is characterized by an altered response to drug-associated stimuli, e.g. cue reactivity.

The three stages of addiction are associated with five major circuits: the mesolimbic dopamine system, the extended amygdala, the ventral striatum, the ventral striatum/dorsal striatum/hippocampus, and the dorsolateral frontal cortex. The latter three are further discussed in this thesis. The brain regions that play a major role in these circuits are depicted in Figure 1.1.

1.2.2 The Ventral Striatum

The ventral striatum comprises the olfactory tubercle and the nucleus accumbens (NAcc). The NAcc is activated by glutamatergic signaling from the frontal cortex, the amygdala, the hippocampus, and the thalamus (Cui et al., 2013). In addition, dopaminergic neurons of the ventral tegmental area project into the NAcc by the mesolimbic pathway, and dopamine release from these neurons into the NAcc is assumed to mediate the rewarding effect of addictive drugs (Taber et al., 2012; Volkow & Morales, 2015). In addition, an interaction of dopamine and glutamatergic signaling in the NAcc is likely (Cui et al., 2013). The NAcc is especially important in incentive learning, and the increase in dopamine in the ventral striatum is thought to mimic the effect of highly salient stimuli in conditioned learning. In drug abuse, this potentially leads to a recalibration of the dopamine-activation/reward threshold for natural reinforcers, i.e., when compared to the dopamine-activation of drugs of abuse, the activation of natural reinforcers such as food is small.

1.2.3 The Dorsal Striatum

When alcohol is consumed for its rewarding qualities, the behavior can be classified as goal-directed, meaning that the association with a desirable outcome mediates the behavior (Dickinson & Weiskrantz, 1985; O'Tousa & Grahame, 2014). Goal-directed behavior is primarily associated with earlier stages of AUD, as the disorder progresses, habit formation increasingly directs behavior. Habit formation refers to behaviors that

have been built through a lengthy reinforcement history and is characterized by an indifference to the value of the reinforcement (O'Tousa & Grahame, 2014). Habits are highly associated with a cue. For example, an alcoholic beverage after work could be consumed for the rewarding qualities. Over time, the consumption could be driven by the cue “coming home from work” rather than drinking the alcoholic beverage for reward. In the neurocircuitry of addiction, this change from goal-directed to habitual/compulsive use is associated with an inner-striatal shift of activation from the ventral to the dorsal striatum (Everitt & Robbins, 2005; Koob & Volkow, 2010). For example, in an fMRI-study, alcohol-related pictures evoked higher activation in the ventral striatum of social compared to heavy drinkers and in the dorsal striatum in heavy compared to light drinkers (Vollstädt-Klein et al., 2010). The dorsal striatum consists of the caudate nucleus (CN) and the putamen (PUT). Both regions are involved in sensorimotor processing and activation in the caudate nucleus is associated with the reinforcement learning necessary for habit formation (Galandra et al., 2018), while the putamen is mainly involved in inhibitory control and habit formation itself (Akkermans et al., 2018). For example, the duration of AUD has been associated with increased cue-related activation in the posterior putamen (Sjoerds et al., 2014). Figure 1.2 shows a section in which the VS, the CN and the PUT are highlighted.

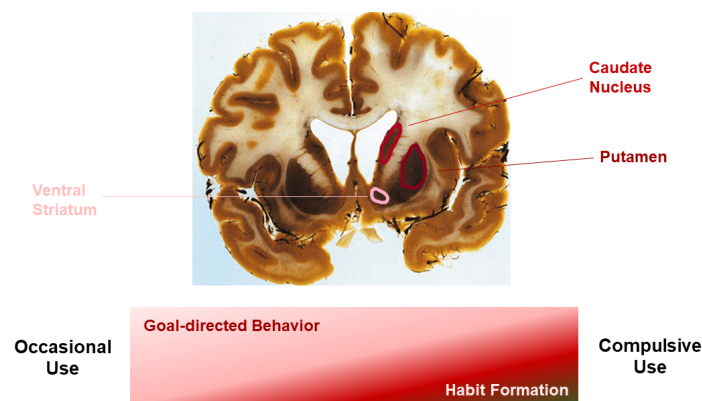

Figure 1.2. Habit formation and the corresponding brain regions in the ventral and dorsal striatum. The section from postmortem human brain tissue is published in Hagens et al. (1990) and was adapted to show ventral and dorsal striatal regions.

1.2.4 The Prefrontal Cortex

The prefrontal cortex plays a vital part, especially in sustaining substance use disorders (Goldstein & Volkow, 2011). During the preoccupation/anticipation stage of addiction, impulse control is important to resist urges and cues associated with drinking (Koob & Volkow, 2010). The dorsolateral prefrontal cortex and Brodmann Area 9 (BA9) in particular are involved in higher-order executive functioning and are an important part of the reward circuitry (Goldstein & Volkow, 2011). The anterior cingulate cortex (ACC) has been associated with attentional biases in AUD (Bach et al., 2015) and self-control (Tang et al., 2015).

1.3 Genetics of Alcohol Use Disorder

AUD is a moderately heritable disorder. Evidence from twin and adoption studies suggests a heritability of around 50% (Goldman et al., 2005; Verhulst et al., 2015), meaning that around half of the variance in the AUD phenotype could be explained by genetics. Over time, different methods have been used to study the genetics of AUD, which are highlighted in the next two paragraphs.

1.3.1 From Candidate to Genome-wide Approaches

In the early stages of molecular genetic studies on the genetic underpinnings of psychiatric disorders, candidate gene studies were used to investigate the association of variation in a single gene with a phenotype (Kwon & Goate, 2000). Genes were selected based on a biological hypothesis. In AUD research, genetic variation in genes encoding enzymes involved in alcohol metabolism were among the first candidate genes (Edenberg, 2007). Studying genetic variation in *ADH1B*, *ADH1C* and *ALDH2* is also an example of successful candidate gene studies, as the first genome-wide significant SNP associated with AUD is located between *ADH1B* and *ADH1C* (Frank et al., 2012). At the same time, it is one of the few examples of candidate genes replicating in genome-wide association studies (GWAS).

During the first ten years of candidate gene research, increasing evidence emerged that candidate gene studies do not produce replicable results and lead to false positive associations (Duncan & Keller, 2011). For example, it has been shown that a set of candidate genes is not more predictive of major depression than a set of randomly selected genes (Border et al., 2019). Candidate gene studies have thus been superseded by genome-wide approaches; not only in genetics, but also in the fields of epigenetics (Shabalín et al., 2015), and gene expression research (Kukurba & Montgomery, 2015), which are discussed in later chapters. Genome-wide approaches are often referred to as hypothesis-generating, meaning that they explore the relationship between a phenotype and a feature, i.e., a genetic variant, without a prior hypothesis about the relationship.

1.3.2 Genome-wide Association Studies of Alcohol Phenotypes

The association of a disease phenotype with common genetic variants can be investigated in GWAS. In a case-control GWAS, a logistic regression is performed for each single nucleotide polymorphism (SNP) with the abundance of the disease phenotype as an outcome and the SNP as the predictor along with covariates. To correct for multiple testing, a Bonferroni corrected p value threshold of 5×10^{-8} is applied. This in turn requires a large samples size to identify small effects withstanding multiple testing correction.

A recent GWAS performed a meta-analysis of DSM-5 AUD in the Million Veteran Program (Kranzler et al., 2019), DSM-IV alcohol dependence in the Psychiatric Genomics Consortium (Walters et al., 2018) and the problem-scale of the alcohol use disorder identification test (AUDIT) using the UK Biobank (Sanchez-Roige et al., 2018). The resulting GWAS of problematic alcohol use (PAU) included 435,563 participants

and identified 29 variants (Zhou et al., 2020). Among them were *ADH1B* and *ADH1C*, but also novel candidates such as *PDE4B* and *CADM2*. The Manhattan plot of the PAU GWAS with all annotated loci is shown in Figure 1.3.

Figure 1.3. Manhattan Plot of the GWAS of Problematic Alcohol Use reprinted by permission from Springer Nature: Nature Neuroscience: Zhou et al. (2020).

The information from GWASs can be further used to create polygenic scores, to perform gene-level tests, and to carry-out enrichment analyses. Interestingly, Zhou et al. (2020) found an enrichment of genes expressed in different brain regions in PAU-related genetic variants. The strongest enrichment was shown for the NAcc, the cortex, PUT, substantia nigra, CN, BA9, and ACC (Zhou et al., 2020).

GWAS are not only useful to genetically characterize a disease phenotype, but are also valuable tools for assessing genetic determinants of treatment response. There was a recent GWAS on responsiveness to acamprosate and naltrexone treatment in AUD, which identified a single genome-wide significant SNP in *BRE* associated with time until relapse to heavy drinking (Biernacka et al., 2021). Although this GWAS was severely underpowered, investigating genetic determinants of treatment outcomes might lead to a more tailored treatment of AUD.

1.4 Epigenetics of Alcohol Use Disorder

1.4.1 Epigenetics and DNA Methylation

Epigenetics refers to the regulation of gene activity not caused by changes in the DNA sequence itself. One epigenetic mechanism is DNA methylation, i.e. the addition of a methyl-group at the 5' position of cytosines (see also Figure 1.4), which most

commonly occurs in cytosine-phosphate-guanine sites (CpG site) (Rakyan et al., 2011). A specific CpG site can either be methylated or unmethylated. DNA methylation can influence gene expression, most often through methylation levels of CpG-islands in promoter regions. CpG-islands are typically at least 200 base pairs long and contain at least 50% GC-content. About 40% of mammalian genes contain CpG islands in their promoters and exonic regions (Fatemi et al., 2005) highlighting them as important sites for gene expression regulation (Deaton & Bird, 2011).

Figure 1.4. A) Addition of a methyl-group through DNA-methyltransferase (DNMT). B) influence of methylated (M) and unmethylated (U) promoters on gene transcription.

CpG sites are commonly classified based on their distance from a CpG-island. The *shore* refers to the ± 0 -2 kilobase (kb) region around a CpG-island and the *shelf* to the ± 2 -4 kb region. CpG sites not annotated to CpG-islands are referred to as *open sea*. This classification helps grade the relevance an individual CpG site might have for gene expression regulation. For example, it has been found that CpG methylation in shore regions has a stronger association with gene expression than methylation in a CpG island (Irizarry et al., 2009; Martino & Saffery, 2015).

Increased DNA methylation levels are typically associated with lower gene expression, which is likely due to impaired transcription factor binding in highly methylated regions (Gibney & Nolan, 2010). However, gene expression and protein translation are influenced by a variety of molecular mechanisms, which makes the disentangling of the effect of CpG methylation on gene expression difficult.

1.4.2 Determining DNA Methylation Levels

DNAm arrays, such as the EPIC BeadChip, depict a reliable and cost-effective alternative to expensive next-generation sequencing procedures such as whole-genome bisulfite sequencing, or methyl-binding domain sequencing, which requires years of laboratory experiences to develop suitable protocols for high CpG coverage (Aberg et al., 2020). Of the around 28 million CpG sites known to exist in the human genome (Lökvist et al., 2016), about 870,000 are captured by the Illumina Infinium HumanMethylation EPIC BeadChip, which is well suited for high-throughput analysis of the methylome (Moran et al., 2016). CpG sites covered by the BeadChip are distributed within several regulatory features such as CpG-islands, promoter regions, open sea regions, and enhancers, but also within exonic and intergenic regions.

To analyze DNA methylation on a microarray, genomic DNA is bisulfite-converted and subsequently pipetted onto the BeadChip. The resulting data from scanning the methylation array are light intensity signals, which are bioinformatically translated to methylation values. A methylation beta-value is a percentage estimate that indicates the mean methylation of a CpG site in the sample. After quality control, these beta values are commonly logit-transformed into M-values (Du et al., 2010), which have the advantage of being more normally distributed than beta values and are thus useful for further statistical analyses.

1.4.3 Epigenome-wide Association Studies

Similar to GWAS, epigenome-wide association studies are hypothesis-generating procedures (Flanagan, 2015). Each CpG-site is tested for an association with the phenotype of interest, usually in (robust) multiple linear regression models. DNAm levels are tissue- and cell-type specific (Lokk et al., 2014). To account for this, cell type proportions are estimated for each sample based on reference data (Houseman et al., 2012) or in a reference-free approach (Houseman et al., 2014). In addition, a correction for technical effects should be applied (Lehne et al., 2015). The EPIC BeadChip contains internal control probes, which allow to capture both technical effects which can be directly observed, such as sequencing batch, as well as other effects, such as a different sensitivity in parts of the scanning systems. A common technique to capture this variation is performing a principal component analysis of the internal control probes and including the first ten resulting principal components in the linear model (Lehne et al., 2015).

In addition to cell type composition and technical effects, smoking and age are known to largely influence DNA methylation levels (Horvath, 2013; Zeilinger et al., 2013) and should therefore be included as covariates in every DNA methylation analysis.

1.4.4 DNA Methylation in Alcohol Use Disorder

1.4.4.1 DNA Methylation in Peripheral Tissues

While investigating DNAm in brain tissue is of primary importance to understand mechanisms of AUD, peripheral tissues, such as blood and saliva, are more accessible. Therefore, past research has focused mainly on these tissues.

The largest EWAS of AUD to date identified 96 CpG sites significantly associated after FDR correction in N=625 participants (Lohoff et al., 2020). Of these, 70 were replicated in in two independent cohorts: Generation Scotland (N=4301) and Grady Trauma Project (N=391). The top hit was annotated to *GAS5*, a long non-coding RNA, which also showed differential expression between AUD cases and controls in postmortem human amygdala tissue (Lohoff et al., 2020).

Because of the high multiple testing burden, sample size is a key factor in epigenome-wide association studies to identify meaningful DMPs. Therefore, many studies investigate alcohol consumption rather than AUD, because this information is usually available in larger population-based cohorts. For example, in an EWAS of alcohol

intake in the Melbourne Collaborative Cohort Study, 1414 significantly associated CpG sites were identified, 1078 of which were replicated in two independent cohort studies (Dugué et al., 2021). In the same study, a longitudinal analysis revealed evidence of changes in DNAm patterns over time dependent on alcohol intake. This is in line with findings from a clinical cohort, in which widespread changes in DNAm were observed in patients at the beginning of withdrawal treatment compared with controls (Witt et al., 2020). At the end of withdrawal treatment, DNAm patterns of patients more resembled those of controls compared to the initial timepoint.

A more recent EWAS of alcohol consumption analyzed N=8161 participants of the Generation Scotland Family Health Study (Lohoff et al., 2022), the largest EWAS to date. The top hit from this study, which was also replicated in an independent clinical cohort, was the cystine/glutamate transporter *SLC7A11*, providing evidence for methylation-mediated glutamate signaling alterations related to alcohol consumption (Lohoff et al., 2022). Interestingly, differential gene expression of *SLC7A11* was observed in postmortem human prefrontal cortex, suggesting a functional relevance of the differential methylation finding.

While EWAS in peripheral tissues are helpful for investigating the effects of alcohol consumption and alcohol use disorder in large cohorts and have led to drug targets such as the PCSK9 inhibitor to treat alcohol-associated liver diseases (Lohoff et al., 2018), there is a lack of knowledge about DNAm in the brain and drug targets for AUD.

1.4.4.2 DNA Methylation in Postmortem Human Brain Tissue

Postmortem human brain tissue valuable resource for research into AUD which is however very sparse. By now, several studies have investigated the association of DNAm and AUD in different brain regions. In most studies, DNAm was measured using an Illumina Methylation EPIC BeadChip. The brain region most frequently studied is the dorsolateral prefrontal cortex, specifically its subregions BA9 and BA10. For example, Wang et al. (2016) identified differentially methylated CpG sites in male, but not female individuals with alcohol dependence compared to controls. A further co-methylation analysis using WGCNA revealed modules enriched for biological processes, such as transcriptional regulation and neural development (Wang et al., 2016). Meng et al. (2021) found two DMRs in BA9 and NAcc of individuals with alcohol dependence compared to controls. Interestingly, this DMR was genotype-dependent on a variant in *DLGAP2*, which was also shown to influence alcohol consumption in a mouse model (Meng et al., 2021). In a study in BA10, differential methylation in *NR3C1* – a gene which encodes the glucocorticoid receptor – was highlighted (Gatta et al., 2021). A recent study investigated differential methylation through MBD-seq, first in 1,132 blood samples and then in postmortem BA10 tissue of N=50 individuals (Clark et al., 2022). While the postmortem brain analysis did not reveal epigenome-wide significant hits, there was a significant overlap between the monocyte- and B-cell-specific association studies in blood and hydroxy-/methylation in brain (Clark et al., 2022).

