Appendix 1 Contributors to the Koala Disease Risk Analysis Project

1.1 Koala Disease Risk Analysis Project Team

Project leader

Simone Vitali	Koala Health Hub, University of Sydney Wildlife Health Australia

Project supervisor

Damien Higgins	Koala Health Hub, University of Sydney

Project consultants

Andrea Reiss	Wildlife Health Australia
Richard Jakob-Hoff	IUCN Species Survival Commission Conservation Planning Specialist Group

Research and administration

Tamsyn Stephenson	Koala Health Hub, University of Sydney
Peter Holz	Koala Health Hub, University of Sydney
Caroline Marschner	Koala Health Hub, University of Sydney
Laura Pulscher	Koala Health Hub, University of Sydney

1.2 Koala Disease Risk Analysis Expert Advisory Group

Alison Wright	Dept for Environment and Water (SA)
Amber Gillett	Australia Zoo Wildlife Hospital
Andrew Hoskins	CSIRO
Cameron Costello	Indigenous representative (Qld)
Cheyne Flanagan	Port Macquarie Koala Hospital
Damien Higgins	Koala Health Hub, University of Sydney
Desley Whisson	Deakin University
Emma Hickingbotham	Dept of Environment, Land, Water and Planning (Vic)
Ian Hough	Koala Life (formerly Intl Koala Centre of Excellence [SA])
Ivan Lawler	Dept of Climate Change, Energy, the Environment & Water (Aust)
Joanna Griffith	Koala veterinarian, SA
Kira Mileham	IUCN Species Survival Commission
Leanne Wicker	Zoos Victoria
Mathew Crowther	University of Sydney
Nicole Gallahar	Dept of Planning, Industry & Environment (NSW)
Sarah Bloustein	Dept of Climate Change, Energy, the Environment & Water (Aust)
Stephanie Shaw	Dept of Environment & Science, Qld

1.3 Koala Disease Risk Analysis Workshop Stakeholders

EAG members plus:

Alistair Legione	University of Melbourne
Bree Talbot	Byron Bay Wildlife Hospital
Carolyn Hogg	University of Sydney
Claire Harrison	Dept of Planning, Industry and Environment (NSW)
David Phalen	University of Sydney
Deborah Tabart	Australian Koala Foundation
Karrie Rose	Australian Registry of Wildlife Health
Denis Rose	Indigenous representative (Vic)
Jon Hanger	Endeavour Veterinary Ecology
Mark Krockenberger	University of Sydney
Martina Jelocnik	University of the Sunshine Coast
Michael Pyne	Currumbin Wildlife Sanctuary
Michelle Campbell-Ward	Australian & New Zealand College of Veterinary Scientists
Mish Simpson	Southern Koala and Echidna Rescue
Natasha Speight	University of Adelaide
Nicole Marin	International Fund for Animal Welfare
Prishani Vengetas	World Wildlife Fund
Rob Porter	National Landcare Australia
Romane Cristescu	University of Southern Queensland
Tamsyn Stephenson	Adelaide Koala and Wildlife Centre
Tania Bishop	Koala veterinarian (Qld)
Tim Portas	RSPCA Queensland
Tracey Wilson	Mosswood Wildlife
Vickii Lett	NSW Wildlife Information, Rescue & Education Service (WIRES)

1.4 Stakeholders in Koala Health

Stakeholders in koala health include people with knowledge relevant to koala health, people who direct conservation action associated with koala health, and those who are affected by those actions. Below are the 193 institutional and government agency stakeholders in koala health. They were kept informed of the progress of the KDRA through a website dedicated to the project (https://sites.google.com/view/koaladra/home).

Appendix 2 Koala Disease Risk Analysis Project Methods

2.1 Koala Disease Risk Analysis Stakeholder Consultation and Communication

The Koala Disease Risk Analysis (KDRA) was developed within a collaborative, multi-stakeholder-inclusive workshop environment. Published and unpublished information was combined with expert opinion to reach the best consensus of knowledge and provide direction for both immediate action and targeted research.

The KDRA Project Team established and worked in collaboration with a 17-member Expert Advisory Group (EAG) which assisted in the design, development, and progress review of the KDRA through a series of four online meetings (*Appendix 1.2*). The EAG provided a consultative and collaborative forum for discussion, as well as technical and strategic review of, and input into, draft components of this report.

The KDRA was supported by the expertise of 24 additional selected stakeholders who formed a group of "Workshop Stakeholders" along with the EAG (*Appendix 1.3)*. The Workshop Stakeholders participated via a series of six additional facilitated online project workshops, to provide additional perspectives from the large community of people with interest or expertise in koala health and conservation.

Due to constraints on face-to-face meeting opportunities caused by the COVID-19 pandemic, all workshops and meetings were undertaken in an online environment. The KDRA workshops and EAG meetings were structured, facilitated sessions through which the Project Team drew on the combined knowledge, expertise and understanding of the stakeholders to increase the level of certainty of the risk analysis, obtain consensus on the priority health hazards and identify means of managing associated risks. Meetings were conducted via Microsoft Teams, and the online collaborative tool MURAL® was used as an interactive platform. The timeline and topics for the various workshops and meetings are shown in Table 6. Figure 20 is an example of the MURAL® workspace.

Table 6 KDRA stakeholder schedule of workshops and meetings

Group	Date	Duration	Subjects discussed
Expert Advisory Group	2 Nov 2021	1.5 h	Introduction to KDRA and EAG
Stakeholder Workshop	16 Nov 2021	2 h	Introduction to KDRA
Expert Advisory Group	17 Nov 2021	2 h	Threat analysis and hazard review Part I
Expert Advisory Group	23 Nov 2021	1 h	Threat analysis and hazard review Part II
Stakeholder Workshop	7 Dec 2021	2 h	Problem description, vision and measuring success
Stakeholder Workshop	14 Dec 2021	2 h	Acceptable risk Part I
Expert Advisory Group	3 Feb 2022	2 h	Risk assessment
Stakeholder Workshop	17 Feb 2022	2 h	Acceptable risk Part II
Stakeholder Workshop	5 Apr 2022	2 h	Hazard pathways and critical control points
Expert Advisory Group	21 April 2022	2 h	Risk management
Stakeholder Workshop	26 May 2022	1.5 h	Overview and project completion
Stakeholder Workshop	4 Oct 2022	3 h	Introduction to implementation process
Stakeholder Workshop	13 Oct 2022	3 h	Infectious hazard prioritisation
Stakeholder Workshop	27 Oct 2022	3 h	Non-infectious hazard prioritisation
Stakeholder Workshop	17 Nov 2022	2 h	Conclusion

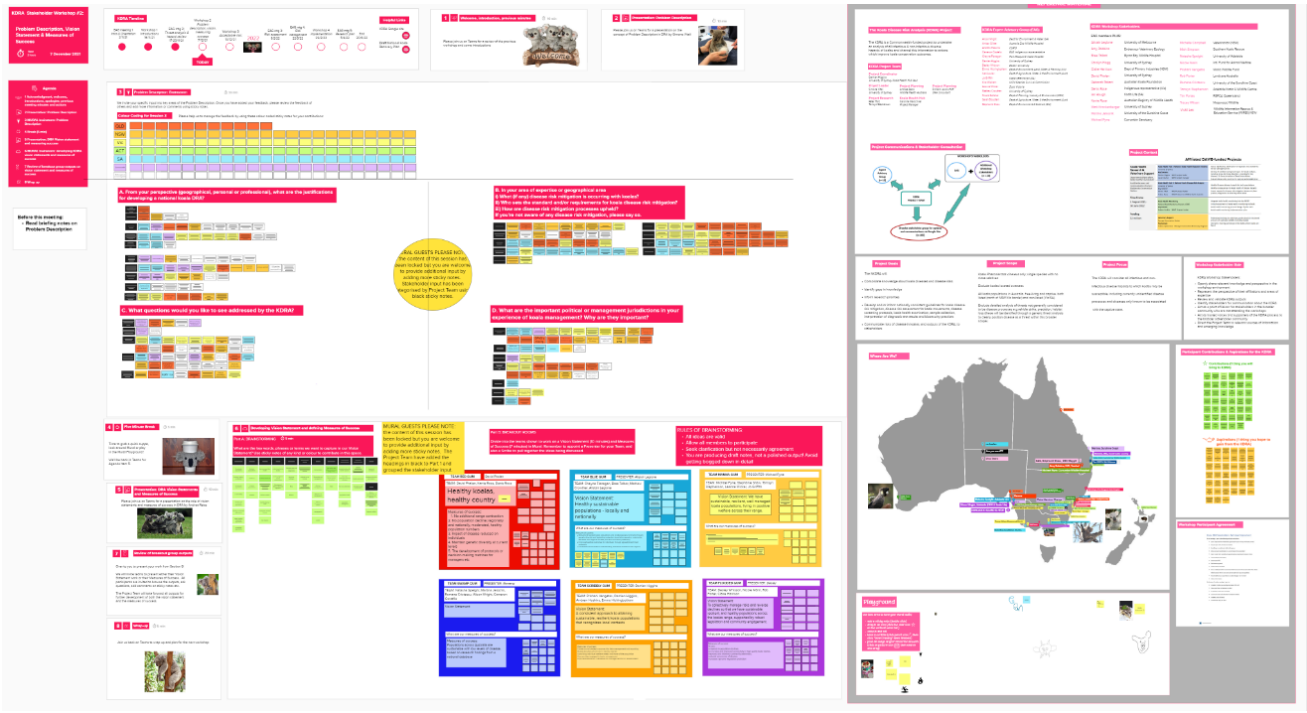

Figure 20 Sample of the MURAL® collaborative workspace used during KDRA stakeholder workshops and meetings

Additional Subject Matter Experts (SMEs) were identified as the project progressed, and invited to help in reviewing chapters of the KDRA relevant to their area of expertise.

The KDRA Project Team established a list of over 300 stakeholders in koala health, from almost 200 organisations and agencies (*Appendix 1.4*). The list included people with interest or expertise in koala health and conservation such as government officers, researchers, veterinarians, rehabilitators, Indigenous representatives, land use managers, non-government conservation representatives, primary industry proponents, communications advisors and policy makers. The development and progress of the KDRA was communicated to the stakeholders through a Google website dedicated to the project that was updated regularly as the project progressed (https://sites.google.com/view/koaladra/home). The website includes biographies of the project team and workshop participants, the KDRA bibliography and selected workshop presentations, the background on the project and information on the DRA process.

2.2 KDRA Hazard Identification and Refinement

2.2.1 Information sourcing

A process of literature review, stakeholder consultation and investigation of databases was implemented to collate and synthesise information on diseases of koalas. An online search for relevant peer-reviewed literature was conducted between September 2021 and March 2022 using the PubMed, Google Scholar and Web of Science (Clarivate Analytics) databases. Relevant literature was identified by searching with terms (“koala” OR “koalas”) AND a list

of search terms compiled manually from citations and information in the following publications:

- *Current Therapy in Medicine of Australian Mammals* (Vogelnest and Portas 2019 [1])
- *Medicine of Australian Mammals* (Vogelnest and Woods 2008 [2])
- *Pathology of Australian Native Wildlife* (Ladds 2009 [3])
- National Recovery Plan for the Koala *Phascolarctos cinereus* (combined populations of Queensland, New South Wales and the Australian Capital Territory) (Australian Govt Dept of Agriculture and the Environment 2022 [4])

Publications were excluded if they discussed disease only relating to humans, non-mammals or non-Australian endemic mammals. Searches were conducted without limits on publication dates or geographical location.

The following disease surveillance databases were consulted in compiling information on koala disease:

- Wildlife Health Australia national electronic wildlife health information system database (eWHIS) (https://wildlifehealthaustralia.com.au/ProgramsProjects/eWHIS-WildlifeHealthInformationSystem.aspx): all cases in koalas, from beginning of database entry to 15 June 2022.
- Australian Registry of Wildlife Health (https://arwh.org): all cases in koalas, from beginning of database entry to 11 November 2021.

Cases reported to these databases represent a small proportion of the overall cases of disease occurring in koalas in Australia, and the datasets are not comprehensive nor spatially or temporally representative. They do not provide a representative picture of the current situation for disease in Australian koalas and there are limitations in the use of these data to make deductions regarding the specific risk of a disease hazard to koalas.

Additional literature and unpublished data were identified through discussion with the EAG and Workshop Stakeholders.

2.2.2 Hazard identification

A list of disease hazards of koalas (see *Section 4 Hazard Identification and Refinement* in KDRA report) was compiled using the information sources outlined in *Appendix 2.2.1*. The EAG and Workshop Stakeholders provided input into the development of the hazard list and confirmed the findings of the Project Team.

Diseases that were only mentioned in a single publication or as a single case in a koala were not included, if subsequent scientific evaluation called the significance of the original finding into doubt (e.g. *Notoedres cati* infestation reported in 1968 [5] but subsequently suspected to have been *Sarcoptes scabiei* infestation [3]). Disease reports were not included if they were isolated occurrences defined only in terms of pathologic abnormalities (e.g. meningitis; enteritis with inclusion bodies; volar hyperkeratosis) rather than causative

processes. All other disease hazards that had been reported in more than one koala were included in the list.

2.2.3 Hazard refinement

Each identified disease hazard of koalas was assessed against the following criteria to determine the hazards to be included for detailed risk assessment:

- Known to occur in koalas in Australia.
- Known to cause disease in koalas.
- Known to cause significant population level disease in wild or captive koalas.
- A lack of epidemiological knowledge of the disease in koalas.

The criteria were applied in a stepwise series of questions as shown in Figure 21 (for Results, see *Section 4 Hazard Identification and Refinement*).

The EAG and Workshop Stakeholders provided input into the development of the refined list of disease hazards and confirmed the findings of the Project Team.

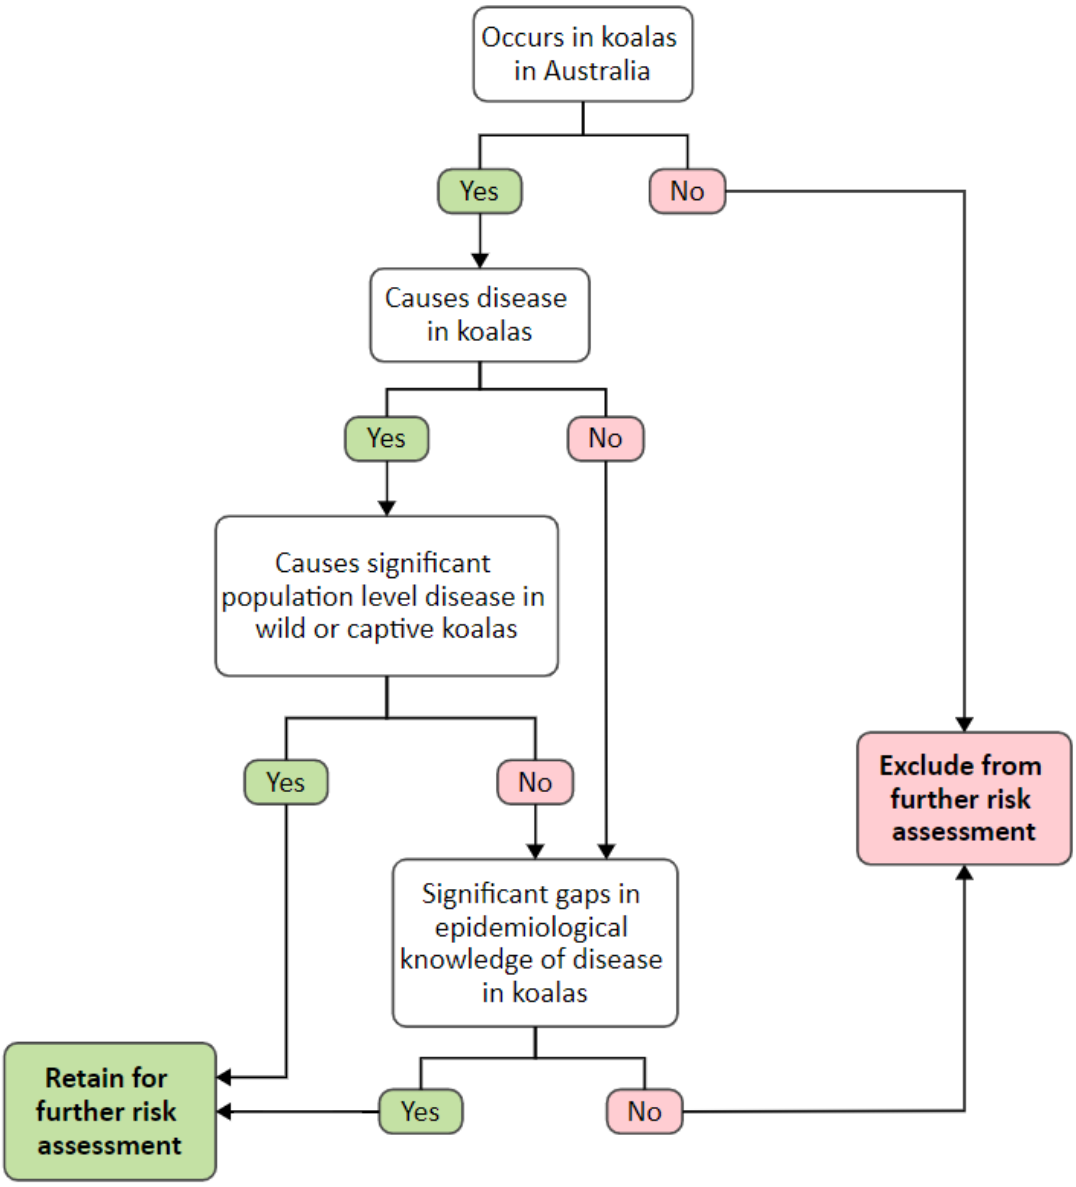

Figure 21 Disease hazard refinement decision tree for KDRA

2.3 Risk Assessment Methods

2.3.1 Hazard transmission pathways and critical control points

Hazard pathways are the means through which a disease hazard poses a risk to the target individuals or populations.

Critical control points (CCPs) are key points in the hazard's biological pathway, where risk mitigation strategies could be implemented most feasibly and effectively, to reduce the overall risk to the species/population of concern. An understanding of the hazard pathways and CCPs enables consideration and evaluation of the most appropriate risk management options.

The first step in the *Hazard Risk Assessment* process for the KDRA involved the creation of a flow chart or model depicting the transmission pathways for each of the selected hazards. In consultation with stakeholders, hazard transmission pathways were scrutinised to identify CCPs, which were then described in the context of each hazard examined.

Nineteen CCPs were identified across all hazards taken forward for risk assessment, although not all CCPs were of relevance to each hazard. Table 5 in *Section 6 Critical Control Points by Disease Hazard* shows the CCPs identified across all hazards selected for detailed risk assessment.

2.3.2 Acceptable risk

Acceptable risk statements

Disease is a natural process and there will always be a level of illness and death in any population. This is recognized in disease risk analyses through a statement of 'acceptable risk' which provides guidance for decisions on how to use available resources to gain the maximum benefit for koala conservation.

Workshop Stakeholders debated the level of risk directly attributable to a disease they would accept on behalf of Australia's koalas. When undertaking the risk assessments for each hazard these statements provided a threshold, above which risk management was recommended (see Table 10).

The acceptable risks defined for this disease risk analysis are:

For koalas:

- For any given wild population of koalas, the number of koalas in the population does not decrease, *as a result of disease.*
- Koala distribution in the wild does not decline from the current geographic distribution, *as a result of disease*.
- Less than 10% of koalas suffer from measurable ill-health at any one time, or as measured over 12 months, in any given free-ranging population, *as a result of disease*.
- Less than 5% of free-ranging koalas experience prolonged or severe negative animal welfare, as measured against recognised scientific criteria, *as a result of disease*.

For other animal species:

- A disease hazard associated with koalas does not present a previously unidentified risk of morbidity or mortality in another animal species.

For humans:

- A disease hazard associated with koalas does not pose a risk of an increase in morbidity or mortality in humans.

Assumptions and limitations of acceptable risk statements

In developing the acceptable risk statements, the following assumptions and limitations were recognised:

- Measuring the absolute number of free-living koalas is difficult, if not impossible, so acceptable risk should focus on trends within populations rather than overall numbers.
- Measuring certain aspects of ill health, such as infertility, can be difficult and may result in under-identification of populations suffering unacceptable risk as a result of disease.
- There are currently no recognised scientific criteria for the measurement of koala welfare in the wild.
- Although koala genetic diversity was recognised as an important facet of defining acceptable risk, there is currently insufficient knowledge of koala genetics to establish a meaningful acceptable risk statement. The sequencing of the koala genome is likely to result in a significant expansion of our understanding of the role of genetics in disease risks [6]. It will be critical to incorporate this understanding into an acceptable risk framework as this knowledge comes to hand.

2.3.3 Likelihood assessment

The following process was used to assess likelihood for each of the hazards taken forward for risk assessment.

The likelihood of a hazard occurring was determined from expert opinion supported by literature and database information.

The likelihood of a *non-infectious hazard* occurring was evaluated in a one step process.

The likelihood of an *infectious hazard* occurring was evaluated in a two-step process. First, evaluations were made of the *likelihood of entry* (also called "likelihood of release" [7]; refers to the likelihood of a hazard entering, or being present, in a specified environment or ecosystem) and *likelihood of exposure* (the likelihood of an individual encountering the hazard in the specified environment or ecosystem). The combined likelihood was determined to be the lowest of the two likelihood ratings for entry and exposure, recognising that the least likely step in a process will be the limiting factor for hazard likelihood. For example, if the entry and exposure likelihoods for a hazard were determined to be **HIGH** and **MODERATE** respectively, the combined likelihood for that hazard would be **MODERATE**.

Likelihood of entry of a hazard into a koala population was considered for the following pathways:

- koala population to koala population
- environment to koala population

- human population to koala population
- other animal population to koala population.

Likelihood of exposure of individual koalas to a hazard was considered for the following pathways:

- koala to koala
- environment to koala
- human to koala
- other animal to koala.

In addition, the *likelihood of an infected koala causing a hazard* to humans or other animals (via their direct or indirect exposure to koalas) was evaluated for contagious hazards.

Likelihood was evaluated as one of four categories as shown in Table 7.

Table 7 Categories and definitions of likelihoods [8]

Likelihood	Descriptive Definition
High	The event is highly likely to occur
Moderate	The event is moderately likely to occur
Low	The event is unlikely to occur but has been known to occur or may possibly occur
Negligible	The event will almost certainly not occur

If the likelihood for a hazard was evaluated as negligible, then the risk estimate for that hazard was classified as negligible and the risk analysis for the hazard was concluded at this point [7].

2.3.4 Consequence assessment

The consequences for a hazard were evaluated as one of four possible outcomes as shown in Table 8. If any one part of a more serious consequence definition was met, the more serious category was applied to the risk assessment. Measures of consequence were also evaluated against acceptable risk statements to determine the need for risk mitigation as noted above and shown in Table 8.

Hazard consequence was evaluated for all pathways where a non-negligible likelihood was identified. If a consequence was evaluated as negligible, then the risk estimate for that population was also negligible and was not considered further in the overall risk estimates for the hazard. If all consequences of a hazard were evaluated as negligible, then the risk analysis for the hazard was concluded at this point [7].

Table 8 Matrix for evaluating consequence, adapted from Cox-Witton et al. 2021 [9]

		CONSEQUENCE			
	Acceptable Risk Statements	**Negligible**	**Minor**	**Moderate**	**Major**
Koala population resilience & viability	For any given wild population of koalas, the number of koalas in the population does not decrease as a result of disease. Koala distribution in the wild does not decline from the current geographic distribution as a result of disease.	No measurable decline in total population numbers. Isolated impacts in a single population.	Small declines in population numbers. Local short-term population loss. Low prevalence of koala illness or deaths in one or more populations.	Small to moderate population level effects with possible population extinctions. Illness or deaths in multiple populations.	Widespread, long-term overall population declines or high likelihood of population extinctions.
Koala individual health & welfare	Less than 10% of koalas suffer from measurable ill-health at any one time, or as measured over 12 months, in any given free-ranging population, as a result of disease. Less than 5% of free-ranging koalas experience prolonged or severe negative animal welfare, as measured against recognised scientific criteria, as a result of disease.	No detectable health and welfare impacts.	Koala illness with low health and welfare impacts.	Koala illness with moderate health and welfare impacts.	Significant koala illness with severe welfare impacts.
Health & welfare of other species	A disease hazard associated with koalas does not present a previously unidentified risk of morbidity or mortality in another animal species.	No detectable consequences.	Sporadic disease or welfare impacts; no population impacts.	Illness & death that may have population impacts on affected species.	Illness & death with significant population or welfare impacts on affected species.
Human health & welfare	A disease hazard associated with koalas does not pose a risk of an increase in morbidity or mortality in humans.	No detectable consequences in humans.	Rare, isolated cases (<1 per year).	Low number of cases (1-3 per year.)	Multiple cases (>3 per year).

2.3.5 Overall risk estimate

The matrix in Table 9 was used to establish the overall risk estimate by combining the likelihood and consequence for each hazard.

Table 9 Matrix for combining likelihood and consequence to determine overall risk estimate. Adapted from Australian Govt Dept of Agriculture and Water Resources 2016 [10]

		CONSEQUENCE		
		Minor	Moderate	Major
LIKELIHOOD	High	Moderate	High	High
	Moderate	Low	Moderate	High
	Low	Low	Low	Moderate

A recommendation for risk management took into account the acceptable risk statements developed by stakeholders as shown in Table 10.

Table 10 Thresholds for determining the need for risk management based on stakeholders' agreed acceptable risk statements

	Acceptable Risk Statements	Threshold for Risk Management
Koala population resilience & viability	For any given wild population of koalas, the number of koalas in the population does not decrease as a result of disease. Koala distribution in the wild does not decline from the current geographic distribution as a result of disease.	Low (or greater) likelihood of: Small declines in population numbers. Local short-term population loss. Low prevalence of koala illness or deaths in one or more populations.
Koala individual health & welfare	Less than 10% of koalas suffer from measurable ill-health at any one time, or as measured over 12 months, in any given free-ranging population, as a result of disease. Less than 5% of free-ranging koalas experience prolonged or severe negative animal welfare, as measured against recognised scientific criteria, as a result of disease.	Low (or greater) likelihood of: Koala illness with low health and welfare impacts, based on an evaluation of current knowledge, including disease prevalence, distribution of clinical cases, severity of clinical signs, welfare impacts and mortality rates.
Health & welfare of other species	A disease hazard associated with koalas does not present a previously unidentified risk of morbidity or mortality in another animal species.	Sporadic disease or welfare impacts; no population impacts.
Human health & welfare	A disease hazard associated with koalas does not pose a risk of an increase in morbidity or mortality in humans.	Low number of cases (1-3 per year.)

2.3.6 Level of confidence in the risk assessment

The level of confidence in each aspect of the risk assessment (likelihood, consequence and overall risk) was evaluated for each hazard according to Table 11. The overall level of

confidence in the risk assessment for a hazard was taken as an average of all confidence assessments for that hazard.

Table 11 Rating scale for level of confidence. Adapted from Cox-Witton et al. 2021 [9]

DESCRIPTION	DEFINITION
High	Strong level of confidence in the assessment based on peer-reviewed scientific evidence which may be supported by unpublished reports provided by relevant experts.
Medium	Moderate level of confidence in the assessment. Limited peer-reviewed scientific evidence or unpublished reports provided by relevant experts. Some key knowledge gaps.
Low	Limited level of confidence in the assessment. Peer-reviewed scientific evidence and previous experience by experts is lacking. High degree of variation across the scenarios considered; high potential for variability in the outcomes. Significant knowledge gaps.

2.4 Development of Risk Mitigation Options and Recommendations

2.4.1 Risk mitigation options

A list of possible risk mitigation options (RMOs) was developed for each of the 13 identified disease hazards of koalas. The RMOs were initially reviewed by subject matter experts. During online workshops, RMOs for the 10 most important disease hazards were reviewed and prioritised by participants. Workshop participants were asked to:

- Review RMOs specific to each disease hazard for completeness and suggest additional RMOs where needed.
- Assess all RMOs specific to each disease hazard for expected effectiveness in mitigating the disease risk, on a three-point scale from most to less effective.
- Assess the RMOs specific to each disease hazard for feasibility, on a three-point scale from most to less feasible (it was assumed that RMOs identified for a hazard, which were general in nature, would be feasible).

The KDRA project team collated scores for effectiveness and feasibility for each RMO and used these to prioritise RMOs for each disease hazard, with the most effective and feasible RMOs specific to each hazard listed first. RMOs for each disease hazard are presented, in order of importance, at the end of each hazard's risk analysis (see *Section 5 Risk Assessments for Selected Hazards* of KDRA report).

2.4.2 Recommendations

Recommendations which were general in nature, and not specific to a particular disease hazard, were collated to form a set of eight Guiding Principles and prioritised into a list of 21 General Recommendations (*Section 1.6 Guiding Principles and General Recommendations* of KDRA report).

Specific recommended actions were developed for each of the 13 identified disease hazards of koalas, drawing in part from the identified risk mitigation options. Recommendations were initially reviewed by subject matter experts. During the online workshops, recommendations for the 10 most important disease hazards were reviewed and prioritised. Workshop participants were asked to:

- Review recommendations specific to each disease hazard for completeness and suggest changes or additional recommendations where needed.
- Score recommendations specific to a disease hazard by importance, using on a three-point scale from most to less important.

The KDRA project team collated scores for each recommendation and used these to prioritise recommendations for each disease hazard. Recommendations for each disease hazard are presented at the end of each disease risk analysis (see *Section 5 Risk Assessments for Selected Hazards* of KDRA report).

2.4.3 Assignment of leaders and participants to recommendations

Workshop participants helped to identify both:

- The most appropriate agency or organisation to lead action on a given recommendation, and
- Those agencies, organisations or individuals who should have a participatory role in actioning the recommendation.

To do this, workshop participants were provided with a list of 15 koala stakeholder agencies and organisations (see *Section 3.5 Stakeholders in Koala Health*) and were asked to select:

- The one stakeholder that they thought would be most appropriate to lead action on a given recommendation (only one could be selected), and
- Additional stakeholder agencies and organisations that they thought would be appropriate to have a participatory role in action on a given recommendation (as many as five different stakeholders could be selected).

Only recommendations considered to be high priority were included in this process.

Votes for leaders and participants were tallied for each recommendation. The range of tallied votes (>0) was divided into three bands (top, middle and lower thirds) for presentation. Collated results of this exercise are presented in *Appendix 6*.

Appendix 3 Hazard Refinement Outcomes and Rationale

Table 12 shows the detailed information collected for each disease hazard and the rationale for prioritising hazards for risk assessment (see decision tree in Figure 21, *Appendix 2*).

Table 12 Detailed information on each hazard and rationale for prioritisation

Hazard	Occurs in koalas in Australia	Causes disease in koalas	Significant population level disease in koalas?	Epidem-iological knowledge gaps?	Retained for further risk assessment?	Notes	Ref.
INFECTIOUS DISEASE HAZARDS							
VIRUSES							
Barmah Forest virus	Yes	No	No	Yes	No – clinical disease not reported in koalas.	Some evidence koalas may be a wild reservoir. Human disease reports increasing but human disease not severe.	[1-5]
Encephalomyo-carditis virus	No	No	No	Yes	No - not reported in koalas.	Non-listed WOAH wildlife disease [6].	[7-9]
Koala retrovirus (KoRV)	Yes	Yes	Yes	Yes	**Yes – significant epidemiological knowledge gaps; likely role in co-morbidities.**		[10-12]
Papillomaviruses	Yes	Yes	No	No	No – sporadic disease only.		[4, 13-15]
Phascolarctid herpesviruses	Yes	Possibly	No	Yes	**Yes – significant epidemiological knowledge gaps; likely role in co-morbidities.**	May have a synergistic role in the pathogenesis of clinical disease in koalas. Significant associations with concurrent *Chlamydia pecorum* infection.	[16-18]
Ross River virus	Yes	No	No	No	No – clinical disease not reported in koalas.		[4, 19-22]
BACTERIA							
Acinetobacter lwoffii	Yes	Yes	No	No	No - reports of disease are rare.	Mastitis and pouch young death reported in captive animals.	[4, 23, 24]
Aeromonas hydrophila	Yes	Yes	No	No	No - disease is sporadic and opportunistic.	Myositis in a captive koala; septicaemia in mixed infections.	[4, 25]
Bacteroides spp.	Yes	Yes	No	No	No - sporadic disease only.	Pyometra and vaginitis (n=4).	[4, 26]
Bordetella bronchiseptica	Yes	Yes	No	No	No - sporadic occurrence in the wild, occasional outbreaks in captive koalas. Further discussion in *Other Disease Hazards* in KDRA report.	Respiratory tract disease.	[4, 27]
Burkholderia pseudomallei	Yes	Yes	No	No	No – only one reported case in a wild koala.		[28, 29]
Chlamydia spp. *(C. pecorum; C. pneumoniae;* novel *Chlamydiales)*	Yes	Yes	Yes	Yes	**Yes – primary pathogen in the wild, possible co-morbidities with other key hazards (e.g. KoRV, PhaHV).**	WOAH animal disease listings include *Chlamydia* spp. but not *C. pneumoniae* and *C. pecorum* [6].	[4, 30, 31]

Hazard	Occurs in koalas in Australia	Causes disease in koalas	Significant population level disease in koalas?	Epidem-iological knowledge gaps?	Retained for further risk assessment?	Notes	Ref.
Chromobacterium violaceum	Yes	Yes	No	No	No – sporadic disease only. Further discussion in *Other Disease Hazards* in KDRA report.	Opportunistic infections associated with flooding events.	[32]
Clostridium piliforme	Yes	Yes	No	No	No - only one reported case in koalas.	formerly *Bacillus piliformis*	[33]
Clostridium septicum	Yes	Yes	No	No	No – only one reported case in koalas.	Acute generalised enteritis.	[34, 35]
Corynebacterium spp.	Yes	Yes	No	No	No - normal flora, may cause infection secondary to *Chlamydia*.	Pneumonia; mucopurulent rhinitis due to *Rhodococcus* (formerly *Corynebacterium*) *equi* - probably secondary to chlamydiosis; vaginitis secondary to chlamydiosis; normal flora of semen and prepuce; otitis media.	[4, 34, 36]
Coxiella burnetti	Yes	No	No	No	No – only two reports in koalas, no link to disease in koala.	WOAH listed disease [6].	[37, 38]
Enterococcus faecalis	Yes	Yes	No	No	No - occasional opportunistic pathogen only.	Mastitis and pouch young death.	[4, 39]
Escherichia coli	Yes	Yes	No	No	No - ubiquitous opportunistic pathogen.	Nephropathy; typhlitis; pyometritis, septicaemia; pouch dermatitis, otitis, cystitis.	[4, 14, 31, 34, 40]
Helicobacter spp.	Yes	No	No	No	No - no clear link to overt disease in koalas.	Detected by PCR in koalas in the absence of clinical disease.	[41, 42]
Klebsiella spp. (including *K. pneumoniae, K. oxytoca)*	Yes	Yes	No	No	No - ubiquitous opportunistic pathogen and co-infections.	Isolated cases in pouch young. Septicaemia, mastitis, stomatitis, keratoconjunctivitis, pouch infections.	[4, 43]
Leptospira spp. (*L. interrogans* serovars)	Yes	No	No	No	No – clinical disease not reported in koalas.	1.5% seroprevalence in koalas in one study. Non-listed WOAH wildlife disease [6]	[4, 34, 44]
Morganella morganii	Yes	Yes	No	No	No – only one reported case in koalas.	Opportunistic pathogen isolated from a septicaemia case.	[4, 45, 46]
Mycobacteria spp. (including *M. ulcerans*, *M. scrofulaceum)*	Yes	Yes	No	No	No - sporadic disease only. Further discussion in *Other Disease Hazards* in KDRA report.	Historic reports of sporadic outbreaks of disease in isolated populations e.g. Raymond Island (Vic). Likely environmental transmission via wounds (e.g. fighting, mating).	[4, 47-51]
Mycoplasma spp.	Yes	Yes	No	No	No – low prevalence, unlikely population-level impacts.		[52]

Hazard	Occurs in koalas in Australia	Causes disease in koalas	Significant population level disease in koalas?	Epidem-iological knowledge gaps?	Retained for further risk assessment?	Notes	Ref.
Nocardia asteroides	Yes	Yes	No	No	No - only one reported case in a free- living koala.	Pneumonia, likely secondary invader.	[53, 54]
Novel *Actinomyces* sp.	Yes	Yes	No	Yes	**Yes - recently emerged, novel bacterial species.**	Noted in SA since 2016; possible association with dental disease.	[55, 56]
Proteus spp.	Yes	Yes	No	No	No - opportunistic infection only.	Normal intestinal flora. Mixed pouch infections with *Klebsiella* spp. & *Pseudomonas aeruginosa.*	[4, 34]
Pseudomonas aeruginosa	Yes	Yes	No	No	No - opportunistic infection only. Further discussion in *Other Disease Hazards* in KDRA report.	Epidemic mortalities reported in pouch young in captivity. Usually fatal in rehabilitation animals. Wide range of clinical manifestations.	[4, 34, 57]
Salmonella spp. (incl *S. typhimurium, S. sachsenwald, S. bovismorbificans)*	Yes	Yes	No	No	No – sporadic disease only. Further discussion in *Other Disease Hazards* in KDRA report.	Mostly associated with captivity – septicaemia and peritonitis.	[4, 34]
Serratia marcescens	Yes	Yes	No	No	No – sporadic disease only.	Mastitis and death of pouch young.	[4, 58]
Staphylococcus spp. (incl *S. epidermidis)*	Yes	Yes	No	No	No –opportunistic infections only.	A variety of clinical manifestations in koalas. Secondary invader in *Chlamydia* infections.	[4, 59]
Streptobacillus moniliformis	Yes	Yes	No	No	No - only one reported case in koalas.	Pleuritis. Causes tendon sheath arthritis in turkeys.	[60, 61]
Streptococcus spp. (including α- and β-haemolytic *Streptococcus* spp.)	Yes	Yes	No	No	No –opportunistic infections only.	Suppurative osteomyelitis secondary to trauma (n=1), mastitis (n=1), stomatitis, pharyngitis.	[4, 34, 62]
Ureaplasma spp.	Yes	Yes	No	No	No – low prevalence, unlikely population-level impacts.		[52]
Yokenella regensburgei	Yes	Yes	No	No	No - only one reported case in koalas.	Otitis in one wild koala.	[31, 63]
FUNGI							
Aspergillus spp.	Yes	Yes	No	No	No - opportunistic disease only.	Cystitis. Captive koalas.	[31, 64, 65]
Candida spp. (including *C. catenulata)*	Yes	Yes	No	No	No - opportunistic disease only. Further discussion in *Other Disease Hazards* in KDRA report.	Stomatitis, colitis; cystitis. Significant clinical problem in koalas in rehabilitation.	[31, 64, 65]
Coccidioides spp.	Yes	Yes	No	No	No - only one reported case in koalas.		[31, 64, 66]
Cryptococcus spp. (*Cryptococcus gattii, C. neoformans)*	Yes	Yes	Yes	Yes	**Yes – significant disease in captive populations.**	Rhinitis, pneumonia; systemic infection.	[31, 64, 65, 67]

