An intercomparison of tidal solutions computed  
with a range of unstructured grid models of the  
Irish and Celtic Sea Regions

## ABSTRACT

Three finite element codes, namely TELEMAC, ADCIRC and QUODDY are used to compute the spatial distributions of the  $M_2$ ,  $M_4$  and  $M_6$  components of the tide in the sea region off the west coast of Britain. This region is chosen because there is an accurate topographic dataset in the area, and detailed open boundary  $M_2$  tidal forcing for driving the model. In addition accurate solutions (based upon comparisons with extensive observations) using uniform grid finite difference models forced with these open boundary data exist for comparison purposes. By using boundary forcing, bottom topography, and bottom drag coefficients identical to those used in an earlier finite difference model, there is no danger of comparing finite element solutions for “untuned unoptimised solutions” with those from a “tuned optimised solution”. In addition by placing the open boundary in all finite element calculations at the same location as that used in a previous finite difference model and using the same  $M_2$  tidal boundary forcing and water depths, a like with like comparison of solutions derived with the various finite element models was possible. In addition this open boundary was well removed from the shallow water region, namely the eastern Irish Sea where the higher harmonics were generated. Since these are not included in the open boundary forcing their generation was determined by physical processes within the models. Consequently an intercomparison of these higher harmonics generated by the various finite element codes gives some indication of the degree of variability in the solution particularly in coastal regions from one finite element model to another.

Initial calculations using high resolution nearshore topography in the eastern Irish Sea and including “wetting and drying”, showed that  $M_2$  tidal amplitudes and phases in the region computed with TELEMAC were in good agreement with observations. The ADCIRC code gave amplitudes about 30 cm lower and phases about  $8^\circ$  higher. For the  $M_4$  tide, in the eastern Irish Sea amplitudes computed with TELEMAC were about 4 cm higher than

ADCIRC on average, with phase differences of order  $5^\circ$ . For the  $M_6$  component, amplitudes and phases showed significant small scale variability in the eastern Irish Sea, and no clear bias between the models could be found. Although setting a minimum water depth of 5 m in the nearshore region, hence removing wetting and drying, reduced the small scale variability in the models, the differences in  $M_2$  and  $M_4$  tide between models remained. For  $M_6$  a significant reduction in variability occurred in the eastern Irish Sea when a minimum 5 m water depth was specified. In this case TELEMAC gave amplitudes that were 1 cm higher and phases  $30^\circ$  lower than ADCIRC on average. For QUODDY in the eastern Irish Sea, average  $M_2$  tidal amplitudes were about 10 cm higher and phase  $8^\circ$  higher than those computed with TELEMAC. For  $M_4$ , amplitudes were approximately two centimetres higher with phases of order  $15^\circ$  higher in the northern part of the region and  $15^\circ$  lower in the southern part. For  $M_6$  in the north of the region amplitudes were 2 cm higher, and about 2 cm lower in the south. Very rapid  $M_6$  tidal phase changes occurred in the nearshore regions.

The lessons learned from this model intercomparison study are summarised in the final section of the paper. In addition the problems of performing a detailed model-model intercomparison are discussed, as are the enormous difficulties of conducting a true model skill assessment that would require detailed measurements of tidal boundary forcing, near shore topography and precise knowledge of bed types and bed forms. Such data are at present not available.

## 1. INTRODUCTION

Although there has been significant progress in recent years in modelling tides and large scale circulation in various geographical areas (e.g. Northwest European Continental Shelf, Davies and Kwong (2000), west coast of Britain, Davies and Jones (1992) (hereafter DJ92), Yellow Sea, Naimie et al. (2001), Irish Shelf (Lynch et al (2003,2004)) the main focus of this work has been outside the very nearshore coastal domain where “wetting and drying”

(Flather and Hubbert 1989, Ip et al 1998) can occur during the tidal cycle. However it must be mentioned that there has been some recent work using high resolution meshes in the nearshore of the Bay of Fundy (Greenberg et al, 2005, Dupont et al 2005). The main reason for this focus on regions where “wetting and drying” does not occur has been the coarse grid nature of these models (e.g. DJ92) which prevented them from resolving these shallow regions. For example shelf wide models of the European continental shelf used a grid resolution of  $1/12^\circ$  and hence could not resolve coastal regions where “wetting and drying” occurred and higher harmonics were generated by non-linear effects. To examine the nearshore generation of higher harmonics, higher resolution limited area finite difference models were developed, for example the 1 km grid model of the eastern Irish Sea used by Jones and Davies (1996) (hereafter JD96). The difficulty of using such limited area models to examine the influence of “wetting and drying” in nearshore regions upon the higher harmonics was that because of the limited extent of the model these harmonics were significant at the open boundary of the model. Hence these harmonics had to be included as open boundary forcing to the model and consequently their distribution over the region was not only influenced by nearshore dynamics but also by open boundary forcing. Consequently the effect of nearshore dynamics could not be examined in detail.

An alternative to using a uniform finite difference grid is to apply an unstructured finite element approach (see Jones (2002), Walters (2005), Greenberg et al (2007) for reviews of the method). This method was used in the English Channel to compare tidal solutions computed with finite difference and finite element models of the area (Werner 1995). However, as the domain of the model was limited higher harmonics were included along the open boundary. In addition there were no appreciable “wetting and drying” areas in the region, hence their effects upon the higher harmonics of the tide could not be investigated.

Consequently although a rigorous model-model and model-data comparison could be performed the solution for the higher harmonics was in part influenced by their distribution along the open boundary. In addition because the model domain had a limited geographic extent the  $M_2$  solution was also in part constrained by the open boundary. In this paper by using a larger domain model, with only  $M_2$  tidal forcing and including “wetting and drying” these problems are to a certain extent minimized (see later). Consequently the higher harmonics are generated entirely by the non-linear processes, in particular momentum advection, quadratic bottom friction and the non-linear term in the continuity equation involving the product of velocity and total water depth (e.g. Davies and Kwong 2000). For a detailed discussion of the generation of higher harmonics the reader is referred to Parker (2007), Walters (1986, 1992). In addition when a nearshore region “wets and dries” over a tidal cycle, the harmonic analysis of the resulting elevation time series contains significant higher harmonics. These arise due to the presence of a Gibbs type effect as drying and subsequent wetting occurs.

In essence this paper extends the work of Werner 1995, by examining a different sea area where the higher harmonics and wetting/drying are important. In addition the sensitivity of the tidal solution in the nearshore region to water depth and finite element resolution is examined in detail. Also, by using a number of finite element models and comparing differences between models and also differences between them and observations, it is possible to illustrate the difficulties in performing a model skill assessment exercise that can reveal “true model” predictive capability in an arbitrary sea region. This problem is discussed in the final part of the paper. These considerations complement the work of Roed et al (1995) who showed how difficult it was to design test cases for model intercomparison.

Recently a finite element tidal model of the west coast of Britain has been developed (Jones and Davies, 2005, hereafter JD05) based upon the application of the TELEMAC code

to solve the finite element equations that describe tidal motion in the region. The TELEMAC code has been used very successfully in other shallow water regions (e.g. Malcherek 2000, Heniche et al 2000, Hervouet 2002, Fernandes et al 2002, 2004) and preliminary calculations (JD05) showed that it could reproduce the major features of the tide off the west coast of Britain without any tuning and using boundary forcing and topography taken from a previous uniform finite difference model. The finite element grid of this model is ideal for examining the effects of nearshore dynamics upon higher harmonics of the tide (Jones and Davies 2007a) for a number of reasons. The most important of these is that the model's open boundary is well removed from the shallow water region, namely the eastern Irish Sea where "wetting and drying" occurs and higher harmonics are generated. Consequently, the model is only forced by the  $M_2$  tide and the higher harmonics are generated solely within the region. In addition the model has high resolution (Fig. 1) in the shallow eastern Irish Sea (Fig. 2a,b) where higher harmonics are important. Also, there is a comprehensive tidal data set, including the higher harmonics for model validation and an accurate solution from a limited area high resolution (1 km) finite difference model of the region, for comparison purposes.