While the largest body of evidence has been accumulated for the prefrontal cortex, there are studies which have investigated other brain regions as well. For example,

Hagerty et al. (2016) utilized postmortem tissue of the precuneus and putamen and found more than 400 DMPs, which also showed enrichment for inflammation-related pathways.

The aforementioned studies were able to identify differential methylation, although often not epigenome-wide significant. This is likely because of the small sample size, which ranged between N=20-96. At the same time, the interpretation of EWAS-findings alone is difficult, because each CpG site usually has a small effect and does not necessarily influence gene expression. Therefore, evidence from multiple layers of -omics are needed to provide convergent evidence and enhance our understanding of the molecular mechanisms of AUD.

1.5 Gene Expression in Alcohol Use Disorder

1.5.1 RNA-sequencing and Differential Expression Analysis

Gene expression is a complex process involving multiple steps during the transfer of genetic information from DNA to messenger RNA (mRNA) or the transition from genotype to phenotype (Gibney & Nolan, 2010).

Next-generation sequencing technologies are the gold standard for analyzing whole-genome transcriptomics and have become increasingly cost-effective in recent years (Levy & Myers, 2016). The RNA-seq workflow is depicted in Figure 1.5. First, RNA is extracted from primary tissue and total RNA is purified for the ribonucleic acid of interest, such as mRNA or small RNAs. Afterwards, the RNA is converted to cDNA, followed by sequencing library construction and amplification. After sequencing, the resulting reads can either be aligned to the genome or transcriptome, or a pseudo-alignment can be performed. Afterwards, aligned reads are quantified in a count matrix and differential expression can be tested.

By now, RNA-sequencing is also possible at the single-cell or single-nuclei (snRNA-seq) level. snRNA-seq allows the measurement of gene expression in each nucleus analyzed, as opposed to bulk-sequencing which estimates the mean gene expression profile in a sample. Because of the high resolution, it is possible to cluster the gene expression profiles of the individual nuclei into known and novel cell-types and perform cell-type specific analyses (Lake et al., 2016).

1.5.2 Gene Expression in Postmortem Human Brain Tissue

So far, gene expression studies in AUD have been conducted primarily in postmortem human brain tissue. In an early study that used microarray technology to measure gene expression, widespread differential expression in the central and basolateral amygdala, and the superior frontal cortex was observed, although this only reached nominal significance (Ponomarev et al., 2012). In the same study, a WGCNA analysis was conducted and the resulting modules were related to different cell types, depicting a common result of WGCNA. However, no information on the association of modules with AUD status was available (Ponomarev et al., 2012). The first study assessing gene expression in substance use disorders applied RNA-sequencing in individuals with cocaine use disorder (CUD), AUD, and controls. They observed two genes differentially expressed in the hippocampus of individuals with AUD compared to controls and eight genes which were genome-wide significant for both, AUD and CUD (Zhou et al., 2011). The strongest association for AUD was for a member of the histone H4 family.

More recent studies have investigated BA9 using next-generation sequencing technologies. Kapoor et al. (2019) found 125 genes differentially expressed in BA9 between individuals with AUD and controls. Network analyses resulted in modules enriched for calcium signaling and immune pathways (Kapoor et al., 2019). A recent study investigated microRNAs and mRNAs in eight brain regions: the amygdala, CN,

cerebellum, hippocampus, NAc, prefrontal cortex, putamen, and ventral tegmental area (Lim et al., 2021). MicroRNA and mRNA networks were also enriched for immunological pathways, such as IL-8 signaling, *CREB* signaling in neurons, and neuroinflammation signaling (Lim et al., 2021).

A snRNA-seq study in BA9 showed differential expression particularly in astrocytes, microglia and oligodendrocytes, and found that DE genes were enriched for neuroinflammation-related pathways (Brenner et al., 2020). When results from snRNA-seq were compared to those from Kapoor et al. (2019), it was shown that there was a moderate overlap between bulk results and those originating from different cell-types, but microglia displayed a very distinct gene expression pattern (Brenner et al., 2020). In summary, there is accumulating evidence of transcriptome-wide differential expression in AUD, but at the same time a lack of studies investigating striatal brain regions. Importantly, investigating a single -omic layer cannot give an accurate picture of the molecular mechanisms associated with AUD.

1.6 Multi-Omics Data Integration

Integrating multiple layers of -omics allows a deeper characterization of the functional mechanisms in AUD. Already there have been some attempts at multi-omics data integration in AUD. Two studies attempted to integrate data from GWAS with DNA methylation and/or gene expression data from postmortem human brain samples. Lin et al. (2020) investigated a potential functional relevance of GWAS-identified variants associated with AUD and comorbid psychiatric disorders, and they observed that methylation (mQTL) and expression quantitative trait loci (eQTL) were enriched in variants for these disorders. Quantitative trait loci describe genetic loci which predict biological processes, such as DNA methylation (Hormozdiari et al., 2018). Similarly, Kapoor et al. (2021) performed fine-mapping of genetic variants from a large GWAS of AUD (Kranzler et al., 2019) and two GWAS of alcohol dependence (Lai et al., 2019; Walters et al., 2018), using eQTL and mQTL data from fetal and adult dorsolateral prefrontal cortex from individuals with and without AUD. The genes prioritized in this study showed an overlap with causal genes that were previously related to neurodegenerative diseases (Kapoor et al., 2021).

While GWAS data have been followed-up in expression and methylation datasets, there is a lack of studies integrating DNA methylation and gene expression data.

1.7 Aims

The following studies aimed to identify epigenetic mechanisms associated with AUD – both on the single site and the regional level – to investigate differential gene expression associated with AUD status in the neurocircuitry of addiction, relate our results to GWAS findings, and to integrate the gene expression with DNA-methylation data using a network approach (WGCNA) in order to identify functionally relevant molecular mechanisms in AUD.

2 STUDY 1: EPIGENOME-WIDE ASSOCIATION STUDY OF ALCOHOL USE DISORDER IN FIVE BRAIN REGIONS¹

2.1 Abstract

Alcohol Use Disorder (AUD) is closely linked to the brain regions forming the neurocircuitry of addiction. Postmortem human brain tissue enables the direct study of the molecular pathomechanisms of AUD. This study aims to identify these mechanisms by examining differential DNA-methylation between cases with severe AUD (n=53) and controls (n=58) using a brain region-specific approach, in which sample sizes ranged between 46 and 94. Samples of the anterior cingulate cortex (ACC), Brodmann Area 9 (BA9), caudate nucleus (CN), ventral striatum (VS), and putamen (PUT) were investigated. DNA-methylation levels were determined using the Illumina HumanMethylationEPIC Beadchip. Epigenome-wide association analyses were carried out to identify differentially methylated CpG-sites and regions between cases and controls in each brain region. Weighted Correlation Network Analysis (WGCNA), gene-set and GWAS-enrichment analyses were performed. Two differentially methylated CpG-sites were associated with AUD in the CN, and 18 in VS ($q < .05$). No epigenome-wide significant CpG-sites were found in BA9, ACC, or PUT. Differentially methylated regions associated with AUD case-/control status ($q < .05$) were found in the CN (n=6), VS (n=18) and ACC (n=1). In the VS, the WGCNA-module showing the strongest association with AUD was enriched for immune-related pathways. This study is the first to analyze methylation differences between AUD cases and controls in multiple brain regions and consists of the largest sample to date. Several novel CpG-sites and regions implicated in AUD were identified, providing a first basis to explore epigenetic correlates of AUD.

M., Rietschel, M., Spanagel, R., & Witt, S. H. (2022). Epigenome-wide association study of alcohol use disorder in five brain regions. *Neuropsychopharmacology*, 47(4), 832-839. <https://doi.org/10.1038/s41386-021-01228-7>

2.2 Introduction

Every year, approximately 5.3% of all deaths worldwide are a result of the harmful use of alcohol and approximately 230 diseases are associated with alcohol use (World Health Organization, 2019). The lifetime prevalence of alcohol use disorder (AUD) varies globally, with North African/Middle Eastern countries having the lowest (0.59%) and Eastern European countries the highest (4.25%) prevalence. With a global prevalence of 1.32%, AUD is an important contributor to global disease burden (Degenhardt et al., 2018). AUD is a moderately heritable disease; a meta-analysis of twin studies estimated a heritability of 49% (Verhulst et al., 2015).

It has been proposed that drug-induced alterations in gene expression in the neurocircuitry of the brain contribute to addiction (Robison & Nestler, 2011). Recent evidence suggests that alterations in DNA-methylation, an epigenetic mechanism affecting gene expression, play an important role in addiction (for reviews see: Longley et al. (2021), Maze and Nestler (2011)). Differential DNA-methylation is associated with alcohol consumption and AUD both in peripheral blood and postmortem brain tissue (for an overview see: Bazov et al. (2013)). Examining alterations in DNA-methylation in epigenome-wide association studies (EWAS) allows for the investigation of inter-individual differences which are attributable to a phenotype (Rakyan et al., 2011). For example, a recent EWAS of AUD in peripheral blood suggests that networks in glucocorticoid signaling and inflammation-related genes are associated with AUD (Lohoff et al., 2020).

Human postmortem brain tissue is a sparse and valuable resource and allows a more direct characterization of AUD mechanisms than possible by analyzing peripheral blood (Edgar et al., 2017). So far, a small number of postmortem brain studies have been conducted, mostly investigating the prefrontal cortex (PFC), which, due to its role in reward regulation and higher-order executive function, is thought to be disrupted in addiction (Goldstein & Volkow, 2011). An EWAS comparing individuals with AUD with age-matched controls detected a range of differentially methylated CpG-sites in Brodmann Area 9 (BA9) in 16 pairs of males, but not in seven pairs of females (Wang et al., 2016). Another study identified AUD-associated differentially methylated CpG-sites in Brodmann Area 10, which did not remain significant after multiple testing correction (Gatta et al., 2021). However, downstream analyses implicated *NR3C1*, a gene coding for the glucocorticoid receptor, which is crucial to stress regulation and found to be functionally relevant in AUD. The increased DNA-methylation in individuals with AUD was also associated with reduced *NR3C1* mRNA and protein expression levels (Gatta et al., 2021).

Investigating DNA-methylation in the wider addiction neurocircuitry may give deeper insights into the pathophysiological mechanisms of AUD, and may reveal potential targets for treatment or prevention (Koob & Volkow, 2010; Noori et al., 2012). Dysfunction in the addiction neurocircuitry, which comprises areas involved in cognitive control such as the dorsolateral PFC, the anterior cingulate cortex (ACC), and regions in the basal ganglia, can have impairing consequences associated with disrupted reward-related decision-making, alcohol craving, and compulsive alcohol consumption (Goldstein & Volkow, 2011; Park et al., 2010). Of particular interest is the striatum,

which is divided into ventral and dorsal subdivisions based on function and connectivity. The ventral striatum (VS), comprises the nucleus accumbens (NAcc) and olfactory tubercle while the dorsal striatum contains the caudate nucleus (CN) and putamen (PUT) (Volkow & Morales, 2015). The NAcc is thought to be important in addiction due to its role in processing motivation, more precisely aversion and reward (Volkow & Morales, 2015). The caudate nucleus and putamen both influence motor function; in addition, the caudate is involved in goal-directed action, executive functioning and cognitive control, while the putamen is implicated in various types of learning, including reinforcement learning and habit formation (Galandra et al., 2018). In a study investigating DNA-methylation in PFC and NAcc, CpG-sites in *DLGAP2* emerged as differentially methylated between 39 male AUD cases and 47 controls in both brain regions; the differences were genotype-dependent (Meng et al., 2021). In the present study, we aimed to identify epigenetic mechanisms associated with AUD, in five brain regions previously implicated in the neurocircuitry of addiction (Volkow & Morales, 2015). Brain-region specific EWAS of AUD were performed in the BA9, ACC, VS, CN and PUT.

2.3 Materials and Methods

2.3.1 Samples

In total, 395 human postmortem brain samples from 111 subjects (53 AUD, 58 controls) were obtained from the New South Wales Tissue Resource Center (University of Sydney, Australia) under study reference number 2009-238N-MA by the Ethics Committee II of the Medical Faculty Mannheim. AUD and control subjects were matched by age and sex. All individuals met the following inclusion criteria, which were determined by next-of-kin interviews: age >18, no history of severe psychiatric, neurodevelopmental, or other substance use disorders (except nicotine use disorder), and Western European ancestry. Individuals with AUD were classified according to DSM-IV criteria and had consumed at least 80g alcohol daily, whereas controls had consumed less than 20g. Methylation data was generated in two batches and each batch was analyzed separately. The first batch comprised 220 samples of BA9, ACC, CN, and VS from 28 cases and 27 controls. In the second batch, 175 samples from 56 additional individuals from the CN, VS, and PUT were analyzed. Material from one to five brain regions was available for each individual. Therefore, the sample composition varies between the brain region-specific analyses. A sample description can be found in Table 2.1. Table 2.2 shows the number of samples for each brain region and each batch. Additional phenotype information, such as cause of death and detailed exclusion criteria can be found in the Supplementary Information (Table 2.S1 and Text 2.S1).

2.3.2 Epigenome-wide Methylation

DNA was extracted from bulk brain tissue using the DNeasy extraction kit from Qiagen (Qiagen, Hilden, Germany). The genomic DNA samples were stored at -20°C. For the microarray analysis, the samples were randomized based on AUD case/control status and sex, and pipetted on processing plates. Due to the sample and different group sizes, samples from each brain region were processed on separate plates. Epigenome-wide methylation levels were determined using the Illumina HumanMethylationEPIC Beadchip and Illumina HiScan array scanning systems (Illumina, San Diego, CA).

Table 2.1

Descriptive statistics of demographic data.

Characteristic	Cases	Controls	<i>p</i>
N	53	58	
Age, years	56.72 (10.81)	56.69 (10.29)	0.989
Sex (M/F)	34/19	40/18	0.737
pH-value	6.5 (0.28)	6.57 (0.32)	0.189
PMI (hours)	35.46 (16.1)	28.17 (15.29)	0.038*
Estimated Smoking	0.72 (0.26)	0.51 (0.31)	> .001*
Blood Alcohol level (N)	8	0	
Blood Alcohol Level (g/100ml)	0.211 (0.179)		
Number of Brain Regions			
	5 19 (35.8%)	19 (32.8%)	
	4 9 (17.0%)	8 (13.8%)	
	3 18 (34.0%)	21 (36.2%)	
	2 0 (0%)	3 (5.1%)	
	1 7 (13.2%)	7 (12.1%)	

Data are presented as count (n/n; n (%)) or mean (\pm SD), PMI: post-mortem interval, pH: pH-value of the brain, p: p-value of t-Test comparing cases and controls, estimated smoking is the likelihood of smoking estimated based on the methylation data.

**significant difference between cases and controls*

2.3.3 Data preprocessing, Quality Control, and Filtering

All data preprocessing and analysis steps were performed using the R statistical environment, version 3.6.1. An updated version of the CPACOR-pipeline published by Lehne et al. (2015) was used to extract methylation data from raw intensity data and perform quality control. Samples were removed if (i) DNA quality was not sufficient (missing rate > 0.10) or (ii) a discrepancy between methylation-based and phenotypic sex emerged. Probes were removed when (i) the call-rate was insufficient (< 0.95), (ii) SNPs with a minor allele frequency > 0.10 were located in the probe sequence, (iii) the probes were located on the X or Y chromosome (chr). After quality control 381 samples

remained. Depending on the brain region, 657 593 – 694 791 sites were available for analysis after filtering. Detailed descriptions of sample size, the number of sites remaining after QC, and the inflation coefficient lambda for each model can be found in Table 2.2.

Table 2.2.
Sample Overview.

Brain Region	Total N	Case		Control		# of CpG sites	Genomic Inflation
		Batch I	Batch II	Batch I	Batch II		
Anterior Cingulate Cortex	54	28		26		657 593	0.958
Brodmann Area 9	46	25		21		657 593	0.942
Putamen	94		44		50	694 572	0.963
Caudate Nucleus	94	28	17	27	22	694 790	0.919
Ventral Striatum	93	28	18	26	21	694 790	0.962

Number of individuals per brain region after quality control. # of CpG-sites refers to the number of sites remaining after quality control, for VS and CN union of the two batches.