Hazard	Occurs in koalas in Australia	Causes disease in koalas	Significant population level disease in koalas?	Epidem-iological knowledge gaps?	Retained for further risk assessment?	Notes	Ref.
Encephalitozoon intestinalis	Yes	Yes	No	No	No - sporadic disease only.	Enteritis in captive joeys (n=2).	[68]
Ringworm fungi (*Trichophyton mentagrophytes*; *Microsporum gypseum)*	Yes	Yes	No	No	No - no significant population impacts.	Face, ears, dorsal feet and lateral limbs most often affected.	[14, 31, 64, 65]
PROTOZOA							
Cryptosporidium spp.	Yes	Yes	No	Yes	No - sporadic disease only.	Transient infection and mortality (n=4) in captive koalas.	[4, 34, 69]
Giardia spp.	Yes	Yes	No	Yes	No - clinical disease not reported in koalas.	Identified by PCR in koalas from Kangaroo Island.	[69, 70]
Toxoplasma gondii	Yes	Yes	No	No	No - sporadic disease only.	Pulmonary congestion and oedema (n=3). Peracute illness and death in captive animals. Non-listed WOAH wildlife disease list [6].	[4, 34, 71]
Trypanosoma spp. (including *T. copemani, T. gilletti, T. irwini, T. vegrandis, T. noyesi)*	Yes	Possibly	No	Yes	**Yes – possible cause of disease, significant knowledge gaps.**	Infected koalas generally healthy. Disease may be more likely with co-infection or immunosuppression [31].	[72-74]
INTERNAL MACROPARASITES							
Bertiella obesa	Yes	Yes	No	No	No - generally non-pathogenic.	Disease more common in debilitated koalas; may contribute to wasting.	[4, 34]
Durikainema phascolarcti	Yes	Yes	No	No	No - generally an incidental finding.	Heavy burdens might cause vascular and respiratory compromise.	[4, 34]
Nematodes (including *Breinlia mundayi; Mar-supostrongylus, Johnstonema & Ophidascaris* spp.)	Yes	Yes	No	No	No - clinical disease is rare.	Most signs of infection are microscopic; mild interstitial pneumonia reported due to *Marsupostrongylus* spp. Larval *Ophidascaris* obstructed hepatic blood vessels in one case.	[4, 34, 75]
EXTERNAL MACROPARASITES							
Ctenocephalides spp.	Yes	Yes	No	No	No - sporadic disease only.	Incidental cat flea cases reported.	[4]
Demodex spp.	Yes	Yes	No	No	No - sporadic disease only.	Periocular dermatitis.	[76]
Fly strike (*Lucilia cuprina)*	Yes	Yes	No	No	No - sporadic disease only.		[4]
Koalachirus perkinsi	Yes	Yes	No	No	No - not usually associated with clinical disease.	Outbreaks have been reported, causing pruritus and partial alopecia.	[4, 14]
Paralysis ticks (*Ixodes holocyclus, I. cornuatus, I. hirsti)*	Yes	Yes	No	No	No - sporadic disease only.	Koalas with no prior exposure may be susceptible to paralysis.	[4]
Sarcoptic mange (*Sarcoptes scabiei*)	Yes	Yes	Yes	Yes	**Yes – increasing cases in wild koalas, significant clinical disease.**	Outbreaks in free-ranging koalas in SA and Vic.	[4, 77]

Hazard	Occurs in koalas in Australia	Causes disease in koalas	Significant population level disease in koalas?	Epidem-iological knowledge gaps?	Retained for further risk assessment?	Notes	Ref.
Ticks other than paralysis ticks (including *Haemaphysalis* spp., *Ixodes tasmani)*	Yes	Yes	No	No	No – secondary to other illness or as a consequence of non-disease threats.	Changes that force koalas to travel on the ground may predispose to heavy infestations. Associated blood loss may be a cause of morbidity and mortality in individual koalas.	[4]
NON-INFECTIOUS DISEASES							
DEGENERATIVE							
Degenerative joint disease	Yes	Yes	No	No	No - sporadic disease in aged animals.	Degenerative disease of the hips is associated with chronic injury in aging, free-living koalas. Generally not associated with mobility issues.	[78]
Degenerative ocular lesions	Yes	Yes	No	No	No - sporadic disease only.	Includes non-chlamydial keratitis and cataracts. Long-standing keratitis (n=22) in in *Chlamydia* negative koalas from Magnetic Island. *Chlamydia* status not confirmed with molecular testing. Bilateral cataracts reported in some koalas entering rehabilitation.	[79, 80]
Hip and shoulder dysplasia	Yes	Yes	No	No	No - sporadic disease only.	Metabolic bone disease due to insufficient exposure to natural UV light postulated as pathogenic mechanism.	[31]
Periodontal disease	Yes	Yes	No	No	No - present in a high percentage of wild and captive koalas, but does not appear to have significant impacts.	Includes calculus, gingivitis, periodontal pockets, gingival recession and loss of gingival attachment. Associated with malocclusion (possibly stemming from low genetic diversity) in southern populations.	[81]
Tooth wear	Yes	Yes	No	No	No - a natural consequence of aging.	Associated with impaction of leaf material, periodontitis and phytobezoars. Can be a limiting factor in older koala's recovery from illness.	[4]
NEOPLASTIC							
Neoplasia (includes lymphoid and non-lymphoid neoplasia)	Yes	Yes	Yes	Yes	**Yes - high incidence of neoplasia in koalas. KoRV may be a causative factor in neoplasia in koalas.**		[4, 12, 82, 83]
TOXICOSIS							
Aluminium toxicosis	Yes	Yes	No	No	No – isolated cases in specific areas only.	Role as an inciting cause vs a consequence of renal failure is unclear.	[4]
Envenomation - snake bite	Yes	Yes	No	No	No - sporadic disease only.	Suspected tiger snake envenomation (n=1) euthanased after lack of response to treatment.	[4]

Hazard	Occurs in koalas in Australia	Causes disease in koalas	Significant population level disease in koalas?	Epidem-iological knowledge gaps?	Retained for further risk assessment?	Notes	Ref.
Fluorosis	Yes	Yes	No	No	No – isolated cases in specific geographic areas only.	May predispose to periodontal disease and skeletal abnormalities (mandibular hyperostosis). Cases associated with increased environmental fluoride emissions.	[31, 84]
DEVELOPMENTAL							
Developmental cardiac disease	Yes	Yes	No	No	No - sporadic disease only.	Includes atrial septal defect & patent foramen ovale.	[34]
Developmental urogenital disease	Yes	Yes	No	No	No - sporadic disease only.	Includes intersex, testicular aplasia or hypoplasia, cryptorchidism and ureteral aplasia. Genetic associations for some of these diseases.	[4, 85, 86]
Hydrocephalus	Yes	Yes	No	No	No - only one reported case in koalas.	Neurological signs in a wild juvenile koala.	[4]
Iris cysts	Yes	Yes	No	No	No - only one reported case in koalas.		[4]
Malocclusion	Yes	Yes	No	No	No - not associated with significant morbidity or mortality.	High incidence in both free range (22%) and captive (30.5%) animals. Predisposes to periodontal disease; may be a genetic link.	[81]
Scoliosis and kyphosis	Yes	Yes	No	No	No - sporadic disease only.	Free-ranging koalas. Mobility generally unaffected but some reports of severe disease leading to emaciation and inability to climb.	[31, 87]
ENVIRONMENTAL							
Ballistics trauma	Yes	Yes	No	No	No - sporadic cases only.	Gunshot and other ballistics (e.g. bow and arrow)	[31]
Entanglement trauma	Yes	Yes	No	No	No - sporadic disease only.	Koalas become entangled in fences, wires, vines etc	[88]
Heat stress	Yes	Yes	Yes	No	**Yes – large numbers of koalas potentially at risk.**	Climate change and habitat loss likely to increase risk.	[31]
Ocular disease secondary to trauma	Yes	Yes	No	No	No - sporadic disease only.	Clinical manifestations include glaucoma, anterior chamber collapse syndrome and keratomycosis.	[4, 31, 34]
Motor vehicle trauma	Yes	Yes	Yes	No	**Yes - common cause of injury in wild koalas.**		[31]
Predator attack trauma	Yes	Yes	Yes	No	**Yes – commonly reported hazard.**		[31]
Reproductive disease secondary to trauma	Yes	Yes	No	No	No - sporadic disease only.	Clinical manifestations include spermatic granuloma and varicocele.	[31]
Thermal burn trauma	Yes	Yes	Yes	No	**Yes – burns sustained in bushfires kill or injure large numbers of wild koalas.**		[31]

Hazard	Occurs in koalas in Australia	Causes disease in koalas	Significant population level disease in koalas?	Epidem-iological knowledge gaps?	Retained for further risk assessment?	Notes	Ref.
Trauma through falling from trees	Yes	Yes	No	No	No – sporadic cases only.	Population level effects where falls occur during harvesting or clear-felling; geographically isolated.	[31]
Trauma from intraspecific aggression	Yes	Yes	No	No	No – not known to have population-level effects; natural koala behaviours.	Injuries inflicted during fighting and mating. Can result in falls from trees in wild koalas. Cause of trauma in captive koalas.	[31, 89]
OTHER NON-INFECTIOUS DISEASES							
Colloid goitre	Yes	Yes	No	No	No - sporadic disease only.	Incidental finding in one study (n=4).	[34, 90]
Diabetes mellitus	Yes	Yes	No	No	No - sporadic disease only.	Disease possibly related to transient stress-related insulin resistance.	[31]
Gastrointestinal torsion, intussusception or entrapment	Yes	Yes	No	No	No - sporadic disease only.	Aetiology unclear; may be related to stress or sudden diet changes.	[34]
Lithiasis (including struvite; calcium oxalate; uric acid)	Yes	Yes	No	No	No - sporadic disease only.	Gout reported in a single case. Urate crystals may occur with calcium oxalate in oxalate nephrosis.	[4, 91]
Microchip transponder reactions	Yes	Yes	No	No	No - sporadic disease only.	Fibrovascular proliferation at the site of implantation.	[34]
Oxalate nephrosis	Yes	Yes	Yes	Yes	**Yes - frequent reports in free-ranging and captive koalas.**		[31]
Phytobezoars	Yes	Yes	No	No	No - sporadic disease only.	May be a consequence of tooth wear, malocclusion or inappropriate captive diet.	[34]
OTHER CLINICAL SYNDROMES							
Gut dysbiosis (caecocolic dysbiosis/typhlo-colitis syndrome)	Yes	Yes	No	Yes	No – lacks a clear aetiology and case definition. Discussed in *Other Disease Hazards in* KDRA report.	Unique hindgut with specialised microbiome is highly susceptible to homeostatic disturbance. May have significant impact on rehabilitation populations.	[31]
Putative KoRV-associated disease syndromes	Yes	Yes	Unknown	Yes	No - lacks clear causality and case definition. Discussed in *Other Disease Hazards* in KDRA report.	Animals with multiple opportunistic infections possibly associated with KoRV status. Syndromes of multiple disease presentations or multisystemic disease.	[92]
Wasting syndromes	Yes	Yes	Yes	Yes	No - lacks a clear aetiology and case definition. Discussed in *Other Disease Hazards* in KDRA report.	May stem from other diseases or from non-disease pressures.	[34]

Appendix 4 Non-disease Threat Descriptions

This Appendix describes non-disease threats that may act as drivers of disease in koalas. These threats were identified during a generic threat analysis process undertaken with KDRA stakeholders during workshop sessions. The causal flow diagram in *Section 3 Problem Description* (Figure 4) in KDRA report was developed with stakeholder input based on the following information derived from the literature and stakeholders' expert opinion.

4.1 Habitat Loss, Degradation and Fragmentation

Australia has lost almost 40% of its forests since European settlement, with disproportionate loss on the fertile coastal soils which represent the best quality koala habitat [1-3]. In Vic, about 66% of native vegetation has been cleared since European settlement; the areas with the most fertile soils in Qld retain less than 10% of their original vegetation; and in the Sydney region of NSW, less than 1% of Sydney blue gum forests persist [1]. In addition to the absolute loss of large areas of habitat, clearing activities lead to alteration of floristic composition within habitats, thinning of tree/understory density, disruption of tree health and reduction in patch size and connectivity, such that remaining forests tend to be highly fragmented, disturbed and ecologically compromised [1, 4, 5].

As a species, the koala now primarily occurs in human-modified landscapes [6]. For the most part, habitat threats are related to direct and indirect anthropogenic pressures, reflecting the marked conflict between human land use and koala habitat requirements [7]. Specific causes include urban expansion (for housing, new roadways, industrial sites), land clearing for production purposes (forestry, agriculture, mining), introduction of pests, weeds and plant pathogens, and the habitat-altering effects of climate change (see *Appendix 4.2 Climate Impacts and Environmental Disasters* below). In areas of localised overcrowding (which can arise as a result of habitat fragmentation in certain cases), koalas may cause habitat destruction by defoliating remaining trees (see *Appendix 4.4 Localised Overcrowding*) [5].

Koalas are particularly sensitive to habitat loss, degradation and fragmentation due to their highly specific habitat requirements, centred around their reliance on particular tree species for food, shelter and thermoregulation, and their limited capability to move safely between disconnected habitats [8, 9]. Absolute loss of habitat, and the disproportionate loss of prime habitat, result in loss of food and shelter for koalas, limiting both the distribution and long-term viability of koala populations in a given area [5, 7, 8, 10]. Degradation in habitat quality can increase physiological stress for resident koalas making populations more susceptible to disease [11-13] and less resilient to other stressors [14].

Koalas in degraded and fragmented habitats spend more time on the ground moving between trees [15], resulting in increased metabolic cost, increased likelihood of encountering misadventure (see *Appendix 4.3 Misadventure*) [9], and increased acquisition of ectoparasites [16]. Fragmentation of habitat also disrupts genetic flow between

populations, isolating groups of koalas and reducing corridors for dispersal of animals, with resultant reduction in opportunities for genetic mixing [17]. Decreased total area and increased fragmentation of habitats may cause koalas to reach unsustainable densities in the remaining habitat which, in turn, may threaten the viability of that habitat (see *Appendix 4.4 Localised Overcrowding*) [5].

Despite the importance of habitat loss, degradation and fragmentation to koalas, this threat is underrepresented in terms of scientific literature, with only 4% of threat-related publications concerning koalas focused on habitat loss and fragmentation [18]. This is particularly the case in the southern states where understanding of the ecology of koalas has received relatively little attention, possibly due to the perception that koala populations in these areas are stable or increasing [18].

4.2 Climate Impacts and Environmental Disasters

Modelling predicts a shift to a hotter and more variable climate in Australia due to climate change [19, 20], along with more frequent and widespread ecological catastrophes such as storms, droughts, fires and extreme rainfall events [21-24]. The widespread and catastrophic Australian bushfires of 2019-2020 had profound impacts on koalas and koala habitat [21, 25, 26], with more than 10% of total koala habitat estimated to have been affected [25]. This impact was cumulative to the effects of sustained drought and temperature extremes in many areas [14, 23, 25, 27, 28]. More recently, extensive flooding across large tracts of koala habitat in NSW and Qld in 2022 demonstrated the vulnerability of koalas to extreme rainfall events, particularly in marginal riparian habitats [29].

Koalas experience direct mortality in fire and heat events through smoke inhalation, burn trauma, dehydration and heat stress [26], and in flooding events through drowning. Extreme weather events also cause indirect mortality through the effects of habitat loss (see *Appendix 4.1 Habitat Loss, Degradation and Fragmentation*), compromised immunity due to physiological stress [8, 30], and an increased tendency to go to ground which exposes them to misadventure and associated disease risks [29, 31]. Fire events can have the potential to cause local extinctions, and fire is a primary contributor to koala population declines in certain regions [24]. Data emerging from the autumn 2022 floods in Qld suggests that significant population decline may also be linked to flooding, with population declines of 5-10% observed in two populations [29].

Climate change, extreme weather events and fire management are drivers of habitat degradation, due to their negative impact on the viability, configuration and abundance of trees [9, 32]. The change in the distribution and availability of preferred tree species directly affects the distribution, carrying capacity and viability of koala populations, with tree selection being mediated by climate [19, 33].

Sustained increases in temperature associated with climate change cause reductions in the moisture content of leaves, a critical consideration for koalas given leaf moisture is an

important factor in eucalyptus choice [34]. Climate-driven increases in both temperature and atmospheric CO_2 also negatively impact the nutritional quality of leaves [22].

There is evidence that extreme weather events can be associated with an alteration of disease prevalence in koalas. An increase in clinical chlamydiosis and chlamydial infection was noted in one population after heatwaves following a decade of drought [14]. A water-borne pathogen, *Chromobacterium violaceum*, was implicated in acute septicaemic deaths of koalas following the 2022 floods in Qld (see *Section 7.2 Opportunistic Infections* in KDRA report) [29].

The cumulative outcome of climate change and extreme weather events is that koalas and some of their preferred food trees are likely to experience significant range contractions, particularly in the northern parts of their range in south-east Qld, eastern NSW and eastern Vic [9, 18, 19, 22, 33, 35, 36]. Conservative climate projections predict a likely contraction of koala populations eastwards and southwards, with climate-driven contraction compounded by the impacts of other threats such as habitat loss and disease [13, 22, 35, 37].

4.3 Misadventure

Misadventure refers to poor health and welfare outcomes which befall koalas as a result of encounters with external (often anthropogenic) influences. Within the natural koala habitat, misadventure includes predator attack, vehicle strike, orphaning, falls from (or with) trees, gunshot and other ballistic injury, attack by non-predator species (e.g. deer, cattle), and natural disasters such as bushfire [38-40]. Koalas may experience misadventure by straying into areas which are not their natural habitat, with potential consequences including attack by domestic pets, trampling by livestock, accidental entrapment, drowning and entanglements [38, 39]. Misadventure also includes unnecessary rescues undertaken by community members who misinterpret the circumstances of their encounters with wild koalas [38].

Misadventure frequently results in traumatic disease and mortality in both healthy koalas and those affected by other disease. Misadventure can impact population viability through loss of breeding animals (particularly young males of breeding age that are dispersing), reduced fecundity, lower resilience and increased mortality [38-41].

Urbanisation and other land management practices which cause habitat fragmentation bring koalas increasingly into contact with human environments which can increase the likelihood of anthropogenic misadventure [9]. Disturbance of koalas in their natural habitat brought about by clearing and logging activities also increases misadventure risk [12, 39].

The estimation of the impact of various causes of misadventure is limited by the capacity to immediately investigate koala deaths. This is particularly the case for predation, which is probably underestimated as a cause of misadventure as carcasses are undetectable after consumption or burial [41].

4.4 Localised Overcrowding

Localised overcrowding occurs when koalas are present in an area at a density where their feeding results in defoliation of preferred food trees [5]. It is associated with koala densities of at least two koalas per ha, but population densities can be much higher, with 23 koalas per ha recorded in one study [42]. Localised overcrowding has been documented in 16 koala populations, almost all of which are southern koala populations in SA and Vic. Most (n=14) have occurred in areas where koalas have been reintroduced after local extinction. Seven populations are currently experiencing overcrowding issues [5].

The problem of localised overcrowding of koalas is commonly referred to as "overabundance" in scientific literature (e.g. [5]), reflecting the fact that koalas in these populations may have been thriving and breeding well, but may have had limited dispersal opportunity due to poor habitat connectivity [5, 42-44]. It was clear during discussions with workshop participants that this terminology creates significant confusion in the general community as to the threatened status of koalas, as well as detracting from the fundamental deficiencies in habitat management that are at the root of this problem. Consequently, for the purposes of this report, the term "overcrowding" is used in preference to "overabundance".

Overcrowding has negative consequences for the ecosystem, koalas and other species. Widespread canopy defoliation depletes koala food resources, resulting in nutritional stress (and mass starvation in severe cases), with significant negative welfare implications for affected koalas [42]. Nutritional stress causes clinical abnormalities such as anaemia and poor growth rates (3), lowers immunity and resistance to disease [30] and is a contributing factor in susceptibility to many of the major disease hazards of koalas (see hazard flow charts in *Section 5 Risk Assessments for Selected Hazards* in KDRA report). Increased koala density provides more opportunity for infectious disease transmission and promotes intraspecific aggression leading to trauma. Defoliation, with or without additive habitat degradation by invasive plants and fungi [45], can lead to the death of individual trees which may have widespread impacts on its capacity to support both koalas and other species [5].

Localised overcrowding can give a false impression that koalas are less vulnerable than they really are, with negative impacts on community and political recognition of the overall threats facing koalas. For example, the relative abundance of southern koalas hindered legislative change to recognise northern koala populations as vulnerable under Commonwealth legislation [46].

Most cases of localised overcrowding are characterised by three factors: i) the presence of *Eucalyptus viminalis* (manna gum) or *E. ovata* (swamp gum), two highly palatable and nutritious species of eucalypt which are associated with small koala home ranges, high site fidelity and a reluctance of koalas to disperse even when trees become completely defoliated; ii) koala population densities of at least 2 per ha; iii) location on islands, or in areas where dispersal opportunities are limited by poor habitat connectivity [5, 42-44].

The gastrointestinal microbiome of koalas has been shown to differ depending on the eucalypt species they are eating [47]. If their diet is predominated by a restricted range of highly digestible species, this may limit their ability to switch to another food tree species, further limiting dispersal tendency when defoliation or increased koala density occur [5].

The management of overabundant koalas raises a debate as to the acceptability of certain response strategies, particularly culling, which often meet with public opposition [48, 49]. Response to localised overcrowding may be characterised by reactive management of koala welfare in response to public outcry, as opposed to more integrated and evidence-based long-term management strategies such as habitat restoration and annual monitoring to enable early recognition and prompt response [5, 44].

4.5 Low Genetic Diversity

Low genetic diversity refers to the loss of heterozygosity and allelic diversity within the koala genome which results from inbreeding.

In southern koala populations, loss of genetic diversity is associated with the low number of founding animals used in reintroduction efforts in the early 1900s [43, 50-52]. By the 1930s, koalas were presumed extinct in SA, and were undergoing dramatic decline in Vic [9]. In response, Vic koala populations were re-established through reintroduction programs, and koalas, sourced mainly from Vic, were introduced to a number of SA sites [9]. The originating sources for these translocations were island populations founded by very few individuals in the late 1800s and early 1900s [53]; the French Island population, which was the source for establishing koalas on Kangaroo Island (SA), is thought to have originated from as few as two or three founder individuals [53]. The interventions to re-establish koalas in Vic and SA resulted in severe genetic bottleneck effects [53] and genetic swamping of the few remnant Vic populations by the restricted gene pool of translocated animals [43]. The threshold of inbreeding which is associated with an increased probability of population extinction is exceeded by all southern koala populations studied to date [54].

Ongoing habitat loss and fragmentation are associated with increasing genetic erosion throughout the koala's distribution [50, 51, 55, 56]. Successful dispersal of juvenile koalas of both sexes is impeded in fragmented habitat due to increased rates of juvenile loss to dog attacks and motor vehicle collisions [51, 57]. Koalas do not appear to exhibit active inbreeding avoidance behaviour (avoiding mating with closely related animals) [58]. Thus, declines in the heterozygosity of koala populations in fragmented habitat may be driven by both impeded gene flow and an increase in inbreeding [50-52, 55].

Inbreeding increases the probability of accumulation of deleterious recessive alleles and inbreeding depression, which in turn can reduce the viability of a population [43]. Although animal populations with low genetic variation are, as a general rule, considered to have lower survivorship, this does not appear to be the case with southern koala populations [51]. However, there is suggestion that loss of genetic diversity may express in other ways among southern koalas, including as elevated juvenile mortality [59], biased sex ratios in

offspring [60] and the occurrence of developmental abnormalities which are not present in listed koala populations [54, 61].

Genetic diversity is an important measure of a population's resilience, as it is a determinant of adaptive capacity to emerging environmental pressures, such as disease or climate change [54-56]. Evaluation of whole genome sequencing data to date has identified a number of immune genes which are likely to be important to the immune response to diseases such as chlamydiosis, and in the future will likely help to quantify the adaptive potential of a population for coping with disease events [52, 56, 62, 63].

4.6 Community Perceptions and Engagement

The koala is a much-loved cultural icon in Australia [64] and a valuable component of the country's international tourism brand [65, 66]. Community actions and perceptions can have a significant impact on koala conservation, both directly (through community action and engagement) and indirectly (through advocacy and voter pressure). Public goodwill towards koalas is generally high, and many community members are closely involved in supporting koala conservation, through volunteer activities such as rehabilitation, local community advocacy, support of conservation organisations, or engagement in personal behaviours to benefit koalas (e.g. [67]). This support reached new heights during the Australian bushfire season of 2019-20, when national and international media attention highlighted the plight of koalas and the need to pro-actively protect them from anthropogenic impacts [64]. However, despite the good intentions of the general public, there are aspects of community perceptions and engagement that can pose threats to koalas.

If community members are not well informed of the risks to koalas they are less inclined to engage in personal actions, including advocacy to their government representatives, to support koala conservation [64]. There may be uncertainty in parts of the general community as to whether koalas are truly threatened with extinction. This uncertainty may stem from a range of factors, including the relative inconspicuousness of koalas in their natural environment, a lack of clarity regarding the number of koalas remaining in the wild [9], the regional disparities in koala population density and conservation status [6, 64] and the use of terms such as 'overabundance' which imply that koalas are thriving in some localities rather than competing for limited habitat remnants (See *Appendix 4.4 Localised Overcrowding*). The complexities of koala population fragmentation, and how habitat pressures and local ecology can result in dramatic population declines in some populations and localised overcrowding in others, may not be well understood by the community [5].

Koalas are increasingly located in areas where there are competing priorities for land use and land management. Some community members may be less inclined to support actions to safeguard koalas and their habitat if those actions compete with other land use priorities of greater personal importance to them [6, 64, 68-70]. Increasing urbanisation, with resultant disconnection of people from wildlife and wilderness, may result in a lack of the necessary public support for policies which promote koala conservation over land

development [69]. In the absence of public awareness of the true threats to koala survival, risk mitigation actions that require changes in personal behaviour may not be widely implemented if they are perceived as too difficult or inconvenient (e.g. [70, 71]).

There are tensions between 'scientific' management of koalas (which is perceived to isolate facts from values) and their 'cuddly' persona in popular culture, particularly where population control strategies are concerned [44]. Public outcry, guided by emotion-charged media portrayals of koalas and fuelled by the immediacy of social media, may stoke sentiment about koalas in ways that do not benefit their conservation or welfare [5]. Community response has resulted in the reversal of management decisions to cull overabundant koalas in southern Australia [44, 68] and the dismissal by state governments of culling as a management option for koalas over the last 25 years [48]. While many consider the elimination of culling a better ethical outcome, localised overcrowding issues have not yet been solved by alternative population reduction strategies, resulting in ongoing negative ecological and koala welfare impacts in these areas [68, 72].

A general public with limited understanding of animal welfare principles - particularly as they apply to population welfare - may not be equipped with the knowledge to recognise and support positive welfare decisions for wildlife [73, 74]. Members of the public who encounter koalas in the wild may also be unable to reliably distinguish between koalas in need of intervention and those that should be left undisturbed, and may "rescue" individuals unnecessarily [38]. Such well-intentioned, but misguided, efforts can be detrimental to koala health and welfare, and may lead to the unnecessary removal of animals from the wild [38, 75, 76].

4.7 Political Factors

The management of koalas in the wild is influenced by a range of policies, legislation, regulations and programs which are managed through all tiers of government (local, state and national), as well as landholders, communities, traditional owners, the private sector and non-government organisations [9]. The active engagement of many stakeholders allows the integration of diverse perspectives into decision-making processes. However, divergent approaches at different jurisdictional levels can present challenges to consistent, integrated and adaptive management of threats to koalas [6, 77], limiting the effective implementation of legislation or policy.

As described in *Appendix 4.1 Habitat loss, fragmentation and degradation*, the viability of koala populations is intimately connected to habitat viability, due to the koala's reliance on particular tree species for food, shelter and thermoregulation [30, 78]. If environmental and land use regulation and legislation is insufficiently robust or inconsistent across jurisdictions, there may not be sufficient protection of koalas or their habitat which puts further pressure on remaining populations [79-81].

As has been recognised in the *National Recovery Plan for the Koala* [9], policy and management actions for koala management and protection must have a solid foundation in

evidence-based science in order to be effective. Where short-term political or economic concerns have prevailed over the needs of koalas, there has been a tendency toward reactive or high visibility koala management decisions, that address a limited aspects of the overall threat without taking into consideration the long-term viability of koala populations [6, 18, 68, 70].

Funding for conservation action in Australia, in the context of the rate of biodiversity loss, is low [18]. When available funding is tied to the prominent or "media-friendly" issues rather than long-term species and habitat viability goals, the overall benefit of the funding dollar to koalas may be short-lived [64]. Plans for koala conservation that lack the necessary processes and funding for implementation are unlikely to deliver tangible, long-term conservation outcomes [6].

5.1 *Chlamydia* spp. in Koalas – Literature Review

5.1.1 Technical Information

Aetiological agent

Chlamydiae are Gram negative, obligate intracellular bacteria. The species that most commonly infects koalas is *Chlamydia pecorum. Chlamydia pneumoniae* is detected rarely and both species are classified in the taxonomic family *Chlamydiaceae* [1-3]. Several other *Chlamydia*-like bacteria outside the *Chlamydiaceae* family have also been identified in koalas using molecular techniques [4, 5] but their significance is unknown.

The taxonomy and nomenclature of the *Chlamydiaceae* has undergone many changes since the 1970s when the organism first isolated from koalas was identified as *Chlamydia psittaci.* For a comprehensive summary of the history of *Chlamydia* taxonomy with respect to koalas see Polkinghorne et al. 2013 [6].

Chlamydia pecorum can be classified into genotypes or sequence types based on genotyping methods that target the major outer membrane protein gene (*omp*A) [7] or multiple genetic loci [8-10]. Multi-locus sequence typing (MLST) identifies diverse sequence types of *C. pecorum* in koalas [11], which are mostly distinct from known livestock strains [12].

Listing

Chlamydiosis in koalas is not a WOAH listed disease [13].

Chlamydiosis in koalas is not a nationally notifiable animal disease [14].

Chlamydiosis is not identified as a key threatening process under the Environment Protection and Biodiversity Conservation Act [15].

5.1.2 Epidemiology

Chlamydial infertility in both male and female koalas can have a profound effect on free ranging koala population viability. Introduction of *Chlamydia* to a naïve population has resulted in rapid population decline, reducing fecundity to zero in as little as 25 years [16]. Modelling studies indicate that active management of chlamydial infection can be a critical component in reversing koala population declines [17, 18].

The relative importance of chlamydiosis as a driver of population dynamics, compared with non-disease threats, is difficult to measure and probably varies across the koala's distribution [19, 20]. Interpretation is hampered by a scarcity of longitudinal population investigations, an inconsistent approach to disease classification, and the interrelatedness of chlamydial disease to other threats to koala populations [21-23]. A clear understanding of the role of chlamydiosis in population declines across the range of the koala is an important knowledge gap.

Host range

Chlamydia pecorum has a very wide host range, which includes domestic livestock (cattle, sheep, goats, pigs, water buffalo, reindeer) and birds [24-26]. It has also been found in other native marsupials including gliders, possums, bandicoots and quolls [24, 27, 28], though chlamydial disease occurs less commonly in these species [28].

The origins of koala *C. pecorum* are unclear. Several sequence types of *C. pecorum* found in koalas appear so far to be unique to the species [12, 29]. However, few Australian *C. pecorum* strains from other species have been genotyped and some koala sequence types may be more genetically similar to livestock strains than to other koala strains [9, 12]. Genotypes identical or very similar to those found in koalas have also been found in other Australian marsupials [28] and in Australian native birds [25].

Due to similarity of *C. pecorum* sequences between koalas and these other hosts, particularly livestock, the potential for cross-species transmission has been raised [28, 29]. However, more studies are needed to clarify whether postulated spill-over events have significant impact on *Chlamydia* epidemiology in koalas or instead represent rare evolutionary events [22, 30].

Chlamydia pneumoniae has been found in many other vertebrate species including amphibians, reptiles, horses and humans. Among Australian native mammals it has been isolated from koalas, Shark Bay bandicoots, and Gilbert's potoroo [31-33].

Zoonotic potential

Chlamydia pecorum and koala *C. pneumoniae* are not known to be zoonotic [24, 34]. Human *C. pneumoniae* is believed to have evolved separately from koala *C. pneumoniae* [32, 35, 36].

There is strong circumstantial evidence that transmission of *Chlamydia* from koalas to humans does not occur. Although many thousands of free-ranging koalas with overt clinical signs of chlamydial disease have been captured, examined or brought into care over the last 80 years, there has been no report of transmission or seroconversion in humans in contact with these animals [37, 38].

Geographic distribution

Chlamydial infection has been recorded in virtually all wild koala populations throughout their range [39]. There are regional differences in the prevalence of both chlamydial infection and disease (chlamydiosis) in free-ranging koala populations.

Prevalence

Prevalence of chlamydial infection

Table 13 summarises the prevalence of *C. pecorum* and *C. pneumoniae* infection in koala populations in studies undertaken from 2013-2022. Confidence intervals are rarely reported

and are likely to be wide due to sample size limitations. Although the prevalence of *C. pecorum* can vary, *C. pecorum* is consistently more prevalent than *C. pneumoniae* in koalas. Reports of infection with *C. pneumoniae* in koalas have declined significantly in the last 20 years in all regions [39]. A 2021 study of koalas in south-east Qld failed to detect *C. pneumoniae* in over 2500 samples (nasal, conjunctival, urogenital and semen), whereas *C. pecorum* was present in over 60% of these samples [40]. Similar results have been found for koalas sampled in NSW from 2014-2022 [41].

Table 13 Prevalence of Chlamydia infection in Australian koala populations 2013-2022

*Chlamydia diagnosis was based on PCR in all cases. Where the same data were used in more than one study, the data are only tabulated once. NR = not reported; * F = free ranging; R = rehabilitation; U = unspecified; n = number of koalas unless otherwise specified.*

The prevalence of *Chlamydia* in SA koala populations was historically thought to be low because of the lack of reports of chlamydial disease. However, with the exception of the

Kangaroo Island population, infection prevalence in the SA populations appears comparable to populations in other states [6, 48, 49].

Assumptions of *Chlamydia*-free status in any koala population should be viewed with caution given the otherwise ubiquitous distribution of chlamydial infection, its high transmissibility and the logistical limitations of screening free-ranging populations. Some island populations of koalas, created by the historic translocation of clinically healthy, ostensibly *Chlamydia*-free animals, were postulated to be free of chlamydial infection based on serological assays and absence of observed disease. This included populations on St Bees Island and Magnetic Island in Qld, French Island in Vic and Kangaroo Island in SA [6, 22, 52]. Molecular techniques (PCR) have since detected *C. pecorum* in clinically healthy koalas on St Bees Island and French Island [9, 12]. Only Kangaroo Island has demonstrated recent absence of *Chlamydia* in koalas using PCR [49].

There are some populations of mainland koalas where scat analysis and absence of clinical disease suggest that *Chlamydia* is either absent or present at very low prevalence; examples include Campbelltown, Kanangra and Mumbulla in NSW [41, 53]. These populations are sometimes referred to as being "*Chlamydia*-free". The circumstances that lead to pockets of low *Chlamydia* prevalence in wild koalas are not well understood. It is likely to reflect a complex combination of factors including geographic isolation, extirpation of infected koalas followed by repopulation with uninfected animals, or a preponderance of *Chlamydia* strains with low pathogenicity.

Chlamydial genotypes (as defined by *ompA*) and sequence types (as defined by MLST) are reasonably distinct in northern and southern koala populations, although a few genotypes occur in both [22]. There appears to be a lower diversity of *C. pecorum* genotypes and sequence types in southern koala populations compared with northern populations [10, 42, 46] which may reflect the restricted genetic provenance of these populations [7, 47]. Differences in sequence types can exist between neighbouring populations within the same region [8], and multiple sequence types can be detected within the same koala population, and also within the same individual from different anatomical sites [12].

Gender bias to the presence of chlamydial infection has not been identified in most studies [1, 3, 48] although one study found that male koalas were 2.7 times more likely to be positive for *C. pecorum* [47]. Although *C. pecorum* infection rates increase with age class in some studies [1, 3], and this is to be expected for a sexually transmitted persistent pathogen such as *C. pecorum*, other studies have not detected statistically significant associations between age and infection status [3, 48].

Prevalence of chlamydial disease

The prevalence of chlamydial disease is variable relative to the prevalence of chlamydial infection and is often lower; chlamydial infection is commonly detected in apparently healthy koalas [1, 48, 54-58]. In some cases these are truly not diseased but, in most cases, disease is not apparent at clinical examination (termed inapparent or subclinical) and is only

identifiable with specialised equipment or via internal or microscopic examination [3, 6, 45, 48, 59]. Depending on the population, many of these individuals will go on to develop disease at a later date; longitudinal data from south-east Qld found that 66% of koalas diagnosed with chlamydial infection via PCR progressed to overt disease within 3-4 years [58].

Both urogenital and ocular disease are reported throughout the koala's range, with urogenital disease more commonly reported in most cases [3, 47, 49, 60-62]. There are recent anecdotal reports that ocular disease is occurring with increasing frequency in some populations in Vic [63]. Although chlamydial disease is generally considered to be less severe in southern populations [3, 47-49], cases of severe disease can still occur [49].

In a Vic study, prevalence of 'wet bottom' ranged from 38-44% in studies of three koala populations and internal sonographic abnormalities were noted in 11-43% of animals [3]. Chlamydial disease appears to be less prevalent in SA populations than in other states, with clinical disease observed in only 4% (3/75) of free-ranging koalas in the Mount Lofty Ranges [64, 65].

Chlamydial disease accounted for 52% of admissions [61] and 59% of post mortem diagnoses [62] in south-east Qld rehabilitation facilities, and 20.4% and 46% of admissions to two NSW rehabilitation facilities [23, 60]. Hospital admissions data are not available for Vic and SA populations but chlamydial disease was present in 63% [48] and 12% [66] of post mortem cases in two SA studies.

Mode of transmission

It is generally accepted that urogenital chlamydial infection is transmitted sexually between koalas [6, 60] as the organism has been found in both the semen of infected males [67, 68] and the urogenital tract of infected females [69]. However, chlamydial disease has been reported in koalas below expected breeding age [1], suggesting that early transmission from infected dams to juveniles may be important. This could occur during pap feeding [6, 45, 70, 71], or through direct contact with the genital epithelium of the infected dam during parturition [72].

Other potential sources of transmission have been proposed but are likely of lesser importance to the epidemiology of the disease in koalas. These include direct transfer of infected discharges from the eyes or urogenital tract, [60, 72], aerosol inhalation [73, 74], and mechanical transfer by arthropod vectors [72, 75].

Incubation period

The incubation period for natural chlamydial infections in koalas is not known but *in vitro* studies using koala isolates have determined a cell cycle of approximately 46 hours for *C. pecorum* [76]. A report of experimental infection undertaken in koalas showed an incubation period of 7-19 days for the onset of ocular disease (conjunctivitis) and 25-27 days for development of cystitis [72, 77].

Persistence of agent

Chlamydia are capable of survival outside of the host under appropriate conditions, despite their obligate intracellular life cycle, which may have implications for potential transmission via fomites. A study undertaken *in vitro* showed that the extracellular elementary bodies could survive drying for two days and remained viable at 18-23°C for up to 28 days [78]. The same study showed *Chlamydia* maintained infectivity for cell culture after three days' exposure on forest red gum (*Eucalyptus tereticornis*) leaves.

Chlamydia pneumoniae survived in aerosols at 15 to 25°C in conditions of high relative humidity for at least five minutes, on various manufactured surfaces for 1-4 hours, and on human skin for up to 30 minutes [79]. *Chlamydia pneumoniae* could also be recovered from hands that had touched contaminated surfaces for up to three minutes [80].

5.1.3 Pathogenesis

Current understanding of the pathogenesis of chlamydiosis in koalas is incomplete, although extrapolation from other species is considered appropriate given the similarities in disease manifestation between koala chlamydiosis and disease in other species [81, 82].

All known members of the *Chlamydiales* share a similar and distinct biphasic life cycle, alternating between the extracellular, infectious elementary body (EB) and the metabolically active, intracellular non-infectious reticulate body (RB) [34]. Following infection, the EB penetrates the target cell, transforms into an RB and undergoes replication within the host cell while enclosed in a host-derived vacuole, or 'inclusion' [36]. The newly-replicated RB transforms back into an EB which is released from the host cell by exocytosis or lysis and is then infectious to other host cells [83].