The objective of this paper is to examine to what extent a range of finite element codes, namely TELEMAC (Hervouet 2002), ADCIRC (e.g. Hinch and Luetlich 2003, Luetlich and Westerink 1995) and QUODDY (e.g. Naimie et al 2001) can calculate the higher harmonics of the  $M_2$  tide in the eastern Irish Sea, and the sensitivity of the solution to changes in nearshore water depth. In addition small scale variations of the tide in the near coastal region are used to examine the sensitivity of the solution to grid resolution. Although tidal calculations are only performed with the  $M_2$  tidal forcing and other calculations (e.g. the three dimensional models of Jones and Davies (1996), Lynch et al (2003,2004)) included more constituents which can influence the tide (see later discussion) the model intercomparisons are very revealing. In addition as shown by Aldridge and Davies (1993)

there is significant spatial variability in bed types and bed forms over the eastern Irish Sea, which besides the presence of other tidal constituents appreciably influences tidal damping in the region. These uncertainties and the fact that the main emphasis of the paper is to compare the various model solutions justifies the use of the  $M_2$  tidal forcing only. In order to compare models, in all calculations the same water depth distribution and bottom friction coefficient was used. As shown by Nicolle and Karpytchev (2007) there is a good case for a spatially variable friction close to the coast. However to perform “like with like” comparisons a constant value was used here. This is consistent with earlier finite difference calculations. In addition open boundary tidal forcing was the same in all calculations and taken from that used by DJ92. The open boundary conditions used in DJ92 were based on limited offshore observations in the region and tidal solution from larger domain models (Kwong et al 1997). Although there may have been some inaccuracy in this boundary forcing they were shown to give an accurate tidal solution in the region when used to force a finite difference model. An alternative used by Lynch et al (2003) is to use assimilation into a model to derive off shore boundary conditions. However, problems in accuracy of tidal data, particularly that of off shore data (see later) and any numerical bias in the assimilation model may lead to a bias in this open boundary forcing. In essence in order to derive a truly unbiased accurate offshore set of tidal data requires precise off shore tidal measurement at locations which have a major influence upon the computed tidal solution. An example of how to use a model to determine the critical tidal measurements that are required in offshore regions is given in Davies (1976). However, in the case of the present model, this would prove to be an expensive measurement exercise. Hence in all calculations, tidal forcing was identical to that used in DJ92. Consequently models were not tuned to give an accurate tidal solution, by adjusting open boundary input, friction or depths, and hence differences in model solution reflected model dynamics.

The fact that all the finite element models were run with the same topography,  $M_2$  tidal open boundary forcing and same bottom friction, taken from an earlier finite difference model of the region, ensures that the forcing and dissipation had not been adjusted to optimize the solution for a particular finite element code. Consequently there was no “built in” bias to favour one particular finite element model. In addition the model-model and model-data intercomparisons are a “true” test of the variability in solutions of each of the finite element models, rather than the usual approach where a model is “tuned” to give the “best fit” to a set of observations.

As will be shown later by not “tuning” the models it is possible to determine the true variability in solutions computed with a range of finite element models. In addition model bias to under/over predict a particular constituent can be assessed. By including or omitting near coastal shallow water regions the extent to which these influence the higher harmonics and hence the degree to which accurate nearshore topography has to be measured and must be resolved can be assessed. In addition the intercomparison exercise illustrates the major problems in doing model-model and model-data intercomparisons, and the enormous difficulties of doing a “rigorous model skill” assessment exercise.

The form of the hydrodynamic equations solved with these various finite element codes is presented in the next section. Solutions from the various codes are given in subsequent sections together with details of their sensitivity to water depth variation, and their variability in nearshore regions. Major conclusions from the study are presented in the last section of the paper, where the difficulties in doing a “true model skill assessment” are discussed.

## 2. HYDRODYNAMIC EQUATIONS

Since the focus of the study is tidal elevation, then it is sufficient to solve the two dimensional vertically integrated hydrodynamic equations, details of which are given in DJ92

and JD96 and will not be repeated here. As the west coast of Britain model spans a range of latitudes (Fig. 1a,b) then spherical coordinates were used, although the region was not sufficiently large to require the addition of tidal potential forcing. Since these equations contain all the non-linear terms necessary to generate the higher harmonics of the tide, then in principle given accurate topography and an appropriate form of bottom friction, together with accurate tidal forcing, they should be able to reproduce the higher tidal harmonics.

The same water depth distribution, finite element grid (Fig. 2) and  $M_2$  tidal open boundary forcing taken from the finite difference model described in DJ92 which yielded an accurate  $M_2$  tidal distribution in the region, were used in the TELEMAC, ADCIRC and QUODDY calculations. Consequently differences in solution arise from differences in the various codes. Solutions were generated from initial conditions of zero elevation and motion at  $t = 0$ , by integrating forward in time over seven tidal cycles and harmonically analysing the final cycle for the  $M_2$ ,  $M_4$  and  $M_6$  constituents. Preliminary calculations showed that because of significant frictional dissipation in the region a sinusoidal solution, that was independent of the initial conditions was established within six tidal cycles. For this reason the seventh tidal cycle was harmonically analysed and used in the comparisons. At closed boundaries the normal component of velocity was zero. In addition the horizontal gradient normal to the coast of alongshore velocity was set to zero, giving a perfect lateral slip condition.

### 3. NUMERICAL SOLUTION

#### 3.1 Grid Generation

The underlying water depths describing the domain and open boundary tidal description originate from the finite difference models of DJ92 and JD96 and were used to generate the finite element grid of JD05 allowing a like with like comparison with these earlier models. Previous calculations with JD05 showed that an optimal  $M_2$  tidal solution in the region was obtained using a mesh refinement based on water depth such that the ratio

between element size and  $(gh)^{1/2}$  was constant, with  $g$  acceleration due to gravity and  $h$  water depth. This approach was applied here with the identical water depths used in JD05, to give grid G3AX (Fig. 2). In this grid the maximum size of element had a side length of order 5 km and occurred in deep water, with nearshore elements of order 0.5 km. As the model water depths included nearshore values that were above mean sea level, “wetting and drying” occurred during the tidal cycle. To examine to what extent the tidal solution, in particular the higher harmonics was influenced by this, a second mesh was generated (G3AX5M) in which all water depths shallower than 5m were replaced by a 5 m minimum water depth. This revised set of water depths was then used to generate a new grid G3AX5M using the identical criteria, namely  $(gh)^{1/2}$ , as that for grid G3AX. Consequently in deep water nodal locations were the same, but in shallow water the two meshes were slightly different. Calculations (Table 1) were performed using all the codes on both meshes, except for the version of QUODDY used here which did not allow for “wetting and drying” and was therefore only run on grid G3AX5M. By this means the influence of including accurate nearshore water depths and the associated “wetting and drying” upon the accuracy of the tide could be determined. We have recently learned from a reviewer that a version of QUODDY now exists (Greenberg et al 2005) that allows for “wetting and drying”. However as the main aim here is to show to what extent “wetting and drying” influences a solution this can be illustrated with the TELEMAC and ADCIRC results.

Although a number of techniques exist in the literature to generate an optimal mesh for a given problem and area (e.g. Hagen et al 2001, 2002, Legrand et al 2006, 2007 and the review of Greenberg et al 2007) these methods were not used here, where the main aim was to compare a number of finite element solutions using the same mesh

## 3.2 TELEMAC

### 3.2.1 *Calculations including detailed nearshore topography, Grid G3AX (Calc 1)*

In an initial calculation (Calc 1, Table 1) tides were computed using the TELEMAC code and grid G3AX. Since detailed results and discussions of the co-tidal charts are given elsewhere (JD05) only the main points are presented here. Comparisons with observations at coastal and offshore tide gauges in the eastern Irish Sea (see Fig. 3, and JD05 for exact locations) for the  $M_2$ ,  $M_4$  and  $M_6$  tidal elevation amplitude and phase are given in Tables 2a,b and c.