2.3.4 Statistical Analysis

Methylation values were log-transformed (base 2) and included as dependent variables in the association analyses, as recommended by Du et al. (2010). Control for batch effects and technical quality was applied by extracting signals of the internal control probes of the EPIC array, performing principal component analysis (PCA), and extracting the first ten principal components. These were included as covariates in all association tests. To control for cell-type heterogeneity, cell counts were estimated using the method by Houseman et al. (2012), with the dorsolateral prefrontal cortex reference data (Jaffe & Kaminsky, 2018). This approach results in two estimates, one for neurons and one for other cell types. These were standardized so that the sum of both counts added up to one. The estimate for neurons was included as a covariate in all analyses.

Data on smoking was not available for all participants (missing for n=11, 10.81%). Smoking status was therefore estimated based on a validated set of sites (Maas et al., 2019). Estimated smoking was included as a continuous covariate. 86% of current smokers were correctly classified; according to the regression model their likelihood of smoking was >50%.

2.3.4.1 Epigenome-wide Association Analysis

Tests of methylation differences between individuals with AUD and control subjects were performed with linear models, adjusting for sex, age, postmortem interval (PMI), pH-value, estimated smoking, standardized neuronal cell count, and the first ten principal components of the internal control probes. Each region and each batch was analyzed separately. The summary statistics for CN and VS were then meta-analyzed based on effect estimates and standard errors using METAL (Willer et al., 2010). P-values were corrected for multiple testing using the Benjamini-Hochberg (FDR) correction (Benjamini & Hochberg, 1995); resulting values are reported as q -values. CpG-sites were annotated using the manufacturer's manifest (<http://webdata.illumina.com.s3-website-us-east-1.amazonaws.com/downloads/productfiles/methylationEPIC/infinium-methylationepic-v-1-0-b4-manifest-file-csv.zip>; downloaded on 10th of August 2018). Regression coefficients of differential methylation for the epigenome-wide significant CpG-sites were summarized for each brain region. As each brain region was processed on a separate plate, no inferential statistical procedure was applied to compare DNA-methylation levels between brain regions (due to confounding of batch and regions). Test statistics from all epigenome-wide significant CpG-sites were reported for each brain region and also for an independent EWAS in peripheral blood, in which DNA-methylation levels of male patients with AUD, who had just entered withdrawal treatment were compared with healthy controls (Witt et al., 2020). As the cause of death of two control subjects from the second batch was "toxicity", a sensitivity analysis excluding these subjects was performed in CN, VS, and PUT.

2.3.4.2 Differentially Methylated Regions (DMRs)

DMRs were identified using the comb-p algorithm (Pedersen et al., 2012), which accounts for autocorrelation between tests of adjacent methylation sites and combines these sites to regions of enrichment, in a given window. The following settings were used: Seed-p value < 0.01, minimum of 2 probes, sliding window 500 bp. The Šidák correction as implemented in comb-p was applied to correct for multiple testing. Comb-p was applied to the result statistics for all brain regions.

2.3.4.3 Pyrosequencing and TaqMan Assay

The DMR in *DDAH2* was replicated by pyrosequencing and gene expression levels were determined using a TaqMan Assay (for details see Supplementary Text 2.S3).

2.3.4.4 Gene-Ontology (GO) over-representation analysis.

Functional analysis to identify gene pathways targeted by differentially methylated CpG-sites was performed for sites with a threshold of $p_{nominal} < 0.001$ using missMethyl (Phipson et al., 2016). missMethyl controls for probe number bias, the increased likelihood of a gene to be differentially methylated, if more probes cover the gene and multi-gene bias, and the fact that probes can be annotated to more than one gene.

GWAS-Enrichment-Analysis. Gene-sets were created consisting of the genes to which the differentially methylated CpG-sites were annotated. Two gene-sets were created for each of the CN and VS results, one for genes implicated by epigenome-wide significant CpG-sites, and one for genes implicated by nominally significant CpG-sites, giving a total of four gene-sets. Multi-marker Analysis of GenoMic Annotation (MAGMA)(de Leeuw et al., 2015) was used to test enrichment of those gene-sets in the results of a genome-wide association study (GWAS) of AUD (Zhou et al., 2020).

2.3.4.5 Weighted Correlation Network Analysis (WGCNA)

The WGCNA R package (Langfelder & Horvath, 2008) was used to generate co-methylated modules and relate those to AUD case-/control status. For each brain region the quantile-normalized beta values of CpG-sites nominally associated ($p < 0.05$) with AUD status were used as input. Soft power thresholds were picked according to the criterion of approximate scale-free topology ($R_{\text{signed}}^2 > 0.90$). The number of CpG-sites and the soft power thresholds picked can be found in Supplementary Table 2.S2. Unassigned CpG-sites were clustered in the “grey” module, which was not taken into account for further analyses. For each brain region, the module of correlated CpG-sites with the highest association with AUD was identified. A GO analysis with the CpG-sites comprising the module was performed using missMethyl (Phipson et al., 2016).

2.3.4.6 GWAS ATLAS

The PheWAS tool from the publicly available database GWAS ATLAS (Watanabe et al., 2019) [<https://atlas.ctglab.nl/>] was used to identify genome-wide significant associations of the genes implied by the top hits in the EWAS.

2.4 Results

2.4.1.1 Epigenome-wide Association Analysis

In the CN, two CpG-sites were epigenome-wide significantly hypomethylated in AUD cases compared to controls. The two sites were annotated to the genes *IREB2* (cg04214706) and *HMGCR* (cg26685658). cg04214706 was also differentially methylated in the ACC ($p_{\text{nominal}} = 0.005$).

In the VS, 18 CpG-sites were epigenome-wide significantly associated with AUD. Nine CpG-sites were hyper- and nine hypomethylated. The top three hits were annotated to *SLC30A8*, *FAM20B*, and *PCAT29*. Of the epigenome-wide significant CpG-sites, cg12049992 in *PIEZO2* and cg16767842 in *GLANT9* were also differentially methylated in CN ($p_{\text{nominal}} \leq 0.023$). Additionally, cg1354575 in *TCL1A* was differentially methylated in PUT ($p_{\text{nominal}} = 0.035$) and cg02849689 (intergenic) in ACC ($p_{\text{nominal}} = 0.012$). Three of the epigenome-wide significant CpG-sites showed nominally significant associations in an EWAS of AUD in peripheral blood, namely cg27512762 in *PCAT29*, cg06427508 in *KLHL6* (effect in opposite direction), and cg02849689,

which was not annotated to a nearby gene. In ACC, BA9, and PUT no epigenome-wide significant differentially methylated CpG-sites were identified ($q \geq 0.57$). Epigenome-wide significant CpG-sites can be found in Table 2.3 and the top 100 associations for each brain region, together with more detailed information on location and annotation to enhancers, in supplementary tables (2.S3a–2.S3e). All coefficients of CpG-sites with $q < 0.05$ for each brain region and in peripheral blood are summarized in Supplementary Table 2.S4. Manhattan plots for EWAS in the ACC, CN, and VS are depicted in Figure 2.1.

Post-hoc power analyses using the web app EPIC Array Power Calculations (<https://epigenetics.essex.ac.uk/shiny/EPICDNAMPowerCalcs/>) were conducted for sample sizes of $n=46$ and $n=94$, to adequately reflect our sample sizes and the additional settings 2% mean difference and significance threshold 1×10^{-7} , which was closest to the FDR corrected thresholds in the present study. This resulted in 11% of CpG-sites having a power larger than 90% to detect mean methylation differences of 2% for a sample size of 94 and 3.18% for a sample size of 46 (see also Supplementary Figure 2.S1). It has to be noted, that the power calculations assumed equal distributions between cases and controls, which was not the case for all analyses. The sensitivity analyses did not reveal major differences between the EWAS in the complete sample and the reduced sample, in which control subjects who died of toxicity were excluded. The effect sizes of the nominally significant CpG-sites in each of the brain regions were highly correlated ($r_{CN} = 0.99$, $r_{VS} = 0.98$, $r_{PUT} = 0.99$, all $p < 0.001$). Scatterplots of the effect sizes for nominally significant CpG-sites in both analyses are depicted in Supplementary Figure 2.S2.

Figure 2.1. Manhattan plots of association of methylation values with AUD in (A) anterior cingulate cortex; (B) caudate nucleus; (C) ventral striatum. Highlighted CpG-sites represent differentially methylated regions. Genes implicated by CpGs (light and dark grey) and DMRs (green) are specified in the figures. Red line indicates FDR-corrected significance.

2.4.1.2 Differentially Methylated Regions

In the CN, 10 DMRs were associated with AUD. The top three regions were annotated to the genes *DDAH2*, *CCDC152*, and *CAMSAP1*. Six DMRs were associated with AUD ($q < 0.05$) in the VS, with the three most strongly associated regions in *TMEM232*, *FANCD2OS*, and *HM13*. All significant DMRs for CN and VS are highlighted in Figure 2.1 and can be found in supplementary tables 2.S5a and 2.S5b. In the ACC, one region in *HLA9* was differentially methylated ($p_{\text{Šidák-corrected}} = 3.25 \times 10^{-6}$). No epigenome-wide significant DMRs were observed in BA9 and PUT.

The DMR in *DDAH2* was replicated by pyrosequencing (cg04074004: $t(76.77) = 2.39$, $p = 0.019$). Differential expression was not observed (all $p > 0.136$). For details see Supplementary Text 3.S3.

2.4.1.3 Gene-Ontology Analysis

The strongest overrepresentation in the CN was for the biological process “homophilic cell adhesion via plasma membrane adhesion molecules” ($p = 5.37 \times 10^{-6}$, $q = 0.12$) and “cell-cell adhesion via plasma-membrane adhesion molecules” ($p = 1.68 \times 10^{-5}$, $q = 0.187$). In the VS, the cellular “Lsm1-7-Pat1 complex” showed the strongest overrepresentation ($p = 6.49 \times 10^{-5}$, $q \approx 1$). Both associations did not remain significant after correction for multiple testing. The ten GO-terms showing the strongest overrepresentation can be found in Supplementary Tables 2.S6a and 2.S6b.

2.4.1.4 GWAS Enrichment Analysis

No significant enrichment was observed in any of the regions and gene-sets tested (all $p \geq 0.277$).

2.4.1.5 Weighted Correlation Network Analysis (WGCNA)

For the caudate nucleus, 15 modules were identified consisting of 49-10,330 CpG-sites (*Median* = 965). The strongest association with AUD was observed for module “black”, which showed the strongest enrichment for the cellular component “PML body” ($p = 0.001$) and the molecular function “G-rich strand telomeric DNA binding” ($p = 0.001$). For CpG-sites nominally associated with AUD status in the VS 14 modules were identified, consisting of 38-12,721 CpG-sites (*Median* = 611). Module “purple” showed the strongest association with AUD and was enriched for a variety of immune-related GO-terms, such as the biological processes “regulation of T-cell proliferation” ($p = 4.32 \times 10^{-6}$) and “regulation of leukocyte cell-cell adhesion” ($p = 6.83 \times 10^{-6}$). For caudate nucleus module “black” and ventral striatum module “purple” the correlations of the gene significance (GS), which reflects the biological significance of a CpG-site with an external trait (here AUD) and the module membership (MM), which reflects the correlation of each CpG-site with the module, were calculated and are displayed in Figure 2.2a and 2.2b. The top enriched GO-terms for these modules can be found in Supplementary Tables 2.S7a and 2.S7b. Results for ACC, BA9, and putamen are described in the Supplementary Information (Text 2.S2, Figure 2.S3).

Figure 2.2. Association of gene significance for AUD status with module membership, for the modules A) “black” in caudate nucleus, and B) “purple” in ventral striatum.

2.4.1.6 GWAS ATLAS

GWAS ATLAS results for the genes implicated by the most strongly associated site and region both in the CN and VS can be found in Supplementary Tables 2.S8a-2.S8d. In brief, *IREB2* has previously been associated with smoking phenotypes (e.g., number of cigarettes a day, numbers of cigarettes previously smoked daily), parental illnesses such as lung cancer and chronic bronchitis, and psychiatric disorders like schizophrenia and bipolar disorder (Furberg et al., 2010; Ruderfer et al., 2018; Watanabe et al., 2019). Genome-wide significant associations of *DDAH2* with phenotypes from a variety of domains, e.g., immunological, metabolic, respiratory, and psychiatric have been found. In the psychiatric domain, *DDAH2* has been associated with schizophrenia and bipolar disorder e.g. (Pardiñas et al., 2018; Ruderfer et al., 2018). *SLC30A8* has been implied in blood sugar levels (Kanai et al., 2018) and *TMEM232* in allergic rhinitis and asthma (Watanabe et al., 2019).

2.5 Discussion

The present study examined DNA-methylation associated with AUD in regions of the addiction neurocircuitry using an epigenome-wide methylation analysis approach employed in human postmortem brain tissue. The largest of its kind to date and first to examine five brain regions, this study identified several novel differentially methylated CpG-sites as well as DMRs associated with AUD, providing potential insight into underlying mechanisms.

We found significant differentially methylated CpG-sites in two striatal regions. In the caudate nucleus, two epigenome-wide significant CpG-sites in *IREB2* and *HMGCR*, were identified. *IREB2* is a gene encoding iron regulatory protein 2, which is an RNA-binding protein that is involved in the regulation of cellular iron metabolism [<https://www.genecards.org/cgi-bin/carddisp.pl?gene=IREB2>]. Iron overload in the brain has previously been associated with cognitive decline in AUD (Listabarth et al., 2020). Neurodegeneration has been reported in two subjects with bi-allelic loss of function variants in *IREB2* (Cooper et al., 2019; Costain et al., 2019). *IREB2* has also been associated with smoking phenotypes (Watanabe et al., 2019). The association with smoking, which strongly affects DNA methylation (Sugden et al., 2019; Zeilinger et al., 2013), may be linked to the relevance of the gene to addiction phenotypes. In the present study, the *IREB2*-CpG-site was also differentially methylated in the anterior cingulate cortex (nominal significance), which might reflect a relevance in addiction phenotypes in multiple brain regions.

In the ventral striatum, 18 CpG-sites were epigenome-wide significantly associated with AUD. The strongest association was observed in a CpG-site in *SLC30A8*, which encodes a zinc efflux transporter that is involved in the accumulation of zinc in the intracellular vesicles. Zinc is a structure-building element in alcohol dehydrogenase (ADH) and thereby important for the proper function of ADH, which is needed to break down alcohol (Baj et al., 2020). Differential methylation in *SLC30A8* may lead to altered Zinc availability and indirectly impact ADH function, and thus alcohol metabolism. *SLC30A8* has also been implicated in type 1 and type 2 diabetes (Sladek et al., 2007). In both types epigenetic and transcriptomic levels of *SLC30A8* have shown to be altered (Gu, 2017). Heavy alcohol consumption is also an established risk factor for type 2 diabetes on the phenotypic level (Baliunas et al., 2009). Three of the epigenome-wide significant CpG-sites were also previously differentially methylated in an independent EWAS of AUD (Witt et al., 2020); these convergent results might point towards a cross-tissue effect of these sites.

Significant regional methylation differences were observed in the anterior cingulate cortex, caudate nucleus, and ventral striatum. One differentially methylated region was observed in the anterior cingulate cortex and that region was annotated to HLA complex group 9, a non-coding RNA in the major histocompatibility complex (MHC). HLA antigens play a role in AUD and alcohol-associated liver disease (Shigeta et al., 1980). In the caudate nucleus, the DMR showing the strongest association with AUD was annotated to *DDAH2*, encoding for dimethylarginine dimethylaminohydrolase, which is involved in the formation of nitric oxide by indirect inhibition of nitric oxide synthase (NOS) [<https://www.genecards.org/cgi-bin/carddisp.pl?gene=DDAH2>]. Nitric oxide has previously been associated with sleep disturbances, as part of the sleep-wake state controlling metabolites (Cespuglio et al., 2012). Sleep disorders and disturbances, such as decreased total sleep time and decreased sleep efficiency, are common in individuals during periods of alcohol consumption and prolonged withdrawal (Koob & Colrain, 2020; Thakkar et al., 2015). In rodent studies, alcohol exposure influenced NOS expression in the brain (Davis & Syapin, 2005) and the knockout of neuronal NOS was associated with increased consumption of highly concentrated alcohol solutions (Spanagel et al., 2002). Although the DMR in *DDAH2*

was replicated by pyrosequencing, we did not observe differential gene expression between AUD cases and controls. It has to be noted, that differential gene expression is only partly explained by DNA-methylation differences. For example, in postmortem brain samples of individuals with schizophrenia and controls, 204 of 71,753 tested CpG gene pairs were significantly correlated (Chen et al., 2014). A potential functional relevance of the DMR in *DDAH2* requires further investigation, for instance in relation to contact frequency maps (chromosomal architecture/Hi-C), which can be simultaneously studied with the methylome in single-cell experiments (Li et al., 2019).