Both RBs and EBs produce a range of virulence factors which act in a variety of ways to exploit the host cell and evade its defences [83-86]. Infected cells produce inflammatory mediators, and chronic hypersensitivity to chlamydial antigens leads to further tissue damage [39].

Chlamydiae can remain in a non-replicative, "persistent" intracellular state within host cells, evading host immune responses while preserving host cell activities [87]. In this state, *Chlamydiae* can elicit a profound host inflammatory response with immunoglobulin production and fibrosis [81, 88].

A complex interplay of host, pathogen, environmental and immune factors appear to determine the disease outcomes following chlamydial infection [10]. These factors are summarised below.

Pathogen factors

Pathogen species

Chlamydia pecorum is consistently the most pathogenic species of *Chlamydia* that infects koalas and is the primary cause of chlamydial disease in this species [1, 6, 47, 60, 61].

Disease due to *C. pneumoniae* in the absence of *C. pecorum* is very rarely reported [73], although PCR detection of *C. pneumoniae* is not always undertaken, so it may have a role in disease where signs of chlamydiosis are found in animals which are PCR-negative for *C. pecorum* [48].

Several novel *Chlamydia*-like bacteria outside the *Chlamydiaceae* family have been identified in koalas in Qld, NSW and Vic [4, 5, 89]. The potential of these bacteria to cause disease is unclear; they have been found predominantly, but not exclusively, as co-infections with either *C. pecorum* or *C. pneumoniae* and have also been associated with several cases of plasmacytic enteritis where neither *C. pecorum* nor *C. pneumoniae* was detected [5].

Pathogen load

Chlamydial load is a strong predictor of urogenital disease, but not ocular disease [90]. The urogenital load of *C. pecorum* is significantly higher when koalas acquire a new infection, and declines in chronic (>3 months) infections [58, 81], although there may still be a high level of shedding from apparently healthy animals [69, 91]. Progression of urogenital tract disease is significantly associated with an increased chlamydial infection load [58].

Pathogen type

Genetic diversity in *C. pecorum* can exist between neighbouring koala populations within the same region [7, 8] and molecular typing is therefore of potential value in understanding multiple disease emergence events and identifying the risks of pathogen transfer between populations.

A lack of prior exposure to *C. pecorum* (or to a novel *C. pecorum* type) may be associated with increased disease expression [49] although more information is needed to inform what degree of strain difference constitutes a 'novel' type, and whether non-exposed individuals from chlamydia-infected populations have inherited or acquired protection or are as naïve as those from chlamydia-negative populations.

Although studies have identified associations between sequence types or genotypes of *C. pecorum* and disease expression in koalas [8, 10, 45, 47, 58, 90], there is no clear causative evidence that particular strains are more pathogenic than others. A recent study examined chlamydial strain diversity nationally and within three NSW koala hospital catchments (Port Stephens, Port Macquarie and Northern Rivers Region). All samples, regardless of geographic location, contained genes associated with virulence in cattle isolates [92, 93].

The potential for differing pathogenicity exists, given that *Chlamydia pecorum* genotypes or sequence types vary in the expression of known virulence-associated factors, including chlamydial cytotoxin genes, effector proteins and chlamydial virulence plasmid [84, 94, 95]. There is some evidence for variation in pathogenesis for *C. pecorum* in cattle [29, 30] and *C. trachomatis* in humans [96].

Host factors

Host signalment

The effect of koala age and gender on chlamydial disease expression is equivocal [23].

A longitudinal study of 38 free-ranging, *Chlamydia* positive koalas in Qld demonstrated no age or sex influence on progression to disease [58], and neither age nor sex were predictors of clinical disease in a modelling study involving 204 free-ranging Qld koalas [90]. Another study found no association between sex and *Chlamydia* infection, however probability of infection increased with age and infection rates were higher in the breeding season, compared to the non-breeding season [44]. Female koalas and aged koalas are overrepresented in post mortem and hospital admission studies of chlamydial disease [23, 48, 60], but this may reflect other biases in data (such as the relative ease of detection of reproductive disease in female koalas compared with males [97, 98]) rather than an intrinsic influence of age or gender in the tendency to develop disease [60].

Low body condition is more commonly encountered in rehabilitation cases admitted for chlamydiosis than other causes such as trauma [23]. It is unclear whether this indicates an increased susceptibility to chlamydial disease in animals with a low body condition, or whether urogenital chlamydial disease is an inciting cause for loss of condition.

Host immune response

An effective anti-chlamydial host response involves a combination of cell-mediated immunity, humoral immunity and cellular inflammatory responses [10, 99, 100]. The balance of immune responses may be a mechanism through which environmental and genetic factors drive chlamydial pathogenicity in koalas [81] but the nature (and relevance) of this balance is not well understood. Koalas with more severe chlamydial disease show increased expression of certain cytokines [101] and high titres of anti hsp60 IgG are associated with chronic infection and fibrosis [81].

Immunogenetics

Studies have identified associations between particular immune genes and susceptibility to chlamydial disease. Chlamydial antigen is detected and presented to the immune system via major histocompatibility complex (MHC) molecules, and some association of MHC genotype with disease expression has been observed [10, 102, 103]. Koalas capable of resolving a *C. pecorum* infection without medical intervention contained variants in a number of immune genes (MHC, toll-like receptor and gamma interferon) when compared to koalas which were unable to resolve infection [100]. Genetic studies found evidence for heritable genetic variation in susceptibility to chlamydial disease in koalas [44]. The role of immunogenetics in chlamydial disease progression and resolution is likely to be influenced by the interaction between particular host and chlamydial genotypes (and potentially other host traits) rather than genetic diversity alone [10].

Site of infection

The ability of a koala to resolve a chlamydial infection may vary with anatomical site of infection. Urogenital tract infections had a 13% likelihood and ocular infections an 85% likelihood of resolution in one longitudinal study [58].

Other urogenital microflora

Koalas with high loads of *C. pecorum* had a lower microbiota diversity at ocular and urogenital sites, dominated by different bacterial species than those seen in koalas with a low or negative chlamydial infectious load [104], though it is not clear whether the changes caused or resulted from infection and inflammation.

Co-infections

The role of host co-infections in *Chlamydia* pathogenesis is discussed below in *Associations with other disease hazards of koalas.*

Environmental factors

The effect of external environment on the development of chlamydial disease is complex and is likely to reflect a range of co-factors operating over different scales of time [90, 105]. In one study, habitat reduction and increasing urbanisation were associated with an increase in the prevalence of chlamydial infection, following a 3 to 4 year time lag, possibly reflecting associated increases in physiological stress, contact rates, sexual encounters and territorial behaviour [105]. However, koalas in high quality habitat may also demonstrate a high prevalence of chlamydial infection [105]. The relative probability of admission of koalas with clinical signs of chlamydiosis did not change over 30 years in one study, in spite of local urbanisation [60]. Increased level and proximity of human disturbance is postulated to increase chlamydial disease expression [54, 55], but this is not a consistent finding [90].

The role of stress in chlamydial disease expression in koalas is difficult to quantify, and direct studies are lacking [21, 22], but stress and malnutrition have been implicated in exacerbating chlamydial disease in several other species [106-108]. A variety of environmental stressors could affect the prevalence of overt chlamydial disease in individual koala populations, including overcrowding, declining food resources and extremes of weather [55, 109-111].

5.1.4 Associations with other disease hazards of koalas

Many studies have identified associations (but not causation) between aspects of chlamydial infection or disease and a range of co-infections and disease states [51, 56, 90, 111-117].

Currently there is no clear causative evidence of KoRV inducing more severe chlamydial disease in koalas, although associations between chlamydial disease severity and increased KoRV proviral or viral load have been identified in a number of studies [65, 92, 118-121]. Detection of certain KoRV variants has been associated with more severe chlamydial disease

in Qld koalas [56, 90, 112, 121]. Presence of replication-competent KoRV in Vic koalas was associated with "wet bottom" [120] and a decrease in gamma interferon IFNγ and interleukin production, which could render koalas more susceptible to developing chlamydiosis [113]. It may be that chlamydial disease leads to increases in KoRV load, rather than the other way round, since koala lymphocytes that are stimulated by inflammation are likely to increase circulating KoRV viral and proviral loads [122]. However, a recent study found that KoRV B prevalence was higher in koalas with clinical chlamydiosis (69%) compared to the overall cohort (31%), and that KoRV transcription did not appear to change significantly during treatment for chlamydiosis. This suggests that KoRV status may drive chlamydial disease, rather than resulting from it, but more work is needed to explore this hypothesis [92].

The presence of koala gammaherpesviruses (PhaHV-1 and PhaHV-2) has been associated with infection with *C. pecorum* in both male and female koalas in Vic, NSW and Qld [92, 114, 115]. An association between reproductive disease caused by *C. pecorum* and PhaHV co-infection has been detected in SA koalas [51]. In co-infected koalas, a reduction in PhaHV-1 shedding was seen following chlamydial treatment, suggesting that PhaHV-1 shedding may be influenced by chlamydial disease status [92]. See *Appendix 5.12 Phascolarctid Herpesviruses – Literature Review* for further discussion.

Chlamydial disease is likely to be exacerbated by opportunistic infections from a range of microbes, including Gram-positive cocci, rods and curved rods; Gram-negative rods, filamentous bacteria and yeasts [37, 91, 111, 116].

5.1.5 Diagnosis

Chlamydial infection may be non-pathogenic, or it may cause disease which can be further classified as 'overt' (clinical) or 'inapparent' (subclinical) [6]. In non-pathogenic infection there are no signs of disease [1, 49]. Overt disease denotes the presence of obvious external clinical signs, while inapparent disease can only be detected using specialist equipment or internal examination [22]. Studies suggest that in koalas inapparent chlamydial disease is commonly misdiagnosed as non-pathogenic infection [45, 48].

Clinical signs

The three main clinical presentations of chlamydiosis are ocular disease, urinary tract disease and reproductive disease, although other manifestations are occasionally seen.

Ocular disease [6, 39, 69, 123] manifests as serous ocular discharge, blepharospasm and conjunctival/scleral hyperaemia in the acute phase, progressing to mucopurulent discharge, conjunctival lymphoid hyperplasia and hyperaemia, sometimes with keratitis and corneal scarring in the chronic-active phase. The chronic inactive phase signifies end-stage ocular disease and is characterised by extensive conjunctival hyperplasia, minimal erythema and mature scarring in the absence of exudate (unless deformity of the eye or nasolacrimal duct occlusion predispose to bacterial infection). Blindness may ensue as a result of chronic

corneal damage or conjunctival hyperplasia; severe ophthalmitis and globe rupture have been reported. Disease may be unilateral or bilateral. Figure 22 shows severe ocular disease in a koala with chlamydiosis.

Figure 22 Image of a koala with severe conjunctivitis as a result of chlamydiosis (credit: Amber Gillet)

Urinary tract disease [59, 69, 82, 91, 124, 125] manifests as frequent and occasionally painful urination and haematuria and pyuria associated with cystitis and subsequent fibrosis. Affected animals develop "wet bottom", a common (but not pathognomonic) finding of urogenital chlamydiosis which refers to the brownish staining and wet fur around the cloaca and rump due to constant wetting with urine. Infection may ascend to cause pyelonephritis and renal fibrosis.

Reproductive tract disease may be inapparent, with reduced fertility of both male and female koalas as the only indicator [5, 6, 48, 49], although granulomatous orchitis in males may present with palpable changes to the testis or epididymis [126]. In females, fibrotic occlusion commonly leads to the development of unilateral or bilateral, fluid-filled para-ovarian (bursal) cysts in the caudal abdomen or pelvic inlet [91, 124], which may be palpable or detectable by ultrasound [59] dorsal to the epipubic bones in anaesthetised females [37]. Endometritis, pyometra, and vaginitis may also occur [65].

Occasional atypical presentations of chlamydiosis occur. Two outbreaks of rhinitis characterised by dyspnoea, coughing, sneezing and a serous to purulent nasal discharge have been attributed to chlamydial infection [37, 73]; in one of these episodes, *C. pneumoniae* infection was present without concurrent *C. pecorum* infection [73]. Some of these cases also demonstrated acute shifting lameness, epidermal ulceration at pressure points and swelling of the hands and feet, possibly associated with polyarthritis [37, 73]. A joey which developed *C. pecorum*- associated pneumonia presented with a cough and audible respiratory noises [74]. Arthritis associated with *C. pecorum* has also been described [127].

There is only circumstantial evidence linking infection by novel *Chlamydia*-like organisms to clinical disease, although post-mortem pathology has been reported [4, 5].

Clinical pathology

There are no consistent haematological or biochemical abnormalities associated with chlamydiosis. Leukocyte counts are often within normal range, although neutrophilia is also common [128]. Debilitated koalas may exhibit a non-regenerative anaemia, hypoproteinaemia and evidence of dehydration. If renal disease is present then urine specific gravity is often lowered and blood urea nitrogen and creatinine values may be elevated [129, 130]. If cystitis is present, urinalysis may demonstrate a range of abnormalities which may occur individually or together, including presence of erythrocytes, leukocytes, bacteria, yeasts, epithelial cells, and occasional renal tubular casts [37].

Pathology

The pathology of chlamydiosis in koalas is characterised by inflammation of mucosal tissues, progressing to fibrosis and scarring with chronicity [91, 124].

Ocular pathology presents histologically as acute active conjunctivitis, chronic active conjunctivitis, or chronic inactive keratoconjunctivitis. Affected koalas may have an accumulation of predominantly plasma cells and neutrophils along with villous hypertrophy and hyperplasia of the conjunctival epithelium, and corneal vascularisation [82, 131].

Urinary tract pathology involves the kidneys, bladder and urethra in both sexes. Cystitis is characterised by mucosal hyperplasia, degeneration and hydropic change of the epithelium with mixed inflammatory cells and fibrosis of the lamina propria and submucosa, which can lead to hydroureter and hydronephron. Severely affected bladders display polypoid hyperplasia and hypertrophy [82, 91, 131]. Renal changes include tubular dilatation and degeneration, protein cast formation and focal to widespread pyelitis or pyelonephritis with mixed inflammatory cell infiltrates and fibrosis [91]. Chronic cases may develop an inactive cystitis with marked bladder wall thickening in the absence of pyuria [82, 91].

Male koalas with reproductive pathology commonly develop prostatitis with degeneration of the glandular epithelium, large accumulations of necrotic debris, inflammatory cells in the ducts and gland parenchyma and fibrosis of the lamina propria and submucosa of the prostatic urethra [131]. Granulomatous orchitis and epididymitis with interstitial fibrosis have been described [125]; involvement of the bulbourethral glands, testes, vas deferens and epididymis is less common [43]. Affected koalas have an increased incidence of sperm fragmentation and abnormal sperm morphology [132, 133].

Female koalas have evidence of vaginitis, cervicitis, metritis, salpingitis and ovarian diverticulitis, all characterised by a mixed inflammatory infiltrate. More chronic cases demonstrate squamous metaplasia of the uterine tubes, cystic dilation and destruction of uterine glands, submucosal fibrosis, and thickening and distortion of the walls of the genitalia. There may be fibrous adhesions between the ovaries and bursal walls. Para-

ovarian cyst formation in the ovarian bursae is commonly encountered and may be unilateral or bilateral. Chlamydial inclusions may be present in epithelial cells in all parts of the reproductive tract as well as in submucosal macrophages [91, 124].

Infection with novel uncultured *Chlamydiales* has been seen in association with plasmacytic enteritis at necropsy, but their aetiological role remains speculative [5].

Differential diagnosis

Signs of ocular disease such as blepharospasm, discharge, hyperaemia and conjunctival swelling can be associated with trauma, exposure to environmental irritants, or other bacterial or fungal infections [37]. However, chronic chlamydial conjunctivitis is characterised by proliferative hyperplasia of the conjunctiva and nictitating membrane which is not commonly seen in ocular disease due to other aetiologies. Keratitis has been observed in *Chlamydia* seronegative koalas on Magnetic Island [37] and St Bees Island [128] which was speculated to be related to exposure to external environmental agents such as insect bites. [48].

While koalas with 'wet bottom' are frequently assumed to have chlamydiosis, the syndrome has been seen in the absence of *Chlamydia* [3, 134], although it should also be noted that it may be difficult to detect chlamydial inclusions in chronic chlamydial disease cases [82, 91].

Nephrosis and nephritis of non-chlamydial origin may be associated with oxalate deposition [135]. *Mycoplasma* spp. and *Ureaplasma* spp. can elicit ocular, urogenital and respiratory disease similar in presentation to chlamydiosis [136]. Recently, PhaHV has been implicated in reproductive disease in female SA koalas [51].

Diagnostic testing

Definitive diagnosis of a chlamydial aetiology for disease is complicated because diseased hosts do not always shed *Chlamydia* organisms, and organisms may be shed by infected hosts in the absence of disease [6]. Reasonable certainty of diagnosis is best achieved by combining sensitive PCR-based detection techniques with a thorough veterinary examination, which includes diagnostic aids such as urinalysis and ultrasound evaluation to detect inapparent disease [6, 39, 48, 59].

Detection of Chlamydia

Molecular detection of *Chlamydia* in koalas is important for the detection of subclinical cases (which may be the most amenable to treatment), for confirming presumptive cases when clinical signs are present and for confirming resolution of shedding following treatment and before release [137].

The preferred chlamydial detection method is PCR testing of ocular and urogenital swabs [39]. PCR testing is highly specific and sensitive, and is capable of detecting subclinical infection. A range of PCR methodologies are used by different diagnostic laboratories [136]. However, there are practical limitations to the use of PCR, as it must be conducted in a

laboratory and may be considered cost prohibitive. Using the correct swabbing technique and correct swab types is also important to consistency and accuracy of PCR testing [138].

The most widely used technology currently in use for point-of-care detection of *C. pecorum* is loop mediated isothermal amplification ("LAMP") DNA amplification. LAMP assays, which are rapid and sufficiently robust for field use [139-141], are now widely used in koala rehabilitation and hospital facilities in Qld and NSW for detection of *C. pecorum* [128]. However, commercially-available LAMP assays do not allow re-use of samples, testing can be expensive, and false negative results are reasonably common, based on anecdotal reports [142].

Detection of chlamydial shedding via PCR-testing of scats is being employed as a non-invasive means of evaluating chlamydia status of free-ranging koalas [46, 143, 144]. Further validation of these methods is required to improve and quantify sensitivity, and at this stage it is not possible to separate active disease from subclinical carrier status on the basis of scat analysis alone.

Diagnostic ultrasound

Sonography is an effective method of detecting and grading the severity of chlamydial urogenital disease in both sexes, and consequently ultrasound evaluation is becoming part of the routine clinical assessment in many koala hospitals [37]. Sonographic changes commonly encountered with chlamydiosis include measurable bladder wall thickening (reflecting cystitis), and the presence of unilateral or bilateral fluid-filled paraovarian cysts in the caudal abdomen or pelvic inlet in females [37, 39, 59]. Sonographic changes in the prostate of males may be seen but are less commonly encountered [39].

Serological testing

Serology is no longer used as a diagnostic screening tool for chlamydia in koalas. A koala-specific ELISA was in use for many years in Australia but is no longer available [37]. Complement fixation tests used in the past were shown to have a sensitivity of only 7%, in addition to which detectable CF antibodies took at least 3-4 months to develop in *Chlamydiae*-naïve koalas [37].

Immunohistochemistry

Immunohistochemistry for chlamydial antigens can be used to assist in localising *Chlamydiaceae* within formalin-fixed material [91] but its sensitivity as a diagnostic tool is impacted by the condition of the mucosal epithelial cells and the variable impacts of formalin fixation.

Surveillance and monitoring

There is no targeted national surveillance or monitoring program in place for *Chlamydia* in koalas, although there is capacity to utilise the Wildlife Health Australia national wildlife

health information system database (eWHIS) as a place for collating these data as part of national general wildlife surveillance activities.

Local population surveillance programs are undertaken for *Chlamydia* in koalas throughout their range, at various times, and generally in association with other koala monitoring activities. For example, the SA Department for Environment and Water (DEW) koala program undertook surveillance for ocular and urogenital disease as part of a regular sterilisation program to control koala numbers on Kangaroo Island for several years [49]. However, such programs are reliant on engagement by particular research groups and screening is not necessarily part of project planning from the outset, which can limit the effectiveness of the surveillance effort.

5.1.6 Treatment

The decision to treat koalas with chlamydiosis is based on considerations of animal welfare and prognosis for eliminating the infection. For wild animals, the potential welfare impacts of prolonged hospitalisation must be balanced against the prospects for release. Animals with co-morbidities, such as other chronic diseases, advanced tooth wear or poor body condition are unlikely to be suitable treatment candidates [39]. It may also be necessary to consider the breeding prospects of koalas which have had reproductive tract infections when evaluating suitability for release [60, 145]. The welfare considerations for captive animals are similar to wild animals, although they may be better habituated to human intervention. Biosecurity risks for conspecifics must also be considered in the captive situation [146].

Treatment for chlamydiosis involves antibiotic therapy in combination with various adjunctive treatments as outlined below.

Systemic antibiotic therapy

Antibiotic treatment of chlamydiosis is complicated by i) the chronicity of disease in many presenting cases, which may make them refractory to antibiotic treatment; ii) the risk of antibiotic-induced gut dysbiosis leading to opportunistic infections (particularly candidiasis) and potentially fatal effects on the koala's digestive physiology; iii) koalas' efficient metabolic pathways for excretion, which may increase the rate of elimination of drugs; and iv) risk of antibiotic resistance development [147-149].

The ideal antibiotic for treating koalas not only requires a favourable microbial cure rate with minimal adverse effects, but must also be practical for use in wild animals in the rehabilitation environment, i.e. readily available and inexpensive, not cause injection discomfort, be deliverable in small volumes by either subcutaneous or intramuscular injection, and require infrequent dosing [147].

Chloramphenicol has been the drug of choice for chlamydiosis in koalas in recent years, administered as an injectable agent to treat systemic chlamydiosis and also as a topical preparation to treat ocular cases [39]. The recent withdrawal of chloramphenicol from

commercial sales in Australia [150], along with some treatment failures [151] and the potential for serious side effects [152] prompted the search for alternatives. Florfenicol, a synthetic analogue of chloramphenicol, demonstrated equivocal efficacy, plasma concentrations below the minimum inhibitory concentration (MIC) for *C. pecorum,* and adverse dysbiosis effects [153]. Fluoroquinolones (enrofloxacin and marbofloxacin) are often used to treat chlamydiosis due to their perceived safety and anecdotal effectiveness [154]. However, re-emergence of infection after treatment is common [155], and based on pharmacokinetic studies fluoroquinolones are unlikely to reach therapeutic levels via oral or subcutaneous administration at the doses generally given [156], which increases the risk of antimicrobial resistance development.

In a recent clinical comparison of five antibiotics in the treatment of koala chlamydiosis, doxycycline had the best treatment success, with a 97% cure rate compared with 81% for chloramphenicol, 75% for enrofloxacin, 66% for florfenicol and 25% for azithromycin. Doxycycline had the advantage of requiring weekly, rather than daily, administration, although it caused irritation at the site of injection, which was reduced by dilution of the drug prior to administration [147]. Anecdotally, doxycycline therapy appears more likely to cause serious gut dysbiosis, and less likely to resolve serious disease, than chloramphenicol, consequently chloramphenicol remains the drug of choice for treating chlamydiosis in koalas [39, 128].

Controlled trials have yet to be conducted to determine the optimum duration of treatment to ensure microbial cure. As a general rule, treatment for 28 days is undertaken for koalas with overt clinical disease [39], but trials in rehabilitation facilities are ongoing to establish the efficacy of shorter (14 day) treatment periods [128]. There is a need to balance the benefits of shorter treatment durations in reducing time in rehabilitation against the risks of encouraging the development of antibiotic resistance by insufficient treatment [157].

The perceived efficacy of antibiotic treatment in curing chlamydial infection may depend on the extent of post-treatment testing used to confirm treatment success, as well as the *Chlamydia* status of the population the koala is released to. If koalas are released back into an area with high *Chlamydia* prevalence, they may be likely to become re-infected [145] which may be perceived as a failure of treatment.

Treatment of ocular disease

Where ocular disease is present, topical ophthalmic antibiotics may be used in combination with systemic treatment. There is little evidence-based data for the relative efficacy of topical treatments for ocular chlamydiosis [137], although including an anti-inflammatory component anecdotally results in the greatest clinical benefit to affected animals [128]. Therapeutic approach varies between rehabilitation facilities and topical preparations which have been used include dexamethasone, chloramphenicol plus hydrocortisone, oxytetracycline plus polymyxin B sulphate, ofloxacin, oxytetracycline HCl plus oleandomycin phosphate plus neomycin sulphate [37, 128].

Many koalas with ocular disease develop persistent exudative build-up, and benefit from flushing of the nasolacrimal ducts [39]. Surgical intervention to remove proliferative conjunctiva is only warranted if the tissue impairs vision at the completion of medical treatment.

Adjunctive treatments

Specialised nursing care, excellent nutritional support and prevention, early detection and treatment of iatrogenic conditions (related to the stress of treatment and antibiotic therapy), are important for positive long-term clinical outcomes for koalas being treated for chlamydiosis [137, 148].

Oral analgesics and anti-inflammatories have been used to treat pain, inflammation and fibrosis associated with chlamydial disease and are essential to treatment success in chronic cases [128].

Koalas surviving antibiotic treatment were shown to have a greater diversity of faecal bacteria than those that died, and a greater abundance of the tannin-degrading *Lonepinella koalarum* [158]. The administration of koala faecal matter or caecal contents to mitigate the risk of dysbiosis is commonly suggested [137, 147, 148] but controlled studies evaluating the efficacy of this treatment are lacking. A study in which faecal microbiome is administered orally to koalas using enteric-coated tablets (to bypass gastric acids) is in progress [159].

Vaccination is showing promise as an adjunctive therapy for reducing the severity of clinical signs [160] – see *Prevention and Control.*

Bilateral chronic structural change in the female reproductive tract is invariably associated with permanent infertility, persistence and progression of inflammation, fibrous adhesions and pain. Ovariohysterectomy is an effective and beneficial treatment for these cases from a welfare perspective [148]. However, not all animals are suitable candidates for surgery: individuals of advanced age, or with associated chronic disease or poor body condition are not suitable candidates for surgery. Furthermore, the future release and holding options for a surgically sterilised animal should be explored within the jurisdiction before surgery is entered into [39].

A plethora of treatments which are not supported by evidence or have no known role in treating chlamydiosis in any species have been incorporated into treatment regimens in the past [137]. All untested ancillary treatments have the potential to do harm, both by increasing stress and by exposing animals to products of unknown safety [137]. Consequently, unsystematic, uncontrolled experimentation with treatments should be avoided.

5.1.7 Prevention and control

Free-ranging populations

Determining the best approach to control and prevention of *Chlamydia* in free-ranging populations is challenging due to the multitude of factors which affect the pathogenesis of chlamydial infection in koalas. There are no standard, nationally-accepted biosecurity and testing requirements for *Chlamydia* in koalas; consequently, organised programs for prevention or control of *Chlamydia* in free-ranging koalas are largely experimental and tend to be localised in approach.

The control of *Chlamydia* in free-ranging populations where clinical disease is prevalent may involve capture of clinically affected animals and transfer to rehabilitation facilities for assessment, treatment or euthanasia, depending on the severity of clinical signs. This can be a resource-intensive but effective tool for reversing population decline in defined populations [17, 148]. Modelling suggests that treatment of individual free-ranging koalas with chlamydiosis can have a significant impact in reversing population declines over a number of years [17]. While antibiotics provide no protection against reinfection [58], treatment of individual koalas may be sufficient, within a coordinated program, to re-establish population growth if other threats are also controlled [17]. A safe and effective vaccine may also be a useful tool in reducing population declines in certain circumstances (see *Vaccination* below).

Given the likely impacts of other stressors, including land management practices, on chlamydial pathogenesis (see *Pathogenesis*), support of good general health of free-ranging populations is an important consideration for controlling the impact of *Chlamydia*. Retention of connected, protected habitat which provides for the nutritional and shelter needs of koalas and reduces their exposure to other threatening processes is likely to promote the capacity of populations to resist the detrimental effects of *Chlamydia*.

Managers of populations that are thought to be *Chlamydia*-free, or which have a very low prevalence of *Chlamydia*, may restrict koala movements to prevent the introduction of diseased individuals into the population [64]. Restrictions should be based on robust evidence of the current *Chlamydia* status of the population. Protocols should consider all entry pathways for disease (including potentially contaminated equipment) and use robust and systematic *Chlamydia* testing methods to screen incoming animals [161].

Translocation might also increase the risk of expression of chlamydial disease through stress-related changes to immune function [105]. In populations where *Chlamydia* is present, avoiding the introduction of novel *Chlamydia* genotypes should be a consideration [3], given recent studies have shown significant geographic diversity of strains even at the local management scale [86]. There remains a need for increased understanding of the differences in disease outcomes due to varying strains. Ongoing advances in diagnostic technology will help to inform decision-making (see *Pathogenesis)*.

Rehabilitation populations

The limited availability of reliable and cost-effective point-of-care diagnostic testing and the lack of standardised biosecurity and testing requirements for *Chlamydia* pose challenges for management of risk in the rehabilitation setting.

Disinfection protocols have not been standardised for koala care facilities in Australia. Guidelines for disinfection of *C. psittaci* exist for avian enclosures and equipment [162], but these do not extend to *C. pecorum* and do not include the types of equipment used in koala care, such as towels and natural bark-covered timber perches. Contamination of the koala's environment by chlamydial organisms has recently been evaluated and this information provides a basis for development of in-house programs to monitor contamination and evaluate biosecurity practices for koalas in care, and in captive facilities [163].

Both general and specific biosecurity principles are important to preventing the spread of *Chlamydia* within rehabilitation facilities [146, 163]. These include excellent facility hygiene, barrier hygiene between animals of different disease status, undertaking health evaluation (preferably with diagnostic testing to detect *Chlamydia*) to identify animals with chlamydiosis on admission, and a rigorous, standardised treatment protocol for chlamydiosis if treatment is indicated.

Decontamination practices (physical removal of organic materials through washing and scrubbing; followed by chemical disinfection) have been shown to significantly reduce both chlamydial loads and pathogen viability in the rehabilitation setting, however they cannot be assumed to completely remove the presence of infective chlamydial organisms. Segregation of animals, staff and equipment is also necessary [163].

Important practices for preventing transmission of *Chlamydia* (and other pathogens) from rehabilitation facilities to free-ranging koalas include isolating animals from different locations while in care, preventing cross-contamination through appropriate decontamination, disinfection, personal protective equipment and equipment use practices and releasing rehabilitated individuals at their location of origin [146, 163]. These practices will also reduce the risk of the dissemination of novel *Chlamydia* genotypes.

Captive populations

Koala management in captive populations is generally oriented towards individual animals. Many Australian zoos and wildlife parks aim to maintain *Chlamydia*-negative captive populations of koalas. The objective is to prevent new acquisitions bringing *Chlamydia* into their collections through stringent biosecurity practices, quarantine and diagnostic testing during isolation. Routine testing of existing captive koala populations may also be undertaken.

Although nationally-accepted biosecurity and testing requirements for *Chlamydia* in koalas are lacking, many institutions will have their own (often comprehensive) protocols. A quarantine period of 45 days is commonly used for koalas entering a *Chlamydia*-free captive

institution; this duration appears to be derived from quarantine regimes used for *C. psittaci* in birds. Incoming animals will commonly be sampled for PCR testing on one or two occasions during the quarantine period. Koalas being moved to other *Chlamydia*-free captive institutions will commonly receive a physical examination and PCR testing prior to shipment. Australian regulations stipulate that koalas intended for export from Australia are tested twice via PCR, with negative results, no less than 21 days apart within a 45 day pre-export isolation period [164].

The response to the detection of *Chlamydia* infection in captive koalas will vary from institution to institution, but may include isolation, systemic antibiotic treatment and follow-up diagnostic testing [37]. Environmental decontamination and disinfection should also be undertaken [72, 163].

Vaccination

Development of a vaccine for *C. pecorum* in koalas has been a prominent focus of chlamydial research, with many vaccination trials having been undertaken over the last 15 years [160, 165-175]. Critical comparison of vaccine trials is limited by the absence of placebo groups in many studies and the diversity of *C. pecorum* antigens, adjuvants and dose regimens which have been used. The development of a safe, effective, widely-available vaccine has the potential to deliver positive impacts to koala health. Possible benefits of vaccination that have been suggested by research include:

- reducing chlamydial load or clearing infection in infected koalas [168, 172].
- reducing severity or prevalence of disease in infected koalas, which may in turn reduce need for antibiotic therapy [160, 172].
- reducing the number and proportion of healthy infected koalas that progress to disease [172].
- conferring a level of ongoing immunity to joeys of vaccinated dams [71].
- enhancing the koala's immune function and improving ability to fight off other infections [176].

Modelling of south-east Qld populations indicated that a vaccine with 75% protective efficacy could be a useful tool in reversing current population declines in that region if a vaccination program covering approximately 10% of the population per year, and targeting young females was used [177].

5.2 Koala Retrovirus – Literature Review

5.2.1 Technical information

Aetiological agent

Family: *Retroviridae*; genus: Gammaretrovirus; species: koala retrovirus (KoRV).

Retroviruses are RNA viruses [1] which replicate by reverse transcribing their RNA genomes to make DNA copies of themselves (proviruses) which integrate into the host cell's genome. If these proviruses are incorporated into germ cell lines (i.e. egg and sperm cells), they become a permanent part of the host's germ line DNA, passed on to the next generation of the host through Mendelian inheritance [2]. A retrovirus inherited in this way is known as an "endogenous" retrovirus. A retrovirus that integrates into the genome of somatic (non-reproductive) cells, rather than germ cells, and is not inherited by the next generation, is termed "exogenous". Koala retrovirus (KoRV) is a relatively young retrovirus which exists in both endogenous and exogenous forms [3, 4].

The complete KoRV genome consists of three genes: *gag*, *pro-pol* (often referred to as *pol*) and *env*. There are twelve identified variants or subtypes of KoRV denoted as KoRV-A to KoRV-M (KoRV-J has been reclassified as KoRV-B), based around phylogenetic groupings of the *env* gene. KoRV-A has the full KoRV gene complement, exists as both an endogenous and exogenous virus, and is thought to be the endogenous virus from which other variants have arisen [5, 6]. Variants other than KoRV-A are thought to be only exogenous. Some exogenous variants lack the full KoRV gene complement, and most are incapable of replication [5, 7-10].

In addition to the variants of KoRV based on the *env* gene, defective (presumably endogenous) retroviral elements, known as recKoRV (recombinant KoRV) occur in koalas throughout their range. RecKoRV elements lack the complete KoRV gene complement and are non-replicating [5, 7, 11].

Listing

KoRV is not a WOAH listed disease [12].

KoRV is not a notifiable animal disease in Australia [13].

KoRV-associated disease has not been identified as a key threatening process under the Environment Protection and Biodiversity Conservation Act [14].

5.2.2 Epidemiology

To understand the complexities of KoRV epidemiology, it is necessary to have some understanding of the endogenisation processes of retroviruses in general, and KoRV in particular. New discoveries are constantly refining this understanding and the reader is encouraged to refer to current publications for the most up-to-date information.

Most endogenous retroviruses within mammalian DNA derive from infections that occurred millions of years ago; these retroviruses have since become "fixed" in their integration sites and consequently are found in most individuals in a population in the same location within the host genome. Many of these ancient retroviruses degrade into "junk DNA"; 8% of the human genome consists of such retrovirus-like elements [15]. In contrast, KoRV-A is a relatively young endogenous retrovirus, which probably initially became incorporated into the koala genome less than 50,000 years ago [3, 4], and is still undergoing transition from an active, newly endogenised retrovirus into a genomically-fixed entity. Consequently, endogenous KoRV-A retains many of the pathogenic features more commonly associated with exogenous retroviruses, including the ability to replicate and produce infectious virus [16, 17]. The endogenisation process is an ongoing conflict between the virus and the host, with provirus repeatedly integrating into the host genome, and causing further host genetic mutations in the process [15]. Research continues into the epidemiological and pathological implications of the ongoing KoRV endogenisation process, with new information continually coming to light.

KoRV-A is present in all individuals that test positive for KoRV and exists in both exogenous and endogenous forms [11]. Other KoRV variants have only been found in koalas that also harbour KoRV-A [6, 9, 18, 19] and they appear not be endogenous only, based on their high genetic diversity, inconsistent detection within koala family groups and relatively low numbers of proviral copies per cell in infected animals [20-22].

Based on *pol* PCR, proviral loads of competent KoRV (which possesses *pol*) are much higher in northern than southern koala populations, with proviral integrations of 165 copies per cell reported in Qld koalas compared with 1 copy per 10,000 cells in some Vic populations [17]. This indicates that KoRV-A endogenisation is more advanced in northern populations then southern populations since copy numbers above 1 per cell suggest that the infection is being inherited rather than transmitted [23].

Testing of koalas for the presence of KoRV has predominantly focused on a conserved region of the *pol* gene [24]. However, studies have identified *pol*-negative, non-replicative, presumably endogenous recKoRV in Vic and SA koalas [11, 25] which are distinct from similar recKoRV versions in northern populations [5, 7], and would have been identified as KoRV negative using *pol* gene PCR. Most notably, recKoRV was found in koala from the population on French Island, from which virtually all southern koala populations are derived. Consequently, it is possible that all southern koalas have recKoRV in their genome. If this is the case, it may be misleading to label these koalas as "KoRV-free" or "KoRV-negative". In recognition of this distinction, for the purposes of this report, the term "*pol*-negative" will be used to refer to koalas which carry recKoRV elements only, *"pol*-positive" will be used for koalas whose genome contains replication-competent KoRV containing the full genome complement, and "*pol* KoRV" will be used to denote KoRV virus that is complete and replication competent.

The presence of recKoRV, in the absence of endogenized *pol* KoRV, has led to speculation on the endogenisation history of KoRV in southern koalas [11]. RecKoRV elements are not replication-competent and are unlikely to have integrated into the genome of southern koalas by themselves. Their presence suggests that southern koalas have historically been exposed to a replication-competent form of KoRV which enabled recKoRV to be "carried" into their genome. It is possible that the host alleles which historically contained replication-competent KoRV never integrated endogenously in southern koalas, or that they were lost from the host genome due to the well-documented genetic bottlenecks which occurred in southern populations [11]. It is also possible that other endogenous viral elements were involved in recKoRV becoming ubiquitous in southern koalas in the absence of endogenised KoRV [25]. Further investigations of southern koalas are required to test these hypotheses.

Host range

Koala retrovirus is host-specific to koalas and has not been shown to transmit to other species *in vivo* [26]. Although several KoRV variants are capable of *in vitro* infection of cells of many different host species, including humans [20, 27-32], this probably reflects the ubiquitous nature of the host cell transporters used for viral entry [20, 27-31].

Retroviruses related to KoRV are found in flying-foxes, *Melomys* rodents and gibbons [33-36]. It appears most likely that KoRV originated via cross-species transmission from a melomid Australo-Papuan rodent [37]. Spillover of KoRV's closest relative, the exogenous gibbon ape leukaemia virus, to endogenised forms in *Melomys* rodents, has occurred [34, 38]. These findings suggest the possibility for trans-species infections with KoRV, although KoRV appears to be substantially less infectious than gibbon ape leukaemia virus, based on *in vitro* studies [20, 39].

Zoonotic potential

The low zoonotic potential of other simple gammaretroviruses, such as feline leukaemia virus (FeLV) [26], suggests KoRV is unlikely to be zoonotic. However, further assessment of routes of transmission, mutation rates and replication ability in human cells as well as interaction with human viral restriction factors are needed to fully assess the zoonotic potential of KoRV [26, 40].