The computed  $M_2$  cotidal chart (Fig. 4a(i)) is characterized by a rapid increase in amplitude in shallow water regions such as the Bristol Channel and eastern Irish Sea. It is important to note that for clarity of contour annotation these co-tidal charts are derived by gridding the detailed output from the finite element model. Consequently there is some loss of resolution in the near shore region. Within the North Channel of the Irish Sea the model reproduces the tidal distribution found in limited area high resolution models of the region (Davies et al 2001) and derived from measurements (George 1980). In addition the amphidromic point in the western Irish Sea, and the overall distribution of the tidal amplitude and phase in the Irish Sea is in good agreement with cotidal charts based on observations (Robinson 1979). A detailed point by point comparison with measurements at coastal and offshore gauges in the Eastern Irish Sea (Table 2a) shows that on average there is good agreement although at some locations tidal amplitude is slightly over-estimated by about 10 cm, with phase of order  $5^\circ$  too high. As the accuracy of the instrument and length of the record used to derive this harmonic analysis varies from location to location, with typically a 2 month record from an offshore tide gauge and 12 months from a coastal gauge then providing error bars on the observational data is very difficult. This is a major consideration in any skill assessment exercise. However as the main aim of the paper is a model-model intercomparison, then the changes in solution given in the various tables are a true measure of inter-model variability.

At a number of shallow water coastal gauges for example Hilbre (location E), Barrow (where there are three gauges at locations Y, Z and AA, in close proximity to each other, see Fig. 3), Morecambe (BB) and Fleetwood (CC), there appears to be some difference between observed and computed values, despite the fact that the finite element mesh has high resolution in these regions of order 50m. To understand this, values at nearby nodal positions a distance  $\Delta$  from the observational point were examined (Table 3a).

It is apparent that at Hilbre at the nearest nodal point ( $\Delta = 1.1$  km,  $h = 9.6$  m),  $h_c = 307$  cm,  $g_c = 310^\circ$  (compared with  $h_o = 292$ ,  $g_o = 317^\circ$ ) that is 15 cm too high and  $7^\circ$  too low. At an equivalent ( $\Delta = 1.1$  km) point in shallower water  $h = 2$  m,  $h_c = 269$  cm,  $g_c = 308^\circ$ , namely 39 cm too low, and  $9^\circ$  too low. This suggests that despite the high resolution mesh in the region, there is significant spatial variability in the tide from one mesh point to the next. At nodes slightly farther away, namely  $\Delta = 1.3$  and 1.8 km, water depths are 16.2 m and 2.3 m, with the higher tidal amplitude occurring in the deeper water (Table 3a) where frictional effects are less. Despite the change in amplitude, the phase changes very little from one point to the next, suggesting that at this location the mesh is sufficiently fine to resolve tidal phase if not tidal amplitude.

At Barrow RI (location Y), at the two closest nodes the water depth is zero compared to mean sea level and significant “wetting and drying” occurs. This leads to an appreciable reduction in  $M_2$  tidal amplitude compared to the observed. At other nearby locations where the water depth is non-zero both amplitude and phase are in good agreement with observations. This suggests that the water depth at the two nearest points in the model may be incorrect, or there is a local deeper water channel that is not resolved in the model. At Barrow HP (location Z), again at the point where the water depth is zero, the  $M_2$  tidal amplitude is under-predicted, with amplitude being slightly over-predicted and phase under-predicted at the other locations, suggesting slight errors in local water depth.

At Barrow HS (location AA), at the three nearest points the water depth is non zero with the model tending to slightly over-predict amplitude and under-predict phase, although there is little variation from one nodal point to another. However, at Morecambe there is appreciable spatial variability in tidal amplitude over the three nearest nodes, although water depth changes by less than 1 m between them. This suggests that the mesh is insufficiently fine to resolve the tidal variability in the region. As at other locations, in very shallow water  $h = 0.9$  m, the tidal amplitude is significantly reduced.

Spatial variability at Fleetwood is comparable to that found at Morecambe, suggesting that the mesh is not sufficiently fine and water depths are not available with sufficient accuracy to obtain a smooth convergent solution in these near coastal regions. In essence the  $M_2$  tidal variation in these nearshore regions is comparable to the mesh resolution of the model. Obviously the model mesh could be continuously refined in the near shore region until a convergent solution was obtained. However, without precise knowledge of water depths in the coastal area, which can change between storm events, and accurate knowledge of bed types and bedforms which influence frictional dissipation in the region (Aldridge and Davies 1993) it is unlikely that continuous mesh refinement will guarantee increased model accuracy. As the main aim here is a model intercomparison on a fixed mesh, then an indication of solution variability for that mesh in the near shore is all that is required. Obviously, in a skill assessment exercise of a model's true predictive capability this will be limited by our knowledge of near shore conditions.

The computed  $M_4$  cotidal chart (Fig. 4b) shows the  $M_4$  tidal amplitude, which was zero on the model's open boundary, increasing over the Celtic Sea to a maximum of 10 cm in the southern part of the Irish Sea. The computed  $M_4$  amplitude decreases from this maximum to a minimum to the west of the Isle of Man (Fig. 4b). This spatial variability is found in observations and shelf wide finite difference numerical models (Davies and Kwong 2000). In

the shallow eastern Irish Sea the  $M_4$  amplitude increases rapidly as the shallow coastal region is approached (Fig. 4b). On average the  $M_4$  tide in the eastern Irish Sea is computed with a comparable accuracy to the higher resolution (1 km grid) limited area (eastern Irish Sea only) finite difference model of JD96. This level of agreement suggests that the TELEMAC model is correctly reproducing the physical aspects of the processes generating the  $M_4$  tide. In JD96 although the finite difference model yielded an accurate solution this was in fact in part due to the specification of the  $M_4$  tide along the open boundary of that limited area model.

Although in general the  $M_4$  tide is adequately reproduced, it is evident that at certain coastal locations there are some significant errors (Table 2b). Considering the near coastal locations used previously for the  $M_2$  tide, it is evident that at Hilbre the  $M_4$  tidal amplitude varies by only 4 cm over the four nearest nodes, although there is a significant variation in phase from  $158^\circ$  to  $228^\circ$  (Table 3b). This is in marked contrast to the  $M_2$  tide where the phase was essentially uniform but the amplitude varied (Table 3a).

At Barrow RI in regions where the water depth was zero, and “wetting and drying” occurred the amplitude was significantly larger than found in the observations (Table 3b). At these locations the  $M_2$  tidal elevation was decreased below the observed (Table 3a) due to excessive energy going into the  $M_4$  tide. At the two locations close to Barrow RI where “wetting and drying” did not occur,  $M_4$  tidal amplitude agreed well with the observed, Table 3b, although the phase was under-estimated. Similarly at Barrow HP, at the location of zero water depth, tidal amplitude was over-estimated (Table 3b). At other sites close to Barrow HP computed and observed amplitude and phase were in good agreement, with phase showing only a small spatial variation. This suggests that at this site the  $M_4$  is well resolved on the mesh.

At Barrow HS computed amplitude and phase show only small scale variability, with amplitude showing good agreement with observed, although the phase was under-estimated

(Table 3b). Significant spatial variability exists in the computed  $M_4$  tide at Morecambe which is related to the variability found in the  $M_2$  tide (Table 2b). At Fleetwood, at the shallow water nodes, the amplitude of the  $M_4$  tide is again over-estimated (Table 3b) with a corresponding decrease in the  $M_2$  tide (Table 3a) due to “wetting and drying” transferring energy into the higher harmonics. As discussed previously this suggests inaccurate water depths or a deep channel not resolved by the model. At the node 2.3 km from the tide gauge,  $M_4$  amplitude is in reasonable agreement with observations, although the phase is under-predicted. These detailed  $M_4$  comparisons in shallow water explain why the  $M_2$  tide at some nodes is significantly below the observed, with an associated over-estimate of the  $M_4$  tide.