Of the six DMRs identified in the ventral striatum, a region in *TMEM232* showed the strongest association. *TMEM232* has previously been associated with respiratory traits, such as seasonal allergic rhinitis (Ramasamy et al., 2011). Another significant CpG-site was annotated to *HM13*. This gene encodes for minor histocompatibility antigen H13. In general, minor histocompatibility antigens function in the immune system by recognizing T cells (Robertson et al., 2007). No studies have investigated direct associations between AUD and H13 expression changes yet, but it is known that the immune system is downregulated in patients with AUD (Erickson et al., 2019).

GO-term analyses investigating molecular functions associated with differentially methylated CpG-sites did not yield significant results after multiple testing correction, which is most likely attributable to the limited statistical power. No significant enrichment was observed for each of the gene-sets in GWAS signals for AUD, which could indicate that differential methylation in the newly identified CpG-sites is more sensitive to environmental factors than genetic effects.

In the WGCNA analysis in VS a module enriched for immune-processes was most strongly associated with AUD, which are known to be influenced by alcohol abuse (Pasala et al., 2015).

In this brain region-specific analysis, comparing individuals with AUD and controls, we focused beside prefrontal areas on striatal regions, as previous studies have indicated that AUD may be associated with a striatal shift in activation from ventral to dorsal, as drug intake changes from goal-directed to habitual (DePoy et al., 2013; Vollstädt-Klein et al., 2010). These studies focus on changes in neurotransmitter release and functional connectivity but it is not known how epigenetic changes impact this functional striatal shift. Our epigenome-wide results provide a first basis to explore epigenetic contributions to functional striatal changes.

This study has several limitations. The first is PMI, which can influence the tissue quality. The longer the individual has been deceased before the tissue was extracted from the body, the further along are degradation processes (Glausier et al., 2019). While we corrected for this in our analyses our results may have been affected by postmortem degradation processes nevertheless. Second, we cannot infer whether the observed differences in DNA-methylation are a result of addiction or long-term alcohol consumption, which affects multiple organ systems. Third, the methylation array used in the present study combined with the bisulfite conversion does not distinguish between methylation and hydroxymethylation. Therefore, no conclusions can be drawn regarding methylation type specific effects. Also, for several CpG-sites the effect in the meta-analysis was driven by a large effect in one, but not the other

batch and in some of the cases this went hand-in-hand with a change in direction. For example, cg04214706 had a small positive effect, which was statistically not different from zero in the first batch, and a large negative effect in the second. Further samples are needed to validate these findings. Due to the sparse availability of human postmortem brain tissue, our sample size is small compared to EWAS in peripheral blood, which results in limited statistical power, especially taking into account the high multiple testing correction burden. However, EWAS analysis of peripheral blood allows to reveal only limited conclusions about differential methylation in the brain, whereas studies that examine multiple brain sites in a comparative fashion point to region-specific functional changes. Lastly, the correlational design of this analysis does not allow conclusions about the causality of the findings. DNA-methylation differences both be a result of AUD and be present in individuals before onset of the disorder.

Here, we identified novel associations of differential DNA-methylation between AUD cases and controls, which are prominent in alcohol-related pathways and diseases linked with AUD. To confirm these observations, larger samples are needed from the respective brain regions. Human postmortem brain tissue is difficult to obtain and very few brain banks focus on substance use disorders. Combining existing datasets, generating a larger amount of DNA-methylation data, and integrating multi-omics data, could lead to more conclusive results that may help to understand the molecular changes due to substance abuse in the brain and eventually to the identification of drug targets for more effective treatment of substance use disorders.

2.6 Funding and Disclosures

The study was supported by the German Federal Ministry of Education and Research (BMBF), “A systems-medicine approach towards distinct and shared resilience and pathological mechanisms of substance use disorders“ (01ZX01909 to Rainer Spanagel, Marcella Rietschel, Stephanie H Witt, Anita C Hansson), “Towards Targeted Oxytocin Treatment in Alcohol Addiction (Target-OXY)” (031L0190A to Jerome C Foo). ERA-NET program: Psi-Alc (FKZ: 01EW1908), and the Deutsche Forschungsgemeinschaft (DFG, German Research Foundation) – Project-ID 402170461 – TRR 265 to Rainer Spanagel, Anita C Hansson and Marcella Rietschel (Heinz et al., 2020). The authors have nothing to disclose.

2.7 Acknowledgments

We thank Elisabeth Röbel and Claudia Schäfer-Arnold for technical assistance. Tissues were received from the New South Wales Brain Tissue Resource Centre at the University of Sydney which is supported by the University of Sydney. Research reported in this publication was supported by the National Institute of Alcohol Abuse and Alcoholism of the National Institutes of Health under Award Number R28AA012725. The content is solely the responsibility of the authors and does not represent the official views of the National Institutes of Health.

2.8 Author Contributions

SHW, MR, RS, MMN, and ACH planned the investigation. MMF and ACH performed the DNA and RNA extraction and SHH, PH, FD and MMN were responsible for generating genome-wide methylation data. LZ, JF, JCF and FS developed the analysis plan. LZ and JF performed all statistical analyses. HD, ACH and MMF performed replication and validation experiments. LZ, MMF, JCF, LS, MR, FS, and SHW reviewed the literature for the paper. LZ, MMF, FS and SHW drafted the manuscript. All authors contributed, revised, and edited the final manuscript critically. All authors agreed to the publication of the final version of the manuscript.

2.9 Supplementary Information

2.9.1 Supplementary Texts

Supplementary Text 2.S1. Detailed description of obtained postmortem human brain samples.

All tissue samples were obtained from the New South Wales Tissue Resource Centre (University of Sydney, Australia). Tissues were collected as described in Harper et al. (2003, *Progress in Neuro-Psychopharmacology & Biological Psychiatry* 27: 951–961), where cases with prolonged agonal life support, cases with a history of cerebral infarction, head injury, or neurodegenerative disease (e.g., Alzheimer's disease) were excluded. Further exclusion criteria were cases with developmental disorder, head injury at time of death, recent cerebral stroke, neurological disorder, history of intravenous drug use, brain on gross examination showing obvious abnormalities, and cases with a history of other psychiatric disorders (e.g. autism, attention deficit-hyperactivity disorder, schizophrenia). We further excluded cases with reported anxiety or mood disorders or suicides have been excluded as well as cases with significant amounts of psychiatric medication (e.g., opioids, benzodiazepines; concentration <0.1 mg/L).

Supplementary Text 2.S2. WGCNA results for Anterior Cingulate Cortex, Brodmann Area 9, and Putamen.

Weighted correlation network analysis for Anterior Cingulate Cortex resulted in 10 modules consisting of 34–11,588 CpG-sites ($Md = 606.5$). The highest correlation with AUD was observed for module “green” ($r = .44$, $p = 8.54e-04$), which was enriched for the molecular functions “ligand-gated sodium channel activity” ($p = 0.0003$), “sodium channel activity” ($p = 0.0004$), and the biological process “noradrenergic neuron differentiation” ($p = 0.0007$). In Brodmann Area 9 20 modules, with a median sizes of 287 CpG-sites per module (range: 38-7,960) were constructed. Module “blue” showed the highest correlation with AUD ($r = -.55$, $p = 4e^{-05}$). GO-analysis revealed enrichment for the cellular components “actomyosin”, ($p = 0.0001$), “stress fiber” ($p = 0.0007$), and “contractile actin filament bundle” ($p = 0.0007$). Eight modules were constructed for putamen, which consisted of 78-13,091 CpG-site with a median size of 2,020. Module “yellow” had the highest correlation with AUD ($r = -.52$, $p = 8.13e^{-08}$). This module was enriched for the biological processes “response to immune response of other organism involved in symbiotic interaction”, ($p = 0.0004$), “response to host immune response” ($p = 0.0004$), and “ventral spinal cord interneuron fate commitment” ($p = 0.001$). Scatterplots showing the association of gene significance and module membership for the three modules can be found in Supplementary Figure 2.S2.

Supplementary Text 2.S3. Methods and results for replication by pyrosequencing and functional validation for *DDAH2*.

Samples

For a subsample of n=87 sufficient material for Pyrosequencing and the TaqMan Assay was available.

Pyrosequencing

The CpG site cg04074004 was analyzed by pyrosequencing, using the commercially available PyroMark CpG assay Hs_DDAH2_03_PM (Qiagen, Hilden, Germany). All samples (n=87) were carefully randomized on positions on sequencing plates. DNA (500ng) was bisulfite-treated using the EpiTect Fast 96 Kit (Qiagen, Hilden, Germany). We controlled for bisulfite conversion reaction, PCR amplification, and pyrosequencing reaction by including unmethylated and methylated DNA (EpiTect PCR Control DNA Set, Qiagen, Hilden, Germany).

The DNA fragment was amplified by PCR (PyroMark PCR Kit, Qiagen, Hilden, Germany) from 2 µl of bisulfite-treated DNA in a PCR volume of 25 µl. Successful amplification and the specificity of the PCR product (137 base pairs) was checked on an agarose gel. To ensure equal amplification in the CpG assay an additional mixture of DNA with a 50% DNA methylation level was prepared from unmethylated, converted and methylated, converted DNA (EpiTect PCR Control DNA Set, Qiagen, Hilden, Germany). Then, 8 µL of PCR product was processed for pyrosequencing analysis with following manufacturer's recommendations (PyroMark Gold Q24 reagents, Qiagen, Hilden, Germany), sequenced with the sequencing primer Hs_DDAH2_03_PM (Qiagen, Hilden, Germany) with the PyroMark Q24 instrument (Qiagen, Hilden, Germany). The percentage of methylation was quantified using the PyroMark Q24 software version 2.0.8 Build 3 (Qiagen, Hilden, Germany). The sequencing was performed in triplicates.

TaqMan Assay

RNA was extracted from caudate nucleus samples using the RNeasy microKit (Qiagen, Hilden, Germany). The analysis was performed on triplicates of each gene and sample using the PCR Master Mix and FAM dye-labeled TaqMan MGB probes from ThermoFisher Scientific (Massachusetts, US). The following primers have been used for the human *DDAH2* gene: Forward primer sequence 1: 5-CAAAGGCTGTCCGGGCAATGGCAG-3, position 854 on cDNA, RefSeq NM-013974.3, TaqMan assay ID Hs00967863_g1, 60 bp amplicon; forward primer sequence 2: 5- GCTCGTAGGCCAGAGGTCGATGGAG-3, position 560 on cDNA, RefSeq NM-013974.3, TaqMan assay ID Hs00967860_g1, 81 bp amplicon). As housekeeping genes the human 18S RNA (TaqMan assay ID Hs99999901_s1, 187 bp amplicon) and human *Gapdh* (TaqMan assay ID Hs02786624_g1, 157 bp amplicon) were used. SDS 2.2.2 software (ABI) was employed to analyze fluorescence intensity and calculation of the theoretical cycle number when a defined threshold was reached (Ct-value).

Statistical Analysis

R version 3.6.1 was used for quality control filtering and statistical analyses of the pyrosequencing results (<http://www.r-project.org>). We removed measurements marked as unreliable by the PyroMark software. Triplicate measurements were averaged after the removal of outliers (values deviating more than 3% for Pyrosequencing and more than 5% for TaqMan Assay). For expression of DDAH2, delta scores between the primer pairs and the housekeeping genes were calculated. We calculated student's t-Tests to compare DNA methylation of cg04074004 and delta-scores of gene expression between AUD cases and controls, as well as an ANCOVA with the same covariates as in the EWAS.

2.9.2 Supplementary Tables

Supplementary Tables 2.S3a-2.S3e have been reduced to show the top 25 findings without information on phantom4 and phantom5 enhancers, the full summary statistics showing all ~670.000 CpG sites are available under <https://www.nature.com/articles/s41386-021-01228-7>

3.1 Abstract

Alcohol Use Disorder (AUD) is a major contributor to global mortality and morbidity. Postmortem human brain tissue enables the investigation of molecular mechanisms of AUD in the neurocircuitry of addiction. We aimed to identify differentially expressed (DE) genes in the ventral and dorsal striatum between individuals with AUD and controls, and to integrate the results with findings from genome- and epigenome-wide association studies (GWAS/EWAS) to identify functionally relevant molecular mechanisms of AUD. DNA-methylation and gene expression (RNA-seq) data was generated from postmortem brain samples of 48 individuals with AUD and 51 controls from the ventral striatum (VS) and the dorsal striatal regions caudate nucleus (CN) and putamen (PUT). We identified DE genes using DESeq2, performed gene-set enrichment analysis (GSEA), and tested enrichment of DE genes in results of GWASs using MAGMA. Weighted correlation network analysis (WGCNA) was performed for DNA-methylation and gene expression data and gene overlap was tested. Differential gene expression was observed in the dorsal (FDR<0.05), but not the ventral striatum of AUD cases. In the VS, DE genes at FDR<0.25 were overrepresented in a recent GWAS of problematic alcohol use. The *ARHGEF15* gene was upregulated in all three brain regions. GSEA in CN and VS pointed towards cell-structure associated GO-terms and in PUT towards immune pathways. The WGCNA modules most strongly associated with AUD showed strong enrichment for immune response and inflammation pathways. Our integrated analysis of multi-omics data sets provides further evidence for the importance of immune-and inflammation-related processes in AUD.

3.2 Introduction

Alcohol Use Disorder (AUD) is a major contributor to the global disease burden, with a prevalence of ~17% among 12-month alcohol users in the US (Grant et al., 2017; World Health Organization, 2019) and an estimated heritability of 49% (Verhulst et al., 2015). Knowledge about the molecular mechanisms can foster understanding of causes and promote prevention. Recent genome-wide association studies (GWASs) have identified 29 genetic loci associated with Problematic Alcohol Use (PAU), a proxy of AUD (Zhou et al., 2020). While GWASs identify increasing numbers of disease-associated loci, the functional interpretation of many of these findings remains inconclusive. Analyzing the transcriptome can extend the understanding of the molecular mechanisms underlying AUD, by identifying associated gene expression patterns. Findings can in turn be integrated with results from GWASs and epigenome-wide association studies (EWASs) to identify the pathomechanisms underlying disease.

Processes in the central nervous system are considered to play a major role in the etiology of addiction, and the transition from chronic alcohol consumption to AUD (Volkow et al., 2016). Therefore, it is of particular interest to examine molecular changes associated with addiction in brain tissue. So far, only few studies have been conducted in postmortem human brain tissue to identify transcriptional changes associated with AUD (Farris et al., 2015; Liu et al., 2004; Ponomarev et al., 2012). These studies mainly focused on the prefrontal cortex (PFC) one important part of the neurocircuitry of addiction (Koob & Volkow, 2010; Noori et al., 2012). The first transcriptome-wide study in the PFC found DE genes implicated in neuronal processes, such as myelination, neurogenesis, and neural diseases, as well as cellular processes, such as cell adhesion and apoptosis (Liu et al., 2006). In Brodmann Area 9 downregulation of calcium signaling pathways has been observed in individuals with AUD compared to controls (Kapoor et al., 2019). In the same study, a weighted gene co-expression analysis (WGCNA) pointed towards modules associated with AUD case/control status, which were enriched for nicotine and opioid signaling, as well as immune processes. Another study in the PFC (Brodmann Area 8) showed that co-expression networks associated with lifetime alcohol consumption were enriched for GWAS signals of alcohol dependence (Farris et al., 2015).