Geographic distribution

KoRV (or recKoRV elements) are present in all free-ranging koala populations that have been tested in Australia [11, 41-44]. Studies of KoRV in museum koala skins confirm that it was ubiquitous in northern Australia by the late 19th century [3, 22]. The variants (KoRV-A through -M) differ in distribution throughout the geographical range of koalas [6, 16, 24, 25, 29, 30, 41, 45-48]. KoRV and most of the variants are also present in many captive populations throughout the world, where they have been the subject of extensive study [29, 30, 32, 45, 49-52].

Prevalence

Based on presence of full viral sequence (including *pol*) in both proviral and viral forms, koalas from northern populations exhibit 100% prevalence of replication-competent KoRV [31]. Replication competent KoRV (*pol* KoRV) is much less prevalent in southern populations and only appears to exist in exogenous form, however endogenous *pol*-negative recKoRV variants have been discovered recently and appear to be widespread [9, 16, 41, 43, 44, 46, 53], with all koalas in southern populations hypothesised to possess recKoRV [11, 31], and with similar, but distinct, versions existing in northern populations.

Table 14 summarises KoRV prevalence reports, based on *pol* detection, in Australia, 2012 to 2022. KoRV was first confirmed at 100% prevalence in Qld in 2006 [16], and in NSW in 2012 [41]. All subsequent studies of northern populations have detected 100% KoRV prevalence [6, 9, 18, 19, 23, 48, 54]. Prevalence, based on *pol* detection, in southern populations varies from 0% to 82% over time and between populations.

The prevalence of KoRV variants other than KoRV-A is difficult to determine due to small sample sizes and non-standardised diagnostic techniques with widely differing sensitivities (see *Diagnostic testing)*. Although some studies indicate that southern koalas possess multiple KoRV variants [9, 11, 31, 56], a recent investigation argued these findings are likely to be artifacts [25]. Table 15 summarises reports of KoRV variant prevalence in Australia from 2012 to 2022.

Table 15 Prevalence of KoRV variants reported in koalas in Australia 2012-2022

[a] Results use pol PCR/qPCR primers as developed in Tarlinton et al. 2005 [24]; [b] KoRV-A and KoRV-B results using specific variant PCRs; [c] deep amplicon sequencing technology used for variant detection; [d] D/F intermediate variants; [e] other intermediate variants accounted for <1% of reads. Four new hypervariable region variants were detected in a small number of koalas (<6%).

\# number tested for KoRV-B = 17

Within captive Australian populations which hold northern koalas, KoRV prevalence is assumed to be 100%, due to the endogenous nature of KoRV-A in northern koalas. This has been confirmed in several captive institutions in Qld and NSW [47, 48, 54] but data on KoRV

prevalence is not available from a wider range of Australian zoos. Japanese zoos have reported prevalence of 100% for KoRV-A, 50-64% for KoRV-B and 50% for KoRV-C [29, 45, 51, 60]. In a study of nine Japanese zoos holding koalas originating from Vic, 36% (4/11) were positive for KoRV-A and 0% for KoRV-B [29].

Mode of transmission

Transmission of retroviruses occurs through endogenous or exogenous means. In endogenous transmission, the provirus within the DNA of the host's germ cell line (oocytes and spermatozoa) is inherited by the offspring, through Mendelian dominant inheritance. Consequently, all the cells of the offspring have retroviral DNA within them and proviral loads are greater than one proviral copy per cell [2, 17].

Based on general retroviral behaviour and the defective nature of many KoRV variant sequences, it is possible that transmission of exogenous variants between koalas does not occur *in vivo*, and that the exogenous variants arise solely through recombination or mutation with endogenous KoRV-A elements in the genome within a single individual [22]. However, studies have identified patterns of KoRV variants in koala family groups, consistent with maternally transmitted exogenous KoRV infection [47, 53]. In addition, many exogenous variants are geographically restricted, but locally abundant, which is consistent with an initial host recombination with endogenous KoRV, followed by transmission to other individuals by exogenous means [25, 47, 53].

If exogenous transmission does occur, it is likely that close contact between animals would be required [61], as most retroviruses do not survive well in the environment [2, 62]. Dam-to-joey transmission is considered the most likely means of exogenous transmission and could occur through infected milk, pouch contact or *in utero* [18, 47, 53, 54, 63, 64]. Sire-to-joey transmission has also been postulated, given that some joeys have exogenous proviral profiles closer to that of the sire than their dam [32, 53]. Sexual transmission, or contact during fighting, have also been suggested but are less likely [18]. Other transmission methods considered theoretically possible include vectors [63] and iatrogenic transmission via blood transfusions and trans-faunation, since KoRV virus and provirus may be present in blood and gut contents [47, 65-67].

Transmission of KoRV via fomites or environmental contamination is considered unlikely, due to the limited survival of gammaretroviruses in the environment [68]. In infection studies of FeLV, environmental transmission was not recognised [69, 70]. However, the fact that koala retrovirus is likely to have transferred at some point from rodents to koalas suggests that the possibility of fomite or environmental transmission should not be entirely discounted.

Incubation period

The incubation period of KoRV, from acquisition of the virus to demonstration of related disease, is currently unknown. Most koalas are found to be positive for KoRV without clinical signs of disease [24, 43, 46, 71, 72].

Persistence of agent

Environmental survival of KoRV has not been examined, but survival of other gammaretroviruses (such as FeLV) is short, and the viral particles are readily inactivated by disinfectants, heat and desiccation. Survival of retroviruses in general is increased in moist, room-temperature settings [68, 73].

5.2.3 Role of KoRV in expression of disease

KoRV provirus (integrations in the genomic DNA) and viral RNA transcripts are readily detected in koalas both with and without signs of disease [24, 43, 46, 71, 72]. The completeness of the KoRV genome determines the capacity of KoRV to replicate and therefore potentially cause disease. In contrast to northern koalas, which have 100% prevalence of the intact KoRV genome [17, 24, 46], KoRV detected in southern koalas often lacks some proviral gene segments, rendering it replication-defective [5, 11, 46, 58]. It is suggested but not proven that this may be an underlying basis for the lower prevalence of clinical disease in southern koalas.

Based on association between disease and presence of some exogenous KoRV variants, in particular KoRV-B/J, it has been proposed that some exogenous variants are more pathogenic than endogenous KoRV-A [30, 72]. However, it is appearing likely that these findings actually reflect an association between disease and proviral load (with higher loads appearing above detection limits of less sensitive assays) rather than differing variant pathogenicity. Many of the studies finding associations between the presence of multiple KoRV variants and disease states in koalas [19, 29, 30, 32, 43, 48, 74, 75] suggest that disease may be more associated with escape and proliferation of the virus in any competent form, rather than with any particular variant. Whether this association is a cause or result of disease is uncertain and it may be that the causation runs in the opposite direction, with severe disease providing opportunity for KoRV proliferation and escape from host immune control [46]. It is likely that a combination of longitudinal and mechanistic *in vitro* studies will be needed to prove or disprove causation [76].

In broad terms KoRV is thought to potentially influence disease expression via two mechanisms: firstly, the active integration of KoRV into the koala genome increases the mutagenic load experienced by the koala; secondly, the replication of KoRV in the koala's white blood cells (WBC) is potentially associated with a range of negative impacts on immune cell function, which for the purposes of this document will be referred to collectively as "immune modulation" (as it is recognised that a variety of different mechanisms, both stimulatory and suppressive, may be involved). The mutagenic and

putative immunomodulatory properties of KoRV may be expressed in a variety of ways, leading to a highly complex and diverse range of disease associations which are the subject of ongoing investigation.

KoRV and neoplasia

KoRV proviral integration into koala DNA is a mutagenic event which is thought to be a key initiating process for many koala neoplasms [15], and which is likely to be a contributing factor to the high incidence of neoplasia in koalas (see *Appendix 5.6 Neoplasia in Koalas – Literature Review*). Several mechanisms have been identified for the oncogenic potential of KoRV integration into the koala genome. Neoplastic tissues from koalas have been found to contain new KoRV integrations in the vicinity of oncogenes, suggesting that upregulated expression of these genes may have occurred, increasing the likelihood of cell transformation or oncogenesis [15, 77]. KoRV integrations in or near oncogenes could lead to an inherited predisposition for specific cancers [15]. KoRV has also been found to acquire oncogenes from the host, re-integrate (transduce) them into its genome, and express the transduced genes as viral oncogenes [15]. "Candidate" genes, that could be associated with the induction of neoplasia by KoRV, have been identified in several recent studies in koalas, but the exact mechanisms of action are not yet confirmed [15, 77, 78].

Further information on the associations between KoRV and neoplasia is in *Appendix 5.6 Neoplasia – Literature Review.*

KoRV and immune modulation

There are several mechanisms by which KoRV might, in theory, cause immune modulation. By replicating within WBC, KoRV may cause these cells to be targeted for elimination by the host's immune system or interfere with cell function pathways. The KoRV provirus integration may cause disruption of the WBC genome and as a result, impact cell function [79]. KoRV is also known to carry an 'immunosuppression domain' (*isu*) which may dysregulate the host's immune response, as has been reported in other retroviruses with this domain [71], though the impact of this domain is contentious. In studies conducted *in vitro,* KoRV significantly upregulates various cytokines, interleukins and interleukin receptors in human embryonic kidney cell lines [31], which is likely to disrupt function of infected cells; its impact on koala immune cells is not confirmed. In southern populations, KoRV *pol*-positive koalas have been shown to have a more limited range of T lymphocyte ratios than *pol*-negative koalas, which might suggest a reduced capacity to regulate immune responses [80].

5.2.4 Associations with other disease hazards of koalas

Many studies have identified statistical associations between various KoRV traits (such as viral load, proviral load, variant prevalence and *pol* prevalence) and a range of disease states and co-infections in koalas [19, 24, 29, 30, 32, 43, 48, 58, 72, 74, 75, 77, 81-84]. While such

studies are important for identifying avenues for future research, they should not be taken to imply a causative link between KoRV and the associated variable.

Increased severity of chlamydial disease is associated with high KoRV proviral and viral loads in koalas throughout their range [24, 43, 46, 58]. In northern koalas, presence of certain exogenous variants has been associated with more severe chlamydiosis [29, 30, 58, 72], or higher incidence of chlamydiosis [48]. In southern populations, KoRV associations with increased incidence of urogenital chlamydiosis and periodontal disease have been identified [43, 77, 81-83]. There are fewer reports of associations between KoRV and other disease states in southern koalas, and associated diseases are often not as severe as those reported in northern populations.

Other infections in koalas, such as koala herpesviruses, trypanosomiasis and pulmonary actinomycosis have not been directly associated with infection by KoRV [77, 85, 86], but studies are in their infancy and further work is needed to develop understanding of these interactions.

The variety of associations between KoRV traits and disease states may suggest that disease is most associated with escape and proliferation of KoRV in any competent form [25]; whether this association is a cause or result of disease is uncertain, and it may be that the causation runs in the opposite direction, with severe disease providing opportunity for KoRV proliferation and escape from host immune control [46].

Recent studies show a high correlation between KoRV-B status and chlamydial disease states, with KoRV-B positive individuals over-represented in the clinically diseased cohort (69%) compared to the healthy cohort (31%, n = 120) [48].

5.2.5 Diagnosis

Clinical signs

There are no clinical signs associated with the presence of KoRV infection *per se*. Disease states associated with KoRV detection or load (i.e. neoplasia, chlamydiosis etc.) are described in the relevant chapters of this report.

"Ill thrift", and other poorly-defined clinical syndromes of koalas, are often presumptively attributed to KoRV infection (see *Section 7.1 Clinical Syndromes with Undefined or Multiple Aetiologies* in KDRA report for further discussion). The term "KoRV koala" has been commonly used by those who care for sick koalas in NSW and Qld to summarise a wide range of signs linked to poor general health, high incidence of opportunistic infections and poor response to treatment. There is an identified need to develop a more definitive and evidence-based syndrome description to capture the range of clinical conditions that might represent putative KoRV-associated immunosuppressive disease [87].

Clinical pathology

KoRV infection *per se* does not cause any consistently recognised clinical pathological changes. However, KoRV viral loads (KoRV RNA copies per µL of plasma) and proviral loads (KoRV DNA/10^3 beta-actin copies) were associated with increased immature red blood cell (metarubricyte) and lymphocyte counts, and decreased erythrocyte and neutrophil counts, in free-ranging Qld and SA koalas [81]. A study from healthy koalas in SA showed that *pol*-positive koalas had significantly lower haematocrits than KoRV negative koalas but the difference was not clinically significant [88]. Clinical pathology changes seen in associated diseases (e.g. neoplasia, chlamydiosis) are described in the relevant chapters.

Pathology

KoRV presence *per se* is not indicated by any typical pathological changes. Pathology changes seen in associated diseases (e.g. neoplasia, chlamydiosis) are described in the relevant chapters.

Diagnostic testing

Diagnostic testing for KoRV is currently only available through research laboratories. These diagnostic tests can be performed on any samples containing DNA (including blood, skin and faecal material), but highest proviral and viral loads are likely to be found in blood, lymph nodes and spleen [89].

Diagnostic testing for KoRV detection is based on molecular technology. Each technique currently available has both diagnostic and logistical limitations, and the selection of the most appropriate approach is dependent on the aim of testing.

PCR (end-point or conventional PCR) can be used to detect presence or absence of particular KoRV genes, as targeted by the selected primers [37]. Design of PCR tests to detect KoRV variants is challenging so this technique is better suited to "presence/absence" studies, as might be indicated for screening southern koalas for the presence of *pol* KoRV.

Quantitative PCR (qPCR, real-time PCR) is approximately ten times more sensitive than PCR [76]. Design of qPCR tests to detect KoRV variants is challenging due to hypervariability. It is best used for *pol*-gene quantification in determining the load of replication-competent provirus (if DNA is used) or the viral load (if RNA is used). Quantification of *pol* might be indicated in both northern and southern koalas to detect associations between KoRV viral or proviral load and disease processes with viral/ transcript load from RNA being more strongly associated [58]. An International KoRV Diagnostics Working Group continues to gather consensus on testing, and seek to define thresholds for decision making, as new information emerges [48].

Deep amplicon sequencing is performed on the *env* gene. It is used for detection and quantification of KoRV variants and is approximately ten times more sensitive than qPCR [76]. This method is best suited to testing large numbers of samples in batches when rapid turnaround time is not required. Use of deep amplicon sequencing might be indicated for

screening of koalas to identify and prevent introduction of novel variants to a naïve population; to gather data on distribution and diversity of KoRV variants; and to identify animals with a high diversity of KoRV variants, which may indicate undesirable traits that allow proliferation of KoRV.

Work is underway to validate deep amplicon sequencing of koala faecal samples for the detection of KoRV variants [90].

Rehabilitation facilities are not currently resourced to undertake KoRV testing routinely. Subtype analysis is expensive, has long turnaround times and is difficult to arrange for small numbers of samples, making it impossible to apply in the clinical context. Cost and availability of *pol* testing is similar to *Chlamydia* PCR [76].

Surveillance and monitoring

There is no co-ordinated surveillance for KoRV status of either wild or captive koalas in Australia. Captive koalas in Australia are tested for KoRV on an *ad hoc* basis and there is currently no central repository for this data. Koalas entering rehabilitation facilities are not routinely tested for KoRV status due to the cost and logistic challenges to accessing diagnostic testing.

There are numerous projects in free-ranging koalas which continue to collect data on KoRV status (using various molecular methods) however there is no nationally coordinated research program for KoRV in koalas.

An International KoRV Diagnostics Working Group is developing recommendations for assessing KoRV-associated disease risk in individuals (and populations). Although associations between KoRV variant (based on the *env* gene) and specific koala health outcomes remain unclear, the consensus is that it is likely that overall KoRV load (as measured by qPCR of the KoRV pol gene) is the most useful indicator of KoRV-associated disease risk, although threshold values or reference ranges for decision making are not clear [48, 91]. Subtyping for KoRV variants may be useful for preventing introduction of novel variants to koala populations during translocation, but there is currently no alternative to large batch, long turnaround approaches such as deep amplicon sequencing of the *env* gene [92].

5.2.6 Treatment

Currently, there are no established regimens for treatment of KoRV by eliminating replicating virus. Many anti-retroviral medications approved for treatment of human immunodeficiency virus have broad antiviral activity and might theoretically be of use in treating KoRV, but koala-specific protocols for their use have not been established. The efficacy of such medications in koalas is unknown, and caution is required as the pharmacodynamics of many drugs in koalas are known to be significantly different to other eutherian mammals [93-95]. There is a report of a koala infected with KoRV-A, KoRV-B and KoRV-F being treated with anti-retroviral medications marketed for humans (raltegravir and

tenofovir), but there was no effect on viral load or disease progression and the animal was euthanased after 33 days of treatment [96]. In addition to questions of drug safety, efficacy and treatment logistics, fundamental questions regarding the indications and goals of anti-retroviral treatment for KoRV remain; for example, anti-retroviral medications do not remove virus from already infected cells and therefore treatment of the dam would need to be started prior to birth if the aim was to minimise the risk of exogenous dam-to-joey transmission [97].

KoRV vaccination has been proposed as a means of controlling the viraemic state in koalas with endogenous KoRV, thereby reducing the likelihood of associated disease [98, 99]. However, no KoRV vaccines are commercially available at present. There are safety concerns that vaccination may lead to auto-immunity in endogenously infected koalas [100], and there is debate as to whether immunotolerance may exist which would render vaccination ineffective [101, 102]; these fundamental immunological questions must be resolved before vaccination can be considered as a treatment tool for KoRV (see further discussion of vaccination in *Prevention and control*).

5.2.7 Prevention and control

There are currently no consistent national or regional approaches to prevention and control of KoRV and KoRV-associated disease states in koalas. Maximising adaptive potential by reducing mortality from other causes, maintaining large population sizes and minimising inbreeding are key considerations in active management of koala populations and these strategies are also likely to maximise the opportunities for resilient koala populations to "co-adapt" to the presence of KoRV.

Some captive and zoo-based koala populations undertake screening for KoRV using various molecular techniques. In most cases this data is not published and may not be shared between koala holders. Increased testing, and improved data sharing between captive koala populations, as well as an evidence based, scientifically coordinated approach to managing KoRV status of Australia's captive breeding koala population is recommended.

A collection of koalas (n=30) with no detectable KoRV based on *pol* and *env* PCR has been established at Cleland Wildlife Park (owned and operated by the SA Department of Environment and Water) [103]. There may be other captive collections in Australia where replication-competent KoRV is absent, although no such collections are reported.

Approaches to prevention and control are necessarily drawn from the currently limited knowledge base. Prevention and control strategies should be revised regularly, given the rapid rate of development of knowledge of KoRV. A range of methods for prevention and control are discussed below.

Identifying and maintaining "*pol*-negative" koala populations

It is assumed that all northern koalas have endogenous replication competent KoRV-A in their genome. Recent studies suggest that some southern koalas are likely to be "*pol*-

negative" rather than entirely "KoRV free", although recKoRV elements are incapable of replication and therefore are unlikely to be infectious [11]. Protecting *pol*-negative populations of koalas from the entry of replication-competent KoRV would involve identification and managed isolation of these populations to prevent breeding with *pol*-positive koalas. The creation of KoRV *pol*-negative populations would protect the future offspring from the disease risks apparently associated with replication-competent KoRV, and act as valuable controls for longitudinal studies to examine the impact of freedom from replicative endogenous KoRV-A on koala clinical health. However, such populations are unlikely to be of benefit to supplementing wild populations due to their narrow genetic base, and the benefits of maintaining *pol*-negative populations must be balanced against other considerations for population genetic management.

Managing risks associated with high KoRV load in individual koalas

Animals with high proviral and viral loads of KoRV, or high diversity of KoRV variants, may have transmissible or heritable traits that have allowed KoRV to "escape" containment. Conversely, *pol*-negative koalas may have some genetic alleles that restrict infectious viral replication and prevent endogenisation of infectious KoRV [11]. Selecting animals with low viral loads for breeding and translocation and avoiding breeding and translocation of those with high viral loads, would encourage the retention of the most robust genetic profiles for avoiding disease consequences of KoRV. There is currently no consistent and clearly articulated protocol to enable selection based on KoRV profile, nor are there defined thresholds or consistent methodologies for quantifying proviral and viral load.

Minimising the spread of exogenous KoRV variants

Prevention and control strategies to minimise the spread of exogenous KoRV variants remain precautionary at present, pending further understanding of KoRV transmission dynamics and pathogenicity. Given that close-contact transfer from dam (or sire) to joey early in life appears to be the most likely route of exogenous transmission, *env* PCR screening of adults to identify their exogenous KoRV variant profiles would enable preferential breeding from adults with the lowest number of variants, or with variants known to be incapable of replication. Screening for KoRV variants prior to relocation would help to avoid introducing novel exogenous variants to a naïve population.

Managing risks of individual koalas with a history of KoRV-associated disease

The possibility of a KoRV-mediated inherited predisposition to neoplasia should be considered in koala populations or genetic lines with a high prevalence of neoplasia. Minimising of breeding from such lines, and investigation of KoRV profile as outlined above, may be indicated (see also *Appendix 5.6 Neoplasia in Koalas – Literature Review*).

Individual koalas from populations or pedigrees that have a history of diseases recognised to be potentially KoRV-associated (e.g., severe chlamydiosis, neoplasia, ill thrift, persistent or multiple "opportunistic" infections) may have heritable deleterious KoRV integrations, or

other traits that have allowed KoRV to “escape” containment and then create deleterious integrations. Clinical syndromes of this nature require better definition (see *Identified gaps in knowledge* in *Section 5.2 Koala Retrovirus - Risk Assessment* in KDRA report) and the presence of these syndromes could flag the need for closer incorporation of KoRV status (as described above) into breeding and translocation decisions.

Vaccination

An effective KoRV vaccine could be an important tool in developing and maintaining populations free from replication-competent endogenous KoRV. Vaccination for KoRV is in the early stages of research and there are no commercially available vaccines. Some studies indicate that endogenous KoRV-A may be protected from host immunological attack because it is incorporated into the inherited genome and is therefore recognised as “self”, limiting the likely effectiveness of vaccination [101, 102]. Other studies suggest that neutralising antibodies may be produced in response to vaccination [104, 105], raising the converse concern that vaccination of endogenously-infected animals might trigger an autoimmune reaction in the host [100]. These risks must be explored carefully if vaccination is to become a useful tool for KoRV treatment, prevention and control.

Anti-retroviral drug therapy

Although some researchers have suggested the theoretical strategies for incorporating antiviral drug therapy into KoRV prevention and control [47], there is insufficient knowledge to warrant their use at this time (see *Treatment*). Theoretically, individual koalas with persistently high viral and proviral loads of KoRV might benefit from anti-retroviral medication, as this may reduce the likelihood of immunosuppression, development of neoplasia or worsening of other disease states. As dam-to-joey transmission is thought to be a significant mechanism for exogenous transfer, focusing anti-retroviral treatment on the period of time when the dam is raising the joey might reduce the risk of exogenous KoRV transfer to the joey [47].

5.3 Heat Stress in Koalas - Literature Review

5.3.1 Technical information

Description of hazard

Heat stress is a physiologic event that occurs when an animal has extended exposure to ambient temperatures above their thermoneutral zone (TNZ) [1]. In heat stress, animals are unable to dissipate heat and their body temperature (T_b) rises above the normal range (hyperthermia) [1, 2]. Heat related illness in mammals can range from mild hyperthermia with panting and sweating, through to severe inflammatory changes, multiple organ damage and disseminated intravascular coagulation [3-5].

5.3.2 Epidemiology

Causes of hazard

Extended periods where the daily maximum ambient temperature remains above the upper limit of the koala TNZ (24.5°C), or where ambient heat dissipation at night is reduced, can lead to heat stress in koalas. This is most apparent when the ambient temperature exceeds 35°C [6].

Since the 1950s, the average ambient temperature in Australia has been increasing and heatwaves have become more frequent, longer, and hotter across the geographical range of koalas [7]. This situation is likely to get worse due to climate change [8].

Periods of prolonged heat and drought have resulted in high mortality in koalas [9-14]. Ambient temperatures and water availability have been shown to impact survivability of koalas in their northern and western range [15, 16].

Geographic distribution

Heat stress has been reported as a cause of morbidity and mortality in koalas across their geographic range [17-20].

Mapping of the likely distribution of koala heat stress events has not yet been attempted. Heat stress mortality in Australian flying-fox colonies can be predicted based on weather forecasting with a high degree of accuracy (>70% within 24-48 hours of a forecast maximum of ≥ 42°C). Extrapolation of such techniques to koala populations should be possible, but would require detailed knowledge of the species' thermal tolerance [21].

Prevalence

There have been few studies to investigate the prevalence of heat stress in koalas. One study from SA reported that 12% (n=225) of presentations to a wildlife centre (2013-2014) showed signs of heat stress [18]. The majority of cases presented on the day of, or the day following, ambient temperatures exceeding 40°C [18]. Retrospective studies of post mortem data for koalas in south-east Qld identified heat stress as a cause of death in some

individuals, but figures were included within the 13% of cases attributed to "other" causes [20]. In 2019-20, drought or extreme heat (as distinct from bushfire) were recorded as reasons for admission in 36 out of 1613 koala rescues (2.2%) reported to the NSW Government [22]. The lack of consistent reporting may reflect the seasonal and sporadic nature of heat stress events [23-25].

The impacts of heatwaves and droughts on koala population viability have been described. In Mungallala Creek, Qld it was estimated that over 60% of the koala population died in the summer of 1979-1980 due to a combination of drought and heat [10]. An estimated 25% of the Gunnedah koala population (NSW) succumbed to heat in 2009 [11]. Monitoring of populations in south-west Qld over the 2000-2009 drought showed an approximate decline of 80% [12].

5.3.3 Pathogenesis

Koalas generally maintain their T_b within the normal range if ambient temperatures do not exceed the upper limit of their TNZ (24.5°C). When the ambient temperature is above 24.5°C, T_b is less well-regulated, and hyperthermia may occur. Increasing T_b correlates strongly with ambient temperature when the latter exceeds 30°C [6].

Koalas use convection, evaporation and behavioural responses to dissipate excess heat. Convectional heat loss via peripheral vasodilation and air currents becomes less effective as ambient temperature increases [6, 26]. Evaporative cooling mechanisms include sweating from hand and foot pads, panting and hypersalivation [26]. These mechanisms become less effective in hotter and more humid conditions, and result in increased water losses for the animal [3, 9, 10, 15]. Koala behavioural responses to increased ambient temperature include seeking cooler microclimates (e.g. lower tree branches, understory, tree hollows), tree hugging, spreading their body out on cool branches and increased free water drinking [13, 15, 27, 28]. These behaviours increase the efficacy of evaporative and convective heat loss. Koalas in severe heat stress will eventually become prone on the ground in any available shade [29].

Koalas obtain about 75% of their water intake from foliage [30]. The remainder of their water needs are met by drinking free water [31]. Koalas need to ingest fluid more frequently in summer to compensate for reduced leaf moisture content [11] and increased water turnover associated with convection and evaporative cooling [15, 28]. Prolonged heat can cause koalas to become inappetent [29], further reducing their water intake and reducing their ability to dissipate heat through evaporative means.

Body heat is generally acquired during the day and dissipated at night. The body temperature of koalas has been shown to peak late in the afternoon, approximately two hours after the peak in ambient temperature. It has been postulated that during hot weather, the koala's peak in T_b shifts to later in the evening or into the night, reducing the night time window of opportunity to efficiently dissipate heat, and further predisposing them to hyperthermia and heat stress [6].

Dehydration may cause increased water re-absorption from the very large fluid volume of the koala caecum. Koalas that develop heat stress may have impaired gut function as a result of dehydration of the caecum and its contents [32].

Prolonged hyperthermia in animals has been demonstrated to cause a significant inflammatory response, widespread endothelial damage and eventually organ damage in dogs and primates [3, 4, 33]. These changes have also been seen in koalas with heat stress [32].

5.3.4 Associations with other disease hazards of koalas

No studies have demonstrated associations of heat stress with other diseases in koalas. However, any disease process that inhibits convection, evaporative or behavioural means of thermoregulation would likely decrease the koala's ability to cope with elevated ambient temperatures. Such diseases could include oxalate nephrosis, chlamydiosis and other renal diseases (due to increased hydration stress), pneumonia or other respiratory disease, and cardiac disease, that might affect panting behaviour and circulation.

5.3.5 Diagnosis

Clinical signs

The normal rectal temperature range for koalas is reported to be 35.5–36.5°C [34], which is similar to the long term diurnal temperature range of 35.4–36.9°C measured in free-ranging koalas using surgically-implanted data loggers [6]. Maximum and minimum core body temperatures for koalas as measured by data loggers were 34.2°C and 39.0°C. The rectal temperatures of heat-stressed koalas are likely to be over 37°C [32], although some affected koalas may have "normal" rectal temperatures [35].

Koalas which are heat stressed may exhibit evaporative cooling behaviours including panting (respiration rates >60), sweating (from palmar and plantar aspects of paws) and hypersalivation [18]. Heat stressed koalas are likely to show signs of dehydration including prolonged capillary refill times, "muddy-coloured" mucous membranes, skin tenting, sunken eyes and weak pulse [36]. They may drink profusely and have small, shrunken faecal pellets if heat stress has led to chronic dehydration [32]. Severely affected koalas may show signs of depression, inappetence, inability to climb and collapse. Heat stressed koalas may be found inactive at the base of a tree [35]. They may be in poor body condition and have increased ectoparasite burdens if they have been trying to survive in a drought-affected environment for prolonged periods [11]. Heat stressed koalas are often too debilitated to eat or drink, leading to secondary complications of chronic anorexia and gut dysbiosis [29]. Figure 23 shows a debilitated, heat-stressed koala at the base of a tree.

Figure 23 A debilitated wild koala sitting at the base of a tree during an extreme heat event (credit: Ian Hough)

While there are no koala-specific criteria for determining the severity of heat-related illness, systems established for domestic dogs are probably appropriate for extrapolation. Table 16 shows a system developed for dogs which uses updated terminology ('mild', 'moderate' and 'severe' heat-related illness) in place of the terms 'heat stress', 'heat exhaustion' and 'heat stroke', and outlines clinical signs and recommended management [5]. Although not all of the signs in Table 16 have been reported in koalas, it is likely that severely affected koalas could suffer similar metabolic and physiologic disturbances as those described in dogs, including hypovolaemic shock, endotoxaemia, metabolic acidosis and DIC leading to reduced organ perfusion and tissue necrosis [5, 33, 37].

Table 16 The VetCompass "Clinical Grading Tool for Heat-Related Illness in Dogs", which could be applied to koalas (adapted from Hall et al. 2021 [5])

Stage	Previous Terminology	Clinical Signs	Suggested Treatment
Mild	Heat stress	Continuous panting or respiratory effort unresolved following cessation of exercise or removal from hot environment. Lethargy, stiffness or unwilling to move.	Active cooling if hyperthermia present. Rehydration (may need oral only). Supportive care for organ systems affected (e.g. oxygen for dyspnoea). Monitor for progression of clinical signs.
Moderate	Heat exhaustion	Progression of mild stage: – no response to cooling and/or fluids. Hypersalivation, diarrhoea and/or vomiting (no blood present). A single seizure. Episodic collapse with spontaneous recovery (no impaired consciousness).	Active cooling if hyperthermia present. Rehydration - may require intravenous fluids. Supportive care for organ systems affected (e.g. gastrointestinal support). Consider hospitalisation to monitor progression of clinical signs.
Severe	Heat stroke	Progression of moderate stage. Any of: • Central nervous system impairment (ataxia, two or more seizures, profound depression, unresponsive, coma). • Liver or kidney dysfunction. • Gastrointestinal haemorrhage. • Petechiae/purpurae.	Requires hospital care. Active cooling if hyperthermia present. Coagulation assessment required. Supportive care for organ systems: • neurological support (e.g. osmotic agents, seizure management) • Intravenous fluid therapy, blood glucose and electrolyte management • Respiratory support (e.g. oxygen, intubation) • Circulatory support (e.g. vasopressors) • Gastrointestinal support (e.g. antiemetics, gastrointestinal protectants) • Transfusion products.

Clinical pathology

Clinical pathology changes are dependent on the severity of heat-related illness and the organs affected.

Heat stressed dogs will show clinical pathology indicative of dehydration including increased total protein and increased symmetric dimethylarginine (SDMA). Renal, liver and muscle parameters may be elevated due to organ damage. Prolonged prothrombin time and activated partial thromboplastin time have been observed in dogs affected by heatstroke-induced disseminated intravascular coagulation [3, 33].

Pathology

There are no detailed reports of koala pathology associated with heat stress. Pathology associated with heat-related mortality in dogs includes generalised congestion, oedema, haemorrhage and thrombosis [38]. Multiple organs are affected, with changes often seen in brain, kidney, liver, heart, intestine and spleen [38]. Hyperthermia can cause inflammatory changes, endothelial damage and damage to multiple organs [3, 4, 33]. Koalas succumbing to heat stress often have noticeably dehydrated caecal contents [32].

Differential diagnosis

Presentations of renal failure may show similar signs of dehydration, depression and water seeking behaviours, however koalas in renal failure are not hyperthermic. Trauma with subsequent unwitnessed seizure activity may present in a similar fashion to heat stress, and koalas may also be hyperthermic. Debilitating infectious disease of the respiratory system that increases respiratory rate, and causes pyrexia, lethargy and depression may mimic heat stress. Figure 24 shows a wild, dehydrated koala drinking from a bowl of water.

Figure 24 A dehydrated koala in rehabilitation care drinking water from a bowl (credit: Adelaide Koala and Wildlife Centre)

Surveillance and monitoring

Currently, there is no monitoring or standardised reporting of heat stress in koalas. There are likely to be records and reports in wildlife hospitals and rehabilitation facilities of heat stress admission and treatment, but currently there are no central records and few published reports.

5.3.6 Treatment

Treatment of heat stress in animals includes provision of a cool environment with good air flow and low humidity, to help restore evaporative and convection heat dissipation mechanisms [5]. Fluid therapy is used to help restore circulating blood volume and to manage dehydration. Supportive care for affected organs should also be provided. As with all cases where koalas require hospitalisation, specialised nursing care and excellent nutritional support are essential. A variety of species of high-quality browse with a high moisture content should be provided, along with additional misting of leaves or sprinkler systems to maintain foliage hydration [32]. Misting of browse may also help to increase the koala's fluid intake if the animal is eating voluntarily. If anorexic, regular syringe feeding of leaf paste provides koalas with fluid and nutrients [35].

Prognosis may be grave if there is progression to severe stages of heat-related illness. Dogs with signs of mild heat-related illness (Table 16) have a much greater chance of survival (85-90%) than dogs with severe signs (7-54%) [5], and this would be expected to be the same for koalas. It is very difficult to restore function to a dehydrated caecum and many koalas with severe dehydration will eventually succumb to caecal dysfunction [32].

5.3.7 Prevention and control

Climate change is likely to play a significant role in the frequency and severity of heat stress events of free-living koalas. Prolonged high temperatures have a profound effect on the quality of koala habitat, reducing both the moisture content of browse, the suitability of trees for shelter, and free water available in the environment [11, 31]. Koalas living in drought-affected landscapes will be more prone to heat stress, due to reduced dietary and free water intake, increased evaporative water turnover and reduced options for behavioural cooling strategies [9, 16]. Understory and midstory habitats provide refugia from heat events [39] and the loss of these are likely to highly disadvantage koalas during times of high ambient temperatures. Mitigation of all aspects of these processes is not possible, but supportive actions could help koalas cope with an increase in ambient temperatures. Actions include ecological assessments, protection of refugia, and mitigation of the cumulative effects of low water availability, low quality browse and fragmented habitat [40, 41].

Koalas will drink free water, especially during times of prolonged heat [31], so the provision of accessible, strategically-placed and well-maintained watering stations would help free-ranging koalas to meet increased water demands [28]. Awareness and education programs

which give clear instructions on how to safely provide water for heat-stressed koalas would ensure that the correct assistance is given by the community and emergency workers [42, 43].

For captive or rehabilitating koalas, misting or spraying browse with water will help to preserve the moisture content of the leaf, as well as incidentally increasing the koala's water intake, both of which offset increased water turnover [34, 44]. Spraying the koala's natural evaporative surfaces (e.g. undersides of feet, oral mucous membranes) may assist with evaporative cooling. Feeding captive koalas in the evening rather than in the morning during warmer months appears to reduce their peak body temperature, and may assist in avoiding heat stress effects [45, 46]. Careful storage of cut browse branches (refrigeration; standing the cut end in water which is replenished daily) will help to maintain leaf moisture [46, 47].

Koalas make use of cooler microclimates to help manage their heat, including lower tree trunks, trees with high foliage cover and trees in cooler gullies [27]. Consequently, ensuring best quality habitat and diversity of tree species and protection of refugia including midstory and non-fodder trees with high foliage cover, will support koalas to employ these behaviours [16, 28, 48]. Actions include ensuring sufficient availability of a diverse range of trees and ensuring effective corridors to connect scattered habitat. Maximising the potential microclimates within the koala's geographical range will mitigate the impacts of increased ambient temperatures. Such actions require planning well in advance of extreme heat events.

Establishing systems for forecasting heat events, similar to the monitoring and interventions recommended for flying-fox colonies [21], may help to target the supply of free water stations, encourage monitoring of populations and prepare resources for care of heat-stressed koalas.

5.4 Predator Attack Trauma in Koalas – Literature Review

5.4.1 Technical information

Description of hazard

This hazard refers to trauma and trauma-related mortality which occurs in koalas as a result of being attacked by a predator species. Predators may be carnivores (e.g. dogs, cats and foxes) or non-carnivore species (e.g. pythons and raptors).

In the context of this chapter and unless otherwise specified, the term "wild dogs" refers to dingoes, dingo-dog crosses and domestic dogs that are no longer living in a domesticated environment (as opposed to stray or unsecured pets).

Other species, including deer, cattle and horses, are implicated in attacks on koalas which can result in significant trauma [1-3]. These attacks are not considered predatory in nature and are not addressed further in this chapter.

5.4.2 Epidemiology

Causes of hazard

Domestic and wild dogs are both responsible for predator attacks on free-living koalas [4-7]. In protected forests or bushland habitat, wild carnivores (mostly wild dogs but also foxes) are primarily thought responsible for predator attacks on koalas [4, 7-12]. Feral and domestic cats are considered capable of attacking and killing an unattended koala joey [13]. A number of non-carnivore native species are also known to be predators of koalas, including carpet pythons, monitors and large raptors such as eagles and owls [9, 14, 15].

Koalas are at greatest risk of predator attacks when moving across open ground [6, 9], although non-carnivore predators such as raptors and carpet pythons may also attack juvenile koalas in the canopy during daylight hours [9, 14]. Factors which increase the likelihood of koalas going to ground will also increase their vulnerability to predation. Such factors include habitat loss and habitat fragmentation, illness, dispersal and breeding activity [4, 5, 16-18]. Figure 25 shows a wild koala crossing open ground, and vulnerable to predator attack.

Figure 25 A wild koala moving across open country is vulnerable to predation (credit: Tamsyn Stephenson)

Predator presence, abundance and behaviour may affect the likelihood of attacks on koalas. Koalas are more likely to encounter domestic pets, particularly dogs, in areas of higher dwelling density, where increased habitat fragmentation combines with higher numbers of predators [19, 20]. Both wild dogs and pythons may be present in degraded, rural and urbanised habitats, as well as being the predominant predators in more intact landscapes [9, 12]. Carnivore predators can readily attack and kill adult koalas, whereas non-carnivore predators disproportionately (but not exclusively) prey on juvenile koalas [9, 14].