The computed  $M_6$  cotidal chart (Fig. 4c) shows a rapid increase in tidal amplitude in shallow water due to an increase in bottom friction. In the Liverpool Bay region there is a gradual increase as the water shallows, with a more rapid increase as the Cumbrian coast is approached. The spatial changes in  $M_6$  are due to local decreases in water depth, with a rapid increase in regions where “wetting and drying” occurs (see later). Similar spatial variability with changes in water depth are found in the observed  $M_6$  tide.

Comparisons at various ports (Table 2c) shows that at a number of locations the model significantly overpredicts tidal amplitude. The reason for this can be understood by examining the spatial variability of the tide in the region of the observational point (Table 3c). Considering initially Hilbre, it is evident that at  $\Delta = 1.1$  km in very shallow water  $h = 2$  m,  $h_c = 21$  cm compared with  $h_o = 2$  cm. However, slightly farther away  $\Delta = 1.3$  km, and  $h = 16.2$ m, or nearer  $\Delta = 1.1$  km,  $h = 9.6$  m,  $h_c$  is reduced to 7 or 8 cm. As for the  $M_4$  tide, the  $M_6$  tide shows significant spatial variability over short distances.

At Barrow RI in regions that “wet and dry”, namely  $h = 0$  m, the amplitude, although not the phase, is in reasonable agreement with observation. However at nearby deeper water nodes there are significant errors in both amplitude and phase. Similarly at Barrow HP at

nodes in deeper water locations the tidal amplitude is larger than at nodes in the shallow water, with a significant difference in phase error. At Barrow HS, all adjacent nodes are in deeper water, and have comparable values, of order 6 cm, which although higher is in reasonable agreement with the observed 3 cm, although the phase is about  $35^\circ$  too low, suggesting a local change that is not resolved in the model. Although there are large phase changes of order  $35^\circ$  in  $M_6$ , the fact that a phase change of  $87^\circ$  represents only a one hour time shift for this constituent, does put these errors into perspective compared with the  $M_2$  tide.

Comparable  $M_6$  tidal amplitudes are found at all nodes at Morecambe, although there is significant spatial variability in the phase. In addition tidal amplitude is over-estimated. This suggests that there are local changes that are not resolved in the model. Similar spatial variability is found at Fleetwood, again suggesting a lack of resolution.

From the  $M_4$  and  $M_6$  cotidal charts (Fig. 4b(i), 4c(i)) it is evident that their amplitude and phase change very rapidly in shallow water, particularly in the eastern Irish Sea in regions such as the Solway estuary and Morecambe Bay. A detailed examination of the tidal distribution in these regions (Fig. 4b(ii), 4c(ii)) clearly shows that more detailed coastal resolution is required, with an associated enhanced refinement of the mesh. As discussed previously the contours shown here were derived by gridding finite element output and do not reflect the high resolution of the finite element grid (Fig. 2) in the near shore region. For the  $M_2$  tide the present resolution appears adequate, although the extent to which it and the shallow water constituents are influenced away from the coastline by details of nearshore topography and the presence of “wetting and drying” is not clear. This problem is examined in the next section.

### 3.2.2. Calculation involving under-resolved nearshore topography Grid G3AX5M (Calc 2)

To examine to what extent the solution away from the nearshore region is influenced by near coastal water depths that are normally not resolved in coarse grid models, or not available with sufficient spatial coverage or accuracy, the previous calculation was repeated with a minimum water depth of 5 m. This also meant that “wetting and drying” did not take place and hence its influence on the solution was removed. Although changing the water depth distribution produced a slightly different grid in the near shore region (namely grid G3AX5M, Table 1), since this is related to  $(gh)^{1/2}$  (see earlier discussion), away from the coastline the nodal distribution was as previously.

Comparison of the model wide computed cotidal chart (not shown) (derived with this modified grid (Calc 1M, Table 1)) with that derived previously (Fig. 4a(i)(ii)) did not reveal any significant differences outside the Irish Sea region. However, within the Irish Sea, in particular the eastern Irish Sea away from the nearshore region there was on average an increase in tidal amplitude (compare Figs. 4a(ii) and 5a(ii)) due to the removal of shallow water coastal regions where significant energy dissipation occurred (Davies and Kwong 2000) and energy was transferred to higher harmonics. It is evident from a comparison of Figs. 4a(ii) and 5a(ii) that in the nearshore region of the eastern Irish Sea the effect of setting the minimum water depth to 5 m is to remove the small scale variability in the  $M_2$  tidal amplitude found with realistic water depths. This gives rise to a much smoother variation in the co-amplitude lines comparable to those found in coarse grid models (Davies and Kwong 2000).

Comparing computed values in Table 2a (Calc 1 and Calc 1M) it is evident that at offshore gauges S, T, U (Fig. 3) the removal of shallow water in near coastal regions leads to a decrease in  $M_2$  tidal amplitude of the order of about 5 cm, although no significant change in phase. A larger decrease of order 8 cm occurs at coastal gauges in the Liverpool Bay region (e.g. gauges B, F) with little phase change. In very shallow regions (e.g. Morecambe BB)

amplitude increases by about 20 cm, although as discussed previously in the case of the G3AX grid, this depends upon the location of the nodal point.

To determine to what extent spatial variability in shallow regions is influenced by grid and water depth change, the same locations used previously were considered (Table 3a). Since the mesh distribution has changed, then both  $\Delta$  and  $h$  are different from those given previously (Table 3a), although again nearest locations are used. Considering initially Hilbre (Table 4a, Calc 1M) it is evident that at this location, although water depth changes significantly from one node to another, the effect of imposing a minimum depth of 5 m is that there is only a small variation in tidal amplitude and phase from one node to another, compared to previously where realistic water depths were applied. This shows that with a minimum depth of 5 m the mesh is adequate to resolve the computed  $M_2$  tide. A similar result is found at Barrow RI and HP, although at Barrow HS there is some small scale variability. As illustrated in Tables 3a and 4a, setting a minimum depth of 5 m significantly increases tidal amplitude (Table 4a) above that found previously using realistic depths at locations where these were below 5 m. At Morecambe and Fleetwood, water depths at nearby nodes (Table 3a) were appreciably less than 5 m, and hence the effect of specifying a 5 m minimum is to produce a region of constant water depth (Table 4a) and increased tidal amplitude. Despite the water depths at Morecambe having  $h = 5$  m, the tidal amplitude varies by 4 cm, and phase by  $4^\circ$  over relatively short distances suggesting that a further mesh refinement is required despite the constant water depth in the region. In addition when more realistic water depths are used, the spatial variability increases, with a significant reduction compared to observations in very shallow water. This suggests that as the grid is refined more detailed accurate nearshore topography that can resolve deeper channels is also required.

Considering the  $M_4$  component of the tide, as for the  $M_2$  tide outside the Irish Sea (not shown) there is not a significant difference between the  $M_4$  tide computed using mesh G3AX and G3AX5M. However in the eastern Irish Sea (compare Figs. 4b(ii) and 5b) the  $M_4$  tidal amplitude is significantly reduced when a minimum  $h = 5$  m is used. This average reduction in  $M_4$  tidal amplitude is evident from a comparison at gauges in the eastern Irish Sea (compare Calcs 1 and 1M in Table 2b). At offshore gauges in deeper water (locations S, T, U) it is evident from Table 2b that amplitude has reduced by 4 cm on average, with phase increasing by  $10^\circ$  to  $15^\circ$ . In Liverpool Bay, at gauges I, Q, R, the amplitude change is small, of order 1 cm, with phase change of  $15^\circ$ . However further north at offshore gauge V the amplitude is reduced by 6 cm, with phase increasing by over  $30^\circ$ . Similarly at coastal gauges in this region namely H and K (Fig. 2b) the amplitude is reduced from 12 cm (Calc 1) to 6 cm (Calc 1M) (cf, observed 12 cm at H), and 13 cm (Calc 1) to 7 cm (Calc 1M) (cf, observed 13 cm) at K. This confirms what is shown in Figs. 4b(ii) and 5b, that although the  $M_4$  tide is affected over the whole eastern Irish Sea, the largest difference is in the northern part of the region. Although amplitude is reduced on average it is evident from Table 2b, that at some locations (e.g. Heysham, Hilbre, Barrow HP) it has increased. To examine this it is necessary to consider the small scale variability close to the tide gauge (Table 4b). As for the  $M_2$  tide the effect of using a minimum water depth of 5m, is to remove a significant amount of the spatial variability (Table 4b) of the  $M_4$  tide in the region of the tide gauge (see Hilbre, Barrow RI, Barrow HP and Fleetwood in Table 4b) compared to previously (Table 3b). This tends to lead to a reduction at nodes where previously “wetting and drying” occurred and an increase elsewhere. However, at locations such as Barrow HS more spatial variability is introduced, with an associated increase in  $M_4$ , reducing the agreement of the nearest node average and the observation. Similarly at Morecambe the use of a minimum water depth of 5 m leads to a significant increase in  $M_4$  amplitude. This suggests that, as for  $M_2$ , as water depth spatial