Despite the importance of striatal regions in addiction processes, genome-wide human omics studies of these brain regions are still missing. The striatum is divided into the ventral striatum (VS), consisting of the nucleus accumbens and olfactory tubercle; and the dorsal striatum, comprising the caudate nucleus (CN) and putamen (PUT) (Volkow & Morales, 2015). The nucleus accumbens is involved in mediating motivational processes such as aversion and reward, which play a significant role in the development and maintenance of substance use disorders (SUD) (Volkow & Morales, 2015). In addition to regulating motor function, the CN and PUT are involved in cognitive processes relevant for addiction, such as executive functioning and cognitive control, reinforcement learning and habit formation (Galandra et al., 2018). Analyses of omics data from striatal regions could complement the knowledge on global molecular changes in the neurocircuitry of addiction in AUD.

In a recent EWAS of AUD in postmortem brain tissue, we identified differentially methylated CpG-sites and regions in the ventral and dorsal striatum (Zillich et al., 2022). Previous studies have shown the utility of integrating epigenetic and transcriptomic data in postmortem brain tissue of SUDs using weighted correlation network analysis (WGCNA) (Langfelder & Horvath, 2008). WGCNA clusters genes or CpG-sites into co-expressed or co-methylated modules based on correlation matrices. By relating modules to each other, WGCNA can be used for data integration, providing more insights than descriptive overlap. For example, whereas a descriptive comparison of histone H3 lysine 4 trimethylation (H3K4me3) and mRNA expression in individuals with AUD and cocaine use disorder revealed no consistent overlap between H3K4me3 trimethylation and gene expression (Zhou et al., 2011), a network analysis identified overlapping modules pointing towards co-expressed genes associated with H3K4me3 trimethylation (Farris et al., 2015). Modules associated with AUD were enriched for CNS functions, such as synaptic transmission and regulation of neurogenesis (Farris et al., 2015). WGCNA has also been used for integrating epigenetic and transcriptomic data and investigating their association with opioid use disorder (OUD) in postmortem human brain, identifying immune-related transcriptional regulation to be enriched in co-expressed and co-methylated modules (Liu et al., 2021).

The aim of the present study was to investigate differential gene expression associated with AUD status in the ventral and dorsal striatum, relate these to GWAS findings, and to integrate the findings with DNA-methylation data using a network approach (WGCNA) in order to identify functionally relevant molecular mechanisms in AUD.

3.3 Materials and Methods

3.3.1 Samples

Postmortem human brain tissue from CN, PUT and VS of a total of 48 individuals with AUD and 51 control individuals (68% male) was obtained from the New South Wales Tissue Resource Centre at the University of Sydney. The Ethics Committee II of the University of Heidelberg approved the study (reference number 2021-681). After quality control (QC), the total sample sizes for each brain region were $N_{CN} = 71$, $N_{PUT} = 77$ and $N_{VS} = 63$. Phenotypic information was assessed by next-of-kin interviews. Inclusion criteria for this study were: age > 18 years, Western European Ancestry, no history of severe psychiatric or neurodevelopmental disorders, or SUDs other than AUD and nicotine use disorder or smoking. AUD was defined as meeting DSM-IV criteria for alcohol dependence and consuming 80g of alcohol a day or more (control group: <20g/day). Descriptive information can be found in Table 3.1 and Supplementary Table 3.S1.

Table 3.1.

Descriptive statistics of demographic data.

Characteristic	Cases	Controls	<i>p</i>
N	48	51	
Age, years	55.58 (10.62)	57 (10.64)	0.51
Sex (M/F)	31/17	37/14	
pH-value	6.53 (0.26)	6.65 (0.25)	0.026*
PMI (hours)	37.07 (15.79)	30.7 (15.57)	0.047*
Blood Alcohol level (N)	7	0	
Blood Alcohol Level (g/100ml)	0.21 (0.21)		
Smoking (yes/%)	32 (66.7%)	12 (23.5%)	<0.001*
Samples per Brain Region			
Caudate Nucleus	36	37	
Putamen	35	42	
Ventral Striatum	31	32	

Data are presented as count (n/n; n (%)) or mean (\pm SD), PMI: post-mortem interval, pH: pH-value of the brain, p: p-value of t-Test/Chi-squared test comparing cases and controls.

**significant difference between cases and controls*

3.3.2 RNA extraction and -sequencing

RNA was extracted from frozen tissue according to the manufacturer's protocol using the Qiagen RNeasy microKit (Qiagen, Hilden, Germany). The RNA Integrity Number (RIN) of all samples was determined using a TapeStation 4200 (Agilent, Santa Clara, CA). RIN values of 273 samples were larger than 5.5, for which libraries were prepared using the TruSeq Stranded Total RNA Library Prep Kit (Illumina, San Diego, CA). RNA sequencing was performed on the NovaSeq 6000 (Illumina) at the Life & Brain Center in Bonn, Germany with read lengths of 2x100bp and a sequencing depth of 62.5 M read pairs per sample on average. Technical replicates were sequenced for all but four samples.

3.3.3 DNA extraction and Methylation Profiling

DNA extraction, methylation profiling, and QC was performed as described in Zillich et al. (2022). In brief, DNA was extracted using the DNeasy extraction kit (Qiagen, Hilden, Germany); the Illumina HumanMethylation EPIC BeadChip and the Illumina HiScan array scanning system (Illumina, San Diego, CA) were used to determine DNA-methylation levels. We used an updated and customized version of the CPACOR pipeline to extract beta values from raw intensities (Lehne et al., 2015). Criteria for the removal of samples and probes can be found in Zillich et al. (2022). In the present analyses, DNA methylation data was included from all subjects from whom gene expression data was available after QC.

3.3.4 Statistical Analyses

All analyses apart from QC and read mapping were performed using R version 3.6.1 (Team, 2013). An overview of the analysis workflow can be found in Figure 3.1. The Benjamini-Hochberg (FDR) (Benjamini & Hochberg, 1995) procedure was used to correct for multiple testing. Differentially expressed genes were considered statistically significant at $FDR < 0.05$. All downstream analyses were performed using genes significantly differentially expressed at $FDR < 0.25$.

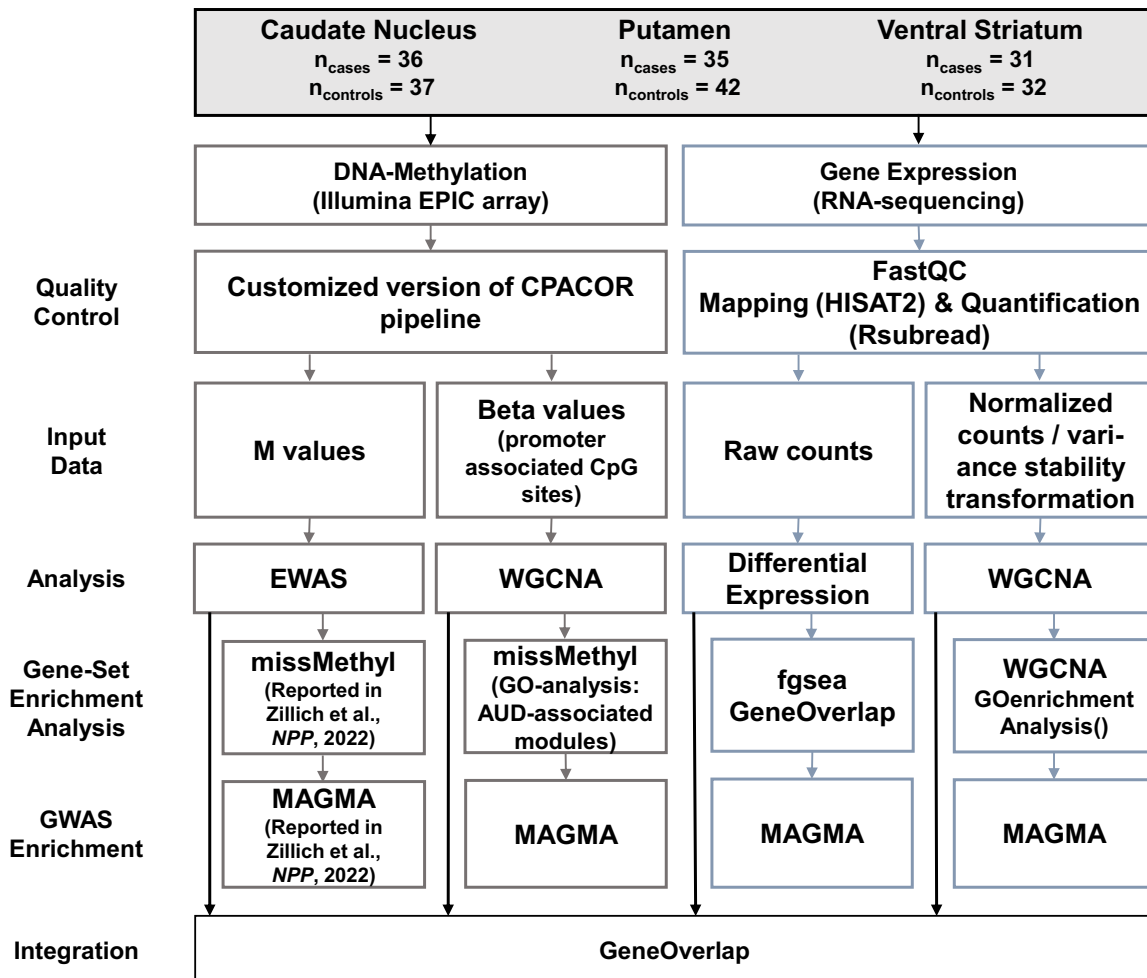

Figure 3.1. Analysis workflow of the present study.

3.3.4.1 Mapping and Quantification

Sequencing quality was determined using FastQC (Andrews, 2010) and 24 samples (11 cases and 13 controls) were excluded due to insufficient sequencing quality (e.g. strong overrepresentation of sequences, GC distribution). Raw reads were mapped to the human genome (hg38) using HISAT2 (v.2.1.0) (Kim et al., 2019). Quantification was performed with the featureCounts function of the Rsubread package (v.2.0.1) (Liao et al., 2019), with hg38 annotation.

3.3.4.2 Differential Gene Expression Analysis

Differential gene expression was determined using DESeq2 (v.1.26.0) (Love et al., 2014). Minimal pre-filtering was applied, removing genes with normalized counts <10 for more than two samples. Technical replicates were merged prior to differential expression analysis using the collapseReplicates function as implemented in DESeq2. For the differential gene expression analysis, we included age, sex, RIN, pH-value of the brain, and postmortem interval (PMI) as covariates, because of their known influence on gene expression (Birdsill et al., 2011; Durrenberger et al., 2010; Trabzuni et al., 2011). To assess residual bias after adjustment for covariates, we generated Q-Q plots and calculated genomic inflation factors (Supplementary Figure 3.S1). We further conducted a variance partition analysis using the variancePartition() function of the corresponding R package (Hoffman & Schadt, 2016), which confirmed the covariates. Results of this analysis can be found in Supplementary Figure 3.S2. Results were filtered for differentially expressed (DE) genes with an absolute log₂ fold change larger than 0.02. Volcano plots displaying up- and downregulation of genes for each brain region are shown in Supplementary Figure 3.S3.

3.3.4.3 Gene-Set Enrichment Analysis

Gene-set enrichment analysis was performed using the R package fgsea (v.1.12.0) (Sergushichev, 2016), for which DE genes were ranked according to p-value. Enrichment analysis was performed for Gene-Ontology (GO) terms (Ashburner et al., 2000) and Hallmark gene sets (Liberzon et al., 2015) and the results were adjusted using FDR correction.

3.3.4.4 Cell Type Enrichment Analysis

To identify cell type specific expression signatures, we performed cell type enrichment analysis using DE genes (FDR<0.25) from the three brain regions. As a reference gene set for brain cell types, we used the “top ranked cell type-enriched genes based on human data” as provided by McKenzie et al. (2018). These contain the 1000 most enriched genes in a cell type and cover astrocytes, endothelial cells, microglia, neurons, and oligodendrocytes. Using the R package GeneOverlap (v.1.22.0) (Shen, 2021), we assessed the overlap of AUD-status associated DE genes with markers from the different cell populations. Results were adjusted for multiple testing using the Benjamini-Hochberg method as implemented in GeneOverlap.

3.3.4.5 Differential Methylation Analysis

Effect sizes and p values for CpG sites were used from the EWAS results as presented in the original publication (Zillich et al., 2022). In brief, the EWAS model was based on methylation M-values as the dependent variable and AUD status as the predictor. As covariates, sex, age, postmortem interval (PMI), pH-value, estimated smoking, standardized neuronal cell count, and the first ten principal components of the EPIC array internal control probes were included.

3.3.4.6 WGCNA

Weighted correlation network analyses (WGCNA, v.1.70-3) (Langfelder & Horvath, 2008) were performed to identify modules of co-expressed genes and co-methylated CpG-sites. We assessed the relationship of these modules with AUD case/control status and tested the overlap between associated modules. WGCNA clusters the input matrix according to a dynamic tree cutting algorithm, using a soft power threshold that approximates the criterion of scale-free topology ($R_{\text{signed}}^2 > 0.80$). Resulting soft power thresholds for expression networks were 6 for CN, 5 for PUT, and 14 for VS; for methylation networks, all power thresholds were 2.

To identify methylation networks associated with gene expression, beta values from normalized intensities of all samples from which gene expression data were available were filtered for promoter-associated CpG-sites based on the manufacturer's manifest (Illumina, San Diego, CA). The resulting 105 796 CpG-sites were used as input.

For the RNA-seq data, count matrices were normalized using the DESeq2 function `normalizeCounts` and variance stability transformation was applied.

Networks were constructed using following settings: minimum module size=30, `mergeCutHeight`=0.25, `maxBlockSize`=36 000. In WGCNA, modules are labeled using colors. In the results section modules are labeled according to type of data, brain region, and color assigned in the analysis, e.g. "e-VS-pink" for module "pink" from the WGCNA analysis of gene expression data in the ventral striatum. For each module, its eigengene was calculated and correlated with AUD status. Association of modules with AUD status and covariates is shown in Supplementary Figure 3.S4. For modules associated with AUD status, we performed enrichment analysis using the `GOenrichmentAnalysis` function implemented in the WGCNA package for expression data and the R package `missMethyl` (v.1.20.4) (Phipson et al., 2016) for methylation modules. Further, we extracted hub genes of AUD associated WGCNA expression modules by calculating the product of module membership and gene significance for each gene of a module. Based on this score, the 10% of highest ranking genes were defined as module hub genes. To investigate the biological relevance of hub genes, protein-protein interaction networks were generated using the *Search Tool for the Retrieval of Interacting Genes/Proteins* (STRING, v.11.5) (Szklarczyk et al., 2021). Graphical representation of gene networks was restricted to high confidence interactions (interaction score threshold 0.7).

3.3.4.7 Expression and Methylation Data Integration

To identify genes both DE and differentially methylated, we analyzed the overlap of DE genes (FDR<0.25) with the results of an EWAS ($p < 0.001$) in the same sample (Zillich et al., 2022). We prioritized CpG-sites based on their functional relevance in gene expression regulation. Thus, promoter-associated CpG-sites were used in the analysis.

At the module level, gene-set overlap tests were performed using the R package GeneOverlap (v.1.22.0) (Shen, 2021). Here, Fisher's exact test is used to identify significant overlap. For each brain region, the overlap of the AUD-associated co-expression and co-methylation modules was tested.

3.3.4.8 GWAS Enrichment Analysis

We analyzed enrichment of DE genes with an FDR<0.25, and genes in AUD-associated WGCNA modules in GWAS summary statistics using Multi-marker Analysis of GenoMic Annotation (MAGMA, v.1.08b) (de Leeuw et al., 2015). We performed GWAS enrichment analysis for several SUDs, such as alcohol use disorder and problematic alcohol use (Zhou et al., 2020), cannabis use disorder (Johnson et al., 2020), and a recent GWAS comparing individuals with opioid use disorder with unexposed controls (Polimanti et al., 2020). Bonferroni correction ($n=4$ tests per gene set) of p values was applied to adjust for multiple testing.