Not all dogs will attack koalas. A Qld survey showed that domestic dogs over 10 kg in size were responsible for the vast majority (96%) of attacks, and attacks were more common if more than one dog was present [21]. Some breeds of dog are over-represented in data as the cause of koala attacks [13], but it is not clear whether this reflects breed propensity to attack koalas or other correlative factors such as breed preference of owners in certain areas. Individual wild dogs may be more inclined to target koalas, with a single individual thought to be responsible for as many as 75 fatalities in one study [12].

The impact of predation on koala populations is difficult to determine because there is limited data on predator attacks and carcasses are rarely discovered [6, 9, 11, 12]. Owners may also avoid reporting predation events if their dogs are involved [3]. Modelling suggests that predation by dogs may lead to koala population declines, particularly in fragmented landscapes [5, 16, 22, 23]. Predation by non-carnivore species is often difficult to quantify but may have significant impact in some populations, as has been demonstrated in the

eastern Moreton Bay region of Qld, where carpet pythons accounted for 7.2% of all koala mortalities, and 14% of confirmed predator attacks on koalas [9, 12].

Geographic distribution

Trauma due to predation occurs throughout the koala's distribution [4, 6, 24, 25].

Prevalence

There are few available prevalence figures for predation in koalas. Predation is very difficult to quantify, and may be an under-recognised threat, because koala population field monitoring rarely finds koalas immediately after death, many researchers are not trained to recognise the signs of predator attack and carcasses are rarely discovered by the public [3, 12, 26]. A small number of longitudinal studies of free-living koalas have identified predation as the predominant cause of mortality in the populations under investigation. One study of approximately 500 koalas (mostly fitted with tracking devices) over four years in the eastern Moreton Bay region of Qld found predation as the cause of 49.5% of all mortalities [12]. The majority (64.3%) of predator attacks were attributed to wild dogs, followed by carpet pythons (11.5%) and domestic dogs (3.3%). The remaining 20.9% of predation mortalities were presumptively attributed to wild dogs. In a study of 40 koalas south-east of Brisbane, dog attacks accounted for 30% of mortalities over four years of monitoring [27]. In the Port Stephens population of NSW, dog attacks were identified as the cause in 43% of mortalities (n=23) in a cohort of 50 radio-tracked animals [5].

Admission and post-mortem records from wildlife hospitals and rehabilitation facilities give an indication of the impact of predator trauma on koalas (Table 17). Data rarely distinguish between different predator species [6]; presumably in many cases the term "dog attack" is used to refer to any case suspected to be caused by a carnivore predator.

SA	240	25 (10.4%)	Stephenson 2021 [33]

In koala hospital and rehabilitation admissions, mortality rate for predator trauma is high. In retrospective studies of admission data, mortality rate from dog attacks for koalas under treatment ranges from 52-69% [6, 28, 30]. Mortality rates for predation by species other than dogs are not widely reported. Predator attacks accounted for 10-29% of mortalities in hospitals in one study [6].

There are seasonal trends in admission data for koala predator attacks, with more admissions and fatalities occurring in spring and summer, coinciding with the peak mobility of breeding males and dispersing juveniles [6, 17, 30, 34, 35]. Male koalas were more commonly admitted as a result of predator attack than females in one study [30], but in most studies no sex or age trends are reported.

The prevalence of non-carnivore predation in koalas has not been extensively studied. In a review of NSW rehabilitation admissions, 2% of all cases were animal attacks which were not clearly identified as dog-related, and included attacks by monitor lizards [30]. In a population north of Brisbane in Qld, carpet python predation was an important cause of death, particularly for near-independent and back-rider offspring. Predation was highly seasonal, with 71% of deaths occurring in the summer months (December to February), coinciding with the peak activity of pythons. Python predation occurred on the ground or in the canopy, and was only recorded on days with maximum daytime temperature exceeding 24^{o}C [9].

An increase in time that koalas spend on the ground, due to debilitation, may be a factor in increasing risk of predation. In one study, 57.5% of koalas which died due to predation were classified as “unhealthy” based on post-mortem findings [4]. Koalas suffering animal attacks are also more likely to be in poor body condition compared with those involved in MVA trauma [4, 10].

5.4.3 Pathogenesis

Predator attacks result in trauma to koalas from biting, crushing, clawing and shaking [4, 25, 26]. Koalas attacked in the canopy may also suffer impact injuries in falling from trees [9]. Injuries may be immediately fatal, or may cause damage to bones, muscles and internal organs (see *Clinical signs*).

Surveys of dog owners in south-east Qld indicate that most domestic dog attacks on koalas occur within the dog's own yard when koalas enter private property [21].

5.4.4 Association with other disease hazards of koalas

No associations between specific infectious disease hazards and predator trauma have been identified, although debilitation and poor health resulting from infectious disease may be a factor in koalas spending time on the ground, thus putting them at increased predation risk [4, 10].

Treatment of koalas with predator injury may require prolonged hospitalisation and rehabilitation, and this may be associated with the development of other diseases related to long-term medical management such as gut dysbiosis, candidiasis and secondary wound infection [26].

5.4.5 Diagnosis

Clinical signs

Koalas attacked by predators have clinical signs consistent with trauma. However, these signs can be subtle and easily missed by untrained observers. External signs may be confined to subtle abrasions, minor punctures or slicking of fur with saliva; internal damage may be severe and extensive in spite of the external appearance [26]. Figure 26 shows a post mortem examination of a wild koala killed by dog attack.

Figure 26 A post mortem examination of a wild koala killed by dog attack trauma, with extensive bruising, haemorrhage and deep punctures (credit: Veterinary Diagnostics Lab, Roseworthy Campus, University of Adelaide)

Injuries from carnivore attacks include canine tooth puncture wounds in the skin with subcutaneous soft tissue and organ damage, fractures and haemorrhage [4, 25]. Blood or saliva may be visible on the fur [25, 26].

Fractures are a common result of dog attacks. Analysis of data from 185 dog attack cases in wild koalas at a Qld rehabilitation facility found that fractures from dog attacks were more likely to involve the ribs and torso. This may be a result of the canine predisposition to maul these areas or the relative fragility of the ribs [35]. Skull and upper forelimb fractures are also commonly reported in rehabilitation admissions, perhaps because dogs tend to grab the head or the limbs if a koala endeavours to escape [3, 13].

It can be difficult to distinguish predation by different species on the basis of clinical signs. Hallmarks of python predation (not present in all cases) include a U-shaped primary bite site, and slicking of the fur around the koala's face with python saliva [9]. Due to the koala's thick fur, the fine puncture marks resulting from a python bite can often be difficult to detect unless the body is thoroughly shaved. There are no reports of koala injuries or pathologies which distinguish raptor predation although raptors have been reported to pluck joeys from their mother's back [13], so talon punctures on the dorsal aspect might be expected. Koalas suffering raptor attacks have talon marks on the face, belly and thorax, which are generally larger than the puncture marks associated with cat bite wounds [3, 36].

Pathology

Dog bites cause crush injuries that can result in fractured bones, significant internal haemorrhage and organ rupture. The most common region of injury is the abdomen, followed by chest, head and peripheral limbs. Haemabdomen is often present in abdominal injuries, and injuries to the chest include haemothorax and rib fractures. Head injuries may include skull fractures, hyphaema and ocular prolapse. In many cases, bites also cause bruising and haemorrhages over the surfaces of abdominal organs [1, 26, 35]. Full thickness puncture of the caecum has also been noted by clinicians, and may be present in the absence of obvious skin trauma [13, 37]. Damage to the caecum can also lead to caecal necrosis and peritonitis [38].

The constrictive attack methods of python predation may cause pulmonary congestion [9].

Differential diagnosis

Visible bite wounds, talon puncture wounds and saliva on the fur can distinguish predator attack from other causes of trauma such as MVA, attacks by other animals, and falls from trees, all of which may also cause wounds, haemorrhage, bruising and fractures [2, 4, 6, 9, 25].

Diagnostic testing

Diagnostic testing for predator trauma cases is similar to vehicle trauma, see *Appendix 5.7 Motor Vehicle Trauma – Literature Review*.

Surveillance and monitoring

There is no targeted national surveillance or monitoring program in place for predator trauma, or trauma of any kind in koalas. However, rehabilitation facilities and veterinary hospitals maintain records of trauma admissions and post-mortem examinations, enabling retrospective studies [4, 6, 17, 25, 33].

5.4.6 Treatment

Treatment of predator trauma in koalas is symptomatic and may include fluid therapy, analgesia, wound management and surgical repair. Reducing stress and providing excellent nutrition are critical to positive outcomes. Systemic antibiotics are generally not required except for severe dog bites or where abdominal trauma and septic peritonitis have been identified. Given the risks of gut dysbiosis and candidiasis, antibiotics should be avoided in koalas unless there is a clear requirement for their use [26, 39]. Serial (every 3 day) abdominocentesis can be used to assess for abdominal haemorrhage or peritonitis [38].

5.4.7 Prevention and control

Viable, connected habitat is critical to allow koalas to minimise their time on the ground while travelling, thus reducing the risk of predator attacks [16, 17, 40, 41]. Even small numbers of non-endemic trees in urban habitat, such as back yards, allow koalas to shelter from dogs and other predators [18].

Prevention of domestic dog attacks on koalas focuses on strategies to lower the likelihood of dog and koala interactions. As most domestic dog attacks on koalas occur in the dog's own yard [21], education and community engagement programs may increase dog owner awareness and provide information on strategies to prevent back yard attacks. Strategies include restricting dog movements to private land during dawn and dusk [4], securing a climbing pole against fences to enable koalas to escape, and fencing yards to prevent koala access [21, 42]. Other aspects of responsible pet ownership include encouraging the selection of smaller breeds of dogs which are less likely to attack koalas, and encouraging obedience and wildlife aversion training for dogs [21, 42]. Covenant restrictions on dog breed size by councils and land managers may help in reducing dog attacks on koalas [3]. The success of community engagement and education in reducing the incidence of dog attacks on koalas is not well studied, but behavioural changes and avoidance training of dogs require significant commitment and engagement of owners to the process [13, 42].

Reducing the number of free-ranging predators, particularly wild dogs, has been successful in reducing koala mortality in certain situations [12]. However, some studies suggest that identifying and removing individuals that are responsible for predation events may be more effective and ethical than reducing overall predator abundance [7, 12]. The fact that dingoes are a threatened species in some jurisdictions may be a complicating consideration, particularly because recent genetic testing suggests that the majority of 'wild dogs' have a high level of dingo ancestry [43]. Dingoes are considered to fill the ecological niche of the

terrestrial apex predator in mainland Australia, and may mitigate the predatory impacts of mesopredators such as cats and foxes [44], so their reduction in the wild may have unintended negative ecological consequences.

Prevention or control of attacks on koalas by native predators such as pythons and raptors has generally not been recommended, as they are considered a natural predator in the ecosystem.

5.5 Thermal Burn Trauma in Koalas – Literature Review

5.5.1 Technical Information

Description of hazard

Koalas suffer burn injuries during bushfires, or subsequent to bushfires as they negotiate a burnt landscape. In the context of this chapter, the term "bushfire" includes wildfires which ignite spontaneously, as well as fires which are deliberately lit for vegetation control ("prescribed" burns) or with malicious intent.

The risk of thermal burns to koalas is not the same as the overall risk of fire to koalas. There are many additional implications of bushfire events to koala health, welfare and population viability that are only discussed in this chapter if they have clear implications for burn trauma, or have a flow-on effects to burn trauma.

Thermal burns sustained due to contact with other sources of heat are not considered in this review, although the principles of assessment and treatment would be similar.

5.5.2 Epidemiology

Causes of hazard

Bushfires are the predominant cause of thermal burns in koalas. Wildfires occur with varying intensity, extent and severity depending on a variety of environmental, seasonal and climatic factors. Prescribed burns may also place koalas at risk of thermal injury [1].

Bushfires are an inherent part of the Australian landscape [1]. Fire is considered an ecologically threatening process to koalas [2], and is recognised as a contributing factor in koala population declines [3-6], including population extirpations [5, 7-9]. Severe wildfire events are often preceded by significant drought and heat events [10-14], and the impacts of all three can have a cumulative impact on koala health and well-being [11, 15, 16]. The devastating 2019-2020 Australian bushfires resulted in an estimated loss of 80% of the koala population of Kangaroo Island [16] and 8.7% of the total NSW koala population [5]. However, koala populations may recover from fire events provided an adequate quality and quantity of unburnt adjacent habitat is present [17, 18].

The nature of the fire determines the likelihood of koalas being injured or killed. Koalas tend to climb higher when they perceive danger, so severe fires that burn the forest canopy, as opposed to the understorey and ground vegetation, are most likely to be associated with koala burns, mortalities and long-lasting population impacts [6, 7, 19]. However, koalas are also susceptible to burn injuries to the hands and feet if they travel along the ground during or after low-intensity fires [1], or when descending burning trunks of trees [20].

Geographic distribution

Fire is a common, but irregular, landscape event throughout Australia, with 55 out of a total of 134 million hectares (approximately 40%) of Australia's forest area burning on at least one occasion between 2011 and 2016 [11].

The 2019-2020 Australian bushfires were unprecedented in extent and severity, burning more than 12.6 million hectares; affecting more than 10% of the total wild koala habitat; and killing an estimated 60,000 koalas [7, 21]. It is anticipated that climate change will increase the frequency of such "mega-fires" [1, 7].

Prevalence

Records of koala admissions to rehabilitation facilities and hospitals during and after a bushfire give an indication of the prevalence of burns, although they underestimate the true number of burn victims, as many affected animals will succumb to their injuries or to secondary hazards (such as shock, predation or nutritional stress) before they can be rescued [16, 17, 22]. There is a high variability in koala admission statistics following bushfires because fires do not occur on a regular or predictable basis, and data are sometimes excluded from retrospective reviews to prevent skewing of data [23]. On Kangaroo Island during the 2019-20 bushfires, burns were observed in 67.4% of koala admissions, with a post-admission fatality rate (from death or euthanasia) of 45.6% [16].

Burns *per se* are not generally separated from general bushfire impacts in rehabilitation admission statistics, and data could include animals suffering displacement, shock, smoke inhalation and nutritional stress due to bushfires without necessarily having burn injuries [24]. Bushfires accounted for 0.7% and 4.2% of admissions in two NSW studies [24, 25] and 0.1% of admissions in a Qld study [26]. The prevalence of burns as a cause of death in koalas is variable, with retrospective studies of koala post mortem records revealing no cases of burns in some instances [27, 28], and a prevalence of 2% in one SA study [29].

Most koala burn admissions are adults, and males and females appear to be equally represented [9, 16].

5.5.3 Pathogenesis

There is no specific information on the pathogenesis of thermal burns in koalas, but human and domestic animal models appear to be appropriate to describe the process [16, 30-32]. Many koalas burnt in bushfires are already suffering dehydration, malnutrition and other disease as a result of preceding drought and heat events [10-14], rendering them more likely to come to ground, where they become burnt, and less capable of withstanding the detrimental effects of burns [16-18, 22, 32, 33].

Application of heat to skin results in three zones of injury: an inner *zone of coagulation* representing tissue destroyed at the time of injury; a surrounding *zone of stasis* characterised by inflammation and low perfusion, and an outer *zone of hyperaemia*, where perfusion is not impaired. The initial burn often expands in area and depth for the first 48

hours as tissue death occurs in the zone of stasis. The release of kinins, particularly bradykinins, cause vascular permeability, smooth muscle contraction and pain at the burn site [31].

In addition to the burn injury itself, severe burns induce responses that affect almost every organ system through a variety of processes, including inflammation, hypermetabolism, muscle wasting and insulin resistance. The initial 24-72 hours after a burn are associated with increased vascular permeability and fluid shifts which lead to oedema, protein loss, hypovolemia and shock. Thermal injury produces deleterious free radicals which induce an immunosuppressed state that predisposes patients to sepsis and organ failure [31].

5.5.4 Association with other disease hazards of koalas

The majority of koalas affected by thermal burns are presumed to be otherwise healthy. However, if treatment requires prolonged hospitalisation and rehabilitation, this may be associated with the development of other diseases related to long-term medical management such as gut dysbiosis and candidiasis [20, 34] – see *Section 7.1 Clinical Syndromes with Undefined or Multiple Aetiologies*. The immunosuppressive state induced by burns contributes to the risk of secondary disease and opportunistic infections, as well as increasing the likelihood and severity of disease expression for infection. For example, it is not uncommon for koalas admitted to care with burns to develop clinical chlamydiosis some weeks after arrival [21].

In the aftermath of a fire, the risk of predation trauma increases due to the loss of habitat which forces koalas to move on the ground in search of food and shelter, and because burn trauma impedes climbing ability and is associated with general debilitation, increasing the likelihood of koalas coming to ground [16-18, 22, 32, 33].

5.5.5 Diagnosis

Clinical signs

It is vitally important that experienced and highly-trained personnel undertake triage of all burnt koalas, as soon as possible after they are brought into care [16, 32]. Individuals with poor welfare or prognosis for release should be considered for euthanasia. Welfare, health and recovery should be re-assessed at regular intervals by experienced and highly trained personnel, with no assumptions that previous prognosis assessments will continue to be valid [20].

Koala fur is highly insulative and burn damage is generally most marked in less furred areas such as the face, ears, genitals and the palms and soles of the paws [9, 16, 19, 29]. Burnt animals may present with singed fur and whiskers and charred claws. Deeper burns present with oedema, blisters and burnt dead tissue (eschars) [32]. Figure 27 shows deep burns on the digits of a wild koala caught in a bushfire. This koala was euthanased due to the severity of the burns.

Figure 27 A wild koala with severe burns to extremities (credit: Cheyne Flanagan, Port Macquarie Koala Hospital)

In alignment with the human model, burns of koalas are classed as superficial, partial thickness or full thickness, depending on the extent of destruction of the various skin layers. Burn severity is further classified based on the percentage of the body surface, or the number of body regions, which are affected [16, 32]. In the 2019-20 fires on Kangaroo Island, the extent of burns was evaluated by counting the number of burnt body regions (with 0 = unburnt and 5 = all body regions burnt); the mean count for 72 koalas was 2.86 [16].

The most common body regions burnt during the Kangaroo Island fires were the limbs (68-78%), followed by the head and face (47%), with burns to the body and trunk rarely seen. Although the site of limb burns was not consistently recorded, 28/128 koalas (approximately 22%) were specifically reported as having burns to hands, feet and nailbeds. Most animals demonstrated superficial burns (61%) with approximately 11% demonstrating full thickness burns [16]. It is not unusual for burnt koalas to have minor burns on furred areas, and significant burns on extremities [17, 21].

Scarring associated with burns can lead to loss of function and may impact suitability for release, especially if affecting the eyelids, nose, genitals, feet and pouch. Progressive digital

necrosis is a very serious sequel of burns to the paws of koalas and may not become apparent until well after the thermal injury was sustained [35].

Poor body condition and dehydration are commonly seen in burnt koalas [11, 16, 32], and affected over 70% of animals in the 2019-20 fires on Kangaroo Island [16]. This may reflect the detrimental impacts of burn injuries on fluid, electrolyte and protein balance [31], as well as the deprivation of both food and moisture associated with the habitat destruction caused by fire. The impact of preceding drought conditions has also been implicated as a cause of poor body condition in some instances [10-14].

Burnt koalas may demonstrate systemic signs of illness including shock, and respiratory distress secondary to smoke inhalation [16, 19], although many koalas with significant smoke inhalation die before rescue can occur [20].

Clinical pathology

Clinicopathologic changes in burnt koalas are non-specific and may reflect shock, inflammation, dehydration and sepsis.

Pathology

The gross appearance of burned koalas includes charred claws, singed fur and whiskers, and typical burn injuries whose appearance will depend on their depth and chronicity [36]. Thermal burns of the upper respiratory tract are less obvious on external examination but may be associated with burns around the nose and blistering of the nasal mucosa [35].

There are no specific reports describing the histopathology of burns in koalas, but presumably it is similar to what is described for domestic animals.

Differential diagnosis

The case history and appearance of a burnt koala are pathognomonic.

Surveillance and monitoring

There is no targeted national surveillance or monitoring program in place for thermal burn trauma, or trauma of any kind in koalas. A study of koalas released to the wild following fires in Port Stephens, NSW, in 1994 found that the 12 month survival of burnt koalas (58%) was not significantly different to the survival of unburnt koalas (67%) [33]. Following the 2019-20 fires, fourteen koalas which were rehabilitated for burns in Vic are being monitored via GPS and radiotelemetry to inform rehabilitation protocols, release location selection criteria and post-release survival [37].

5.5.6 Treatment

Treatment of thermal burns in koalas is symptomatic and may include cooling of burnt areas, fluid therapy, analgesia and wound management [34]. Reducing stress and providing excellent nutrition are critical to positive outcomes [34]. Systemic antibiotic treatment is

generally not required and given the risks of dysbiosis and candidiasis, should be avoided unless burns are infected or there is evidence of sepsis [19, 34].

Deeper and more extensive burns, poor body condition and dehydration in burnt koalas carry a poor prognosis for return to the wild. Partial or full thickness burns to the hands, feet, claws and nailbeds carries a poor prognosis due to the importance of viable claws and footpads to the koala's ability to climb and forage [16, 20]. Of 304 koalas evacuated from fire grounds in the 2019-2020 fires on Kangaroo Island, 54.4% were released to the wild, with burnt koalas having a significantly lower likelihood of successful rehabilitation than unburnt animals [16]. A decision to euthanase should be made if burns cover >50% of the body, if extensive full-thickness burns are present, or if there are severe burns affecting the face, hands or feet (particularly pads, nail beds and claws) or genitals [19, 20, 34].

5.5.7 Prevention and control

Mitigation of the impact of fire on koala populations has been a focus of national consideration in the aftermath of the 2019-2020 mega-fires. The National Environmental Science Programme of the Threatened Species Recovery Hub has developed a decision support framework to help identify management actions that can be taken to support koalas in fire prone landscapes. Prevention strategies outlined in the framework include: recognition and management of co-existing threats to koala populations; long-term monitoring of koala populations; restoring habitat connectivity; understanding local habitat response to fire; maintaining appropriate ecosystem fire regimes which incorporate alternatives to prescribed burning [1].

Restoration and preservation of habitat is an important aspect of risk mitigation for thermal burns in koalas [17, 18, 22, 33]. Koalas will be less likely to be burnt if they are able to move through the landscape via the canopy, rather than having to move at ground level; this requires improved habitat quality as well as connectivity. Maintaining habitat connectivity provides means of escape and refugia options for koalas during fire and may also make habitats more resilient to fire by decreasing edge flammability [1, 6, 38].

Where prescribed burning is used, a number of recommendations and actions have been identified which can be applied to reduce the risk of koala burn trauma and mortality. Strategies related to reducing the frequency, intensity, nature or extent of burning include strategic lighting patterns; test burning to ensure canopy preservation; incorporating alternatives to burning; supporting indigenous-led wildfire planning and recovery; and using knowledge of traditional owners on habitat-preserving fire management practices [1, 2, 39, 40]. Strategies which focus on specific koala risk mitigation include: use of koala detection dogs to assist in relocation of koalas; exclusion of areas known to be used by koalas; timing burns to avoid breeding and dispersal periods when koalas are more likely to be mobile; and wetting and reducing fuel load around the base of trees known to be used by koalas [1, 39].

Thermal burns are more likely to result in irreversible damage if there is a delay in treatment of koalas. Rapid post-fire response and assessment is needed to allow early

identification of koalas in need of intervention, and to facilitate rescue and evaluation by competent and experienced personnel [16, 41]. Timely access to firegrounds by experienced wildlife rescue teams would improve koala outcomes by enabling evacuation before koalas are burnt, or rescue before their burns are untreatable [16, 20]. Significant prior planning is required to incorporate wildlife workers and veterinarians into the incident response [41].

The care of burnt koalas may take a high emotional and psychological toll on responders, who must often make decisions based on incomplete information in an emotionally charged environment. This can result in management decisions which may not be in the best welfare interests of koalas [42, 43]. In recognition of this gap, programs to provide wildlife first aid awareness and training to fire fighters, and to provide training in wildlife triage and response to veterinary personnel and wildlife carers, have been developed [41, 44].

5.6 *Cryptococcus* spp. in Koalas – Literature Review

5.6.1 Technical information

Aetiological agent

Cryptococcosis is caused by fungal agents of the *Cryptococcus* genus, particularly *C. gattii and C. neoformans* species complexes [1]. Other species in the genus may cause disease in mammals but have not been reported in Australian wildlife [2].

The nomenclature of the pathogenic members of the genus has a complex history which is comprehensively summarised in Krockenberger et al. 2019 [2] and Danesi et al. 2021 [3]. In this chapter, the nomenclature of two species complexes (*C. gattii* and *C. neoformans* species complex), and their respective molecular types (*C. gattii* VGI-V; VGIV/VGIIIc; *C. neoformans* VNI-IV; VNB) will be used [3].

Listing

Cryptococcosis is not a WOAH listed disease [4].

Cryptococcosis is not a notifiable animal disease in Australia [5].

Cryptococcal disease is not identified as a key threatening process under the Environment Protection and Biodiversity Conservation Act [6].

5.6.2 Epidemiology

Cryptococcus species complex organisms are widely distributed in the environment [7]. The *C. gattii* complex is more important as a pathogen of Australian wildlife than the *C. neoformans* complex. *C. gattii* VGI is the most widespread and commonly documented cause of cryptococcal disease in koalas [8], probably because of its strong association with *Eucalyptus* spp. trees [9], particularly *E .camaldulensis* and *E. tereticornis*, both of which are consistent environmental sources of the organism and common feed species for koalas across their range [9-11].

Both *C. gattii* and *C. neoformans* can cause disease in immunocompetent animals, including humans, although in humans *C. neoformans* occurs more commonly in immunosuppressed individuals [12]. There is little evidence that *C. neoformans* infection is associated with immune status in other species, including koalas [13].

Given the vast majority of cases of cryptococcus infection in koalas are caused by *C. gattii,* the remainder of this chapter will focus on the *C. gattii* species complex unless explicitly stated.

Host range

Cryptococcus gattii infection and disease has been documented in a wide range of domestic and wild species, including dogs, cats, goats, horses, ferrets, cheetah, squirrels, porpoises, dolphins, parrots, cockatoos and kiwi [14]. Among Australian wildlife, in addition to koalas,

C. gattii infection has been reported in phascogales, bandicoots, gliders, wallabies, potoroos and native rodents [2, 8, 15-19]. *Cryptococcus gattii* is both a primary and an opportunistic pathogen in humans [20].

Zoonotic potential

Direct zoonotic transmission of *Cryptococcus* spp. does not occur [21], although koalas can amplify the organisms in the environment [22], thus increasing environmental load.

Geographic distribution

Cryptococcus gattii has a global distribution in soil, trees and tree hollows [14], although different molecular types predominate in different regions of Australia. *Cryptococcus gattii* VGII is considered endemic to south-western WA and NT [23], while VGI is more widespread and has strong associations with trees in the *Eucalyptus* genus throughout Australia, thus presenting an important source of infection to koalas [23]. VGI has been detected in association with eucalypts (*Eucalyptus, Angophora* and *Corymbia* spp.) and other native trees (*Melaleuca*, *Myoporum,* and *Syncarpia* spp.) in eastern, inland, southern and western parts of Australia [2]. The various molecular types of *C. gattii* have been isolated from the soil and hollows of over 50 species of tree worldwide, and it has been suggested that the species of tree is less important than the capacity of the tree to form decayed hollows, thus providing an effective substrate and environmental niche for the organism [3, 24, 25].

Most reported cases of cryptococcosis in koalas occur in NSW, with cases in free ranging and captive koalas mostly occurring in the Sydney region and on the north coast [22, 26, 27]. However, cryptococcosis is more extensively studied in NSW koala populations than in other areas of Australia, so the occurrence of disease in other regions is probably under-represented [28]. Clinical disease occurs sporadically in free-ranging and captive koalas in northern and south-east Qld [29, 30]. Recent retrospective necropsy studies of koalas in SA (n=85) did not detect any cases of cryptococcosis [31] and there are no reports of cryptococcosis in free-ranging koalas in SA or Vic.

Cryptococcal disease has been reported in captive populations in Qld, NSW and WA [23, 32]. An unusual cluster of cryptococcal disease, nasal colonisation and subclinical infection due to *C. gattii* (predominantly VGII) that occurred in three captive facilities in northern Qld was associated with movement of infected koalas between the facilities, and may have involved transmission from an infected animal imported from WA [23]. Isolated cases of *C. gattii* VGII have occurred in captive koalas in south-western WA, where this molecular type is endemic [3, 23, 26].

Prevalence

There are three phases of cryptococcus infection in koalas: nasal colonisation, subclinical infection, and cryptococcal disease (see *Pathogenesis*). Subclinical infection is characterised by the presence of antigenaemia (cryptococcal antigen detectable in the blood of the host) in the absence of disease.

In captive environments, high koala density may be important to maintaining a high environmental presence of *C. gattii* [13], but this is not the case in natural habitat, where heavy environmental loads of *C. gattii* may occur in the absence of koalas [22]. The density of Eucalyptus trees with hollows, and the presence of hollows colonised by *C. gattii* within a koala's home range, were significant predictors of nasal colonisation in free-ranging koalas in the Liverpool Plains of NSW, but the cryptococcal load in tree hollows was not associated with nasal colonisation [25, 33]. These findings suggest that frequency of exposure is more important than the environmental load per se in driving nasal colonisation.

In considering the prevalence of nasal colonisation in koalas, it should be noted that the sensitivity of nasal swabbing as a means of determining and quantifying cryptococcal colonisation is unknown [34]. The prevalence of cryptococcal nasal colonisation (6%) and antigenemia (7%) in free-ranging koalas in NSW is much lower than in captive populations, where nasal colonisation has been reported at close to 100% prevalence, with subclinical antigenemia prevalence of >50% in some facilities [22, 27, 35]. The high prevalence figures for captive populations in NSW support the hypothesis that koalas amplify *C. gattii* VGI in their immediate environment [22, 34]. The mechanisms of amplification are not clear. In free-ranging koalas, no clear epidemiological pattern to the occurrence of nasal colonisation or subclinical infection has been identified, although a possible link between high relative abundance of *E. camaldulensis* in a koala's habitat and the development of antigenemia merits further study [34].

No seasonal or gender variations have been detected in the prevalence of nasal colonization or antigenaemia in free-ranging koalas, or antigenaemia in captive koalas [22, 34]. One study of captive NSW koalas indicated a significant bias of nasal colonisation in males, which was suggested to reflect the greater tendency of males to use smell to explore territory [36]. There are no published data on prevalence of colonisation and antigenemia in koalas outside of NSW.

Cryptococcal disease (cryptococcosis) is well recognised in koalas, but is much less prevalent than nasal colonisation or subclinical infection. In retrospective post mortem studies, only 3–4% of koalas (mostly from NSW) had cryptococcal lesions [34]. The comparative rarity of clinical disease, given the ubiquity of *Cryptococcus* in the environment, suggests that, in the majority of cases of infection, the host response is sufficient to contain or eliminate the pathogen [37].

In a survey of Australian institutions housing koalas in captivity (n=16 institutions in Qld, NSW, SA, WA and Vic), cryptococcosis was noted in 11% of 263 diseased koalas (from any cause) [32]. Although cryptococcal disease is predominantly observed and documented in captive koalas, case clusters also occur in free-ranging populations [26, 34], and represent 39% of all reported cases of cryptococcal disease in koalas [3]. There does not appear to be a gender bias to cases of clinical disease [3].

Mode of transmission

Cryptococcus organisms exist in the yeast form within the host, and likely as a filamentous fungus in the environment [7]. Transmission occurs when the host makes direct contact with environmental cryptococcal organisms. In koalas, inhalation of airborne cryptococcal organisms into the nasal passages, with subsequent colonisation of the sino-nasal mucosa, is the most common route of entry [2, 36].

Solitary cutaneous cryptococcal lesions have been identified in numerous koalas [26], suggesting that direct inoculation is also a possible route of infection, possibly via minor grooming injuries [38]. In one case, spinal osteomyelitis occurred in the absence of lesions in other tissues. Overlying rake marks suggested that direct inoculation may have occurred via fighting injuries [39].

Seemingly healthy koalas are able to carry *C. gattii* VGI and VGII with them when translocated within Australia or internationally, either through nasal colonisation or within constrained foci of infection [23, 40, 41].

Incubation period

As with many fungal diseases, the incubation period for *Cryptococcus* remains poorly defined because the time of exposure is often unknown [42]. Incubation period for *C. gattii* infections in people during outbreaks in USA and Canada ranged from 2-13 months [24, 42], with a median incubation of 6-7 months in the Canadian outbreak [42].

In koalas the incubation period is thought to be variable and extended [26]. In a study of 28 healthy koalas with subclinical cryptococcal infection, one animal developed cryptococcal pneumonia within 6 months, while another developed cryptococcal meningoencephalitis two years after the start of the study [27].

Determination of incubation period is complicated by the fact that transmission does not always result in disease. Progression from one phase to the next may occur rapidly or slowly, but is not inevitable; nasal colonisation may occur in the absence of the development of clinical disease or subclinical infection (see *Pathogenesis*), and both colonisation and subclinical infection may spontaneously resolve over time with effective adaptive immune response [3].

Environmental exposure may significantly pre-date disease development: a cluster of *C. gattii* VGII cryptococcosis cases in captive koalas in eastern Qld was attributed to environmental seeding by an infected koala imported from WA approximately 10 years prior, which introduced *C. gattii* VGII into environments previously free of *Cryptococcus,* and also into environments where *C. gattii* VGI was endemic [23].

Persistence of agent

Cryptococcus gattii can colonize the environment in tropical, subtropical, temperate and dry climates. Environmental isolates tolerate temperatures as high as 37^{o}C [20] and are adapted for survival in dry, nutrient-deprived soils [20].

There is some evidence that *C. gattii* may persist longer in the environment in the presence of plant tissue, reflecting the organism's strong environmental association with plants [43]. The bark of eucalypts is high in dihydroxyphenylalanine, which is metabolised by *Cryptococcus* species to produce melanin, and may contribute to their environmental survival by helping them to resist UV irradiation [20].

In studies of *C. gattii* in Mediterranean Europe, the organism was unable to tolerate low temperatures during winter and did not survive when the minimum temperature dropped below 0^{o}C. Survival also dropped rapidly if rainfall in the driest month increased beyond 100 mm [44]. These conditions correspond with the climatic requirements for olive trees, an important ecological niche for *C. gattii* in the region. It is likely that *C. gattii* in Australia is subject to similar environmental constraints, which also favour the presence of the organism's preferred Australian tree species.

The virulence factors which promote the organism's survival in mammalian hosts (see *Pathogenesis*) also promote environmental persistence, including survival within soil amoebae [3].

5.6.3 Pathogenesis

As noted, there are three phases of cryptococcus infection in koalas: i) nasal colonisation; ii) subclinical infection; and iii) clinical disease.

Colonisation of the sino-nasal mucosa occurs very commonly in koalas, particularly in captivity (see *Prevalence*), and probably requires a threshold environmental exposure of infectious agent in order to occur [25]. Once colonisation is established, infection may either spontaneously resolve (a common occurrence in young koalas soon after independence), or may progress to subclinical infection or clinical cryptococcal disease [22, 36].

Subclinical infection probably reflects early, limited invasion of the respiratory mucosa. It is defined as cryptococcal capsular antigenaemia (as determined by a positive serological titre) in the absence of clinical signs or identifiable lesions. Subclinical infections can either i) resolve in an immunocompetent host, ii) persist as a localised infection, or iii) progress to clinical disease [22, 27, 36]. The presence of concurrent adverse factors such as stress and poor nutrition may play a role in the progression of subclinical infection to clinical disease [2, 34].

Key virulence factors for *Cryptococcus* pathogens include [3, 45, 46]:

- the organism's thick polysaccharide capsule, which enables avoidance and suppression of host immune response. The capsule undergoes "phenotypic switching" during infection, developing its mucoid properties which enables longer survival in macrophages, and avoids antibodies and complement-mediated phagocytosis. The mucoid forms are associated with a low inflammatory response and the formation of granulomas.
- the ability to grow at mammalian body temperature.
- the ability to produce melanin to resist host and environmental free radicals.
- production of binding proteins and sugars which facilitate tissue invasion and help evade host immune response.
- development of "titan cells" which further resist phagocytosis.

The relative importance of these virulence factors to pathogenesis is not known.

Different cryptococcal antigen proteins are produced during different phases of the infectious process in koalas, possibly reflecting shifts in virulence pathways as disease progresses [37]. Some antigenic proteins are unique to particular molecular types of *C. gattii*, possibly indicating differences in the virulence mechanisms which might explain differences in the epidemiology and pathogenesis of *C. gattii* molecular types in koalas [37]. Additionally, it is possible that genetic variation exists between different strains within molecular types which may affect the virulence of the organism in a given situation [25].

5.6.4 Associations with other disease hazards of koalas

The role of immunosuppression or association with co-infection in the pathogenesis of cryptococcosis in koalas remains unclear. Given cryptococcal disease in koalas is commonly caused by *C. gattii,* which generally infects immunocompetent hosts in other species, an association with the potential immunosuppressive effects of KoRV is perhaps less likely [2]. Investigations into this association are ongoing [34].

A 9 year old koala which was diagnosed with a novel alphaherpesvirus infection was also found to have cryptococcal organisms in the lung, cultured as *C. gattii.* Cryptococcal organisms were not cultured or detected histologically in any other tissues. It was postulated that cryptococcal disease may have contributed to physiological stress which activated a latent herpesvirus infection in this individual [30].

5.6.5 Diagnosis

Nasal colonisation and subclinical cryptococcal infection can be diagnosed by serological detection of cryptococcal antigen (see *Diagnostic testing)*. Serology alone is insufficient to diagnose cryptococcal disease, which generally requires a combination of clinical signs presenting in conjunction with indicative serological titres, culture or cytology [2]. Diagnostic imaging techniques such as radiography, computed tomography and magnetic

resonance imaging are useful complementary tools where discrete masses or bony involvement occur [2, 38, 47].

Identifying cryptococcal infection at the colonisation or subclinical stage/s may enable interventions which prevent progression to clinical disease, an important consideration given the poor prognosis once clinical signs are apparent (see *Treatment* and *Prevention and control*).

Clinical signs

Most koalas with clinically apparent cryptococcosis appear to be systemically unwell, and may demonstrate general signs of illness including inappetence, lethargy, depression and weight loss [2, 48]. However, some may only exhibit minor signs of ill health such as coughing, sneezing and nasal discharge, and only become systemically unwell when the lesion becomes obstructive or progressive [49]. Occasionally, sudden death may be the only presenting sign [48].

The typical presentation in the koala are signs localising to the respiratory tract [2, 26]. Most common is upper airway disease with sino-nasal disease characterised by sneezing, difficult or noisy breathing, nasal discharge, nose bleed and facial distortion. Nasopharyngeal involvement may result in dyspnoea, swallowing air and gastric dilatation. Involvement of the lower respiratory tract, including trachea, lungs or pleural space, is likely to be more subtle in clinical presentation, but may be associated with dyspnoea and coughing [2, 26].

Signs of neurological disease typically reflect meningoencephalitis and include blindness, nystagmus, limb paresis, opisthotonos and seizures [2, 26, 48, 50].

A case of cryptococcal osteomyelitis of the distal tibia and proximal tarsus due to *C. gattii* VGI was associated with lameness, an extensive ulcerative mass, diffuse soft tissue swelling and local lymph node enlargement. There was radiographic evidence of severe osteolysis in the affected bones [38].

Unilateral exophthalmos was the only presenting sign in a case of *C. neoformans* cryptococcosis in a captive koala in a European zoo [47].

Clinical pathology

There are no haematological or serum biochemistry findings which are diagnostic for cryptococcal disease in koalas. An inflammatory leukogram indicative of a general stress response may be seen [38]. Cytological methods may be used to detect the characteristic gram positive yeasts with a wide, poorly staining extracellular capsule in infected or colonised tissues [2].