variability is reduced, so the mesh resolution can be coarser, although the error in the computed tide is enhanced giving rise to inaccuracies in the model.

For the  $M_6$  tide the distribution of co-amplitude and co-phase lines outside the Irish Sea (not shown) computed with mesh G3AX5M (Calc 1M) is comparable to that given in Fig. 4c(i). However, within the eastern Irish Sea particularly in the northern and nearshore region there are appreciable differences (compare Figs. 4c(ii) and 5c). In particular in the calculation with a minimum water depth of 5 m the spatial variability is smoother, and there is not a rapid increase close to the coast.

Comparisons at both offshore and coastal gauges in the eastern Irish Sea (Table 2c, Calc 1 and Calc 1M) show that at offshore gauges (e.g. locations Q to U) there is little change in amplitude although phase changes by a few degrees. This is to be expected since the  $M_6$  tide is generated by local bottom friction and influenced locally by “wetting and drying”. Since these effects at offshore locations are not appreciably changed between meshes G3AX and G3AX5M, then this is to be expected. However, in nearshore regions there are significant differences in the solutions.

From calculations 1 and 1M in Tables 3c and 4c, as for  $M_2$  and  $M_4$ , specifying a minimum water depth, at all locations appreciably reduces the spatial variability in the solution. However, at Morecambe the amplitude still changes significantly over relatively short distances, suggesting that a finer mesh is required. In addition the  $M_6$  amplitude is appreciably larger than the measured value. This suggests that the large value found in both solutions is not due to “wetting and drying” or the effect of harmonically analysing a discontinuous time series, but arises from non-linear effects in particular bottom friction which may be incorrectly formulated in these shallow regions.

### 3.3 ADCIRC

#### 3.3.1 *Calculations including detailed nearshore topography, Grid G3AX (Calc 3)*

In order to quantify (Tables 2a-c) and examine the spatial variability of the differences between the tides computed using TELEMAC and ADCIRC, differences in amplitude and phase between the  $M_2$ ,  $M_4$  and  $M_6$  constituents computed with TELEMAC and ADCIRC are given in Figs. 6a-c. Since both models are forced with identical open boundary input, then it is evident that in the region of the open boundary, the two solutions are the same. However, the location of the amphidromic point off the south-east corner of Ireland is slightly further north in the calculation with ADCIRC compared to the TELEMAC calculation. This gives rise to a positive difference in the region to the north of the amphidrome and negative to the south, as shown in the difference plot (Fig. 6a). In addition there are phase differences in the region of the amphidromic point. Similarly in the region of the North Channel there are differences in the tidal distribution computed with each of the models, as shown in the distribution of differences (Fig. 6a). The differences in the two solutions increase within the Irish Sea, particularly in the eastern Irish Sea, where the tidal amplitude computed with ADCIRC is of the order of 30 cm below that computed with TELEMAC, with phase  $8^\circ$  higher (Fig. 6a). These differences are clearly evident (compare Calcs 1 and 2, Table 2a) at the coastal gauges given in Table 2a, with ADCIRC having a tendency to underpredict the tide in shallow regions, although TELEMAC gave good agreement. In terms of  $M_2$  phases, it is evident from Table 2a and Fig. 6a, that ADCIRC computed phases of order  $8^\circ$  higher than TELEMAC. This gave rise to slightly better agreement with the observed phase than that found with TELEMAC. The reason for this difference in amplitude and phase in the eastern Irish Sea is that at offshore gauges V, U, S, T in the eastern Irish Sea (see Fig. 3b for gauge locations) the  $M_2$  tidal amplitude derived from TELEMAC (Calc 1, Table 2a) was significantly (of order 10 cm) higher than the observed whereas for ADCIRC it was about 20 cm lower. In addition the phase is of the order of  $8^\circ$  higher at these offshore gauges. This suggests that it is not just differences in numerical

damping in the nearshore region between the two models that produce differences in the agreement at coastal gauges, but also the  $M_2$  tidal propagation over the whole domain. The fact that the  $M_2$  tidal solution from TELEMAC is in better agreement at eastern Irish Sea coastal gauges than ADCIRC (compare Calcs 1 and 2 in Table 2a) is in part due to the fact that this model tended to overpredict the tide at the offshore gauges V, U, S and T and in essence both models have a tendency to overdamp tidal energy in the shallow eastern Irish Sea. This may in part be due to the fact that no attempt was made to optimize bottom friction in this region or elsewhere in the model.

In terms of differences in the computed  $M_4$  co-tidal chart, it is evident (Fig. 6b) that these are small outside the eastern Irish Sea. This is to be expected since Fig. 4b(i) shows that the  $M_4$  tide is largest in the eastern Irish Sea. In the southern half of the eastern Irish Sea it is apparent (Fig. 6b) that the  $M_4$  tidal amplitude computed with TELEMAC is larger than that determined with ADCIRC, whereas in the north of the region the  $M_4$  amplitude from ADCIRC is slightly larger. In addition, away from the very near coastal region in the northern half of the eastern Irish Sea, ADCIRC computes phase of order  $10^\circ$  higher than TELEMAC. However, in the southern half of the eastern Irish Sea the phase difference between the two solutions is small (Fig. 6b). These differences are apparent at offshore gauges T and V (Table 2b). This may also be seen at northern coastal gauges e.g. H and K, where  $M_4$  amplitude from ADCIRC exceeds that from TELEMAC, whereas at southern gauges e.g. E and O, TELEMAC  $M_4$  amplitudes exceed those from ADCIRC (see Table 2b, Calcs 1 and 2). Also, phases from TELEMAC exceed those from ADCIRC. In view of the fact that TELEMAC gives a larger  $M_2$  tide in the eastern Irish Sea than ADCIRC, and  $M_4$  is mainly produced by  $M_2$  interacting with itself, suggests that  $M_4$  computed with TELEMAC (Calc 1) should exceed that computed with ADCIRC (Calc 2). This is found on average over the whole Irish Sea, but does not explain the difference between the northern and southern

regions of the eastern Irish Sea. One possibility why this difference occurs in  $M_4$ , is that  $M_2$  interacts with  $M_4$ , to give  $M_6$ , takes some energy from the  $M_4$  tide. Although the amplitude of the  $M_6$  tide, even in shallow water is small compared with the  $M_2$  tide (typically of order 10 cm compared with 2 m) and consequently it is not important in terms of total tidal elevation, it is a valuable indicator of a model's accuracy in shallow water. To examine to what extent  $M_2$  and  $M_4$  interaction produce  $M_6$  in the eastern Irish Sea it is useful to consider the distribution of the  $M_6$  tide in the eastern Irish Sea. However, contours of the difference in the  $M_6$  tidal amplitude computed with TELEMAC and ADCIRC (not shown) did not show substantial differences except in the nearshore region, due to the small (of order 1 cm in the north eastern Irish Sea and 5 cm in the south eastern Irish Sea, see Fig. 4c) amplitude of the  $M_6$  tide. Comparison of  $M_6$  tidal amplitudes (Calcs 1 and 2) at coastal gauges where there was an appreciable signal (Table 2c) showed that there was a bias for the  $M_6$  computed from TELEMAC to exceed that from ADCIRC. This probably arises because the  $M_2$  tide in shallow water computed with TELEMAC exceeds that derived with ADCIRC. However, this does not explain the differences in the  $M_4$  distribution. The above analysis of  $M_2$  interacting with itself to give  $M_4$ , and subsequent  $M_2$  and  $M_4$  interaction to give  $M_6$  is based upon an energy cascade from lower to higher frequencies. In practice just as  $M_2$  interacts with itself to give a tidal residual,  $M_2$  can interact with  $M_4$  and  $M_6$  to transfer energy to lower frequencies (see Walters 1986, 1992) although the amplitude of the lower frequencies generated by this process will be small.