3.4 Results

3.4.1 Differential Gene Expression

Gene expression analysis of postmortem brain tissue from AUD cases and controls revealed DE genes at FDR<0.05 in both dorsal striatal regions. In the caudate nucleus, 49 DE genes were identified at FDR<0.05 (39 up- and 10 downregulated). Tubulin Tyrosine Ligase Like 4 (*TTL4*, $\log_2FC=0.11$, $p=2.3 \times 10^{-8}$) and GATA Binding Protein 2 (*GATA2*, $\log_2FC=-0.27$, $p=8.6 \times 10^{-7}$) were the most significantly upregulated and downregulated genes, respectively. Top up- and downregulated genes in the putamen were found to be Transcription Elongation Factor A Like 2 (*TCEAL2*, $\log_2FC=0.09$, $p=5.8 \times 10^{-5}$) and Desmin (*DES*, $\log_2FC=-0.86$, $p=2.6 \times 10^{-6}$), the latter being the only significant gene after correction for multiple testing. Nine genes were downregulated in both dorsal striatal regions, with *HLA-DOB* having the highest \log_2FC in both regions. In the ventral striatum, no DE genes were detected at FDR<0.05. The most significant differential gene expression in the ventral striatum was observed for Ankyrin Repeat And Ubiquitin Domain Containing 1 (*ANKUB1*) which was upregulated in AUD cases ($\log_2FC=1.35$, $p=5.8 \times 10^{-5}$). In the VS of AUD cases Caseinolytic Mitochondrial Matrix Peptidase Chaperone Subunit B (*CLPB*, $\log_2FC=-0.11$, $p=5.2 \times 10^{-6}$) was the most significantly downregulated gene.

None of the DE genes at $FDR < 0.05$ overlapped between multiple brain regions. Therefore, the less conservative significance threshold of $FDR < 0.25$, which was also used for downstream analyses, was applied to compare the overlap of DE genes. At $FDR < 0.25$ the cardiomyopathy associated 5 (*CMYA5*) gene showed an upregulation in both caudate nucleus and putamen. *ARHGEF15* (Rho Guanine Nucleotide Exchange Factor 15) was upregulated in all three brain regions at $FDR < 0.25$. The Top 5 DE genes from each brain region are listed in Table 3.2; complete summary statistics are listed in Supplementary Table 3.S2 (CN), 3.S3 (PUT), and 3.S4 (VS). Overlap between DE genes in the different brain regions is shown in Figure 3.2A.

Figure 3.2. Venn Diagrams of gene overlap of A) DE genes at $FDR < 0.25$ in caudate nucleus (CN), putamen (PUT), and ventral striatum (VS), B) genes forming WGCNA expression-modules showing the strongest association with AUD status for CN, PUT, and VS, C) genes forming WGCNA expression-module “e-CN-magenta” and those forming the methylation-modules “m-CN-red” and “m-CN-midnightblue”. Network plots depicting the WGCNA gene expression modules showing the strongest association with AUD: D) module magenta from caudate nucleus, E) module black from putamen and F) module pink from ventral striatum.

3.4.2 Gene-set Enrichment Analysis

Pathway analysis using a pre-ranked enrichment analysis revealed significant enrichment of dorsal striatum DE genes for several GO terms and Hallmark gene-sets. Genes in the CN were found to be related to cilia- and microtubule-associated GO-terms, while none of the Hallmark gene-sets was significantly enriched. GO-term and Hallmark gene-set analysis in PUT samples showed enrichment for immune processes, such as “acute inflammatory response to antigenic stimuli” ($p_{FDR} = 0.006$) and “adaptive immune response” ($p_{FDR} = 0.006$). In the VS the most significantly enriched GO-terms were also related to cilia and microtubules, as well as antigen

processing. All GO-terms and Hallmark gene-set with FDR <0.10 are listed in Supplementary Tables 3.S5 (CN), 3.S6 (PUT), and 3.S7 (VS).

Top 5 differentially expressed genes in caudate nucleus, putamen and ventral striatum.

3.4.3 Cell Type Enrichment Analysis

In the CN, upregulated DE genes were significantly enriched for astrocytic markers ($p_{\text{FDR}} = 7 \times 10^{-6}$), whereas an enrichment for endothelial cell marker genes was detected among downregulated genes ($p_{\text{FDR}} = 2 \times 10^{-7}$). No significant cell-type enrichment of DE genes was found in the putamen and the ventral striatum. GeneOverlap heatmap visualizations for the three brain regions are displayed in Supplementary Figure S3.5.

3.4.4 WGCNA

3.4.4.1 Expression

In the CN, 21 modules with a median size of 352 genes (range: 64-7 259) were identified. Module “e-CN-magenta”, consisting of 328 genes, showed the strongest positive association with AUD status ($r=0.42$, $p=2.89 \times 10^{-4}$). In the PUT, of the 25 modules (median size 249 genes, range: 33-5 381) identified, module “e-PUT-black”

was most strongly correlated with AUD with a positive direction of effect ($r=0.41$, $p=2.31 \times 10^{-4}$). For expression data from the ventral striatum, 16 modules with a median size of 429 genes (range: 35-9 708) were identified; module “e-VS-pink” had the strongest positive association with AUD ($r=0.41$, $p=0.009$). Interestingly, in a GO-term analysis the three AUD associated modules were all enriched for immune processes, such as “defense response” and “inflammation response”. Gene network representation of hub genes in modules “e-CN-magenta”, “e-VS-pink”, and “e-PUT-black” revealed the signal transducer and activator of transcription 3 (*STAT3*) gene as a conserved hub node in all three brain regions (Figure 3.2D-2F). There was also a wide overlap of the genes in the three modules: 174 (22.54%) were partially shared between all three modules corresponding to the three brain regions, while another 21.76% were shared between at least two modules (Figure 3.2B). A gene network analysis of the 174 shared genes between regions identified *STAT3*, *TP53*, *ICAM1*, *MYC*, and *NFKBIA* as the top 5 hub nodes of the network. A visualization of the network is depicted in Figure 3.3.

3.4.4.2 Methylation

In the CN, WGCNA resulted in 36 modules with a median size of 346 CpG-sites (range: 66-41 423). Module “m-CN-red”, consisting of 2 117 CpG-sites, showed the strongest association with AUD case control status ($r=-0.27$, $p=0.021$). This module was most highly enriched for the biological processes “cell activation” ($p=1.52 \times 10^{-5}$) and “leukocyte activation” ($p=2.09 \times 10^{-5}$). In PUT 177 modules were identified (median size=57 CpG-sites, range: 30-42 248). Module “m-PUT-plum” consisted of 70 CpG-sites and was significantly associated with AUD case/control status ($r=-0.29$, $p=0.023$) and enriched for the biological processes “positive regulation of I- κ B kinase/NF- κ B signaling” ($p=0.002$) and “regulation of I- κ B kinase/NF- κ B signaling” ($p=0.005$). WGCNA in the VS methylation data resulted in 85 modules (median size=178 CpG-sites, range: 35-30 370). The module with the strongest association with AUD was “m-VS-lavender” ($r=-0.29$, $p=0.023$), which consisted of 117 CpG-sites and was enriched for the molecular function “natural killer cell lectin-like receptor binding” ($p=3.43 \times 10^{-4}$) and the biological process “susceptibility to natural killer cell mediated cytotoxicity” ($p=3.65 \times 10^{-4}$). The top 10 enriched GO-terms for all AUD-associated modules can be found in Supplementary Tables 3.S8-S10.

3.4.5 Expression and Methylation Data Integration

In the CN, 12 genes showed both differential methylation and differential gene expression. DE statistics, EWAS summary statistics and functional annotation for these genes are provided in Supplementary Table 3.S11. No overlap was observed in the VS and PUT. At the module-level, co-expression module “e-CN-magenta” showed significant overlap with the methylation modules “m-CN-red” ($p=0.003$) and “m-CN-midnightblue” ($p=0.014$) (Figure 3.2C), while expression module “e-CN-purple” did not show significant overlap with the methylation modules in CN. Of the 3 AUD-associated expression modules in the VS, only “e-VS-salmon” showed significant overlap with the

3.5 Discussion

In the present study, we identified DE genes, co-expression networks, and pathways associated with AUD in the dorsal and ventral striatum. The results were integrated with DNA-methylation data and results from GWASs of SUDs.

We discovered that one gene (*ARHGEF15*) was consistently upregulated in all investigated brain regions of AUD cases compared to controls. *ARHGEF15* encodes a specific guanine nucleotide exchange factor for the activation of Ras homolog family member A (RhoA), a GTPase, which has been linked to higher blood pressure and hypertension over the Rho/ROCK signaling cascade (Wirth, 2010). It is postulated that the Rho Guanine Nucleotide Exchange Factor 15 negatively regulates excitatory synapse development by suppressing the synapse-promoting activity of EPHB2 (Margolis et al., 2010). EPHB2 deficiency has been linked to depression-like behaviors and memory impairments in animal studies (Zhen et al., 2018). In line with this, genetic variation within *ARHGEF15* has been associated with hematocrit, red blood cell count, and hemoglobin concentration (Astle et al., 2016), but also with psychiatric traits, such as neuroticism and worries (Nagel et al., 2018) as well as bipolar disorder (Ikeda et al., 2018).

Among the genes that were downregulated in both dorsal striatal regions, *HLA-DOB* displayed the highest fold change. HLAs of the Major Histocompatibility Class II are an essential part of the acquired immune system presenting antigens to T-lymphocytes (for review: Howell et al. (2010)). The most significantly downregulated gene in the VS is *CLPB*, a mitochondrial chaperone, which has been associated with progressive brain atrophy (Saunders et al., 2015) and with the cellular response to alcohol-induced stress (Tóth et al., 2014). In a recent GWAS, *CLPB* was associated with the amount of alcohol consumed on a typical day ($p=9.67 \times 10^{-5}$, $N=116\ 163$) (Watanabe et al., 2019).

DE genes in the ventral striatum were enriched for GWAS signals of PAU, but not AUD. This could be a result of the larger sample size of the PAU GWAS, but also point towards differences in genetic variation as responsible for differential expression.

Our results from the pathway and network analyses further underline immune-related effects of chronic alcohol exposure; the pathway and network modules most strongly associated with AUD case-control status were also enriched for immune system and inflammation processes. This was observed for all three brain regions, and both in expression and methylation data, providing further evidence for the important role of immune processes in AUD.

Gene networks derived from WGCNA hub genes similarly revealed genes related to inflammatory processes as strongly connected network nodes. Here, *STAT3* represents a conserved network hub node in all three brain regions. *STAT3* is a member of the JAK/STAT pathway and acts as a transcription factor upon activation by cytokines, hormones and growth factors (Nicolas et al., 2013). Interestingly, a recent study assessing expression signatures of alcohol withdrawal in rats discovered a very similar gene network in the hippocampus with *STAT3* as a hub node surrounded by a network of downstream targets (Chen et al., 2021). The authors also discovered increased levels of *STAT3* and its neuroinflammation-related target genes in

postmortem brain tissue of subjects with AUD. Activation of the *STAT3* gene network was found to be primarily restricted to astrocytes. This supports the results of the cell type enrichment analyses, where enrichment of astrocytic expression signatures was detected for upregulated DE genes in the CN.

These results strongly reflect the well-described effect of chronic alcohol exposure on different aspects of the innate and acquired immune systems (Szabo & Saha, 2015). Chronic alcohol exposure accelerates the inflammatory response and reduces anti-inflammatory cytokines (Szabo & Saha, 2015). An activated immune response in response to chronic alcohol exposure has been shown on the cell level (McClintick et al., 2019), as well as on the transcription (McClintick et al., 2019), and protein levels (Donnadieu-Rigole et al., 2016; Yen et al., 2017). In a previous EWAS, we found strong enrichment of immune processes in differentially methylated CpG-sites associated with alcohol withdrawal (Witt et al., 2020). Neuroinflammation has been repeatedly associated with AUD and both the glutamate excitotoxicity and the production of acetaldehyde, key processes in AUD metabolism, have been suggested to produce an inflammatory response in the brain (de Timary et al., 2017). On a phenotypic level, there is also widespread overlap between symptoms of inflammation and of SUDs, such as anhedonia, depression, and decreased cognitive functioning (Crews et al., 2017). In addition, in candidate gene studies in postmortem human PFC, hippocampus, and orbitofrontal cortex, increased mRNA levels of *HMGB1*, which encodes a proinflammatory cytokine and toll-like receptor genes have been associated with alcohol consumption in AUD cases, providing evidence for chronic neuroinflammation in response to alcohol (Coleman et al., 2017; Crews et al., 2013; Vetreno et al., 2021). Notably, there is an overlap of findings not only on the single-gene level but also on the level of pathways and networks/modules. This overlap underlines that alcohol consumption has common biological effects in different brain regions, i.e., most prominently, effects on immune and inflammation processes.

Several limitations apply to our study. First, we cannot distinguish between effects being a consequence of chronic alcohol consumption or addiction. Second, although we corrected for PMI, which can influence tissue quality as a confounding factor, it cannot be ruled out that other characteristics not easily accounted for, such as cause of death, or blood alcohol level for which the majority of individuals have missing data, influenced gene expression. Third, although the sample size is comparatively large for postmortem brain studies in the addiction field, the small number of differentially expressed genes is likely attributable to limited power. Lastly, analyzing bulk tissue does not adequately reflect the diversity of cell types across different brain regions and future studies on single-cell level are needed to investigate cell-type specific transcriptional changes associated with AUD.

It has to be noted that besides DNA methylation, epigenetic mechanisms such as histone and chromatin modifications, or microRNA expression profiles can influence gene expression and are especially important in addiction research (Robison & Nestler, 2011). Future studies should therefore expand the epigenetic profiling of AUD to include these mechanisms.

In summary, the present study provides further evidence from multi-omics data sets for the importance of immune-and inflammation-related processes in AUD. Notably,

drugs that reduce neuroinflammation to reduce drinking, such as phosphodiesterases, may be promising approaches for novel treatment options for AUD. Recently published randomized controlled trials suggest that a phosphodiesterase inhibitor reduces heavy drinking whereas an antibiotic compound was not effective (Grodin et al., 2021; Petrakis et al., 2019). A deeper understanding of the underlying mechanisms will enhance the discovery of drug targets and drive forward the development of precision medicine within in this field.

3.6 Acknowledgments

The study was supported by the German Federal Ministry of Education and Research (BMBF), “A systems-medicine approach towards distinct and shared resilience and pathological mechanisms of substance use disorders“ (01ZX01909), “Towards Targeted Oxytocin Treatment in Alcohol Addiction” (031L0190). 3.7 Author Contributions

LZ, SHW, MR, RS, MMN, GB, and ACH planned the investigation. MMF and ACH performed the DNA and RNA extraction and SHH, PH, FD, AH and MMN were responsible for generating genome-wide methylation and gene expression data. LZ, EP, JF, JCF and FS developed the analysis plan. LZ and EP performed all statistical analyses. LZ, EP, MMF, JCF, LS, MR, FS, and SHW reviewed the literature for the paper. LZ, EP and SHW drafted the manuscript. All authors contributed, revised, and edited the final manuscript critically. All authors agreed to the publication of the final version of the manuscript.