Pathology

A positive culture from a normally sterile site such as lung, lymph node or cerebrospinal fluid is diagnostic for cryptococcosis. In contrast, a positive culture from a nasal swab in the

absence of a positive cryptococcal antigen test is not evidence of disease and should be considered colonisation until proven otherwise [2].

Cryptococcal organisms have a classic microscopic appearance. They are 5-30 µm, round or ovoid, gram positive staining yeasts with a wide, poorly staining or negatively staining extracellular capsule. Organisms are easily detected by cytology of fine needle aspirates of masses, or from smears of nasal exudate, nasal washes or bronchoalveolar lavage, and are readily identified on histopathology [2]. Molecular detection of cryptococcal DNA using panfungal PCR and sequence analysis may be attempted, although yields may be low from formalin-fixed tissue [2].

Grossly, cryptococcal lesions tend to appear as masses, but may be ulcerative if mucosal surfaces are involved. Masses may range in appearance from classic gelatinous multinodular lesions to solid granulomatous lesions. The host response may vary from minimal tissue response to a florid granulomatous response. Early inflammatory exudates can be neutrophilic or eosinophilic in nature. Abscessation and pus formation is seen rarely [2, 28].

The most common site of pathology in koalas is the respiratory tract (78% of cases). 73% of cases with respiratory tract involvement have pneumonia and 48% have upper respiratory tract pathology [2]. The organism is neurotropic in koalas with 32% of cases showing central nervous system involvement, although relatively few cases (14%) have neurological disease without involvement of other organ systems [3]. Oral cavity lesions have been observed in several individuals [49].

Disseminated disease is relatively common (34% of cases). Both upper and lower respiratory tract disease can lead to haematogenous dissemination. Disseminated disease can localise in the skin, bone, gastrointestinal tract, urogenital tract, spleen or lymph nodes [26, 38].

Skin involvement may be seen as a primary focus [26] or following haematogenous dissemination from a respiratory infection [38].

Spread of disease to regional lymph nodes is commonly present (20% of cases) but is rarely found in isolation of other tissue involvement [3, 26].

Differential diagnosis

In Australia there are few diagnostic alternatives for large encapsulated budding yeasts, and identification of such organisms in diseased tissue is diagnostic for *Cryptococcus* [2]. Culture and serology are useful ways of eliminating rare fungal diagnostic alternatives. Major differential diagnoses for upper and lower respiratory tract disease in koalas include chlamydiosis, *Bordetella* rhinitis and neoplasia. Neurological signs in koalas may be associated with trauma, meningoencephalitis due to other infectious agents, or neoplasia. Palpable or visible tissue masses may be indicative of neoplasia, trauma, or lymph node enlargement due to other pathogens. Ulcerative skin lesions may be consistent with trauma, burns, bacterial dermatitis or other fungal infections such as ringworm.

Diagnostic testing

There are two major antigen detection methods for cryptococcosis in koalas: the latex cryptococcal antigen test (LCAT) and the lateral flow immunochromatography assay (LFA). Both detect cryptococcal capsular antigen and are highly sensitive and specific. However, serological testing should always be interpreted in the light of clinical findings [2].

The LFA may be run on blood, plasma, serum or urine, is inexpensive, and is simple to use in a field situation. LFA has a high sensitivity and excellent negative predictive value for the diagnosis of cryptococcosis in koalas, and is therefore an excellent screening test for the disease, although positive results should be confirmed via LCAT [2].

LCAT is useful for determining serological end-point titres for monitoring subclinical and clinical disease [2, 27]. Low level positive LCAT titres (1:2 to 1:8) are generally typical of self-limiting subclinical infection, although they may also indicate early clinical disease. Titres less than 1:64 often resolve spontaneously in captive koalas, particularly in the absence of concurrent stressors such as poor nutrition and transport [27]. Titres ≥ 1:64 are strongly suggestive of clinical disease and warrant further investigation [2].

Surveillance and monitoring

There is no targeted surveillance program for cryptococcosis in koalas. However, the finding of cryptococcal disease in samples from free-ranging koalas would be considered interesting and unusual and would therefore be logged in the Wildlife Health Australia national wildlife health information system (eWHIS) as part of national general wildlife surveillance activities.

Cryptococcosis is a substantial management concern in captive koala facilities, particularly due to the potential role of stressors in promoting the progression of nasal colonisation and subclinical infection to disease. Serological monitoring via LFA or LCAT is generally recommended as a component of a standard health check at least once or twice a year, and prior to transporting koalas between facilities [3]. Nasal cytology or mycological culture may assist in understanding the prevalence of subclinical infection in a captive group, which may provide indication for environmental decontamination strategies such as substrate change and furniture replacement [2, 3].

5.6.6 Treatment

Successful treatment of cryptococcal disease in koalas is extremely challenging once clinical signs are present, and is almost exclusively attempted in captive koalas. Aggressive antifungal drug therapy, alone or in combination with surgical debulking of lesions, is required [2, 35, 41, 47, 51]. Signs of neurological involvement are a very poor prognostic indicator [48].

The drug regimens used for koalas are based largely on those used with success in domestic cats [26]. Amphotericin B is a fungicidal formulation which is an essential component of the treatment regimen in cases of extensive or disseminated disease, but care must be taken to avoid its nephrotoxic effects by concurrent administration of fluids, and renal function

should be monitored throughout treatment [48]. The liposomal formulation of amphotericin B is less toxic, but is very expensive and requires IV administration [2].

Amphotericin B may be used alone or in combination with oral triazole antifungals, most commonly fluconazole [35, 41, 51], but also itraconazole [35, 41, 47]. Second generation triazole formulations (e.g. voriconazole, posaconazole, isavuconazole) are very expensive and untested in diseased koalas, and the gastrointestinal absorption of posaconazole in koalas is highly variable [52].

Triazole drugs are relatively less toxic than amphotericin B but are fungistatic rather than fungicidal and are therefore less effective in treating symptomatic disease. The elimination half-life of fluconazole in healthy koalas is much shorter than in many species, and oral bioavailability is low, with MIC values failing to reach the levels required to inhibit *C. gattii* when used as the sole therapeutic agent [51, 53]. There appears to be substantial variability in bioavailability of fluconazole between individual koalas, which may be related to differences in disease status, drug formulation, gastrointestinal absorption and the nephrotoxic effects of concurrent amphotericin B administration [51]. Monitoring of drug plasma concentrations is therefore essential to effective triazole therapy [2, 41, 51]. Specific antifungal sensitivity testing is also recommended, as certain strains of *C. gattii* show intrinsic resistance to fluconazole *in vitro* [51]. In spite of these limitations, triazoles have been used successfully as the sole therapy in koalas to manage early, localised or subclinical infections [38, 48, 49].

Where cryptococcal disease presents as accessible localised lesions, surgical excision or debulking of lesions may be a useful adjunct to successful treatment [41].

Serial monitoring of cryptococcal antigen titres via LCAT is an essential component of determining effectiveness of treatment regimens [41]. Antifungal drug therapy should be continued until antigen titres are continuously negative for at least one month [48]. In one case of a captive koala in the USA where antigen titres persisted in spite of clinical resolution after surgical debulking and combined antifungal therapy, treatment with itraconazole was continued indefinitely [41].

There is a single report of treatment of a free-ranging koala, in which a joey whose mother was euthanased due to disseminated cryptococcosis was treated with oral fluconazole twice daily for 15 months, with response to therapy based on resolution of cryptococcal antigenemia. This animal was released approximately 21 months after admission [38].

5.6.7 Prevention and control

Early diagnosis of subclinical infection is the key to successful outcomes [2]. In captive colonies, a screening program should be established to monitor for cryptococcal colonisation through monitoring of antigenic titres, and possibly also nasal cytology and culture (see *Surveillance and monitoring*). Management options for low positive antigen titres might include monthly monitoring, with or without triazole medication [2].

In captivity, re-use of eucalypt browse from koala enclosures appears to be associated with the development of cryptococcosis in other captive species [2]. Environmental decontamination strategies such as regular changes of substrate and disinfection or replacement of enclosure furnishings may be recommended in colonies where disease outbreaks or subclinical infection are present. It may also be prudent to avoid collecting browse from locations where cryptococcal disease outbreaks have been reported in free-ranging koalas.

The stress of transport appears to be a key cause of progression to cryptococcal disease [2, 23]. Preshipment screening for subclinical infection should include serological testing and nasal cytology. Animals with evidence of subclinical infection should not be subjected to the stress of transport due to the risk of precipitating clinical disease [2, 23].

Given the predilection of *C. gattii* for environments and plant species also favoured by koalas, there is little capacity for preventing exposure of free-ranging koalas to the organism. However, translocation of free-ranging animals from regions where *C. gattii* is environmentally abundant is likely to present similar risks as shipment of captive animals. Every effort should be made to minimise stress during translocation. Serological testing via LFA should be used to avoid translocating animals with subclinical infection. Given the inherent stress in the rehabilitation process, serological testing of koalas entering rehabilitation from areas where *C. gattii* is commonly present is also likely to be an important tool.

5.7 Motor Vehicle Trauma in Koalas – Literature Review

5.7.1 Technical information

Description of hazard

In the context of this report, "motor vehicle trauma" refers specifically to road vehicle trauma, because collisions between koalas and road vehicles (cars, trucks etc.) are by far the most common type of motor vehicle trauma [1]. Much of the information on hazard diagnosis, treatment, prevention and control will also apply to train collisions.

5.7.2 Epidemiology

Causes of hazard

Koalas encounter motor vehicles when moving across open ground [2]. Their movements across a landscape reflect their search for trees which meet their nutritional and shelter needs [3, 4], their drive to establish solitary home ranges [5], and the seasonal mate-seeking behaviour of males [6]. These movements bring them into contact with roads and the vehicles which use them.

The tendency for individual koalas to cross roads reflects the roles of breeding activity and juvenile dispersal as key drivers of koala movement along the ground. Males are three times more likely to cross roads than females. Females with joeys are particularly unlikely to exhibit road crossing behaviour [7-9]. Younger koalas (<5 years old) are four times more likely to cross roads than older animals [8].

Few studies have examined individual koala road-crossing behaviour but there are indications of significant individual variability. In one study of 51 koalas in south-east Qld, only 18 koalas (35%) ever exhibited road-crossing behaviour over the 30 month period of study, and two individuals accounted for 50% of observed road crossings [8]. In a study of koalas in north-east NSW, all koalas crossed roads at some stage over a two year tracking period, but frequency of crossing ranged from 5 to 53 times, with one individual koala crossing a busy highway at least 32 times [10].

Human population growth, with associated urbanisation of landscapes, leads to a corresponding increase in road density and traffic volumes [11], as well as an increase in habitat loss and fragmentation [12]. These landscape changes increase the risk of motor vehicle accidents (MVA) for koalas by increasing the likelihood and frequency of attempted road crossings [2, 13-15]. This is particularly the case where development coincides with high (>1.0/ha) koala population density [14] or abundance [16, 17]. A study in north-east NSW demonstrated that koala home ranges in that area contained, on average, four times more "non-habitat" than habitat with primary feed trees [10].

The vast majority of koala road crossings occur at night. Although koalas are usually encountering roads at the time of lowest traffic volume, it also coincides with lowest visibility, and potentially higher levels of driver fatigue [18, 19].

The fatality rate from MVA is very high in koalas, with reports ranging from 50-83% [1, 2, 10, 14, 20-22]. Motor vehicle accidents may cause sufficient mortality to contribute to koala population decline, and may render vulnerable or small populations intrinsically unviable or reliant on immigration from other source populations in order to persist [23]. Motor vehicle accidents tend to involve otherwise healthy animals [24, 25], thus potentially affecting population viability by reducing healthy breeding animals.

Geographic distribution

Mortality and trauma to koalas from MVA occurs throughout their natural distribution although the relative impact varies with the particulars of the landscape (see *Prevalence*) [2, 13, 15, 24-28]. The hazard is not restricted to urban areas, as major roads also cross through relatively intact koala habitat [28].

Prevalence

Trauma from MVA accounts for a variable proportion of wild koala admissions to veterinary clinics (Table 18), but is the most common cause of trauma admissions across the koala's distribution [13, 15, 21, 22, 24-26, 28, 29]. Trauma caused by MVA was the most common cause of death among rehabilitation admissions in studies conducted in Vic [2, 15], NSW [30, 31] and Qld [14], although other causes such as disease and predation may dominate in certain populations [26, 28, 32]. The adverse effect of motor vehicle trauma is likely to be underestimated by wildlife admissions; a recent study identified that, in addition to 596 hospital admissions due to MVA over 31 years, an additional 544 koalas were sighted as roadkill during the same reporting period [32].

Table 18 Prevalence of MVA trauma in koalas

[a] includes sightings as well as rehabilitation admissions; [b] longitudinal population study.

Male koalas appear to be more commonly affected by MVA trauma based on rehabilitation admissions [2, 6, 13, 14, 32, 33] although this is not a consistent finding [27, 34]. Male koalas tend to travel more frequently and broadly than females due to sexual activity, particularly during the breeding season [6]. Seasonal variation and peaks in MVA mortality have identified greater prevalence of admissions and fatalities occurring between August and December [2, 6, 9, 13, 14]. This coincides with the peak mobility of breeding males and the dispersing season for juveniles, although it may also reflect a seasonal influx of tourists and traffic in certain areas [13]. There is also evidence for an age predisposition to MVA trauma, with young animals significantly more likely to be involved [14, 27]. The dispersal age for koalas is around 20-36 months [35], and animals of this age are likely to range more frequently and more broadly seeking home range territory [14].

Estimations of the prevalence of trauma in koalas demonstrate a sampling bias, as reports are generally a subset of rehabilitation or veterinary admissions, or necropsy studies. Where there is concerted effort to sample koalas which have not come to ground for other reasons, or koalas are monitored longitudinally, different prevalence patterns may emerge (e.g. Beyer et al. 2018 [28]).

Once koalas have established a home range, they may be less at risk of MVA trauma. A two year study of 14 radio-collared koalas in northern NSW recorded no cases of MVA in the six mortalities during the study although two animals died of MVA shortly after the collars were removed [9].

Although MVA trauma can occur concurrently with disease [6], it more commonly affects healthy animals [30]. Most MVA admissions are in good to excellent body condition, suggesting that these animals are active, robust individuals which suffered vehicle strike as a result of increased mobility [24, 25].

5.7.3 Pathogenesis

Motor vehicle collisions cause physical impact injuries to koalas which may be immediately fatal, or may cause damage to bones, muscles and internal organs (see *Clinical signs*).

5.7.4 Association with other disease hazards of koalas

Post mortem studies of koalas in NSW [6] and SA [25] suggest that healthy koalas are more likely to suffer MVA trauma than those with pre-existing disease conditions.

Treatment for motor vehicle trauma may require prolonged hospitalisation and rehabilitation, and this may be associated with the development of other diseases related to long-term medical management such as gut dysbiosis, candidiasis and secondary wound infection [36].

5.7.5 Diagnosis

Clinical signs

Koalas struck by vehicles have clinical signs consistent with trauma. External signs include skin abrasions, broken claws, deformities associated with fractures and external haemorrhage.

Internal traumatic injuries caused by MVA may include limb fractures, haemothorax, haemopericardium, liver rupture and diaphragmatic hernia [27, 30]. Head injuries are common, and often involve fractures of the skull and mandibles, as well as intracranial haemorrhage [1, 30]. It has been suggested that the koala's skull height in relation to the ground clearance of a car predisposes them to head trauma during MVA [6].

Koala MVAs have a high fatality rate due to the debilitating effects of massive haemorrhage and shock and the high incidence of head injuries and irreparable fractures [1, 24]. Figure 28 shows a live wild koala recovering from motor vehicle trauma.

Figure 28 A wild koala recovering in a rehabilitation facility after significant motor vehicle trauma injuries to the head (credit: Yasmine Muir)

Cellulitis, abscessation and cutaneous myiasis (fly-strike) are also reported, and may reflect a prolonged period between injury and examination [15].

Pathology

Gross pathology of MVA trauma is associated with blunt trauma impact, and includes head and limb fractures, haemoperitoneum, haemothorax and spinal injuries [6, 27]. Injuries of the front half of the body, particularly the head, are commonly encountered [27, 30].

Diagnostic testing

Diagnostic testing for koala trauma cases is similar regardless of the nature of the trauma and should include full body radiographs, complete blood count and biochemistry, in addition to any screening for pre-existing disease [36]. Abdominocentesis and ultrasound are indicated in all cases of trauma as internal bleeding and gastrointestinal tract rupture are common. Thoracocentesis may be indicated based on radiography [37, 38].

Koalas with haemorrhage may demonstrate red blood cell indices consistent with haemorrhage, including regenerative anaemia and hypoproteinaemia. Packed cell volume (PCV) and total protein (TP) should be monitored daily for at least three days post trauma [36]. Repeat ultrasound, abdominal and thoracocentesis may be performed on a daily basis, along with analysis of fluids obtained, to monitor for haemorrhage, peritonitis or organ rupture [39].

Differential diagnosis

Other causes of trauma, particularly animal attacks, may cause similar injuries to MVA trauma, including fractures, internal haemorrhage and head injuries [36, 40]. Puncture marks and dried saliva on the fur can distinguish predator attacks from MVA [36].

Koalas struck by vehicles are likely be found on or near a road, which may assist in differentiating them from other causes of trauma.

Surveillance and monitoring

There is no targeted national surveillance or monitoring program in place for trauma of any kind in koalas. However, rehabilitation facilities and veterinary hospitals maintain good records of trauma admissions and post-mortem examinations, enabling retrospective longitudinal studies [2, 13, 24, 25, 27]. Online databases hosted by the state governments of Qld [41] and NSW [42] collate koala rehabilitation admission data for their respective states, including information on the number of admissions attributed to vehicle trauma.

5.7.6 Treatment

Koalas with motor vehicle trauma should be triaged and treated for life-threatening injuries. Once the animal is stabilised, further investigation and diagnosis can direct prognosis and inform the decision to euthanase or continue with treatment and rehabilitation [39]. The

prognosis for koalas with MVA trauma is generally poor [1]. There is a high case fatality rate, and many animals will be euthanased on prognostic or welfare grounds.

Treatment of MVA trauma in koalas is symptomatic and may include fluid therapy, analgesia, wound management and surgical repair. As with all hospitalised koalas, reducing stress and providing excellent nutrition are critical to positive outcomes [36]. Antibiotics are generally not required and given the risks of dysbiosis and candidiasis, should be avoided unless there is a clear requirement for their use [36, 43].

Based on a retrospective study of admissions to wildlife hospitals in Qld over a period of 13 years [1], traumatic injuries associated with a decision to euthanase included:

- jaw fractures - associated with cranial trauma, and may lead to misalignment of molar teeth which affects the koala's ability to chew leaves properly.
- damage to the gingival junction of the jaw– commonly associated with intractable impaction of vegetation and secondary infection.
- fractures in close association with vital organs (skull, spine and pelvis).

However, it is difficult to generalise about the prognosis of traumatic injuries, and many injuries involving the jaw, skull and pelvis may be suitable for treatment [37, 38].

5.7.7 Prevention and control

Prevention of MVA trauma is vitally important given the high fatality rate and poor prognosis for injured koalas. Koalas which die as a result of MVA trauma are often the healthiest individuals, and strategies to reduce trauma are likely to increase the number of healthy koalas in a given population [25].

Understanding koala behaviour patterns in relation to encounters with roads is an important aspect of successful risk mitigation. Breeding and dispersal are inevitable and predictable activities of wild koala populations, so the provision of viable, connected habitat is an important (and under-utilised) strategy for reducing koala encounters with vehicles [10, 13, 44, 45].

In many cases, road routes which present a risk of MVA trauma to koalas are long-established, so it is necessary to explore mitigation methods for prevention and control [17]. Over 40 types of road mitigation measures that aim to reduce wildlife mortality on roads have been identified, but there is little information about the relative effectiveness of the different measures in reducing risks to wildlife, including koalas [11, 18, 44, 46]. In many cases, selection of wildlife road mitigation strategies is based on considerations of cost and opinion rather than evidence of effectiveness [44].

Strategies that may be used in the context of koalas are outlined below.

Road planning: There is growing recognition that the design of public infrastructure, including roads, must acknowledge and better address the environmental cost of their establishment [18, 45]. Modelling suggests that modifying existing roads to carry more

traffic is generally more effective in mitigating MVA risk to koalas than building more roads to accommodate increased traffic [18]. If new roads are necessary, locations close to existing high value habitat should be avoided [11]. Road architecture which deters the approach of koalas may also be a strategy for exploration; there is some indication that koalas may be less inclined to approach roads across a long and steeply inclined cutting [17].

Traffic management: Traffic-calming efforts are commonly proposed as a method to reduce MVA risks for koalas [15, 47]. However, introducing warning signs and reducing the speed limit from 80 km/h to 60 km/h did not result in a significant reduction in koala mortalities in one study in south-east Qld [14], suggesting that much lower speed limits would be necessary to effectively mitigate the risk of koala MVA trauma. While dynamic road signs (particularly those displaying a koala) have been shown to be effective in causing motorists to reduce their speed [47], it is not clear whether this translates to a reduction in MVA trauma and fatalities for koalas. A longitudinal study of radio-collared koalas monitored one individual which successfully crossed a road at least 32 times over a two year period (although several near-misses were reported to researchers). The authors speculated that the presence of a roundabout in the vicinity which slowed traffic to 40 km/h may have been a factor in this koala's ability to cross unharmed [10].

Studies of the frequency and timing of daily road crossings by koalas indicate that switching to daylight saving time in Qld could reduce koala vehicle collisions by 8% on weekdays and 11% on weekends, by changing the timing of peak commuter traffic relative to the peak ground travel times of koalas [48].

Wildlife road crossing structures: Koalas show variable use of wildlife road crossing structures and their impact in reducing MVA hazard is not widely studied. Koalas have been shown to use underpasses, but not overpasses [7, 11, 49]. "Escape ramps" embedded in roadside exclusion fences to enable wildlife to escape if they find themselves on the wrong side, appear poorly used by koalas [49]. The effectiveness of road crossing structures depends on their size and location; in the case of koalas, such structures would only be of use if located within their home range [45]. Some studies suggest that wildlife crossing structures are not effective unless fences are also present [46], but this is not a consistent finding [50].

Physical barriers: Construction of exclusion fencing, either on its own or as an adjunct to fauna crossings, has been successful in reducing koala road-kill in several instances [9, 50]. Barriers and road-crossing structures require good maintenance and careful attention to location and design in order to be effective [44, 45].

It is likely that the ideal prevention and control plan will incorporate both habitat connectivity and road mitigation strategies, and will consider the specific characteristics of a particular landscape, and the behaviours of koalas, in determining which combination of strategies is likely to be most effective.

Driver behavioural change: drivers may elect to slow down, or alter driving behaviour in high risk koala zones, if their value system includes the desire to protect koalas. However, drivers may be motivated by different factors, and a behavioural change program that takes these factors into account, and applies varied psychological strategies, is most likely to be effective [51].

5.8 Neoplasia in Koalas – Literature Review

5.8.1 Technical information

Description of hazard

Neoplasia is the uncontrolled, abnormal growth of cells and is a common cause of disease and mortality in both free-ranging and captive koalas [1].

5.8.2 Epidemiology

Causes of hazard

In general terms, neoplasia arises as a result of the transformation and subsequent damage to cellular DNA, resulting in uncontrolled cell growth and division, as the neoplastic cells no longer respond to normal growth-controlling mechanisms [2].

The majority of the diagnoses of neoplasia in both captive and wild koalas are lymphoid tumours, followed by craniofacial tumours (osteochondroma) and mesothelioma [1, 3-5]. A large number of other types of neoplasia have been reported as isolated cases.

Lymphoid tumours include lymphoma/lymphosarcoma and lymphoid leukaemia. Generally, lymphoid leukaemia is defined as neoplasia arising from progenitor cells in the bone marrow, whereas lymphoma and lymphosarcoma arise from other lymphoid tissues. Lymphoma and lymphosarcoma may also have a leukaemic phase, and conversely lymphoid leukaemia can infiltrate the tissues and give rise to solid tumours, so the three are not necessarily separate clinical entities [6, 7].

Osteochondroma is a benign neoplasia of cartilage and bone. In koalas, the bones of the skull are most commonly affected, but similar proliferations in other locations have been recorded, including the pelvis, ribs, clavicles and long bones [6].

Mesothelioma is a distinct serosal proliferative neoplasm of koalas which was historically classified as nodular or granulomatous peritonitis, fibrosarcoma or myxofibrosarcoma [8]. It is usually a diffuse, malignant nodular tumour of the abdominal surfaces (e.g. peritoneum, mesentery, and gastro-splenic ligament) or the pleura or pericardium [6].

Koala retrovirus (KoRV) status is likely to play a key role in the high incidence of neoplasia in koalas [9]. Viral particles associated with cases of lymphoid neoplasia were recognised as far back as 1988 [10]. The identification and sequencing of KoRV followed in 2000 using koala blood samples and lymphoma tissue [11]. The development of neoplasia in koalas shows strong epidemiological links to *pol*-positive KoRV status [12-19]. KoRV viral loads have been shown to be increased in koalas suffering from leukaemia or lymphoma when compared with healthy animals [12], and there is a significant association between KoRV proviral load (the form of the virus which is initially integrated into the host genome) and koala neoplasia [20]. *Pol*-positive KoRV-A is present in all northern and some southern koalas. Other KoRV variants are also present in northern and southern koalas. The complex nature of KoRV

infection in koalas does not support simplistic associations between KoRV prevalence and the occurrence of neoplasia [9].

The wide variety of non-lymphoid neoplasms recorded in koalas are listed in Table 19.

Table 19 Neoplasia types (other than lymphoid neoplasia, osteochondroma and mesothelioma) described in koalas

Type of neoplasm	Sites	References
Adenocarcinoma/ cystadenocarcinoma	Bile ducts; genitourinary tract; liver; lung; intestine; kidney; mammary gland; pancreatic duct; urinary bladder	Ladds 2009 [1], Hanger and Loader 2014 [6], Blanshard and Bodley 2008 [8], Gillett 2014 [18], Canfield et al. 1987 [21], Canfield et al. 1990 [22], Higgins and Canfield 2009 [23], Stephenson 2021 [24], Giovannini et al. 2015 [25]

Squamous cell carcinoma	Digit; lung; nictitating membrane; skin; tongue	Tong 2019 [5], Blanshard and Bodley 2008 [8], Gillett 2014 [18], Kobayashi et al. 2021 [31]
Teratoma	Testis	Canfield et al. 1990 [22]

Geographic distribution

Neoplasia of various types have been reported throughout the koala's wild distribution [4, 5, 18, 20-22, 32, 33]. Neoplasia is also widely reported in captive collections of koalas in Australia [3, 18, 21, 22, 33, 34]. A survey of koalas in Australian captive institutions found that neoplasia accounted for approximately 55% of disease cases [18]. There were 30 primary cases of neoplasia in koalas in the national wildlife disease database [35].

Prevalence

Prevalence of neoplasia varies geographically throughout the wild koala's range.

McEwen (2021) reports that the prevalence of lymphoma in koalas is "at least an order of magnitude higher than in humans [9]. Other publications report a high incidence of neoplasia in koalas, relative to most other species [21, 22, 36-39].

In studies of both post mortem and clinical admission records, neoplasia is more prevalent in northern populations of koalas than in southern populations [4, 18, 20, 24, 32, 33]. One study of admissions to wildlife hospitals in Qld found that 1% of koalas presented with neoplasia [40]. A second retrospective study of Qld koala rehabilitation admissions found a prevalence of 3.2% [6]. It is likely that these figures under-represent neoplasia prevalence as rehabilitation data may not include cases where neoplasia was diagnosed incidentally, or where neoplasia was found as a co-morbidity to other disease processes, and will not capture data on cases that occurred in wild koalas which did not enter the care or rehabilitation system [41].

There is growing evidence that regional differences in the prevalence of neoplasia are associated with differences in the nature of KoRV infection in northern and southern koala populations [9, 19, 42, 43]; see *Appendix 5.4 Koala Retrovirus - Literature Review* for further discussion. Other unidentified factors may also be at play. Table 20 summarises reports of post mortem detection of neoplasia in koalas admitted to rehabilitation.

Table 20 Post mortem detection of neoplasia in koalas admitted to rehabilitation

Lymphoid tumours include lymphoma, lymphoid leukaemia and lymphosarcoma. Mesothelioma includes serosal neoplasia diagnosed as myxosarcoma.

		% of most commonly diagnosed neoplasia types			
Location	**Neoplasia cases n/total (%)**	**Lymphoid tumour**	**Osteochondroma**	**Mesothelioma**	**Reference**
Northern populations					
Qld	9/67 (13%)	56%	33%	11%	Fabijan et al. 2020 [4]

SA	5/92 (5%)	80%	20%	0%	Fabijan et al. 2020 [4]
Vic	0/44 (0%)	-	-	-	Obendorf 1983 [44]

Lymphoid neoplasia is by far the most commonly reported neoplasia of koalas in both northern and southern populations [4]. Reports of higher than expected prevalence of lymphoid tumours in koalas date back to the 1970's [45]. Lymphoid neoplastic disease comprised 16.1% of all disease diagnosed in koalas submitted to the Australian Registry of Wildlife Health from 1998-2018 [5]. Koalas affected by lymphoid neoplasia are usually middle-aged (3-7 years), but may be as young as one year or as old as 10 years [1]. No sex predilection to lymphoid neoplasia has been noted in koalas [21].

Lymphoid neoplasia in koalas has four morphologic types: leukaemic (i.e. extends to the circulation); multicentric; alimentary; and focal [37]. Of 45 cases of lymphosarcoma in koalas in the Australian Registry of Wildlife Health database from 1998–2017, 51% were leukaemic and 42% were multicentric [5].

Cases of osteochondroma have been reported in both captive and free-ranging koalas in both northern and southern populations but appear more common in NSW and Qld [4, 6]. Osteochondroma is seen most commonly in mature age koalas [39]. One report suggests that males may be overrepresented in osteochondroma cases [39], but this sex bias has not been explored in recent studies.

Koalas affected by mesothelioma are most commonly 3-8 years of age [1]. No sex predilection has been noted. Other neoplasms of koalas (Table 1920) are reported only as isolated events and no prevalence data are available.

Neoplasia is a common cause of disease in captive koalas. A survey of 15 captive facilities found that neoplasia was overwhelmingly the most prevalent condition of koalas, affecting almost 56% of 263 cases [18]. The relative prevalence of neoplastic types reflected the

trends in wild populations, with lymphoma the most prevalent tumour (70% of neoplasia cases), followed by osteochondroma and mesothelioma (equal prevalence at 4.8% of neoplastic cases).

5.8.3 Pathogenesis

Oncogenesis is a multi-stage process of initiation, progression and maintenance of abnormal cell growth and division. This sequence is almost certainly a consequence of gene changes within the host, either by over-expression through gene amplification, inappropriate expression of normal genes, or mutations in a critical region of a gene [2]. This sequence is commonly initiated by exposure to a cancer-producing agent (carcinogen).

There is a growing understanding of the means by which KoRV integration into the koala genome (a mutagenic event) may promote development of neoplasia in koalas. Retroviral oncogenesis is a phenomenon recorded in many species, and molecular research in koalas suggests that the insertion of KoRV within the koala genome could be a key initiating process for many neoplasms [9]. Every cell of the body of a northern koala contains at least one KoRV copy because endogenised, replication-competent KoRV is inherited within the DNA of northern koalas [9, 20]. In any individual koala, further integrations can occur in somatic cells through reintegration of endogenous KoRV, and also by the integration of exogenous KoRV variants. The presence of exogenous KoRV variants in southern koalas is disputed [42, 46-49], and endogenised replication-competent KoRV appears absent from southern populations [19, 48-50]. Consequently, KoRV has more opportunities to exert a mutational effect in northern koalas, and the chances of a KoRV integration occurring near a site where it could alter gene expression and lead to neoplasia is correspondingly higher in northern koalas. Regional differences in the nature of KoRV infection in northern and southern koalas is described further in *Appendix 5.4 Koala Retrovirus - Literature Review*.

There are integration 'hot spots' within the koala genome where KoRV insertions are more likely to occur. These hot spots are often in close proximity to genes involved in cell growth and proliferation [9]. Neoplastic tissues of koalas have also been found to contain new KoRV insertions in the vicinity of oncogenes. The insertion of KoRV into the genome can induce gene dysregulation, potentially compromising the removal of early neoplastic cells, and promoting tumour growth and malignant transformation [51]. *In vitro* studies of the effect of KoRV on naïve human cell lines also demonstrates significant upregulation of several oncogenes, including those associated with lymphocytic leukaemia [46].

Two captive koala facilities in Qld noted a potential hereditary pattern of lymphoma and leukaemia in koalas, with at least three successive generations of animals succumbing to these neoplastic conditions at similar ages. This may reflect the inheritance of KoRV proviral copies within the genome [18], but may also indicate unidentified inherited predispositions which are independent of KoRV status.

5.8.4 Association with other disease hazards of koalas

The associations between KoRV and development of neoplasia have been discussed earlier in this chapter.

Neoplasia is commonly reported concurrently with chlamydiosis, with 39% (16/41) of koalas with neoplasia also diagnosed with chlamydiosis in one post mortem study [32]. This association may reflect the high prevalence of *Chlamydia* as a co-morbidity, or possibly co-infection with KoRV, rather than a direct association between chlamydiosis and the development of neoplasia. Associations between KoRV and *Chlamydia* infection are discussed in the respective chapters.

A wide range of other associations and causal factors for neoplasia have been identified in other species, particularly humans [2]. Osteochondroma in humans, horses and dogs can be inherited as an autosomal dominant trait [52]. The development of mesothelioma in humans and other animals has been associated with exposure to asbestos, the SV40 virus and chemicals such as ethylene oxide, nitrofurazone, nitrotoluene and potassium bromate [53]. Gammaherpesvirus infections of humans are responsible for thousands of new cases of neoplasia annually [54]. Other than KoRV, no such predisposing factors or associations have been investigated for the development of neoplasia in koalas.

5.8.5 Diagnosis

Clinical signs

Clinical signs of lymphoid neoplasia in koalas are variable. Body condition may be good or poor, and illness may be protracted or result in sudden death [1, 29]. Signs of lymphosarcoma reflect the location and severity of body system involvement, although lethargy, depression, listlessness and weakness are commonly encountered [1, 5, 29].

Alimentary lymphosarcoma in koalas commonly results in non-specific signs of gastrointestinal dysfunction including diarrhoea, abdominal pain which manifests as grunting or moaning, and soil pica [1]. Pale mucous membranes may be seen if anaemia is present. Lymphomatous infiltration of the reproductive tract can be associated with vaginal prolapse [38] or loss of pouch young [1]. Other signs of lymphoma may manifest depending on the location of lesions, including polydipsia [1], ocular discharge and swollen conjunctivae [21, 38], lameness [14], posterior paralysis [34], nystagmus and head tremors [37], and terminal convulsions [37]. Figure 29 shows a wild koala with a large facial swelling due to lymphoma.

Figure 29 A wild koala in care with a large facial lymphoma (credit: Amber Gillet)

Enlargement of superficial lymph nodes is a common finding, reported in 35% of lymphosarcoma cases [37]. The spleen and thymus may also be palpably enlarged and thymic enlargement may be accompanied by dysphagia [1].

Clinical signs of osteochondroma are associated with obstruction and compression of adjacent structures. Facial distortion is commonly seen but is not a consistent presentation. Disruption of the temporomandibular joint can cause malocclusion and degenerative joint disease. Obstruction and expansion into the nasal cavities can cause difficulty breathing and eating, a chronic nasal or oculo-nasal discharge and bleeding. Neurological signs may be seen if the tumour compresses the brain [5, 8].

Koalas with mesothelioma may present with few clinical signs until disease is advanced. Abdominal distension due to ascites may be seen if the neoplasia is localised in the abdomen, or dyspnoea if localised in the pleura. Affected individuals are often in fair to poor body condition. Abdominocentesis or thoracocentesis usually yields viscous, blood-tinged fluid [5, 6].

Clinical pathology

Approximately 50% of koalas affected by lymphoid neoplasia have circulating neoplastic cells (i.e. leukaemic lymphosarcoma), resulting in markedly elevated white cell counts in excess of 100 x 10^9 cells/L. If the white cell count is normal, a relative lymphocytosis or

lymphoblastosis may be present. Affected koalas may be neutrophilic or neutropaenic, and thrombocytopaenia is common. Mild to severe anaemia, which is usually non-regenerative, often accompanies lymphoid neoplasia. Common biochemical findings include elevated lactate dehydrogenase, elevated blood urea and hypoalbuminaemia [1, 5, 8, 37].

Neoplastic changes in mesothelial cells may be observed during cytological examination of abdominal fluid from koalas with mesothelioma. Dysplastic cell types are also seen on bone marrow examination.

Pathology

The major gross finding in lymphoid neoplasia is often enlargement of superficial, mesenteric or thoracic lymph nodes, and commonly splenic enlargement. The enlargements seen grossly are due predominantly to infiltrates of neoplastic lymphocytes [1, 21, 37, 55]. Pale nodules or streaks may be visible at gross necropsy although it is possible for significant infiltration of the tumour to occur without any grossly visible signs in the affected organ [1, 29]. Immunohistochemical studies showed that approximately half of lymphoid neoplasia cases were of T cell origin, one quarter of B cell origin and one quarter failed to stain with the markers used [3].

In a post mortem study of 51 koalas with lymphoid neoplasia, 54.8% of cases involved abdominal organs, especially the liver (13.8%) and spleen (12.1%). Solitary or multiple lymph nodes were frequently involved (12.9%). Infiltrates were also observed in a range of atypical sites such as lung, brain and conjunctiva (collectively 13.3%), and 5.8% in the cervico-mediastinal area including thymus [3].

Craniofacial osteochondromas present as firm masses of the facial bones, including the orbit, buccal cavity, nasal cavity, maxilla and hard palate. Masses are white to cream, smooth, shiny, nodular and with a lobular appearance on cut surface. Microscopically they consist of neoplastic nodules divided by connective tissue septae. These nodules contain dysplastic cartilage and bone with cartilage matrix and hypertrophied chondrocytes. Tumours are benign and do not metastasize. Necrosis and inflammation may be associated with ulceration of compressed and displaced tissues [1, 5, 8, 39].

Mesotheliomas are located in the abdominal or thoracic serosal layers. Grossly there is serosal thickening with multiple glistening nodules distributed diffusely across serosal surfaces. Lesions are most common in the abdominal cavity, associated with ascites, but may also occur in the pleura, pericardium, pelvic cavity and scrotum. Fluid accumulating in cavities is notably high in volume and of a viscous consistency. Histologically, tumours demonstrate various proportions of fibrous, myxoid and mesothelial tissues [1, 5, 6, 8, 56].

Differential diagnosis

As many neoplasms present with non-specific clinical signs, there are a range of differential diagnoses, including infectious disease, malnutrition, exposure to toxins and trauma. Craniofacial facial swelling associated with cryptococcosis may mimic osteochondroma.

Diagnostic testing

Diagnosis of neoplasia is made based on cytological or histological examination of affected tissues. In the live animal, cytological examination of aspirates from enlarged lymph nodes or masses, bone marrow or free thoracic or abdominal fluid may demonstrate neoplastic cells [5, 8, 37, 55]. Lymphoid neoplasia may manifest as leukaemia, which is diagnosed by examination of blood smears for circulating neoplastic cells [8].

Diagnosis of mesothelioma can be confirmed by cytological assessment of abdominal fluid and histopathology using immunohistochemistry [57].