In terms of  $M_6$  phases, it is evident from Table 2c that there is significant spatial variability in both computed and observed phases in coastal regions. Also, there does not appear to be a consistent difference between  $M_6$  phases computed with TELEMAC and ADCIRC in these regions.

As was found in the  $M_2$  tidal solution computed with TELEMAC there is significant spatial variability in the  $M_2$  tidal amplitude computed with ADCIRC in the region surrounding a coastal gauge (see Calc, 2 Table 3a).

In essence the high spatial variability found in the TELEMAC calculation of the  $M_2$  amplitude (Calc 1, Table 3a) at nodal points adjacent to shallow water ports is also found in ADCIRC (Calc 2, Table 3a). Also, as found on average throughout the model domain, the amplitude computed with ADCIRC (Calc 2) is below that found in TELEMAC (Calc 1). In addition phases computed with ADCIRC are very slightly (of order  $3^\circ$  on average, Table 3a) larger than those computed with TELEMAC. However, both models give consistent phases and show that the phase does not change appreciably at nodal points near the gauges.

For the  $M_4$  component of the tide, the ADCIRC calculation shows comparable spatial variability in tidal amplitude with nodal location (Calc 2, Table 3b) to that found with TELEMAC (Calc 1, Table 3b). However, as discussed previously in terms of the eastern Irish Sea  $M_4$  tidal distribution, the  $M_4$  amplitude computed with ADCIRC, is less than that due to TELEMAC (compare Calcs 1 and 2 in Table 3b). As suggested previously because  $M_4$  is generated by the non-linear interaction of  $M_2$  with itself, then a reduction in  $M_2$  amplitude will reduce the  $M_4$  amplitude. The significant spatial variability found in the  $M_4$  phase computed with TELEMAC also occurs with ADCIRC. Although ADCIRC on average gives a larger phase than TELEMAC, at some nodal locations the phase is below that computed with TELEMAC (compare Calcs 1 and 2 in Table 3b). This suggests that there is significant small scale variability in the solutions computed with these models.

This small scale variability is also found in the  $M_6$  tidal amplitude computed with ADCIRC (Calc 2, Table 3c). For the  $M_6$  component at most locations there are significant differences between Calcs 1 and 2, and these differences vary appreciably from one point to another. However, at some locations, namely Barrow HS and Morecambe both models give

comparable amplitudes although there are appreciable phase differences from one node to another, suggesting that there are differences in the model's ability to reproduce phase variations for the higher harmonics in near coastal regions.

### 3.3.2 *Calculation involving under-resolved nearshore topography, Grid G3AX5M (Calc 2M)*

To examine to what extent the inclusion of complex nearshore topography contributes to the differences in tidal solutions computed with ADCIRC and TELEMAC, the ADCIRC code was used to compute the tide using the G3AX5M grid. This solution is then compared with that using TELEMAC on the same grid (Calc 1M, Table 1). As a detailed discussion of the influence of near shore topography upon the tidal solution has been presented for the TELEMAC code, only brief details in terms of ADCIRC will be given here.

Contours of the difference in  $M_2$  tidal amplitude and phase between Calc 1M and Calc 2M (Fig. 7a), outside the eastern Irish Sea, show similar distributions to those found with detailed topography (Fig. 6a). However, in the eastern Irish Sea in the near coastal region the small scale variability in these differences is reduced (compare Figs 6a and 7a).

From Table 2a, it is clear that the reduction in  $M_2$  tidal amplitude and change in phase at eastern Irish Sea coastal gauges found between Calcs 1 and 2, is also found between Calcs 1M and 2M. On average the reduction in  $M_2$  amplitude computed with ADCIRC, using grid G3AX5M is comparable to that found with G3AX, namely of the order of 30 cm, with phase changing by the order of  $8^\circ$ . In essence this is consistent to that found between TELEMAC and ADCIRC using grid G3AX, suggesting that each model responds in the same way to the removal of shallow water regions.

For the  $M_4$  tide the difference outside the eastern Irish Sea between TELEMAC and ADCIRC using grid G3AX5M (Fig. 7b) and the higher resolution grid G3AX (Fig. 7a) mainly occurs in the region of the  $M_2$  amphidromic point off the southwest corner of Ireland.

The change in position of this amphidromic point between the solutions influences the distribution of the  $M_2$  tide along the west coast of Wales (Fig. 6a). When the water depth in this region changes between grids G3AX5M and G3AX, this influences the local generation of  $M_4$  in the region leading to an increased difference between  $M_4$  amplitude computed with TELEMAC and ADCIRC using grid G3AX5M than G3AX (compare Figs. 6b and 7b). However, in the eastern Irish Sea the difference in  $M_4$  tidal amplitude computed with TELEMAC and ADCIRC is reduced (compare Figs. 6b and 7b). However the phase difference in the solutions in the north of the eastern Irish Sea increases slightly.

A detailed comparison of  $M_4$  solutions (Table 2b) suggests that although the two models still give appreciably different  $M_4$  solutions using grid G3AX5M, they show consistent differences in the solution using high resolution (G3AX grid) or smooth topography (G3AX5M) in the nearshore region.

For the  $M_6$  component of the tide the difference plot (not presented) together with point by point comparison of ADCIRC solutions (Table 2c) shows that as for the TELEMAC code at offshore gauges S, T, U, V changing from grid G3AX to G3AX5M does not appreciably influence the amplitude, but does affect the phase. However the change in phase going from G3AX to G3AX5M is different in the two models. A detailed analysis (not presented) shows appreciable differences in phase between TELEMAC and ADCIRC even when  $M_6$  is computed using grid G3AX5M where there is no small scale variation in topography and “wetting and drying” does not occur. This suggests that for  $M_6$  the computed solution derived from each model is significantly different. This may in part be due to a lack of grid resolution in the nearshore region even when the smooth topography is used.

To finalize the comparison of the TELEMAC and ADCIRC solutions using grid G3AX5M it is useful to look at the spatial variability at nodes surrounding various nearshore gauges (Table 4a). As with the TELEMAC solution once a minimum water depth of 5 m is

specified in the nearshore region of the eastern Irish Sea, the spatial variability at nodes surrounding an observational point for all tidal constituents is significantly reduced (see Calc 2M in Tables 4a-c). However, as discussed previously there are significant differences in the solutions computed with TELEMAC and ADCIRC even with this smooth idealized nearshore topography.

### 3.4 QUODDY

As shown previously, even when smoother nearshore topography (namely grid G3AX5M) is used in the calculations, and “wetting and drying” does not occur there are significant differences in tidal solutions computed with TELEMAC and ADCIRC. Although QUODDY, as used here, does not include “wetting and drying” and hence cannot be run on grid G3AX, it is still useful to examine the tidal solution on grid G3AX5M, and see how this compares with other solutions.

Difference plots between the TELEMAC and QUODDY solutions (Calcs 1M and 3M) for the  $M_2$  tide (Fig. 8a) and point comparisons in the eastern Irish Sea (Table 2a, Calcs 1M and 3M) show that on average the tidal amplitude computed with QUODDY exceeds that determined with TELEMAC.