Supplementary Table 3.S11 continued

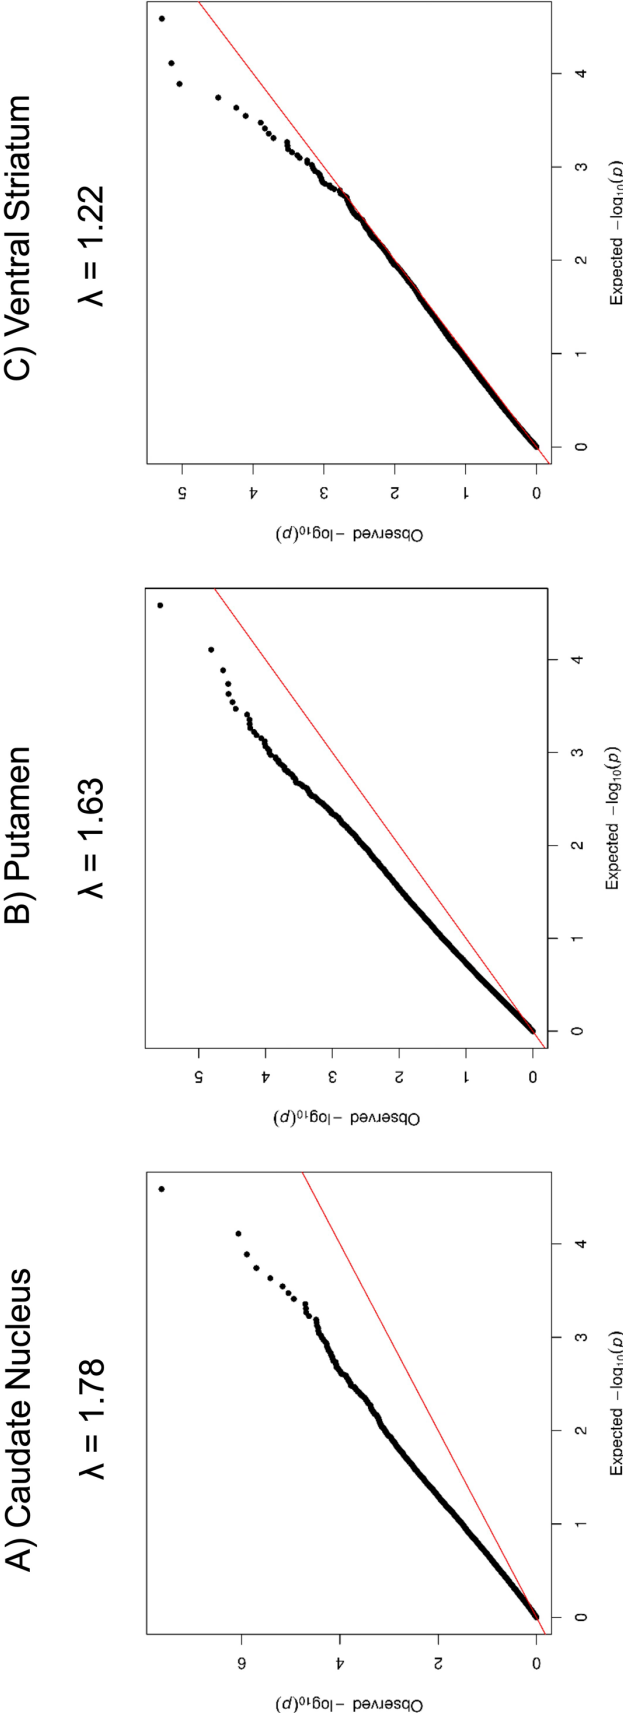

Chr	Pos	Gene	Functional annotation (retrieved from UniProt)
1	43283185	<i>ERMAP</i>	Possible role as a cell-adhesion or receptor molecule of erythroid cells.
3	48754518	<i>IP6K2</i>	Converts inositol hexakisphosphate (InsP6) to diphosphoinositol pentakisphosphate (InsP7/PP-InsP5). May play a role in spermatogenesis or folliculogenesis (By similarity). Binds hyperacetylated chromatin and plays a role in the regulation of transcription, probably by chromatin remodeling. Regulates transcription of the <i>CCND1</i> gene. Plays a role in nucleosome assembly.
6	32937414	<i>BRD2</i>	?
6	112409342	<i>FAM229B</i>	Acts as one of several non-catalytic accessory components of the cytoplasmic dynein 1 complex that are thought to be involved in linking dynein to cargos and to adapter proteins that regulate dynein function. Cytoplasmic dynein 1 acts as a motor for the intracellular retrograde motility of vesicles and organelles along microtubules. Binds to transport cargos and is involved in apical cargo transport such as rhodopsin-bearing vesicles in polarized epithelia. May also be an accessory component of axonemal dynein. Plays a role in neuronal morphogenesis; the function is independent of cytoplasmic dynein and seems to be coupled to regulation of the actin cytoskeleton by enhancing <i>Rac1</i> activity. The function in neurogenesis may be regulated by association with a G-protein beta-gamma dimer. May function as a receptor-independent activator of heterotrimeric G-protein signaling; the activation appears to be independent of a nucleotide exchange. Plays a role in regulating neurogenesis; inhibits the genesis of neurons from precursor cells during cortical development presumably by antagonizing <i>ARHGEF2</i> . Involved in the regulation of mitotic spindle orientation (By similarity). Unrelated to the role in retrograde microtubule-associated movement may play a role in the dimerization of cytoplasmic proteins/domains such as for <i>ACVR2B</i> . Binds to the cytoplasmic domain of <i>ACVR2B</i> and, in vitro, inhibits <i>ACVR2B</i> signaling
6	159066182	<i>DYNLT1</i>	Substrate-specific adapter of a BCR (BTB-CUL3-RBX1) E3 ubiquitin ligase complex. The BCR(KLHL7) complex acts by mediating ubiquitination and subsequent degradation of substrate proteins. Probably mediates 'Lys-48'-linked ubiquitination.
7	23145770	<i>KLHL7</i>	?
8	69246056	<i>C8orf34</i>	Synthesis and degradation of fructose 2,6-bisphosphate.
10	6244686	<i>PFKFB3</i>	Serine/threonine-protein kinase involved in transcription regulation, apoptosis and steroidogenic gene expression. Phosphorylates JUN and RUNX2. Seems to negatively regulate apoptosis by promoting FADD phosphorylation. Enhances androgen receptor-mediated transcription. May act as a transcriptional corepressor for NK homeodomain transcription factors. The phosphorylation of NR5A1 activates SF1 leading to increased steroidogenic gene expression upon cAMP signaling pathway stimulation. In osteoblasts, supports transcription activation: phosphorylates RUNX2 that synergizes with SPEN/MINT to enhance FGFR2-mediated activation of the osteocalcin FGF-responsive element (OCFRE).
11	33278681	<i>HIPK3</i>	Involved in centrosome duplication and mitotic progression.
11	64808285	<i>SAC3D1</i>	Selectively involved in CSF2 deprivation-induced apoptosis via a mitochondria-dependent pathway.
17	7339721	<i>TMEM102</i>	
		<i>ZNF295-</i>	
21	43429288	<i>AS1</i>	?

Supplementary Figure 3.S6. Bar plots depicting the $-\log_{10}$ transformed p values of GWAS enrichment analysis for DE genes and the WGCNA expression and methylation modules showing the strongest association with AUD in all three brain regions. Color represents the GWAS: dark blue = alcohol use disorder (AUD), light blue = problematic alcohol use (PAU), grey = Cannabis use disorder (CUD) and red = opioid use disorder (OUD). Dotted line represents nominal significance, solid line depicts significance threshold after multiple testing correction.

4 DISCUSSION

Multi-omics analyses represent an approach to gain a deeper understanding of AUD, paving the way towards novel and more targeted treatment approaches in the future. We identified differentially methylated positions and regions in the dorsal and ventral striatum of individuals with AUD compared to individuals without AUD. DMPs and DMRs were in genes previously associated with neurodegenerative diseases, cancer phenotypes and type 2 diabetes. The top hit in the ventral striatum could affect alcohol metabolism. While one of our top hits in the caudate nucleus, a DMR in *DDAH2* was replicated by pyrosequencing, we did not observe differential expression for this gene, neither with PCR nor by RNA-sequencing. Overall, there was little overlap on the single-gene level between the DNA methylation investigated in the first, and the gene expression in the second study. When we analyzed DNA methylation and gene expression together in the second study, we observed evidence for increased immune response and neuroinflammation in AUD. This main finding, as well as additional considerations, which emerge from the comparative analysis of both studies, are discussed in the following paragraphs.

4.1 Neuroinflammation

The main finding in these studies was the increased neuroinflammation associated with AUD. This is in line with previous studies, both in whole blood samples (Witt et al., 2020) and postmortem human brain tissue (Brenner et al., 2020; Kapoor et al., 2019). Alcohol consumption leads to increased inflammation and an activated immune response, which has been shown repeatedly: Witt et al. (2020) found differential DNA methylation between participants with and without AUD was enriched for inflammation-related pathways and that the differences between the groups were reduced after two weeks of withdrawal treatment. This also underlines the reversibility of AUD-associated DNA methylation changes. Evidence for (neuro-) inflammation in AUD further comes from a transcriptome-wide gene expression study in BA9. Here, network analyses revealed an AUD-associated module that was highly enriched for immune response processes (Kapoor et al., 2019). Also, in a snRNA-seq study of AUD in BA9, it was shown that the expression genes involved in neuroinflammation pathways differed between cell types, with astrocytes expressing the highest number (Brenner et al., 2020). Next to genome-wide approaches, candidate gene studies in postmortem human brain have investigated neuroinflammation in AUD (Crews et al., 2017).

In both the DNA methylation and gene expression data, we observed enrichment of immune- and inflammation-related pathways. In our network analysis, we identified *STAT3* as a conserved hub gene across all striatal brain regions and a similar gene network has been observed in the hippocampus in a rodent model of alcohol withdrawal (Chen et al., 2021). *STAT3* is a member of the JAK/STAT signaling pathway and is further known to play a role in the transcriptional activation of the C-reactive protein (Zhang et al., 1996), a key inflammatory protein, which is mainly synthesized by liver hepatocytes (Sproston & Ashworth, 2018). While *STAT3* activation

promotes inflammation, it can also have a protective effect on liver injury (Zhao et al., 2021) and vice versa. For example, a knockout of *STAT3* in mice has been associated with increased alcohol-associated liver injuries (Miller et al., 2010). In light of this study and similar findings in rodents (Chen et al., 2021), the influence of *STAT3* knockout and overexpression on alcohol intake behavior and alcohol-associated organ damage should be investigated in a rodent model, which allows for harvesting both liver and brain from the animal.

At the same time, it is known that many solid tumors show increased *STAT3* activation (Bharti et al., 2004; Kanda et al., 2004; Mora et al., 2002), which promotes cell survival and immune tolerance in tumor cells (Avalle et al., 2012). Further, *STAT3* activation is required for tumorigenesis in a variety of cancers, e.g. in skin (Pedranzini et al., 2004) and thyroid cancer (Couto et al., 2012), and inhibition of *STAT3* leads to growth arrest and apoptosis in tumor cell lines (Bharti et al., 2004; Mora et al., 2002). It is therefore important, that future studies not only explore further how knockout and overexpression of *STAT3* affect rodents with and without an AUD phenotype, but specifically investigate tumorigenesis in the animals as a potential side effect of *STAT3* overexpression.

4.2 Methodological Considerations

4.2.1 Methodological Differences between Study 1 and Study 2

In study 1, we performed an EWAS and a network analysis, WGCNA, in BA9, ACC, VS, CN and PUT. In the second study, the three striatal brain regions were additionally analyzed using RNA-sequencing and data integrated with DNA methylation. RNA-sequencing is much more cost intensive than analyzing DNA methylation on a microarray. Therefore, we focused on the brain regions for which we observed significant methylation differences in the EWAS. In addition, the Kapoor et al. (2019) study used samples from BA9 stemming from the same brain bank and we aimed to avoid sample overlap.

Another difference is the procedure of WGCNA network construction. Before performing WGCNA on DNA methylation data, a filtering step needs to be applied to reduce the number of CpG sites analyzed. In study 1, we filtered for AUD-associated CpG sites in the EWAS, following the example of a previous study (Liu et al., 2021). This approach enables the identification of co-methylated modules within the AUD-associated CpG sites. However, one of the strengths of WGCNA is related to its potential to identify regulatory networks based on the intercorrelation of features. By filtering for AUD-associated features, this ability is somewhat diminished, as other CpG sites that are not themselves associated with AUD could also be an important part of a module. Therefore, we repeated the WGCNA analysis in study 2 applying a less biased filtering approach. Here, quantile normalized beta values were filtered for promoter and enhancer associated CpG sites. The rationale was to select sites which are likely to influence on gene expression, while retaining the bottom-up approach of WGCNA.

4.2.2 Batch Effects and the Neurocircuitry of Addiction

The goal of this study was to investigate the molecular mechanisms of AUD in multiple brain regions belonging to the neurocircuitry of addiction. At the same time, we did not compare the different regions directly. One reason was because of confounding between sequencing batch and brain region. Batch is a very prominent driver of variation in both DNA methylation (Michels & Binder, 2018) and RNA sequencing studies (Conesa et al., 2016). To balance out batch effects, samples need to be randomized across processing plates. In our experiment we had several potential drivers of variance, such as AUD status, sex and smoking. Therefore, we decided to process each brain region on a separate plate and randomize samples on each plate for AUD status, sex, and smoking. While this approach provided us with a well-randomized balanced design within each brain region, it does not allow for a direct statistical comparison between the regions.

It also has to be noted that the entire set of five brain regions was not available for each donor. This has implications for within-subject testing, which is now possible in a multi-omics framework as discussed in the next section.

4.3 Multi-Omics Analyses

4.3.1 Overlap of DNA Methylation and Gene Expression

In the present studies, the investigation of multi-omics was not only able to show convergent evidence for neuroinflammation in AUD, but it also underlined that differential methylation does not necessarily lead to differential gene expression. Many of the CpG sites differentially methylated in study 1 were not associated with differential gene expression in study 2. There are several reasons for this observation. First, to impede transcription factor binding, several CpG sites in close proximity need to be methylated (CpG islands) and a single DMP might not have a direct impact on gene expression (Moore et al., 2013). Second, there is a variety of other epigenetic mechanisms, such as histone modifications and chromatin accessibility, but also hydroxymethylation of DNA, which also affect transcription (Gibney & Nolan, 2010). DNA methylation studies can have different trajectories, such as the discovery of biomarkers predicting diseases, which has been successfully done for smoking (Bollepalli et al., 2019). In our study, the aim was to identify functional mechanisms of DNA methylation differences in AUD using a microarray technology which is associated with several limitations. While the EPIC BeadChip covers about 850.000 CpG sites, the majority of probes are located in intergenic regions and in the gene body. When analyzing DNA methylation together with gene expression, DNA methylation in promoter and enhancer regions, which commonly harbor CpG islands, is of particular interest. These areas only represent a small percentage of the probes on the EPIC BeadChip and usually promoter regions are covered by not more than 2 or 3 CpG sites. As established in previous studies in the field of cancer research, drastic changes in DNA methylation are required to produce changes in gene expression. Yet, it can be argued that profound changes in DNA methylation should

be adequately represented by a small number of sites. When investigating functional mechanisms of phenotypes, which may have smaller effect sizes, a more detailed characterization of DNA methylation, such as using reduced representation or whole genome bisulfite sequencing may be advantageous.

4.3.2 Multi-Omics Integration Methods

There is a rapid increase in the number of multi-omics integration tools available. A recent publication presented MEFISTO, which allows for within and between subject comparisons in multi-omics data (Velten et al., 2022). This could have enabled direct statistical comparison of gene expression between the brain regions in study 2, but was released just after the manuscript was reviewed. MEFISTO is based on the multi-omics factor analysis (MOFA) tool representing the first dimensionality reduction multi-omics method (Argelaguet et al., 2018). Although we applied MOFA to our dataset, the results were not interpretable, because DNA methylation did not explain enough variance. This could be related to the microarray technology used, or because of the type and quality of tissue we investigated.

4.4 Tissue

Postmortem human brain tissue is a very valuable resource, but has several limitations that need be considered. One limitation that has an immediate impact on statistical procedures is the sample size, which has already been discussed. Even more important is tissue quality, which varies greatly between individuals as well as between tissue resources. As discussed in studies 1 and 2, this can be in part accounted for by controlling for RIN, postmortem interval and the pH value of the brain sample. Adding RIN, PMI and/or pH as covariates assumes that they affect the outcome, gene expression and DNA methylation, linearly. For gene expression, it has been shown that including RIN in the linear model is an adequate control, if RIN and the effect of interest are not associated (Gallego Romero et al., 2014). However, it is unclear how AUD status affects RIN.

Another major factor that has not been sufficiently described in the literature is how cause of death is related to DNA methylation and gene expression patterns in the brain. It is unknown whether the same biological processes occur independently of the cause of death or if a sudden death, e.g., traumatic brain injury after a car accident, and a prolonged phase of dying have differential impact on the molecular architecture of the brain. For peripheral blood it has been shown that the transcriptomic profile is more dependent on whether blood was taken pre- or postmortem than on cause of death (Ferreira et al., 2018). In our sample, cause of death is very heterogeneous between individuals, but also between groups. In addition, it is not clear how DNA methylation and gene expression might differ in living and postmortem brain tissue. In line with this, it must be noted that brain banks differ in their sampling procedures. Donors die not only due to different causes, but also in different environmental conditions, such as extreme heat, which can affect RNA quality.

In conclusion, while postmortem human brain tissue is the best available way to non-invasively study molecular mechanisms directly in the brain, it comes with many caveats.