Surveillance and monitoring

There is no active surveillance and monitoring program for koala neoplasia. However, cases of neoplasia are commonly captured by the Australian Registry of Wildlife Health and the surveillance database of Wildlife Health Australia (eWHIS), and wildlife hospitals and rehabilitation facilities may keep records of cases of neoplasia.

5.8.6 Treatment

The prognosis for the commonly encountered neoplasms in koalas (lymphoid, osteochondroma and mesothelioma) is very poor, and treatment is rarely attempted [5]. Surgical resection of focal masses has been successful in a very small number of cases [8, 58], but success probably depends on early diagnosis [5]. Craniofacial osteochondromas treated by surgical resection have recurred [8].

Most cases of neoplasia in koalas are diagnosed during end-stage disease or at post mortem examination. In one review of 41 cases of lymphoid neoplasia, 49% were diagnosed at necropsy and 29% were euthanased at first clinical presentation based on a diagnosis or a strong suspicion of neoplasia. Five of the koalas were given supportive care but died, on average, within two weeks [5].

High doses of prednisolone may provide temporary symptomatic relief in a koalas with lymphoid neoplasia, but are unlikely to cause clinical remission [8]. Chemotherapy using other agents has been attempted on very rare occasions without success [29].

5.8.7 Prevention and control

Options for prevention and control of neoplasia are limited due to the lack of information on the causal factors of neoplasia in koalas. The association between KoRV status and neoplasia indicates that prevention of some cases of neoplasia in koalas may be addressed through prevention and control measures for KoRV. Proposed prevention and control measures for KoRV are outlined in *Section 5.2 Koala Retrovirus - Risk Assessment* and *Appendix 5.2 Koala Retrovirus - Literature Review*.

The possibility of inherited predisposition to neoplasia should be considered in koala populations or genetic lines with a high prevalence of neoplasia. Prevention of breeding from such lines may be indicated. As a general principle, maintaining genetic diversity in

koala populations will encourage retention of the most robust koala genetic profiles to minimise the impact of neoplasia on the species.

5.9 Sarcoptic Mange in Koalas – Literature Review

5.9.1 Technical information

Aetiological agent

Sarcoptic mange is a highly contagious skin infection caused by the parasitic mite, *Sarcoptes scabiei* [1].

Listing

Sarcoptic mange is not a WOAH listed disease [2].

Sarcoptic mange is not a notifiable animal disease in Australia [3].

Sarcoptic mange is not identified as a key threatening process under the Environment Protection and Biodiversity Conservation Act [4].

5.9.2 Epidemiology

Sarcoptic mange can have dramatic short-term effects on wildlife populations, with epidemics associated with very high morbidity and mortality [5]. In many populations, epidemics are self-limiting and population recovery occurs, but long-term effects may be much more serious in fragmented and isolated populations, leading to local extinctions [5, 6]. Sarcoptic mange is a disease of emerging significance in koalas, and its effect on koala population viability is currently unknown.

Host range

Sarcoptes scabiei has been documented to infect a broad host range of approximately 150 mammal species globally, including humans [7, 8]. Sarcoptic mange is considered to be an emerging infectious disease in Australia, based on its continued spread into new hosts [7, 9, 10]. It has been documented in many Australian native mammal species, including bare-nosed wombats, southern hairy-nosed wombats, koalas, bandicoots, dingoes, possums, potoroos and wallabies [1]. Mange is recorded in non-endemic mammalian species in Australia and non-endemic canids (wild dogs, domestic dogs and foxes) are likely to be significant in the origins and epidemiology of mange in Australian wildlife [7].

Historically, *S. scabiei* was thought to have a number of relatively host-specific varieties [5]. However, the taxonomy of sub-species varieties is no longer used and *S. scabiei* is now considered a single mite species which can develop local adaptations to enable sustained transmission in new host species [7, 11].

Zoonotic potential

Disease in humans caused by *Sarcoptes scabiei* is known as ‘scabies’, and is acquired from other infected humans or animals [12]. Humans have acquired scabies from infected Australian wildlife [13], and zoonotic transmission from koalas has been anecdotally reported [14].

Geographic distribution

Sarcoptes scabiei is believed to be widely distributed throughout Australia and was probably introduced via European settlers and their domesticated animals [7, 15]. It is primarily a public health and domestic dog issue in northern Australia [16, 17] and a wildlife and feral animal disease in southern areas of Australia. While there is little detailed information on the geographic distribution of *S. scabiei* across the country [1], it seems likely the mite is present in most locations where koalas populations are present, given that sarcoptic mange has been reported in bare-nosed wombats in NSW, Vic, SA and the south-eastern regions of Qld [18] and reports of mange outbreaks in wild canids occur sporadically throughout Australia [15, 18-21].

Sarcoptic mange as a disease of wildlife is most commonly reported in the southern regions of Australia [7, 19]. This also appears to be the case in koalas, with confirmed cases reported sporadically in Vic and SA [22-26], but rarely in NSW and Qld [26-31]. Victorian cases are widely distributed, with reports in koalas from northern, western, eastern and central Vic populations [22, 26]. South Australian cases are less widespread, with all reports occurring within a 12 km radius of the index case [22].

Prevalence

There is little information on the prevalence of sarcoptic mange in koalas. Written reports of mange in koalas date back almost 50 years, but until recently, disease appeared to be restricted to isolated cases, usually occurring in koalas in rehabilitation or captivity [14, 24, 32]. Since 2011, localised outbreaks of sarcoptic mange in wild koalas have been reported from various sites in the north, west, east and central regions of Vic [22, 26] and around the Mt Lofty Ranges (MLR) in SA [22, 23]. Prevalence of sarcoptic mange in the 2012-13 outbreak in MLR was 8% [23]. A recent post mortem study of 240 koalas from MLR identified sarcoptic mange in 4.2% of cases [33]. In a retrospective post mortem study from the mid-1970s in Vic, prevalence of sarcoptic mange was 3.6% [24].

In other areas of Australia, reports of sarcoptic mange are scarce and often anecdotal, suggesting a low prevalence outside of Vic. Retrospective studies of rehabilitation facility admissions and post mortem records in NSW and south east Qld, spanning 17-30 years, did not identify sarcoptic mange or skin disease as a reason for admission [27-30]. Sarcoptic mange was not reported as a cause of disease in a 2014 survey of 16 captive koala facilities across six Australian states [34].

In koalas, most reported cases occur in adults, although cases in juveniles [14] and subadults [22] have been reported. Male koalas appear over-represented and it has been suggested that they are more likely to become infested due to roaming and fighting behaviour [22]. In contrast to sarcoptic mange in wombats, mange in koalas appears least likely to occur in winter [22], but comprehensive epidemiological studies are lacking.

Mode of transmission

Transmission of *S. scabiei* mites occurs via contact, which may occur directly between hosts, indirectly via contaminated environments, or by both means [12, 15, 35]. The predominant means of transmission varies among host species, with direct transmission more likely to be important in social species with a high host density (e.g. herd species), and indirect transmission through shared environments more important in species with more solitary habits (e.g. bears, wombats) [35].

The source of the *S. scabiei* mite in koala cases has not been confirmed, and it is unclear whether sustained koala-to-koala transmission occurs, or if koala cases represent repeated transmission from other species or the environment [14, 36]. There is a high genetic similarity between mites infecting koalas and those infecting wombats, suggesting that transmission between these species may occur [15]. Genomic sequences detected in koalas in Vic and SA have also been identified in foxes in Vic and dogs in NT, supporting the hypothesis that canids may be an important reservoir for marsupial *S. scabiei* infestation [19]. Outbreaks in Vic koalas coincided with the observation of several foxes with clinical signs of advanced mange, possibly suggesting spillover from foxes [22].The possibility of mite transmission to koalas via tree surfaces has been suggested, based on the fact that the distribution of lesions corresponds with the areas of the koala's body which are in contact with trees [22], however there is no evidence to support this hypothesis at this stage.

Incubation period

There is no information on the incubation period for *S. scabiei* in koalas. Experimentally infected wombats showed clinical signs of infection by day 14 [12, 37].

Persistence of agent

Sarcoptes mites are able to survive off the host for up to 19 days in an optimised microclimate of high relative humidity (97%) and low temperatures (10-25^{o}C) [38, 39] .

5.9.3 Pathogenesis

The pathogenesis of sarcoptic mange has not been studied in koalas. The following information is based on studies in other species, including wombats.

Sarcoptes mites burrow into the skin and consume host cells and secretions, creating tunnels and depositing irritating and allergenic material including mite excretions, dead mites, moulted exoskeletons, and egg casings [5]. The acute signs of sarcoptic mange (skin inflammation and itching) are caused by hypersensitivity reactions to this allergenic material [5]. A type I hypersensitivity response (dominated by mast cells and eosinophils) is associated with relatively mild disease, whereas the most severe forms of mange are characterised by a type IV hypersensitivity reaction (dominated by lymphocytes) [35, 40]. Hair loss, erosions and crusting are a result of self-trauma caused by pruritus; as pruritus increases, the number and severity of secondary lesions also increases [5].

There is a marked variation in severity of sarcoptic mange between different host species. The factors which lead to this variability probably include previous exposure, differing environmental conditions and host co-morbidities [41]. It is not known whether koalas can mount an effective immune response to clear *S. scabiei* infection, rather than developing sarcoptic mange.

Mange-infected animals suffer a cascade of physiological and behavioural effects that increase the pathogenic impacts of infestation with *S. scabiei* [42]. Individuals with mange lose more heat to the environment than healthy animals due to hair loss [42-44], and have higher metabolic rates due to inefficient thermoregulation and the inflammatory response [42]. They may also be less capable of meeting increased metabolic demand because foraging activities are less effective than in healthy animals [42, 44-46], They are also less able to rest, due to interruptions from mite-associated irritation [42, 46, 47].

Sarcoptic mange may also alter nutritional balance in detrimental ways. The fatty acid composition of mange-affected bare-nosed wombats has been shown to shift toward chronic inflammatory (omega 6) rather than anti-inflammatory (omega 3) fatty acids, which may promote disease progression and accelerate host mortality [42].

5.9.4 Associations with other disease hazards of koalas

No disease hazard associations have been postulated for koalas with mange. In wombats, sarcoptic mange appears to be more common in animals with co-morbidities, and it is possible that mange contributes to the development of co-morbidities in the host [1]. A link between new or reactivated herpesvirus infections and debilitation caused by sarcoptic mange has also been suggested in wombats [48]. The role of debilitation due to sarcoptic mange in exacerbating or activating other pathogenic processes has not been investigated in koalas.

Given the importance of immune response in the pathogenesis of sarcoptic mange in other species, co-infection with pathogens which might affect host immune function (e.g. KoRV) might have an impact on disease expression of *S. scabiei* infection.

5.9.5 Diagnosis

Clinical signs

Most reports of sarcoptic mange in koalas describe animals with severe clinical signs that are very debilitated by the time they are rescued [1, 49]. At that stage, disease is characterised by dry, pruritic, encrusted lesions which may occur over the entire body, but commonly affect the face and distal fore- and hind-limbs, particularly the interdigital areas [22]. Exudative fissures are commonly seen on digits and paws and may ooze serosanguinous fluid [22]. Enlarged lymph nodes in affected body regions were noted in a number of koalas [22]. Many affected animals are found dead, presumably due to the septicaemic effects of secondary bacterial infection of affected skin [22].

In other species, pathological manifestations of sarcoptic mange range from mild to severe depending on chronicity of infection; on first principles it is likely that the same occurs in koalas. Early signs of sarcoptic mange in one captive koala colony were reported as small, dry, raised, circumscribed lesions beneath the fur [32]. Figure 30 shows a wild koala with severe sarcoptic mange on the abdomen.

Figure 30 A wild koala with sarcoptic mange on the abdomen (credit: Pam Whiteley)

Clinical pathology

No specific clinicopathological changes are reported for sarcoptic mange in koalas. Wombats infected with mange demonstrate significant changes in haematology and serum biochemistry, including lower red cell parameters (haematocrit, mean cell volume, mean cell haemoglobin and total haemoglobin), creatinine and albumin, and elevations in white blood cell counts (particularly neutrophils and lymphocytes), globulins, liver enzymes and creatine kinase [50, 51]. Changes are consistent with anaemia, inflammation and starvation [50].

Pathology

Sarcoptes mites cause classic thickening and scale production in the skin of affected koalas associated with a hyperplastic and hyperkeratotic dermatitis [22]. Microscopic lesions are characterised by acanthosis, orthokeratotic and segmentally parakeratotic hyperkeratosis, and numerous intracorneal mites [22]. Chronic cases with secondary bacterial infection demonstrate intracorneal pustules and mixed perivascular and interstitial dermatitis [22].

Differential diagnosis

Chronic dermatophyte infection ('ringworm') may also present with dermatitis and skin thickening, although it is not generally pruritic in koalas [52]. Ringworm is distinguished from sarcoptic mange by the presence of fungal hyphae within hair follicles on skin biopsy, and the absence of mange mites on skin scraping.

Benign disorders of keratinization such as volar hyperkeratosis may cause crusting and skin thickening in koalas, but these conditions are not pruritic and are distinguishable from sarcoptic mange due to absence of mites and characteristic histopathology [53]. Mild and moderate clinical effects of sarcoptic mange in koalas are not described, but based on the manifestations in wombats, differential diagnoses for mildly affected animals could include trauma, or infections due to bacteria, fungi or other ectoparasites [54, 55].

Diagnostic testing

Classical diagnostic testing for sarcoptic mange involves skin scraping the epidermis for visualisation of the mite or its eggs by microscopy. In studies of wombats, the sensitivity of this method was variable, especially in the early stages of disease, when false negative diagnosis was commonly encountered [56]. PCR detection was more sensitive than microscopy in detection of mites in skin scrapings, and may also be of potential value for detecting mites in less invasive samples such as skin swabs [56]. The use of PCR techniques in the diagnosis of sarcoptic mange in koalas has not been investigated. Clinical cases in koalas are commonly at an advanced stage at the time of diagnosis. Microscopy of superficial skin scrapings generally identifies numerous mites [22].

Surveillance and monitoring

There is no formal surveillance or monitoring program for sarcoptic mange in koalas. However, there is capacity to utilise the Wildlife Health Australia national wildlife health information system database (eWHIS) as a place for entering cases of sarcoptic mange in koalas as part of national general wildlife surveillance activities.

5.9.6 Treatment

There is no accepted global standard treatment regimen for mange in wildlife, and there is species-specific variation as to what constitutes best-practice treatment in free-ranging wildlife [1].

The study of the treatment of mange in Australian wildlife is most advanced in wombats, as sarcoptic mange is the most frequently observed debilitating disease condition in bare-nosed wombats and also impacts southern hairy-nosed wombats [1]. Extrapolation of treatment protocols to koalas should be undertaken with caution, as koalas have demonstrated idiosyncratic pharmacokinetics for a number of drug formulations [57-59].

General principles of treatment

In making decisions on treatment of sarcoptic mange in wildlife, general recommendations are as follows [54, 60]:

- Confirmation of the diagnosis should be undertaken where possible prior to treatment, to rule out differential diagnoses, especially for mild or moderate skin disease.
- Pre-treatment assessment should be carried out by a suitably experienced veterinarian. This should include evaluation of disease severity (preferably using a standardised approach as has been developed for wombats in some jurisdictions [61]), body condition, general health and presence of other disease. This evaluation ensures that treatment is only undertaken after assessing the costs and benefits for the individual from a welfare and prognosis perspective.
- Suffering of affected animals should not be prolonged if the prognosis for recovery is poor. [54] includes guidance on euthanasia criteria for mange-affected wombats, which could be modified for use in koalas.

Use of antiparasitic drugs

As is the case with other Australian wildlife species [1], the efficacy of many antiparasitic drug regimens in treating koalas with mange is anecdotal, with combinations of medications and variable dose regimens being used off-label with unknown animal health and welfare implications. Anecdotally, mortality of mange-affected koalas has been attributed to the use of certain anti-parasitical formulations [49, 62], but evidence-based investigation and clinical reporting is lacking. Antiparasitic medications which have been used in the treatment of sarcoptic mange in koalas include ivermectin (subcutaneous injection), topical selamectin (Revolution®), pour-on moxidectin (Cydectin®), topical fluralaner (Bravecto®) and topical benzyl benzoate [1, 26, 49, 62].Where humane and practical, the current recommended antiparasitic treatment options **for wombats** are:

- injectable ivermectin at recommended livestock doses given weekly over several months [36, 54].
- topical moxidectin or selamectin for repeated treatments (special permit required), particularly as a means of reducing handling when efficacy of injectable avermectins has been established [54, 63].
- topical fluralaner (special permit required) [26, 64, 65].

Due to the need for multiple treatments and handling, injectable ivermectin is only considered feasible for wombats in captivity or in rehabilitation [54], and it is likely this would also be true for koalas. Oral ivermectin has been used safely in koalas at relatively high doses to treat demodectic mange [55], suggesting that it might also be appropriate to use for sarcoptic mange via the oral route.

Repeated applications of topical selamectin pour-on over prolonged periods has been used under special permit conditions for treatment of free-ranging wombats via medicated burrow flaps or a "pole and scoop" method of direct application to individual wombats [54]. Dose rates and regimens vary widely and the lack of controlled trials poses safety and efficacy risks to populations under treatment [66].

Tropical fluralaner has shown efficacy against mild to moderate mange in trials on bare-nosed wombats [64]. Anecdotally, this drug has also been used with success for treating mange in common brush-tailed possums [54]. A pharmacokinetic study of fluralaner found the drug to be safe in koalas, with a duration of action of approximately one month [26]. Use of this drug in koalas is only possible under the direct supervision of a veterinarian, as the product is currently not approved for use in koalas [36].

Other antiparasitic treatments historically used to treat sarcoptic mange in koalas and other wildlife (such as malathion baths [14] and amitraz [32]) are considered obsolete.

Supportive therapy

Supportive treatment can greatly improve the success of sarcoptic mange treatment and the welfare of the individual. Supportive therapies which are recommended for wombats would also apply to koalas and may include pain relief, fluid therapy, antibiotics (if secondary infections are present), excellent nutrition and careful management of the thermal environment, as well as removal of crusts and organic debris from affected skin [54, 60]. Juvenile koalas may particularly benefit from supplementary feeding during treatment; iron and vitamin B supplementation have also been used [62].

Treatment of free-ranging koalas

Effective treatment of free-ranging individuals and populations for mange would benefit from good understanding of the parasite's epidemiology, including transmission pathways and sources of infection [54]. This information is limited for koalas, and consequently individual and population-level treatment has not been attempted *in situ* in this species [1]. Treatment of entire populations of free-ranging mammals has been undertaken in several species worldwide, with varying success [44, 67-70]. In Australia, treatment of free-ranging wombat populations has been attempted using various antiparasitic medications and administration methods. The long-term feasibility and outcomes of treating wombats remains poorly understood. Considerations of feasibility, efficacy, ecologic impact, drug resistance and cost should all be part of the evaluation process in determining if and how

antiparasitic medications should be used for population level management of sarcoptic mange [71].

5.9.7 Prevention and control

It is presently challenging to eliminate or sustainably control sarcoptic mange in wildlife populations, and this challenge can be compounded when there is greater than one pathogen reservoir present (e.g. free-ranging canids and wombats)[1].

Biosecurity precautions may be an important consideration for preventing spread of mange within rehabilitation facilities [14].

Measures which reduce environmental stress to koalas, such as conserving habitat and minimising human disturbance, are likely to be of general benefit to reducing the impact of this disease, as appears to be the case for wombats [72].

Improving or at least maintaining genetic diversity in koala populations as a whole is likely to encourage the retention of the most robust koala genetic profiles for avoiding serious consequences of infection with *S. scabiei.*

5.10 Oxalate Nephrosis in Koalas – Literature Review

5.10.1 Technical information

Description of hazard

In the context of this document, nephrosis is defined as a degenerative or inflammatory disease primarily affecting the tubules of the kidney [1]. Nephrosis is commonly associated with acute and chronic renal failure in koalas.

This chapter considers only oxalate nephrosis (ON) i.e. nephrosis associated with renal oxalate crystal deposition.

Listing

Oxalate nephrosis is not a WOAH listed disease [2] or a notifiable animal disease in Australia [3].

It is not identified as a key threatening process under the Environment Protection and Biodiversity Conservation Act [4].

5.10.2 Epidemiology

Causes of hazard

The causes of ON in koalas are poorly understood. It is likely that the disease involves a combination of genetic, dietary, gastrointestinal and environmental factors [5, 6].

A genetic predisposition to abnormal oxalate metabolism is suspected in koalas, due to the marked regional bias in the prevalence of this condition, with the majority of cases recorded in the Mount Lofty Ranges (MLR) population in SA [7, 8]. SA koala populations are principally derived from a small number of founder animals and demonstrate high inbreeding coefficients, which have been associated with testicular abnormalities [9]. Some Vic koala populations which are similarly derived from a very small number of founder animals from French Island have also been shown to have a higher prevalence of ON than more genetically diverse Vic koalas [10].

In humans, a well described disease called 'primary hyperoxaluria' occurs (hyperoxaluria = elevated oxalate levels in the urine). Affected humans have gene mutations that cause liver enzyme dysfunction and endogenous oxalate overproduction, causing increased oxalate excretion and deposition within the kidneys [11]. It is not known if this specific syndrome exists in koalas from populations with a high prevalence of ON [12]. Primary hyperoxaluria has been recently identified in another marsupial, the Gilbert's potoroo [13]. Another gene candidate for ON has been recently identified in a KoRV-based study which analysed the differential expression of genes in lymph node tissue between koalas in Qld, where ON is less prevalent, and koalas in MLR. This study revealed statistically significant upregulation of a mutated gene in MLR koalas that codes for an anion transporter involved in oxalate transport in the kidney and intestine [14]. In experimental studies with mice and rats this

gene is linked to increased urinary oxalate levels and renal oxalate deposition [15-17]. The gene has also been investigated in a limited number of preliminary studies in humans [18, 19]. In koalas the upregulation of this mutated gene may reflect a dysfunctional transporter that results in elevated oxalate levels, or conversely, a compensatory response to high oxalate due to another cause. As not all koalas demonstrating this genetic upregulation develop ON, the involvement of other genes and other factors in disease manifestation is likely [14].

In humans with inherited predisposition to abnormal oxalate metabolism, increased dietary oxalate exacerbates disease [20]. The leaves of eucalypt species eaten by koalas have a relatively low total oxalate content (<1% dry weight) when compared with plant species such as soursob, which are known to cause acute oxalate toxicity in other herbivore species (>10% dry weight), suggesting that excessive dietary oxalate intake is unlikely to be a primary cause of ON in koalas [12]. However, SA eucalypt species favoured by koalas have significantly higher (although still generally low) levels of oxalate than Qld species, and oxalate content of leaves may increase in times of drought, so there is potential for koala oxalate intake to increase depending on the types and quality of leaf being ingested [12]. An increase in dietary oxalate intake might in turn have an influence on the occurrence of ON in koalas already predisposed to the condition.

Gastrointestinal oxalate-degrading bacteria play an important role in ON manifestation in humans [21]. The role of these bacteria, particularly *Oxalobacter formigenes,* in the development of ON has received some attention in koalas. A study of faecal and caecal samples from MLR koalas (n=22) found that *O. formigenes* was present in all subjects, irrespective of ON status, and there was no significant difference in the relative abundance of *O. formigenes* or other known oxalate-degrading bacteria between affected and unaffected koalas [5]. Koalas from the MLR population had much lower levels of *Oxalobacter* spp. than previously detected in two Qld koalas [22], but this may reflect differences in methodology rather than true differences in overall abundance. It has been suggested that antibacterial treatment may be a factor in the depletion of koalas' oxalate-degrading gastrointestinal bacteria, thereby predisposing to the development of ON [23, 24]. Further investigation is required to clearly elicit the role of *O. formigenes* or other oxalate-degrading bacteria in oxalate metabolism and development of ON in koalas.

Dehydration can be a risk factor for ON in the koala. Koalas ingest water through the moisture content of the browse they consume or by drinking free water [25]. In hot weather, they experience increased water loss through convection and evaporative cooling [26, 27], and have reduced water intake due to lower leaf moisture content and lower availability of free water [25, 28], making them vulnerable to dehydration and renal stress. Food and water intake are closely associated in koalas, which obtain about 75% of their water intake from the foliage they feed on [29]. A reduction in food (and therefore water) intake due to ill health, injury, physiological stress, loss of habitat or inappropriate husbandry may similarly increase the risk of dehydration, thereby increasing the risks of ON.

Mount Lofty Ranges koalas with ON were more likely to die or be euthanased in the months following high ambient temperatures and in the months following low rainfall, although seasonal measures of eucalypt leaf water content were not associated with deaths [6]. These findings suggest that evaporative water loss and lack of availability of free water exacerbate ON in koalas in SA, which typically has long hot and dry summers. The relationship between hydration and ON has also been seen in captive koalas. In one captive institutions in SA, which has a prevalence of ON over 50%, based on presence of oxalate in urine, maintaining free water availability and hydration of browse are important to preventing exacerbation of clinical signs [30].

Marsupial young are born at a very early stage of development, and consequently are heavily dependent on their mothers' milk during organogenesis [31]. Maternal nutritional stress during lactation can have negative impacts on renal development for the joey, including nephron numbers. This may reduce the functional capacity of the growing kidneys, thereby making the joeys of nutritionally compromised dams more vulnerable to developing ON if they are otherwise predisposed [31]. This possibility warrants further investigation given the high incidence of ON reported in young koalas [32].

Geographic distribution

The majority of reported cases of ON in free-ranging koalas are associated with the MLR population in SA [7, 8, 10], with sporadic cases reported elsewhere in both captive and free-ranging koalas in Qld, NSW and Vic, and in captive WA koalas [32-36]. Oxalate nephrosis is a leading cause of disease in the MLR population in SA [7]. Other populations with increased prevalence are emerging outside of SA as targeted investigations are undertaken [10].

Prevalence

Reported cases of ON are presented in Table 21. Oxalate nephrosis is reported in both free-ranging and captive koalas in SA. In the MLR population, there was a reported prevalence of 25-54.9% in wild koalas at post mortem examination [7, 20, 37]. The Kangaroo Island population of koalas is less well studied in the context of ON but appears to have a lower prevalence of disease based on presence of oxalate crystals on urinalysis of wild koalas [32]. Several clinical cases were diagnosed in wild koalas rescued from the 2019-20 bushfires [38]. Urinary oxalate levels in SA koalas (both Kangaroo Island and MLR populations) were reported to be 5-20 times higher than those of Qld koalas [32], supporting the likelihood of higher oxalate intake or impaired endogenous oxalate metabolism in SA koalas [12, 32].

Oxalate nephrosis prevalence in free-ranging koalas in Qld and NSW ranges from 0 to 12% [32, 34-36, 39-42]. In these populations, disease is more commonly seen in koalas admitted to care for other reasons, that develop ON subsequent to admission [44]. In Qld, ON is only reported in free-ranging koalas. Facilities housing both captive and rehabilitation koalas, receiving the same range and species of browse, report that only individuals from the wild develop the disease [23]. The reason for this is not clear, but a difference in the prevalence of oxalate-degrading bacteria in the microbiome has been hypothesised [44].

Oxalate nephrosis is reported in both free-ranging and captive koalas in Vic. In Vic, ON has been recorded in wild koalas on French Is, and in several other Victorian populations which received significant numbers of koalas from French Island during reintroduction programs in

the 1930s [10, 45]. In contrast, the Strzelecki Ranges population in Vic, which is believed to be a remnant original population rather than reintroduced, had no evidence of ON based on histological examination of a small number of kidney samples [10]. The association between provenance and ON prevalence in Vic is based on low numbers of animals and is not conclusive, given ON was absent from two Vic populations (central region and Somers) which were derived from French Island founders. However, the finding lends support to the likelihood that inherited abnormalities of oxalate metabolism underlie regional patterns in the prevalence of ON [10, 14].

5.10.3 Pathogenesis

The primary pathogenic mechanism for ON in koalas is physical damage and associated inflammation caused by the deposition of calcium oxalate crystals in renal tissue [23]. The blockage of nephron tubules by crystals is also a common feature and can lead to widespread tubule dilation, tubule rupture and glomerular atrophy [20]. The progressive damage to the renal tissue compromises the kidney's ability to concentrate urine, leading to renal insufficiency and eventually renal failure [32]. It has been suggested that oxalate may also cause renal damage prior to precipitation of crystals, and that this may explain the finding of renal dysfunction in the absence of renal calcium oxalate deposition in some MLR koalas, which were shown to be hyperoxaluric [32]. In chronic cases of oxalate nephrosis, fibrosis replaces functional renal parenchyma, contributing to further deterioration in renal function [20].

Elevated levels of oxalate in the urine of affected koalas support the premise that ON is a primary cause of renal disease, since ON which occurs secondary to renal failure is generally associated with a decrease in urinary oxalate [32]. The fact that many koalas succumbing to ON are less than 2 years old also supports a primary pathogenesis [7, 32], as renal failure is not otherwise a common cause of disease in young animals.

The factors which lead to hyperoxaluria and the triggers for crystal formation within renal tissue are poorly understood [23], although a number of causes have been suggested (see *Epidemiology*).

5.10.4 Associations with other disease hazards of koalas

Any disease hazard which predisposes koalas to dehydration (or inappetence leading to dehydration) might also be expected to increase the risk of development of ON in susceptible individuals.

Prolonged antibacterial therapy, as is commonly used for the treatment of chlamydial infection, can markedly alter the koala microbiome [46]. Antibacterial therapy would be expected to deplete oxalate degrading bacteria in the koala digestive tract, although whether this could precipitate ON is yet to be demonstrated. At one wildlife hospital in Qld, over 70% of koala ON cases were associated with animals in rehabilitation receiving antibacterial treatment [23].

A post mortem study of 240 koalas from the MLR population found that koalas with ON were less likely to be infected with replication-competent KoRV than koalas without ON. It was speculated that the insertion of the KoRV provirus into host DNA might disrupt genes associated with ON development, but further understanding of KoRV pathogenesis, and the role of genetics in ON, is required to test this hypothesis [37].

5.10.5 Diagnosis

Clinical signs

Clinical signs associated with ON reflect a loss of renal function. Affected koalas may demonstrate acute, dramatic weight loss (400-1000g within less than 5 days), polyuria and polydipsia, reduced appetite, dehydration and high rates of mortality [23, 32]. Free-ranging koalas affected by ON in SA are usually rescued after being found on the ground in poor body condition or with signs of polydipsia and polyuria [20, 23, 47].

While ON is commonly associated with signs of ill health, mild ON has been detected as an incidental finding in otherwise healthy free-ranging koalas and as an incidental post mortem finding [23, 36]. Whether this reflects a preclinical phase of disease in which renal function remains adequate is unclear.

Clinical pathology

Clinical pathology findings are consistent with renal dysfunction. Serum biochemistry is consistent with renal insufficiency and is often characterized by azotaemia in conjunction with poorly concentrated urine [23, 32]. Symmetric dimethylarginine (SDMA) levels in affected koalas correlate well with other renal function parameters and are elevated above reference intervals in most cases of ON [48]. Other biochemistry parameters are generally unremarkable.

Urinary oxalate to creatinine ratio becomes elevated in animals with hyperoxaluria, although hyperoxaluria is seen in SA koalas both with and without ON, so it may not be a good indicator of clinical disease [32].

Total blood calcium is anecdotally reported to be low in affected individuals and has been used as a prognostic indicator[23]. However, this finding is not supported by systematic studies of calcium levels in affected koalas in SA [32].

Urine sediment examination is characterised by the presence of oxalate crystals, although not all affected animals will show crystalluria [32]. “Wheat-sheaf” or “bow tie” crystal formations (consistent with calcium oxalate monohydrate) are commonly seen in SA cases, whereas crystals in koalas from Qld are typically rectangular or oval, consistent with calcium oxalate dihydrate [23, 32]. Crystalline urinary casts may be visible in fresh urine samples, suggesting that in SA koala urine sediment the crystals are renal in origin [32]. In severe cases, a macroscopic pale yellow sediment is visible in the urine without the need for sedimentation techniques. Infrared spectroscopic analysis of the urine crystal sediment, and

renal precipitate, have shown a consistent pattern of calcium oxalate with some uric acid and phosphate components [20, 32].

Pathology

Pathological changes mainly involve the renal system. Kidneys may show surface pitting, mottling or streaking in the cortex, cortical pallor and white foci in the medulla [10]. Severe cases may show streaks of heavy precipitation in the papilla and medulla and a gritty yellow precipitate in the renal pelvis [20].

Renal histopathology includes tubular loss and dilation, cortical fibrosis and glomerular atrophy [20]. Yellow or clear birefringent crystals and crystal 'ghosts' (where crystals are lost during processing) may be visible, arranged in rosettes or fan shapes and varying in morphology as previously described [10, 20, 37]. A mixed intratubular inflammation may be associated with the crystals or a multifocal mononuclear interstitial inflammation [10].

Differential diagnosis

The most common cause of urinary tract disease in koalas is chlamydiosis, which can be distinguished from ON by the presence of bladder pathology and pyuria, pathology of other organ systems and the absence of crystalluria.

Clinical signs of dehydration and weight loss seen with ON are non-specific and may be associated with most koala diseases. Polydipsia may be seen in animals that are dehydrated or heat stressed, but this is not accompanied by polyuria unless there is renal compromise.

Diagnostic testing

Definitive diagnosis of ON is based on identification of the characteristic crystal morphology in sediments of voided urine or on renal histopathology [20, 32]. Renal ultrasound is an important diagnostic tool in live animals [23]. Renal function testing through serum biochemistry (urea, creatinine and SDMA) and urinalysis should be part of the diagnostic process where ON is suspected [48].

Surveillance and monitoring

There is no targeted national surveillance or monitoring program for ON in koalas, although there is capacity to utilise the Wildlife Health Australia national wildlife health information system database (eWHIS) as a place for collating these data as part of national general wildlife surveillance activities.

5.10.6 Treatment

Treatment of ON is challenging and generally unsuccessful in advanced cases. Prevention, early detection and early intervention are important to successful management. Most aspects of treatment are supportive in nature, including fluid therapy, optimising nutrition and minimising stress [23].

The provision of a high diversity of good quality eucalypt and non-eucalypt browse species is always important in the supportive care of koalas. In cases of ON it may be important to specifically supply low oxalate browse to the koala, and to manage dehydration by leaf spraying and provision of drinking water, particularly on hot days [6, 12, 23]. Increasing fibre and fluid intake through syringe feeding of leaf or pumpkin puree has been recommended by clinicians [30].

Maintaining a healthy gut biome is considered critical in the clinical management of ON [30]. As well as providing high quality nutrition, oral administration of koala caecal contents may be beneficial in restoring oxalate-degrading bacteria to the gut. In humans with abnormal oxalate metabolism, the administration of probiotics containing *O. formigenes* has a supportive role in reducing urinary and plasma oxalate levels, but this treatment has not been tested in koalas with ON [5, 23].

Some therapeutics used in the treatment of humans with renal disease and ON, including benazepril [49], stiripentol [50] and vitamin B6 [51], have been incorporated into the treatment of koala cases. No pharmacokinetic studies of these treatments have been undertaken in koalas, although benazepril anecdotally appears to reduce ON disease severity and likelihood of recurrence [30]. Propentofylline (Vivitonin®) has been used by some clinicians as an adjunctive therapy [30] as this family of drugs has been shown in some species to improve renal blood flow [52, 53], although its effects on the koala kidney function have not been investigated. Such ongoing medical treatments are likely to be most suitable for managing ON cases in captive koalas.

Oral treatment with calcium carbonate theoretically assists in binding dietary oxalate in the gastrointestinal tract and reducing absorption of unbound oxalate in cases of ON [51]. Anecdotally, this has been beneficial in preventing advancement of disease in rehabilitation koalas in Qld, allowing them to maintain sufficient renal function to enable eventual release [44], but no such therapeutic benefit has been seen in SA koalas [30]. Calcium carbonate therapy may induce temporary hypercalcaemia, causing diarrhoea and inappetence [23].

Response to rehydration and return of urine specific gravity to normal levels within 3 days of treatment are considered good prognostic indicators in koalas with ON that experience episodic illness [30].

5.10.7 Prevention and control

Prevention of ON in free-ranging koalas focuses on strategies to prevent dehydration. Maintaining habitat quality, quantity, diversity and connectivity is likely to be important in this context. Strategies which reduce hydration stress on trees, such as improving catchment and slowing water outflow, are important considerations for maintaining the moisture content of foliage on koala feed trees [54], and may also reduce the concentration of oxalate in leaves [12]. Habitat quality, quantity, diversity and connectivity are also essential to provide refugia from thermal stress for koalas [55].

Free water stations may be a practical management tool for offsetting water loss in free-ranging koalas and might slow or prevent development of ON in susceptible populations [6, 27].

Strategies to prevent dehydration of koalas and koala browse are also important to preventing the development of ON in captive and rehabilitation facilities. Misting or spraying browse with water will help to preserve the moisture content of the leaf, as well as incidentally increasing the koala's water intake [6, 12, 56]. Careful storage of cut browse branches (refrigeration; standing the cut end in water which is replenished daily) will help to maintain leaf moisture [23]. Supportive strategies to reduce stress, concurrent disease or debilitation are important for ensuring good nutrient and moisture intake in koalas in captivity and in rehabilitation. This is particularly important for lactating mothers to ensure healthy renal development in joeys.

There is currently insufficient information to determine the feasibility or benefit of diversifying the genetics of populations susceptible to ON. However, supporting genetic diversity in koala populations individually and as a whole will encourage retention of the most robust koala genetic profiles for adapting to a changing climate and coping with the impacts of high ambient temperatures and drought.

5.11 Novel *Actinomyces* sp. in Koalas – Literature Review

5.11.1 Technical information

Aetiological agent

Actinomyces is a genus of anaerobic or facultative aerobic, Gram-positive, filamentous bacteria [1]. A novel species of *Actinomyces* (termed here *Actinomyces* sp. nov.) has been found, associated with pneumonia in a number of free-ranging South Australian koalas [2]. The *Actinomyces* sp. found in koalas was sequenced from multiple isolates and showed less than 95.1% similarity to the closest *Actinomyces* species, *A. timonensis* [2].

Listing

Novel *Actinomyces* sp. is not a WOAH listed disease [3].

Actinomycotic pneumonia is not a notifiable animal disease in Australia [4].

Actinomycotic pneumonia is not identified as a key threatening process under the Environment Protection and Biodiversity Conservation Act [5].

5.11.2 Epidemiology

Actinomyces spp. can be found in the healthy microbiota of the human oropharynx, gastrointestinal tract and urogenital tract [6-9] and on nasal, oral or oropharyngeal mucosal surfaces and within the urogenital tract of other animals [1, 8-11].

Species of *Actinomyces* can cause sporadic or rare disease in humans and animals [1, 6, 7, 12-14]. Disease from *Actinomyces* spp. are most often associated with opportunistic infections where there has been a breakdown in the normal immunological defence of the animal, which has allowed opportunistic entry of the bacteria [1, 9]. Lumpy jaw (caused by *A. bovis*), a disease of cattle, occurs when there is a loss of integrity of the oral mucosa (generally caused by a penetrating wound). Bacteria then gain entry to the submucosal tissues and cause disease [15]. *Actinomyces* spp. have also been found in cases of progressive periodontal disease in macropods, as a part of multi-organism infections [16-18]. In humans, dental disease has been associated with pulmonary actinomycosis [6, 12, 19].

Novel *Actinomyces* sp. has been found as the predominant bacteria isolated from 17 cases of pneumonia in wild South Australian koalas since 2016. The disease in koalas has been termed pulmonary actinomycosis [2].

Host range

The host range of the novel *Actinomyces* sp. found in koalas is not known, however it has not been identified in host species other than the koala.

A small number of other wildlife species have been reported with pulmonary actinomycosis, including two free-ranging chamois [20], one free-ranging black-tufted marmoset [21], a

captive red kangaroo [22] and a captive bare-nosed wombat [23]. Most studies did not differentiate the *Actinomyces* involved to the species level but *A. hyovaginalis* was identified in the bare-nosed wombat [23].