From Fig. 8a it is apparent that the amphidromic point off the southeast coast of Ireland computed with QUODDY is farther north than that computed with TELEMAC. Also a detailed comparison of cotidal charts showed that the amphidrome computed with QUODDY was slightly to the east of that derived with TELEMAC. This gives rise to tidal amplitudes computed with QUODDY that are lower than TELEMAC in the region to the north of the amphidromic point (Fig. 8a). A similar distribution of the difference between the models was found with ADCIRC (see Fig. 6a) However the difference between the  $M_2$  tidal amplitudes computed with TELEMAC and QUODDY decreases to the west of the Isle of Man, with QUODDY giving larger amplitudes in the eastern Irish Sea than TELEMAC (Fig.

8a). This is significantly different than that found with ADCIRC , where the difference between TELEMAC and ADCIRC increased in the eastern Irish Sea (Fig. 6a). One reason for these different distributions is that the difference between TELEMAC and ADCIRC given in Fig. 6a, is based on mesh G3AX, but Fig. 8a uses mesh G3AX5M. However since Fig. 6a is comparable to Fig. 7a, based on mesh G3AX5M, this difference appears to arise from using QUODDY rather than ADCIRC, rather than differences in mesh.

It is evident from Table 2a (comparison of Calcs 1M and 3M) that at locations on the western side of the eastern Irish Sea in deeper water e.g. locations Douglas and offshore gauge S that the  $M_2$  tidal amplitude and phase computed with QUODDY, exceed those computed with TELEMAC by about 5 cm and  $8^\circ$  (see Fig. 8a). This difference on average has a tendency to increase as the water shallows, giving on average in the coastal region a difference in amplitude of 10 cm and phase of  $5^\circ$  to  $10^\circ$  (Fig. 8a). This suggests that the  $M_2$  tidal solution in shallow water computed with QUODDY is slightly less damped than in TELEMAC.

For the  $M_4$  component of the tide (Fig. 8b) it is evident that in some regions outside the eastern Irish Sea, particularly close to the amphidromic point off the southeast coast of Ireland there are some appreciable differences in  $M_4$  computed with TELEMAC and QUODDY (Fig. 8b). The distribution of these differences and their magnitudes is quite different from that found in the TELEMAC/ADCIRC intercomparison (Fig. 7b) suggesting that although all three models are forced with the same  $M_2$  tide, there are differences in the numerical representation of the processes generating the  $M_4$  tide. These are most likely to be in the numerical formulation of the non-linear momentum terms that move energy towards shorter waves and higher frequencies, and the implicit or explicit momentum diffusion terms which control this movement and stabilize the solution by removing energy at short waves. To fully identify these terms and their differences in the various models would require a

range of calculations using the codes to solve the simple advection problem in an idealized domain, possibly with and without the linearization of non linear terms. Such an exercise is outside the scope of this paper. However, from a comparison of Figs. 7b and 8b it is evident that although ADCIRC underestimates  $M_4$  amplitude compared with TELEMAC (Fig. 7b), in the case of QUODDY the computed  $M_4$  amplitude is larger in near coastal regions than that computed with TELEMAC (Fig. 8b). In both calculations there was a tendency for the  $M_4$  phase to be overpredicted in the northern part of the region, compared to TELEMAC.

For the  $M_4$  component of the tide, Fig. 8b and Table 2b, show that on average in the shallow water region of the eastern Irish Sea the QUODDY code (Calc 3M) gives a slightly higher amplitude of order 2 cm, than TELEMAC (Calc 1M). As discussed previously this is probably due to the slightly higher  $M_2$  tidal amplitude in the region. However, in some very shallow water locations where TELEMAC computes a very large  $M_4$  amplitude e.g. Heysham and Morecambe, the amplitude computed by QUODDY is significantly increased (e.g. Heysham Calc 1M,  $h_c = 39$  cm, Calc 3M,  $h_c = 50$  cm and Morecambe Calc 1M,  $h_c = 66$  cm, Calc 3M,  $h_c = 83$  cm). This increase in  $M_4$  amplitude computed with QUODDY in shallow near coastal regions is particularly strong in the Barrow region as shown in Fig. 8b. Although there is consistent agreement in the amplitude between solutions computed with both codes, there is some variation in the phase close to the coast. It is not clear what is the reason for these differences between the  $M_4$  solution in shallow water computed with TELEMAC and QUODDY.

For the  $M_6$  component the cotidal chart (not presented) shows that outside the eastern Irish Sea there are some differences in the  $M_6$  amplitude computed with TELEMAC and QUODDY, in particular in the western Irish Sea, to the north of the  $M_2$  amphidromic point. This is different to that found with ADCIRC, although in general, outside the nearshore region the  $M_6$  tide is small. In the eastern Irish Sea  $M_6$  amplitude differences between

TELEMAC and QUODDY are appreciably larger (Table 2c), than those between TELEMAC and ADCIRC. In addition the  $M_6$  amplitude computed with QUODDY changes very rapidly in the region of Barrow.

From Table 2c, there does not appear to be a consistent difference between the  $M_6$  computed with TELEMAC and that derived with QUODDY. However, as found for the  $M_4$  tide at locations where  $M_6$  is large e.g. Birkenhead and Morecambe, that computed with QUODDY is significantly larger than that derived with TELEMAC.

It is evident from Table 4a, (Calc 3M) that as in Calcs 1M and 2M, when the minimum water depth is set at 5 m there is significantly less spatial variability in the QUODDY solution than found with TELEMAC or ADCIRC using realistic depths (e.g. Calcs 1 and 2). As discussed previously, at all these shallow water locations the  $M_2$  amplitude from QUODDY (Calc 3M) exceeds that from TELEMAC, which has the closest agreement with observed shallow water amplitudes. This is in contrast to that found with ADCIRC (Calc 2M) where the amplitude is underpredicted. In terms of phase, that computed with QUODDY (Calc 3M) is very slightly (of order  $1^\circ$  or  $2^\circ$  on average) higher than that computed with TELEMAC.

For the  $M_4$  component of the tide, as for  $M_2$ , using a minimum water depth removes the spatial variability in the region of the nodes found with G3AX (Calc 3M, Table 4b). In addition at most tidal locations the  $M_4$  amplitude computed with QUODDY (Calc 3M) is not appreciably different from that determined by TELEMAC (see Calcs 1M and 3M in Table 4b). However, as discussed in connection with Table 2b, at locations such as Morecambe where TELEMAC gives a large  $M_4$  tide (Calc 1M), there is a tendency for QUODDY to compute a larger amplitude than TELEMAC (compare Calcs 1M and 3M, Table 4b). For  $M_4$  phase, on average that computed with QUODDY is of the order  $10^\circ$  below that computed with TELEMAC (compare Calcs 3M and 1M, Table 4b).

Considering the  $M_6$  component of the tide, as found for TELEMAC and ADCIRC, there is significantly less variability at nodal positions surrounding the observational point when the minimum depth is set at 5 m. In addition as discussed previously, at a number of shallow water locations, namely Barrow RI, Barrow HP and Morecambe, QUODDY has a tendency to overpredict the  $M_6$  tidal amplitude compared with TELEMAC and ADCIRC, and at Barrow HS, it underpredicts the phase (Table 4c). However at other locations e.g. Fleetwood, the amplitude is in good agreement with the other solutions, although the phase is too low (see Table 4c). The reason for this is not clear, although it is evident from Table 4c, that even when a minimum depth is set at 5 m, there is significant variability in the  $M_6$  solution computed with the various models.

#### CONCLUDING REMARKS

Three finite element codes, namely TELEMAC, ADCIRC and QUODDY with two different finite element meshes, namely G3AX, which resolves the detailed nearshore eastern Irish Sea topography, and G3AX5M which does not, have been used to compute the spatial distribution of the  $M_2$ ,  $M_4$  and  $M_6$  tides over the west coast of Britain. This region was chosen because an existing finite difference uniform coarse grid (7 km) model solution of the region existed, in addition to a solution from a fine resolution (1 km) eastern Irish Sea model. Also a detailed observational data set was available over the region for comparison purposes, particularly in the eastern Irish Sea where higher harmonics of the  $M_2$  tide were produced.