4.5 Outlook

4.5.1 Translational Indications

Multi-omics analyses in postmortem human brain tissue inevitably investigate long term changes of AUD rather than mechanisms involved in the development. This can be seen as a limitation, but also as a chance to develop treatments that target the consequences of AUD instead of reversing the AUD status. For example, Lohoff et al. (2018) were able to identify PCSK9 inhibitors as a possible treatment for AUD-associated health consequences, such as liver fibrosis and increased stroke risk, through EWAS. Treatment with the PCSK9 inhibitor does not target abstinence, but aims to improve the quality of life for patients with AUD. A similar approach could be explored for inflammation-reducing drugs.

4.5.2 Meta-Analysis

By now, several studies of DNA methylation in AUD in postmortem human brain tissue have been published. Many of them had not been published prior to the presented studies 1 and 2. A meta-analysis of these datasets could significantly reduce noise and identify true signals. Of course, this proposes challenges, especially in harmonizing the data. Because technical effects and the correction for them heavily influences microarray and sequencing analyses, findings should not be compared exclusively based on summary statistics. Instead, a joint preprocessing of raw data is necessary to reduce technical variability between individual studies.

4.5.3 Extending Multi-Omics

The joint analysis of DNA methylation and gene expression is only one example of multi-omics. There are many other molecular features that can and should be integrated to deepen the understanding of molecular mechanisms in AUD. Just as differential DNA methylation does not necessarily lead to differential mRNA expression, differential mRNA expression does not necessarily result in differential protein expression. For now, it is not possible to accurately depict all molecular mechanisms in a tissue sample, but it might be sufficient to focus analyzes on a couple of -omics, which allow conclusions about other biological processes. For example, in single nuclei ATAC-seq enrichment for transcription factor binding motifs can be tested instead of having to analyze it in the wet lab. In any case, extending our efforts to proteomics and the study of small RNAs could help to get a more detailed picture of the molecular interplay that is associated with AUD.

In addition, DNA methylation and gene expression should be studied on the single-nuclei level, which enables a cell-type specific investigation. More importantly, single-

nuclei multiome analyses allow the characterization of DNA accessibility and gene expression in the same cell. Single-nuclei analyses could be a great asset to postmortem human brain studies, as quality metrics can be calculated for each cell enabling a more targeted correction and exclusion procedure than adding covariates to a linear model.

4.6 Conclusion

We identified epigenetic and transcriptomic signatures of AUD in postmortem human brain samples of individuals with and without AUD. We present convergent evidence for the importance of neuroinflammation in AUD and provide a basis for the functional validation of inflammation and immune response pathways in animal or iPSC models. It has been shown that multi-omics analysis is beneficial for interpreting findings from single-omics analyses. At the same time, our studies underline the rapid development of the field and analysis techniques that are consistently refined and extended.

5 SUMMARY

5.1 English Summary

Alcohol use disorder is characterized by a loss of control over alcohol intake and contributes to a large number of premature deaths worldwide by representing a strong risk factor for numerous diseases. Despite decade-long research on alcohol use disorder, treatment options are limited and relapse rates following withdrawal treatment are high. Currently, alcohol use disorder is understood as a brain disorder as neuroimaging studies have shown substantial alcohol use disorder-associated connectivity and activity alterations in the human brain. This led to the hypothesis of a neurocircuitry of addiction involving multiple brain regions such as the ventral and dorsal striatum, but also cortical regions that display aberrant functional connectivity patterns in alcohol use disorder. These profound brain changes in alcohol use disorder are assumed to be established by molecular processes such as aberrant DNA methylation and gene expression patterns. To investigate these processes in the human brain, postmortem brain tissue depicts a valuable resource. Previous studies have been published reporting on alcohol use disorder-associated differential methylation or differentially expressed genes mainly in the prefrontal cortex. So far, no analysis has integrated DNA methylation and gene expression data in a multi-Omics approach. Further, it remains unclear how alterations in DNA methylation and gene expression are related to each other in the alcohol use disorder brain. The overall aim of the presented studies was to identify functionally relevant molecular mechanisms of alcohol use disorder in the neurocircuitry of addiction.

To address these points, the first paper aimed to expand the epigenetic characterization of alcohol use disorder to the neurocircuitry of addiction by performing an epigenome-wide association study of DNA methylation in alcohol use disorder in five brain regions: the cortical regions anterior cingulate cortex and Brodmann Area 9, and the striatal regions caudate nucleus, putamen, and ventral striatum. In the second study, the gene expression profile of the striatal brain regions was investigated using RNA-Sequencing enabling the integration of DNA methylation and gene expression data in a multi-omics approach. The biological implication of alcohol use disorder-associated DNA methylation and expression signatures was investigated in both studies using a comprehensive set of bioinformatic tools including Gene Ontology- and gene-set enrichment analyses, weighted correlation network analyses, enrichment analyses of results from genome-wide association studies of substance use disorder phenotypes, and protein-protein interaction networks.

In the epigenome-wide association study of alcohol use disorder in five brain regions, 20 differentially methylated CpG sites were detected, two in caudate nucleus and 18 in the ventral striatum, that were associated with alcohol use disorder at epigenome-wide significance. Alcohol use disorder-associated DNA methylation signatures were strongest in the caudate nucleus, putamen, and ventral striatum and were enriched within immune-related cellular pathways. Gene expression analysis in the second

study suggested converging evidence for inflammatory and immunological signaling in alcohol use disorder. While the overlap of differential methylation and differential expression at the gene level was limited, it was evident on the network level. Consistent differential expression of the *ARHGEF15* gene was found in the caudate nucleus, putamen, and ventral striatum in alcohol use disorder. Further, the *STAT3* gene was identified as a conserved hub node in alcohol use disorder-associated gene networks and might be a promising candidate for further evaluation.

In conclusion, this is the first study that integrated DNA methylation and gene expression data from the same individuals in multiple brain regions in the context of alcohol use disorder. Converging evidence from this study supports the role of (neuro) inflammation in the pathophysiology of alcohol use disorder. Methods for multi-omics integration are rapidly emerging and the integration of multiple omics including epigenome-wide DNA Methylation, transcriptomics, proteomics, and non-coding RNAs enables the complementation, but also the prioritization of findings from single omics layers. In follow-up studies, functional validation of multi-omics-derived candidate genes and pathways should be performed using animal models and patient-derived brain organoids. Conducting such precision medicine approaches might lead to the discovery of novel therapeutic strategies in alcohol use disorder, which are urgently required.

5.2 German Summary – Zusammenfassung in deutscher Sprache

Die Alkoholkonsumstörung ist gekennzeichnet durch Kontrollverlust über den Alkoholkonsum und trägt in hohem Maße zur weltweiten Morbidität und Mortalität bei, da sie einen Risikofaktor für zahlreiche Erkrankungen darstellt. Trotz jahrzehntelanger Forschung auf dem Gebiet der Alkoholkonsumstörung sind die Behandlungsmöglichkeiten begrenzt, und die Rückfallquoten nach einer Entzugsbehandlung hoch. Gegenwärtig wird die Alkoholkonsumstörung als eine Störung des Gehirns verstanden, da Neuroimaging-Studien erhebliche, mit der Alkoholkonsumstörung zusammenhängende Konnektivitäts- und Aktivitätsveränderungen im menschlichen Gehirn nachgewiesen haben. Dies führte zu der Hypothese einer „neurocircuitry of addiction“ (neuronaler Suchtschaltkreis), an der mehrere Hirnregionen, wie das ventrale und dorsale Striatum, aber auch kortikale Regionen beteiligt sind, die bei der Alkoholkonsumstörung abweichende funktionelle Konnektivitätsmuster aufweisen. Es wird angenommen, dass diese tiefgreifenden Veränderungen des Gehirns bei der Alkoholkonsumstörung durch molekulare Prozesse wie veränderte DNA-Methylierung und Genexpressionsmuster bedingt sind. Postmortales Hirngewebe stellt eine wertvolle Ressource dar, um diese Prozesse im menschlichen Gehirn zu untersuchen. In früheren Studien wurde über eine mit Alkoholkonsum assoziierte differentielle Methylierung oder differentielle Genexpression vor allem im präfrontalen Kortex berichtet. Bislang gibt es keine Studie im Feld der Alkoholkonsumstörung, die DNA-Methylierungs- und Genexpressionsdaten in einem Multi-Omics-Ansatz integriert. Darüber hinaus ist nach

wie vor unklar, wie Veränderungen der DNA-Methylierung und der Genexpression im Gehirn bei der Alkoholkonsumstörung zusammenhängen. Das übergeordnete Ziel der vorgestellten Studien bestand darin, funktionell relevante molekulare Mechanismen der Alkoholkonsumstörung in der neurocircuitry of addiction zu identifizieren.

Dazu wurde eine epigenomweite Assoziationsstudie zur DNA-Methylierung bei Alkoholkonsumstörung in fünf Hirnregionen durchgeführt: in den kortikalen Regionen anteriorer cingulärer Kortex und Brodmann Area 9 sowie in den striatalen Regionen Nucleus caudatus, Putamen und ventrales Striatum. In der zweiten Studie wurde das Genexpressionsprofil der striatalen Hirnregionen mittels RNA-Sequenzierung untersucht, was die Integration von DNA-Methylierungs- und Genexpressionsdaten in einem Multi-omics-Ansatz ermöglichte. Die biologische Bedeutung der mit Alkoholkonsum assoziierten DNA-Methylierungs- und Expressionssignaturen wurde in beiden Studien mit Hilfe einer umfassenden bioinformatischen Analyse-Sequenz untersucht, darunter Gene-Ontology- und Gene-set-Enrichment-Analysen, Netzwerkanalysen, Enrichment-Analysen von Ergebnissen aus genomweiten Assoziationsstudien zu Phänotypen von Substanzkonsumstörungen und Protein-Protein-Interaktions-Netzwerke.

In der epigenomweiten Assoziationsstudie zur Alkoholkonsumstörung in fünf Hirnregionen wurden 20 differentiell methylierte CpG-Sequenzen entdeckt, zwei im Nucleus caudatus und 18 im ventralen Striatum, die auf Ebene der epigenomweiten Signifikanz mit der Alkoholkonsumstörung in Verbindung gebracht wurden. Die mit der Alkoholkonsumstörung assoziierten DNA-Methylierungssignaturen waren im Nucleus caudatus, im Putamen und im ventralen Striatum am stärksten ausgeprägt und zeigten eine Anreicherung für immunbezogene Signalwege. Die Genexpressionsanalyse in der zweiten Studie wies in Zusammenhang mit den Ergebnissen der ersten Studie auf konvergierende Befunde für entzündliche und immunologische Signalwege bei der Alkoholkonsumstörung hin. Während die Überschneidung von differentieller Methylierung und differentieller Genexpression begrenzt war, zeigte sich eine Überschneidung der Befunde in der Netzwerkanalyse. Eine konsistente differentielle Expression des *ARHGEF15*-Gens wurde im Nucleus caudatus, im Putamen und im ventralen Striatum bei der Alkoholkonsumstörung festgestellt. Darüber hinaus wurde das *STAT3*-Gen als konservierter Knotenpunkt in Gennetzwerken identifiziert, die mit der Alkoholkonsumstörung in Verbindung stehen. *STAT3* stellt damit einen vielversprechenden Kandidaten für weitere Untersuchungen dar.

Zusammenfassend ist dies die erste Studie, in der DNA-Methylierungs- und Genexpressionsdaten von denselben Personen in mehreren Gehirnregionen im Zusammenhang mit der Alkoholkonsumstörung integriert wurden. Die konvergierenden Erkenntnisse aus dieser Studie unterstützen die Rolle der (Neuro-) Inflammation in der Pathophysiologie der Alkoholkonsumstörung. Die Methoden für die Datenintegration auf Basis eines Multi-Omics-Ansatzes entwickeln sich rasant, und die Integration mehrerer Omics-Ebenen, einschließlich epigenomweiter DNA-Methylierung, Transcriptomics, Proteomics und nicht-kodierender RNAs, ermöglicht

eine Erweiterung der Datenbasis und die Priorisierung von Erkenntnissen aus einzelnen Omics-Ebenen. In Folgestudien sollte eine funktionelle Validierung der aus der Multi-Omics-Analyse abgeleiteten Kandidatengene und Signalwege anhand von Tiermodellen und aus Patientengewebe generierten Hirnorganoiden durchgeführt werden. Die Durchführung solcher präzisionsmedizinischen Ansätze könnte zur Entdeckung dringend benötigter neuer therapeutischer Strategien bei der Alkoholkonsumstörung beitragen.

8 CURRICULUM VITAE

PERSONALIEN

Name und Vorname: Lea Sigrid Silke Zillich

Geburtsdatum: 30.09.1994

Geburtsort: Heidelberg

SCHULISCHER WERDEGANG

(2004) – (2012) Alexander-von-Humboldt Gymnasium Konstanz

19.06.2012 Abitur

UNIVERSITÄRER WERDEGANG

WS2013/14 Beginn des Bachelorstudiums Theaterwissenschaft an der Ludwig-Maximilians-Universität München

WS2014/2015 Beginn des Bachelorstudiums Psychologie an der Universität Mannheim
Bachelorarbeit: *Entwicklung und Validierung des Identitätsfragebogens bei Depressionen*

WS2016/2017 Auslandssemester an der Drexel University Philadelphia, PA, USA

19.06.2017 Bachelor of Science, Note: 1,8

WS2017/2018 Beginn des Masterstudiums Kognitive und Klinische Psychologie an der Universität Mannheim
Masterarbeit: *Changes in Internalized Stigma during Cognitive-Behavioral-Therapy*

17.07.2019 Master of Science, Note: 1,4

BERUFLICHER WERDEGANG

08/2022 – 12/2022 Forschungsaufenthalt am National Institute on Alcohol Abuse and Alcoholism (NIAAA) in Bethesda, MD, USA

Seit 09/2019 Wissenschaftliche Mitarbeiterin (Doktorandin) in der Abteilung für Genetische Epidemiologie in der Psychiatrie am Zentralinstitut für Seelische Gesundheit

09/2017-09/2019 Studentische Hilfskraft in der Abteilung für Genetische Epidemiologie in der Psychiatrie am Zentralinstitut für Seelische Gesundheit

03/2015-07/2017 Studentische Hilfskraft am Zentrum für Psychologische Psychotherapie Mannheim

9 DANKSAGUNG

Als erstes möchte ich mich bei meiner Doktormutter PD Dr. Stephanie Witt für die Überlassung des Themas dieser Arbeit und die ausgezeichneten Möglichkeiten, es zu bearbeiten, bedanken. Vor allem aber möchte ich mich für die kontinuierliche Unterstützung, den Austausch von Ideen und die vielen schönen und lustigen Momente bedanken.

Mein Dank gilt ebenso Professor Dr. Marcella Rietschel, in deren Abteilung ich optimale Bedingungen erhalten habe dieses Thema zu bearbeiten und die notwendigen Fähigkeiten zu erwerben.

Ich bin sehr dankbar zwei so eindrucksvolle Frauen als Vorbilder und Mentorinnen zu haben.

Ich danke meinen wundervollen Kolleg*innen Dr. Fabian Streit, Lea Sirignano, Dr. Josef Frank, Dr. Jerome Foo, Maja Völker, Helene Dukal, Christine Hohmeyer, Viola Lahr und Mariana Espinola, sowie allen Ko-Autor*innen, die diese Arbeit mit ihrer Expertise bereichert haben.

Mein besonderer Dank gilt Markus Dreier und dem Team der Forschungs-IT am ZI. Vielen Dank für das Beantworten meiner Fragen, das schnelle zur Verfügung stellen von immer noch mehr Speicherplatz und die Lösung meiner IT-Probleme.

Ich danke allen Spender*innen, die ihre Organe und Körper der Wissenschaft zur Verfügung stellen. Es gibt in dieser Arbeit einen Absatz der auf die Probleme mit postmortalem Hirngewebe hinweist. Das soll nicht darüber hinwegtäuschen wie wertvoll der Beitrag jede*r einzelne*n Spender*in ist. Es ist mir eine Ehre mit diesem Gewebe arbeiten zu dürfen.

Ich danke meiner Familie und meinen Freundinnen, die so viel Liebe, Spaß, Leichtigkeit und Kreativität in mein Leben bringen. Besonders meiner Mutter, die schon immer der festen Überzeugung war, dass ich forschen werde. Auch wenn mir das die ersten 25 Jahre meines Lebens absurd vorkam, hatte sie, wie so oft, recht.

Eric, für alles.