In all calculations the same open boundary forcing and water depth distribution to that used in earlier finite difference calculations was employed. By this means all finite element models were forced in the same way and had identical water depths. Consequently there was no bias in the solution obtained by adjusting the input or water depths in one model compared to another. Also the same bottom friction coefficient, that was constant over the whole region, and bottom stress formulation was used in all calculations. This however is a major

approximation, in that as shown by Aldridge and Davies (1993) there is significant variation in bed types and bed forms over the eastern Irish Sea which should be taken into account in any attempt at a highly accurate simulation of the tides. In addition to this as shown in JD96, other tidal constituents in particular  $S_2$ ,  $N_2$ ,  $K_1$  and  $O_1$  need to be included in order to get the correct level of frictional dissipation. Consequently a “true model-model and model-data intercomparison” has been performed in the sense that no optimization was performed, rather than the “conventional skill assessment” where a model-data comparison is performed after optimizing the model. However, as discussed previously this falls short of a “true skill assessment” of the predictive capabilities of a range of finite element models, but is somewhat different to the “conventional skill assessment” of a single model where a model-data comparison is performed after the model has been optimized in terms of friction etc. In addition by using a range of finite element models, with identical forcing and water depths any bias in a particular model for example to over/under predict amplitude and phase in a consistent manner could be identified and the model adjusted for future use. For example an under-prediction of amplitude and over-prediction of phase could indicate enhanced numerical dissipation that could be corrected by using a less dissipative algorithm. However, as shown in the calculations and discussed later such simple biases between models did not occur, due to the complex physical nature of tidal propagation and the high non-linearity of the solution in this region.

For example initial calculations with TELEMAC and ADCIRC showed that even for the  $M_2$  tide with a detailed topographic data set there were differences in amplitude and phase over the whole region. These appeared to arise from the fact that the two models gave slightly different locations for the amphidromic point off the southeast coast of Ireland. This gave rise to, on average a 30 cm difference in amplitude and  $8^\circ$  difference in phase for the  $M_2$  tide in the eastern Irish Sea computed with the two models, with the TELEMAC solution in

this region in closer agreement with observations. However, as found in previous finite difference calculations (DJ92, Davies and Kwong 2000) the location of amphidromic points in the interior of large domain models is sensitive to small changes in open boundary forcing. This is true in the present case, but since the open boundary forcing was taken from an accurate earlier finite difference model (DJ92) no adjustment had been made in any finite element calculation. Consequently although the significant differences between TELEMAC and ADCIRC in the eastern Irish Sea might at first sight be attributed to differences in numerical damping in shallow water, in practice it is probably due to small subtle differences in model formulation, which slightly moves the position of the  $M_2$  tidal amphidromic point.

This difference in  $M_2$  in the eastern Irish Sea subsequently feeds into the local  $M_4$  in this region. Thus, a consequence of the larger  $M_2$  tidal amplitude computed with TELEMAC than ADCIRC is that the  $M_4$  amplitude is also larger in the eastern Irish Sea. This suggests that to get a correct  $M_4$  tide, the model must be able to accurately compute the  $M_2$  tide, not only in the region of the  $M_2$  amphidrome, but as it propagates into the eastern Irish Sea. At first sight, differences in  $M_4$  distributions between models in the eastern Irish Sea may be attributed to numerical differences in the non-linear momentum advection terms, since these are primarily responsible for  $M_4$  generation. Certainly this would be so for the idealized case of a one dimensional solution of a tidal wave propagating into shallower water. In such a case any reduction in higher harmonics could be readily attributed to artificial viscosity introduced into the finite element representation of momentum advection. However as shown here in a “true model-model assessment” the reason can be more complex and relate to “far field” errors in  $M_2$  tidal propagation.

For  $M_6$  both TELEMAC and ADCIRC exhibit significant spatial variability in the near coastal region over relatively short distances. In addition neither model exhibits good agreement with observations which also show appreciable small scale variability. One reason

for this, as discussed in JD96, is that in order to get an accurate  $M_6$  tide it is essential to have an accurate description of bottom friction and this requires the inclusion of other tidal constituents (namely  $S_2$ ,  $N_2$ ,  $K_1$  and  $O_1$ ). However, even without these constituents, and ignoring the observations that are generally small which could be prone to error, it is evident from a comparison of TELEMAC and ADCIRC  $M_6$  computations, that there are appreciable differences in the solutions and there is no clear trend in this difference. This is a different situation from that found for the  $M_2$  and  $M_4$  tide where there were consistent large scale differences in the solution. This suggests that these differences in  $M_6$  may arise from small scale nearshore topographic variations in water depth that are unresolved even on the fine nearshore eastern Irish Sea grid used here, or due to differences in model formulation. However, even when a minimum nearshore depth of 5 m is used in the calculation, it is apparent that there are changes in the  $M_6$  tide computed with TELEMAC, ADCIRC and QUODDY. In an idealized calculation such as that involving tidal propagation in a one dimensional shallowing estuary, then changes in the  $M_6$  tide between different models can in part be related to how they parameterize and discretize the bottom friction term. However, as shown here, because of differences in the  $M_2$  and  $M_4$  tides compared with the different models, the reason is more complex. However, some of the difference in the  $M_6$  solution must arise from differences in model formulation, and the possibility of under-resolving this component of the tide in the nearshore region. In addition the absence of other tidal constituents and the use of a single friction coefficient over the whole domain must be a source of error. As shown by Aldridge and Davies (1993) and Davies and Lawrence (1995) bed types vary significantly over the eastern Irish Sea, suggesting an appreciable variation in bottom drag coefficient (Nicolle and Karpytchev 2007). To this end, further calculations are in progress with the use of additional tidal constituents, bed type dependent friction and enhanced nearshore resolution. For a large number of nearshore processes (e.g. Levasseur et

al 2007), such as sediment transport and the spread of pollutants it is essential to have a correct description of both the  $M_2$  component of the tide and its higher harmonics as well as the tidal residual (Jones and Davies 2007b). To this end further work is in progress to improve the tidal description of the eastern Irish Sea.

The calculations presented here, clearly show that a model skill assessment based upon model-data comparison after the model has been optimized in one particular region may not be a true indication of model accuracy in other regions. In addition by comparing results from three models that have not been optimized for the area examined, it is clear that small differences in the location of the  $M_2$  tidal amphidromic point can feed through to significant differences in the  $M_2$ ,  $M_4$  and  $M_6$  tides in shallow regions. These differences are primarily caused by “far field” effects (i.e. small inaccuracies in location of the  $M_2$  amphidrome) rather than differences in model algorithms, that might at first sight be thought to be the principal factor. This clearly shows the limitations of interpreting local deficiencies in a model containing a range of physical processes and covering a wide domain, in terms of results that are found using very idealized calculations of limited domains.

In terms of a rigorous “skill assessment” of a number of models this suggests that besides accurate validation data, detailed accurate open boundary conditions are required at sufficient locations (see Davies (1976) for a discussion of this) to provide accurate and unbiased model forcing. In addition a detailed accurate topographic data set, containing not only water depths, but bed types and forms is required, particularly in the near shore region, bearing in mind that close to the coast these can change between major storm events. At present no such comprehensive data sets exist, and the cost of making the necessary measurement would be large. In essence the model intercomparison exercise presented here, reinforces the conclusions reached by Roed et al. (1995), concerning the difficulties of formulating and carrying out rigorous model intercomparisons.

## ACKNOWLEDGEMENTS

The origin of the TELEMAC system is EDF-LNHE and is therefore ©EDF-LNHE. The authors are indebted to R.A. Smith for help in preparing diagrams, E Ashton and L. Parry for typing the paper. The authors are indebted to two anonymous reviewers for valuable comments particularly concerned with “model skill assessment”.