Zoonotic potential

There is no evidence of animal-to-human transmission of any *Actinomyces* spp. Human-to-human transmission of *Actinomyces* spp., via contaminated bite wounds, has been reported [8].

The zoonotic potential of the novel *Actinomyces* described in koalas has not been determined, but due to the nature of the non-transmissible, opportunistic autologous infections seen in other animal species, the zoonotic potential is considered very low.

Geographic distribution

Species of *Actinomyces*, and resulting disease, have been reported globally [1, 6, 7, 12-14]. The novel *Actinomyces* sp. causing pneumonia in koalas has only been reported in SA [2]. Investigations in Qld have detected *Actinomyces* spp. in a case of aspiration pneumonia in a wild koala (eWHIS case 14690) but the species is not known [24].

Prevalence

A mortality study of SA koalas (2016-2019) reported 17 cases of pulmonary actinomycosis, of a total of 240 cases [25]. Subsequently, there have been at least four more cases of pulmonary actinomycosis reported in SA koalas [26].

Mode of transmission

Actinomyces spp. infections are classified as endogenous. These bacteria are not considered contagious and are generally not transmitted directly between individuals [1, 9, 12]. The pathway by which koalas acquire novel *Actinomyces* infection is currently not known. It is hypothesised that *Actinomyces* sp. nov. is a normal part of the koala's gastrointestinal microbiome, as *Actinomyces* spp. have been found in both healthy and diseased oral microbiomes of other mammals [1, 6, 10, 18]. Opportunistic infections may arise when there is a disturbance in immunological defence mechanisms in the individual koala.

Incubation period

The incubation period for Actinomyces spp. in general is not known, however the development of disease as a result of Actinomyces infection is generally considered to be slow and chronic in nature. Due to the prolonged timeline, the inciting cause often cannot be identified. Cases of pulmonary actinomycosis in humans have shown chronic progression over months [6, 12, 19]. The incubation period in koalas is not known.

Persistence of agent

Assuming *Actinomyces* sp. nov. is a commensal organism, persistence in the environment is unlikely to be important in the epidemiology of the disease. However, this remains unverified.

5.11.3 Pathogenesis

There is limited understanding of the pathogenesis of pulmonary actinomycosis in the koala. It is assumed that the non-contagious, commensal bacteria, forming part of the healthy gastrointestinal microbiome of the koala, opportunistically invade the lower respiratory system, as a result of unidentified initiating factors [2].

In humans, aspiration is a leading initiator of *Actinomyces* pneumonia with parenchymal or lobar pneumonia affecting the lower lung lobes [6, 7, 27]. A similar pattern of pneumonia has been seen in affected koalas. Other types of aspiration in koalas are generally assocaited with bottle-feeding orphaned joeys, and have a more cranial lung lobe distribution [28, 29]. Histological plant fragments, indicative of aspiration, were found in microscopic examination of lung tissues in two of the cases of pulmonary actinomycosis in koalas [2]. Culture of lung tissue from cases of pulmonary actinomycosis in koalas also isolated other anaerobic bacteria species which are commonly found in the oral microbiome of the koala [2, 30].

Because actinomycotic pneumonia has only be diagnosed in SA koalas, one hypothesis is that the disease may have a genetic component [31]. Koalas that develop pulmonary actinomycosis may be genetically predisposed to the disease because they lack key immune alleles that would enable them to mount an effective immune response. Koalas may also be genetically predisposed to carry novel *Actinomyces* sp. as part of their alimentary microbiome, rendering them more likely to develop pulmonary actinomycosis if inhalation of alimentary tract content occurs. Alternatively, affected koalas may have genetically-based anatomical differences that predispose them to aspiration, such as an elongated soft palate, a straighter trachea which encourages laminar flow to deep within the lungs, or dental malocclusions which lead to a to dental disease [32]. These factors are speculative but may underpin a predisposition to actinomycotic pneumonia in the SA population [31].

5.11.4 Associations with other pathogens

No associations have been found in affected koalas between pulmonary actinomycosis and infection with koala retrovirus (KoRV) or *Chlamydia pecorum* [2, 21], although only a few cases have been investigated. No other disease associations have been investigated or hypothesised at this stage.

5.11.5 Diagnosis

Clinical signs

Koalas presenting with pulmonary actinomycosis may show signs of respiratory distress and may also have a reduced body condition score (emaciated, poor or fair). Radiographic investigations may show extensive or lobar pneumonia, but this is not specific for pulmonary actinomycosis [2].

Secondary hypertrophic osteopathy was found in four cases of pulmonary actinomycosis in koalas, and was diagnosed radiographically [33].

Clinical pathology

There are no reported clinical pathology findings diagnostic of pulmonary actinomycosis [2].

Pathology

Pulmonary actinomycosis in koalas is characterised by marked pyogranulomatous lobar pneumonia, most commonly affecting the left caudal lobe. *Splendore-Hoeppli* phenomenon and intralesional, variably Gram-staining, non-acid fast filamentous bacteria, consistent with *Actinomyces* sp., were present in all investigated cases. These findings support the hypothesis that a significant pathogen in all reported pneumonia cases is a novel *Actinomyces* sp. The observed lesions in koalas were consistent with actinomycotic lesions observed in other species [20, 21]. Disseminated actinomycosis has been reported in one free-ranging koala from SA, with lesions in the kidney and skeletal muscle, as well as lung [34].

Differential diagnosis

Pathogens reported to cause pneumonia in koalas include *Bordetella bronchiseptica* [35, 36], *Chlamydia* spp. [29, 37, 38] and *Cryptococcus gattii* [35, 39]. *Bordetella bronchiseptica* has been identified in outbreaks of pneumonia in captive koala colonies in Qld [36] and NSW [35, 40], either as a primary pathogen, or secondary to other diseases such as cryptococcosis or chlamydiosis [35]. Cryptococcal infections have not been reported in koalas in SA, therefore this is considered less likely as a differential in SA koala populations. Other bacterial infections have been reported to be associated with pneumonia in koalas [40-44].

Secondary hypertrophic osteopathy has not been reported in koalas in the absence of pulmonary actinomycosis [33].

The histopathological changes seen in actinomycosis (*Splendore-Hoeppli* phenomenon) may also be seen in nocardiosis or botryomycosis [20]. Differentiation of the pathogen occurs through special staining and histopathological examination. *Nocardia* are acid-fast, but *Actinomyces* are not, and in botryomycosis, the organisms implicated are generally non-filamentous [20].

Diagnostic testing

Broncho-alveolar lavage or tracheal wash can be used to help diagnose the presence of pneumonia and differentiate the cause. Ultrasound-guided fine needle aspirate of lung lesions has been used to aid diagnosis in a macropod [22]. Diagnosis of novel actinomycosis in koalas was via histopathology of lung tissue [2].

Surveillance and monitoring

Novel *Actinomyces* of koalas is an emerging disease, and no formal surveillance or monitoring is currently being conducted.

5.11.6 Treatment

No treatment protocols have been trialled or established for novel *Actinomyces* infection in koalas. Choice of antibiotic should be based on culture and sensitivity testing of samples obtained via bronchioalveolar lavage. Chloramphenicol has been used to treat similar cases in other animals and humans.

Cattle with lumpy jaw are treated with intravenous sodium iodide with concurrent broad-spectrum antibiotic therapy, with a guarded prognosis if deformity and malalignment of the jaw is present [45]. Cats and dogs with actinomycosis have been treated with drainage of abscesses or effusions and prolonged antibiotic therapy, inclusive of penicillin, amoxicillin and chloramphenicol [46]. In humans, prolonged high dose antibiotic treatment (6-12 months) with penicillin or amoxycillin is needed and surgical resection may help reduce the longevity of treatment [6].

5.11.7 Prevention and control

Currently, no prevention or control methods have been identified for actinomycotic pneumonia in koalas. Novel *Actinomyces* is not considered transmissible between koalas. It is considered unlikely that a vaccine would be developed for this pathogen. As dental disease has been associated with pulmonary actinomycosis in humans, and dental disease is often seen in koalas [47, 48], it is thought that this may contribute to the incitement of pulmonary actinomycosis [2]. A greater understanding of the likely initiating factors, incubation period and treatment options will be required before prevention and control strategies for pulmonary actinomycosis in koalas can be developed.

5.12 Phascolarctid Herpesviruses – Literature Review

5.12.1 Technical information

Aetiological agent

Koalas are known to be hosts to three herpesviruses, designated phascolarctid herpesvirus 1 (PhaHV-1), phascolarctid herpesvirus 2 (PhaHV-2) and putatively phascolarctid herpesvirus 3 (PhaHV-3) [1, 2]. PhaHV-1 and PhaHV-2 are gammaherpesviruses [1-3]. A novel alphaherpesvirus (PhaHV-3) was identified in a sick captive female koala from Qld [4]. The animal had pneumonia, hepatitis and adrenalitis as well as concurrent lung disease due to *Cryptococcus gattii*. The novel alphaherpesvirus was shown to be most closely related to macropod alphaherpesvirus-1. No other cases have been reported of this novel herpesvirus and it is not known if the natural host of the novel virus is the koala, or if in this instance the virus spilled over from another host. This alphaherpesvirus is not considered further in this literature review.

All herpesviruses detected so far in marsupials belong to the *Alphaherpesvirinae* and *Gammaherpesvirinae* subfamilies [1, 2, 5].

Listing

Phascolarctid herpesviruses are not WOAH listed animal diseases [6].

Herpesvirus infection due to phascolarctid herpesviruses is not a notifiable animal disease in Australia [7].

Disease due to phascolarctid herpesviruses is not identified as a key threatening process under the Environment Protection and Biodiversity Conservation Act [8].

5.12.2 Epidemiology

The study of koala herpesviruses is still in its infancy, although epidemiological data are now available for koala populations in Vic [9, 10], SA [11], NSW and Qld [12]. Only a few studies have attempted to evaluate the association between PhaHV infection and risk factors for disease [4, 9-11, 13].

Phascolarctid herpesviruses 1 and 2, like other gammaherpesviruses, appear to be host specific and probably co-evolved with their host [5]. The detection of PhaHV-1 and -2 in the French Island koala population, which has been closed to introductions for over 100 years, supports the likelihood that these viruses have been present since before European habitation of Australia [10]. More data are required from more geographically widespread captive populations to fully support this theory.

Once infected with a herpesvirus, an animal remains infected for life. The virus generally lies dormant within host cells (“latent” infection), until infection is reactivated by factors such as stress or immune compromise. During the “lytic” (active) phase, the virus replicates within the host cell, and releases a new generation of viruses when the infected host cell lyses. The

viral infection can be transmitted to other individuals during the lytic phase (see *Pathogenesis*) [14].

Adult koalas in both SA and Vic free-ranging populations were found to be significantly more likely to be positive for PhaHV-1 (but not PhaHV-2) than juveniles [10, 11]. For PhaHV-2, juveniles were as likely to be positive as older animals. Increasing age was a significant risk factor for co-infection with PhaHV-1 and -2 in both female (Vic and SA) and male (Vic) koalas [10, 11]. The discrepancy in age associations between the two viruses might point to differences in transmission dynamics (see *Mode of transmission*).

No differences in sex prevalence have been identified for PhaHV-1 and -2 infections. However, female koalas without pouch young were more likely to be positive for PhaHV-1 or PhaHV-2 or coinfected with PhaHV-1 and PhaHV-2, than females with pouch young, suggesting a possible association between herpesvirus infection and reduced fertility [10].

Where one gammaherpesvirus subtype is detected in an individual koala, there is a high likelihood that the other gammaherpesvirus will also be detected. Oropharyngeal detection of PhaHV-1 was 3.5 times more likely if PhaHV-2 was also present [11].

Host range

The only known host of PhaHV-1 and PhaHV-2 is the koala, consistent with the host specificity of gammaherpesviruses in general [5].

Zoonotic potential

The zoonotic risk of PhaHV is considered very low as gammaherpesviruses are highly host-specific [3, 14].

Geographic distribution

Both PhaHV-1 and -2 have been detected in all free-ranging and captive populations of koalas tested in Vic and SA koalas [10, 11]. PhaHV-1 has been detected in a range of NSW and Qld free-ranging populations (PhaHV-2 was not examined in this study) [13].

Prevalence

Prevalence studies of PhaHV in koalas have been undertaken using PCR assays. PCR tests cannot differentiate between the lytic and latent phases of PhaHV infections [10]. PhaHV occurs at moderate to high prevalence in studied populations. A survey of 810 koalas from widespread locations across Vic demonstrated significant variation in prevalence, ranging from 7.4-45.5% for PhaHV-1 and 0.9-54.6% for PhaHV-2 [10]. Significant longitudinal variations in prevalence have been reported. Over the course of three years, the prevalence in the Raymond Island population decreased from 45% to 17%, and that of the Cape Otway area population reduced from 39% to 22%. Conversely, PhaHV-2 prevalence was higher in the French Island population in 2013, compared to 2011 [10].

A study of wild koalas in the Mount Lofty Ranges of SA detected PhaHV in 73% (58/80) of individuals. The prevalence of PhaHV-1 and -2 was 57.5% (46/80) and 40.0% (32/80) respectively in wild caught koalas, and 46% (40/87) and 27.5% (24/87), respectively in necropsied koalas [11]. Positive oropharyngeal swabs were found in 74.6% of the infected cases (54.0% of the euthanased cohort). Co-infection with both PhaHV-1 and PhaHV-2 (as determined from post mortem sampling of spleen) was significantly correlated with presence of both virus subtypes in oral swabs.

Studies of koala populations in Qld and NSW found PhaHV-1 in all sampled regions, however study design did not allow for prevalence data to be developed [13].

Mode of transmission

The means of transmission of herpesviruses in koalas has not been extensively studied, and what is known is mostly extrapolated from studies of related viruses in humans and other animal species. Gammaherpesviruses may be shed from various sites in the body during their infective lytic stage, which affects the possible means of transmission; for example, the viral load of ovine herpesvirus-2 is high in the lung and the vesicular gland, suggesting that both respiratory and venereal transmission might be possible [15].

The fact that PhaHV-1 prevalence increases with age while PhaHV-2 prevalence does not appear to do so, may suggest PhaHV-1 is more likely to be acquired through activity related to maturation, such as sexual contact or aggressive behaviour associated with breeding, whereas PhaHV-2 may be more likely to be acquired in infancy, through close contact with the mother while in the pouch [10].

Incubation period

There is no information available on the incubation period of PhaHV. Because initial infection with gammaherpesviruses can be asymptomatic, it is difficult to determine incubation period. The permanency of gammaherpesvirus infection, and the latency and reactivation behaviour of these viruses also means that incubation period is not likely to be of epidemiological relevance.

Persistence of agent

The persistence and stability of PhaHV in the environment has not been studied. Herpesviruses in general are fragile in the environment and have known sensitivity to several different chemical disinfectants, solvents and detergents [3].

The persistence of herpesviruses as a latent infection within the host is discussed in *Pathogenesis.*

5.12.3 Pathogenesis

Knowledge of the pathogenesis of PhaHV-1 and -2 is based on extrapolations from other herpesviruses. Features of pathogenesis common to all herpesviruses include destruction of infected cells during lytic infection; the occurrence of virus transcription, DNA synthesis and

nucleocapsid assembly in the nucleus of infected cells; and the reversion to latency within host cells, from which reactivation to the lytic stage can occur [14].

Gammaherpesviruses are lymphotropic by nature, infecting epithelial cells initially, then typically establishing latency within lymphocytes in the host spleen and lymph nodes [5, 14]. During latency, only a small subset of the herpesvirus genome is expressed, and the virus lays dormant. The virus prevents the death of the infected cell via the translation of effector proteins which interfere with natural cell pathways, thus evading the host's immune system. Reactivation from the latent state to the replicating, lytic state is typically associated with host immunosuppression, external or environmental stressors, or concurrent infection [15]. Reactivation is followed by rapid virus replication, lysis of the host cell, and shedding of active virus [14].

The viral and cellular mechanisms controlling latency and reactivation by gammaherpesviruses are not well understood, but it is thought that latency represents a "default" mechanism where failure of immediate gene expression leads to maintenance of the genome in a circular configuration [14].

It is likely that the typical cellular behaviour of gammaherpesviruses also occurs with PhaHV-1 and PhaHV-2, although the details have yet to be elucidated. Sites of latency and shedding for PhaHV-1 and -2 have not been confirmed [10]. In the SA study of euthanased koalas, all koalas which tested positive on oropharyngeal swab also had positive tests from splenic swabs, which was postulated to suggest that PhaHV forms latent infections in the spleen [11]. However, if lymphocytes are sites of latency for PhaHV, this finding might also reflect the high concentration of these cells within the spleen, rather than the spleen being a specific organ for viral latency [14].

The detection of both PhaHV-1 and -2 in oropharyngeal swabs suggests that virions may be shed from epithelial cells in koalas, but it is also possible that detection of PhaHV-1 and -2 in swabs of rostral and caudal epithelial sites may represent detection of latent virus at those sites. Severe lymphoid depletion in lymph nodes and spleen was reported in the index cases of PhaHV-1 and PhaHV-2 infection but this may have been related to other disease [1, 2].

In humans, gammaherpesviruses include the lymphotropic tumour viruses Epstein-Barr virus and Kaposi's sarcoma-associated herpesvirus, both important causes of lymphomas and other neoplasms in immunosuppressed populations, particularly in association with the lentivirus human immunodeficiency virus [16]. Given the high incidence of lymphomas and other neoplasia in koalas and the likely role of KoRV in increasing neoplasia risk (see Appendix 5.6 *Neoplasia in Koalas – Literature Review*), this association merits further exploration.

5.12.4 Associations with other disease hazards of koalas

The presence of both PhaHV-1 and PhaHV-2 has been strongly associated with concurrent infection with *Chlamydia pecorum* in koalas [9, 10, 13], although in one SA study this

relationship was only identified in females [17]. The nature of the association between *Chlamydia* and herpesvirus infection in koalas remains unclear but possibilities include reactivation of latent PhaHV infection secondary to the immunological challenge of concurrent *Chlamydia* infection (or vice versa); concomitant transmission of both pathogens; increased susceptibility to PhaHV entry in *Chlamydia*-infected cells; or PhaHV-induced persistence of *Chlamydia* [9, 10, 13]. In one study, koalas co-infected with *Chlamydia* and PhaHV-1 were treated for chlamydial disease, with a resultant 10-fold decrease in PhaHV-1 shedding, suggesting that active chlamydial disease may drive PhaHV-1 shedding [18]. *In vitro* studies of *C. trachomatis* and human herpesviruses have demonstrated synergistic effects of co-infection for pathogenicity of both agents. Herpesvirus can induce persistence of chlamydial infection within cells, while the entry of herpesvirus into cells is facilitated if cells are infected with *Chlamydia* [19, 20].

The link between PhaHV and KoRV status in koalas is unclear and associations have not been extensively studied. KoRV-positive female koalas in Vic were twice as likely to be positive for PhaHV-1 (but not PhaHV-2) than those where KoRV was not detected [10]. There was no identified relationship with KoRV status in males. Interactions between PhaHV-1 and KoRV could result in an increased risk of opportunistic infections causing disease [10].

In other species, including birds [21] and humans [22], retroviral oncogenesis is augmented in the presence of gammaherpesvirus infection. An association has been identified between the incidence of neoplasia and co-infection with KoRV and PhaHV-2 [17], although the data are insufficient to draw any conclusions regarding viral cooperation in oncogenesis.

Molecular testing of 137 koalas from the Mt Lofty Ranges in SA found co-infection with KoRV, *Chlamydia* and PhaHV in 16.1% of individuals, but the only significant co-infection association was between *C. pecorum* and PhaHV-1 [17].

5.12.5 Diagnosis

Clinical signs

There are no clinical signs that are pathognomonic (uniquely diagnostic) for PhaHV infection. However, associations have been described between PhaHV infection and certain clinical presentations.

Associations between herpesvirus infection and general markers of ill health, have been identified in a study of koalas (n=87) euthanased on welfare grounds in SA [11]. In this study, increased tooth wear was positively and significantly correlated with PhaHV-1 detection. In addition, koalas positive for PhaHV-2 (but not PhaHV-1) were 3.5 times more likely to have a low body condition score than those which were not positive for the virus. These findings may suggest a role for herpesvirus in contributing to overall debilitation in koalas or may be reflective of increased shedding of virus due to compromise in an animal's health status. The possibility of reactivation and subsequent detection of herpesvirus

secondary to other disease processes, or due to general poor health of the host, should be considered when interpreting PhaHV results in koalas [10].

Clinical disease of the urogenital tract has been associated with herpesvirus infection. “Wet bottom”, a clinical syndrome often attributed to chlamydiosis in koalas [23-25], was identified as a significant risk factor for concurrent infection with both PhaHV-1 and -2 in koalas in Vic populations [10]. The presence of both PhaHV-1 and -2 are significantly associated with urinary incontinence and genital tract abnormalities (uterine and ovarian cysts; testicular malformation) in female and male koalas, as well as lowered fertility in females [10, 26]. The association with reproductive abnormalities was stronger with PhaHV-2, whereas the association with wet bottom was stronger for PhaHV-1 [10]. Because of the high incidence of co-infection between the herpesviruses and Chlamydia, it is difficult to separate the clinical variables associated with each individual agent. However, given that wet bottom is not pathognomonic for chlamydial infection (see Appendix 5.1 *Chlamydia spp. in Koalas - Literature Review*), the role of herpesviruses in this syndrome warrants further investigation.

A retrospective study of koala post mortem cases in SA found an association between reproductive disease and PhaHV infections. Of koalas with paraovarian cysts, 81% were infected with either PhaHV-1 or PhaHV-2, and *C. pecorum* was only ever identified in co-infection with PhaHV in koalas with paraovarian cysts, never as the sole infectious agent present [17]. This may suggest a role for PhaHV in exacerbating reproductive disease in koalas.

Conjunctivitis was associated with PhaHV-1 detection, and not with *Chlamydia* detection, in a study of SA koalas [17]. This may suggest a possible role for herpesvirus as a differential diagnosis for ocular disease in cases where *Chlamydia* is not detected.

The three koalas in which PhaHV-1 and -2 were first identified demonstrated clinical signs associated with various comorbidities, including dermatitis associated with sarcoptic mange, and chronic interstitial nephritis, cystitis and conjunctivitis consistent with chlamydiosis (although the *Chlamydia* status of these individuals was not reported). No signs were common to all three animals [2].

Clinical pathology

No clinical pathology signs have been typically associated with PhaHV-1 and -2 infection, although systematic studies are lacking.

Pathology

There has been no systematic study of pathology in koalas infected with PhaHV-1 and -2, with studies to date identifying correlations but not causations. Although intranuclear inclusion bodies have been identified on histopathology for other marsupial herpesviruses and for PhaHV-3 [4, 5], they have not been reported for PhaHV-1 and -2.

The three koalas in which PhaHV-1 and -2 were first identified demonstrated marked to severe lymphoid depletion in the spleen and various lymph nodes, consistent with chronic stress or chronic infectious disease [1, 2]. However, in the absence of detailed information on disease screening for other infectious aetiologies (particularly *Chlamydia*), it is not possible to determine the extent to which this pathology was attributable to PhaHV infection.

Differential diagnosis

In the absence of a definitive clinical picture, there is no clear differential diagnosis for PhaHV-1 and -2 infection.

Diagnostic testing

Phascolarctid herpesvirus DNA has been detected from conjunctival, nasal, oropharyngeal, cloacal and prepuce swabs, and from the liver and spleen of koalas, using PCR techniques [1, 2, 4, 5, 9-11, 13, 27, 28]. Current molecular methods used to detect PhaHV-1 and -2 are sensitive but labour intensive. A loop-mediated isothermal amplification (LAMP) assay has been developed as a point-of-care test for PhaHV-1 in koalas [12], however there are no commercially-available diagnostic tests for PhaHV-1 and -2 that would enable diagnosis in a clinical setting.

In Vic populations, PhaHV-1 and 2 were twice as likely to be detected by PCR from urogenital/cloacal swabs, rather than swabs collected from oral/nasal/conjunctival sites [10]. In SA populations, the oropharyngeal site was most likely to detect PhaHV in live animals, and the spleen was the most likely site of detection in necropsied koalas [11]. This may reflect the high concentration of lymphocytes within the spleen rather than the role of the spleen as a site of latency [29]. Current recommendations include collection and testing of multiple pooled samples from urogenital and oropharyngeal areas to maximise sensitivity [28].

Koalas that test positive on PCR should be assumed to have lifelong infections, given the latency potential of herpesviruses [5]. Currently, latent and lytic infection cannot be differentiated by PCR test.

Tests to detect serum antibodies against PhaHV are not currently available. Serological tests would be a valuable means to detect herpesvirus exposure in animals in which PCR tests are negative at the time of sampling.

Surveillance and monitoring

There is no targeted surveillance or monitoring program in place for PhaHV in koalas. However, there is capacity to utilise the Wildlife Health Australia national wildlife health information system database (eWHIS) as a place for entering data as part of national general wildlife surveillance activities.

5.12.6 Treatment

There is no effective treatment for marsupial herpesvirus infections and there are no reports of the use of antiviral drugs for treating clinical cases in koalas. Further *in vivo* studies are required before recommending the clinical use of antiviral drugs in herpesvirus disease in koalas [5].

Treatment of herpesvirus infections in koalas is likely to include supportive care such as good nutrition, symptomatic treatment for clinical illness and management of concurrent diseases. Given the role of immunosuppression and stress in the pathogenesis of gammaherpesviruses, reducing sources of stress and demands on the koala's immune system is also a priority [5].

5.12.7 Prevention and control

There are few prevention or control methods identified for PhaHV. PhaHV-1 and -2 have been detected in all free-ranging and captive populations of koalas tested to date, at high rates of prevalence [10, 13], and it is highly likely that they have co-evolved with their host [5]. Therefore, the options for preventing exposure to the virus in wild koalas are likely to be limited. Testing koalas in rehabilitation for herpesvirus, and managing individuals while in care based on their herpesvirus status has been proposed as a possible risk mitigation option [13]. Koalas undergoing rehabilitation are likely to be physiologically stressed, and this may increase their likelihood of shedding virus if latently infected, or increase the rate of viral expression [15], thereby increasing herpesvirus transmission risk.

Management of concurrent infections and minimising external environmental stressors are likely to be very important to control of herpesvirus-associated disease [5].

5.13 *Trypanosoma* spp. in Koalas – Literature Review

5.13.1 Technical information

Aetiological agent

Trypanosomes are flagellated protozoa which have an indirect life cycle involving an arthropod vector and a vertebrate host [1, 2]. Trypanosomes found in Australian mammals appear to be endemic to the continent [3]. Among the introduced trypanosome species believed to be widely distributed in Australia (*Trypanosoma lewisi, T. melophagium* and *T. theileri*), only *T. lewisi* has been identified in an Australian mammal, specifically an endemic rodent [3]. The remainder of this chapter will therefore focus on endemic Australian trypanosomes.

Seven trypanosome species have been identified to date in koalas: *T. irwini, T. gilletti, T. copemani, T. vegrandis*, *T. noyesi*, a novel species currently identified as *Trypanosoma sp.* AB-2017 and a potentially novel species within the *T. cruzi* clade [4-8].

Listing

Surra (*T. evansi*) and tsetse-transmitted trypanosomiasis (*T. congolense, T. vivax, T. brucei, T. uniforme, T. simiae*) are the only WOAH listed trypanosome diseases [9].

Koala trypanosome infections are not notifiable animal diseases in Australia [10].

Disease due to trypanosome infection is not identified as a key threatening process under the Environment Protection and Biodiversity Conservation Act [11].

5.13.2 Epidemiology

Host range

With the development of sensitive molecular techniques and increasing surveys of vertebrates over a wider geographical range, a growing number of hosts are being identified for Australian trypanosome species [3]. Table 22 summarises current knowledge of host range and distribution in Australian mammals.

Table 22 Host range and geographic location for trypanosome species found in koalas [1]

Trypanosome species	Native Australian mammalian hosts	Geographic locations	References
T. irwini	Koala, eastern bettong, brush-tailed rock wallaby, yellow-footed rock wallaby, eastern quoll, swamp wallaby	Qld, NSW, Vic	Barbosa et al. 2019 [1], Krige 2022 [12], Barbosa et al. 2017 [13], Howard 2022 [8]
T. gilletti	Koala, brush-tailed bettong	Qld, NSW, WA	McInnes et al. 2011 [5], Barbosa et al. 2017 [7], Cooper et al. 2018 [14], McInnes et al. 2011 [15], Howard 2022 [8]
T. copemani	Koala, brush-tailed possum, bare-nosed wombat, Gilbert's potoroo, quokka, quenda, eastern quoll, spotted-tailed quoll, chuditch, brush-tailed bettong, brush-tailed rock wallaby, Tasmanian devil	Qld, NSW, Vic, Tas, WA	McInnes et al. 2011 [5], Barbosa et al. 2017 [7], Krige 2022 [12], Austen et al. 2011 [16], Austen et al. 2009 [17]
T. vegrandis	Koala, northern brown bandicoot, quenda, tammar wallaby, western grey kangaroo, chuditch, brush-tailed bettong, Gould's wattled bat, lesser long-eared bat, black flying-fox, little red flying-fox	Qld, NSW, WA, NT	Barbosa et al. 2019 [1], Barbosa et al. 2017 [7], Krige 2022 [12]
T. noyesi	Koala, eastern grey kangaroo, common brush-tailed possum, burrowing bettong, brush-tailed bettong, banded hare wallaby, swamp wallaby, bush rat, chuditch	Qld, NSW, ACT, Vic, WA, NT	Barbosa et al. 2019 [1], Krige 2022 [12], Botero et al. 2016 [18]
Trypanosoma sp. AB-2017	Koala	Qld	Barbosa et al. 2017 [7]
Novel species within the *T. cruzi* clade	Koala	SA	Howard 2022 [8]

Zoonotic potential

While some trypanosome species are zoonotic, no Australian trypanosome species have been known to infect humans. However, *T. copemani* has been shown to grow in human serum *in vitro* [19] and further research is required to determine its zoonotic potential [7].

Geographic distribution

Trypanosome infection has been reported in koalas in NSW, Qld and SA (Table 22). Isolated studies (n <10 individuals) involving koalas located elsewhere in Australia, have not detected trypanosomes [20, 21]. Several of the trypanosome species known to infect koalas have been detected in other Australian mammals elsewhere in Australia (Table 22), so a broader distribution of trypanosomal infection in koalas is likely.

Prevalence

An understanding of the true prevalence of trypanosome infection in koalas is hindered by the limited investigations to date [1]. A high proportion (almost 74%) of koalas in one study were infected with at least one trypanosome species, with *T. irwini* being the most commonly detected species (71.1%), followed by *T. gilletti* (21.5%) and *T. copemani* (4.4%) [15]. *T. vegrandis, T. noyesi*, and the two novel *Trypanosoma* spp. have been less commonly reported, but this in part may reflect low levels of parasitaemia and the use of non-specific PCR primers rather than truly low prevalence [7].

In another study, trypanosome prevalence was 80.6% in koalas from Moreton Bay, Qld and 20.2% in koalas from Mount Lofty Ranges, SA [8]. Koalas from Moreton Bay carried a number of previously identified *Trypanosoma* species, with *T. irwini* and *T. gilleti* infections being most prevalent. All *Trypanosoma* isolates from SA koalas formed a unique, highly diverse grouping within the *T. cruzi* clade [8].

It is difficult to interpret the significance of geographic variations in overall trypanosome prevalence, or trypanosome species presence and prevalence based on current data. *T. irwini* and *T. gilletti* infection were significantly more prevalent in koalas in NSW than in Qld in one study, but this result may have reflected sampling bias [15].

There is some evidence to suggest that prevalence of some *Trypanosoma* sp. infections increases with age, with koalas younger than dispersal age (2-4 years old) having a lower prevalence of *T. irwini* than adults. This may reflect an increased risk of contact with infected vectors which coincides with the increase in social behaviour, movement and activity patterns associated with dispersal and commencement of breeding [15].

Variation in prevalence by gender has not been extensively investigated. In one study, male koalas had a significantly higher prevalence of infection with *T. gilletti* and *T. copemani* (but not *T. irwini*) than females. The reasons for this difference are unclear, but could reflect different physiological status, or differential activities of the sexes that are associated with differences in vector exposure [15].

Polyparasitism with as many as five trypanosome species has been observed in koalas [5, 7], with the prevalence of multiple infections (27.4%) being significantly higher than the prevalence of single infections (4.8%) [7]. Co-infections composed of *T. irwini, T. gilletti* and *T. copemani* are most frequently observed [7].

Mode of transmission

The transmission dynamics of Australian trypanosomes are not well studied and there are significant knowledge gaps in regard to our basic understanding of host-parasite relationships, developmental biology and potential for cross-species transmission [22]. The information here is largely extrapolated from the behaviour of non-endemic trypanosome species.

The trypanosome life cycle generally involves a vertebrate definitive host and an intermediate host vector [3]. Within the vertebrate host, trypanosomes are deposited in dermal connective tissue by the infected vector, from which they enter draining lymphatics and the bloodstream. The "slender" trypomastigote stage multiplies by binary fission during this parasitaemia event, with the level of parasitaemia peaking, going into remission or recrudescing as host antibodies are produced to the variable antigen types (VSGs) presented by successive generations of organisms. Infected blood is ingested by the intermediate host vector, where further development takes place, unless the vector is a strictly mechanical host [23].

There are two broad means of trypanosome transmission from vector to vertebrate host: "salivarian" trypanosomes develop into their infective stage after migrating to the mouthparts and salivary glands, and are transmitted when the vector obtains a blood meal from the vertebrate host [12]. "Stercorarian" trypanosomes transform into their infective form in the hindgut, and are transmitted to a vertebrate host via faecal contamination of the bite site during feeding [12]. Certain *Trypanosoma* species can also be transmitted mechanically, as an invertebrate vector passes infective blood forms from one vertebrate host to another [12].

Intact *T. copemani* life stages have been detected in the faeces of *Ixodes australiensis* ticks after 30 days of incubation, suggesting stercorarian transmission dynamics in this species [16]. It may be that some trypanosomes employ more than one strategy, as well as behaving differently in different vectors. For example, intact *T. noyesi* parasites have been demonstrated within the salivary glands and proboscis of tabanids, suggestive of salivarian and mechanical modes of transmission, but within the gut contents of questing ticks, suggesting the stercorarian route [12].

The vectors of the trypanosomes infecting koalas and other Australian wildlife remain unconfirmed, and there are significant logistic challenges to conclusively confirming vector candidates [22]. Trypanosomal DNA of six of the species infecting koalas has been identified in tick species that infect koalas [7, 12]. However, these studies have not conclusively demonstrated that DNA originated from viable trypanosomes, as opposed to being genetic remnants from an infected blood meal [24]. Recent detection of *T. noyesi* in "questing" ticks (i.e. ticks off the host) supports the likelihood that ticks are vectors rather than accidental dead-end ingesters of this parasite, since a tick which enters the questing state has metabolised its previous blood meal [12].

Other arthropods, including fleas and mites, have been suggested as possible vectors for koala trypanosomes on the basis of their close association with trypanosome-infected koalas [4], but to date none of the trypanosomes infecting koalas has been detected in arthropod species other than ticks. The detection of trypanosomal DNA in arthropods which parasitize Australian species also supports a role for tabanid flies [12, 18], sand flies [18] and leeches [25] as vectors for various Australian trypanosome species.

Incubation period

The incubation period of trypanosome infection in the koala is unknown. The incubation period of other trypanosome species is highly variable and can range from four days to two months [26], with incubation periods of years reported in some instances [27].

Persistence of agent

Trypanosome survival outside of a host is very limited. They may survive for a few hours in blood [26].

5.13.3 Pathogenesis

Many trypanosome infections are subclinical and the majority of wildlife trypanosomes have historically been considered benign to their vertebrate hosts [1]. The mechanisms of pathogenesis described here are generic to trypanosomes rather than representing a confirmed process in koalas.

Trypanosomes may cause extravascular erythrocyte destruction through the attachment of trypanosome antigen to host erythrocytes, increasing antibody mediated erythrophagocytosis. Trypanosomes can also physically damage erythrocytes, release cytotoxic and haemolytic factors and interfering with the coagulation cascade, potentially resulting in thrombocytopaenia and disseminated intravascular coagulation [2].

As well as erythrocyte effects, some trypanosome species can invade other host tissues. Among the species known to infect koalas, *T. copemani* has this capacity, although intracellular entry is not an obligate stage of its life cycle [28, 29]. *T. copemani* infections in brush-tailed bettongs were associated with inflammatory infiltrates in the muscles of the heart, oesophagus and tongue in three individuals, which may have reduced host fitness and increased susceptibility to predation [29].

Trypanosomes have been shown to suppress both cellular and humoral immunity, affecting the activity and function of B cells, T cells and macrophages [1, 30, 31]. The predominant surface antigens of trypanosomes are variant-specific glycoproteins (VSG) which promote chronic parasitemia and prevent lysis by inhibiting the complement pathway. By inducing host immunosuppression, trypanosomes can potentiate concurrent infections, and also reduce the capacity of the host to respond to immunisation against other pathogens [15].

Trypanosomes can demonstrate ‘condition dependent pathogenicity’, increasing in virulence when they encounter a new or naïve host species [3], or immunosuppressed individuals [15].

5.13.4 Associations with other disease hazards of koalas

Although koalas (and other vertebrates) demonstrate a high incidence of infection with multiple trypanosome species within a single host, the implications of trypanosome polyparasitism for levels of parasitaemia, individual parasite virulence or pathogenicity are not clear [7].

Because trypanosomes can compromise the immunity of their host (see *Pathogenesis*), they can potentiate the effects of concurrent infections [1]. Outside of Australia, infection with trypanosome species has been associated with severe, sometimes fatal, disease in the presence of co-infections [15]. It has been suggested that co-infection of *Trypanosoma* spp. with pathogens such as *Chlamydia* and KoRV may be associated with poor health and decreased survival of koalas [7], but in the absence of studies to elucidate this relationship, these associations remain speculative.

5.13.5 Diagnosis

Clinical signs

The majority of koalas infected by trypanosomes are clinically healthy [4, 15], reflecting the general premise that most trypanosomal infections of wildlife are subclinical and benign [1]. Clinical manifestations may be most likely to arise where concomitant infections with other pathogens exist, or where immunosuppression occurs due to other stressors [32].

Disease caused by trypanosome infection (trypanosomiasis) in other species often manifests as haemolytic anaemia caused by extravascular erythrocyte destruction [1]. Signs consistent with such a process were observed in the index case for *T. irwini* in a koala, which demonstrated depression, pale mucous membranes and generalised weakness associated with a profound anaemia [4]. A few juvenile koalas in Qld have also been observed to have profound and highly regenerative anaemia in association with detection of circulating trypanosomes on blood films, and in the absence of other identifiable causes for the anaemia. It is possible that joeys transitioning to independence are more susceptible to the haemolytic effects of trypanosome infection [33].

Few studies have explored associations between clinical disease and trypanosome infection in koalas; where clinical signs are noted, it is often unclear if these signs can be attributed to the trypanosomes [1]. Clinical signs consistent with trypanosomiasis, including severe regenerative anaemia, neurological signs (nystagmus, tremors and seizures) and lethargy, have been observed in a small number of koalas with parasitaemia [1, 4, 33].

The most comprehensive study of the clinical impact of trypanosomes on koalas examined clinical records of koala admissions to a Qld rehabilitation facility over three years [15]. This study found that koalas infected with *T. gilletti* alone, or in co-infection with *T. irwini,* had significantly lower body condition scores than uninfected koalas [15]. This association was not seen for koalas infected with *T. irwini* or *T. copemani* alone. Koalas in the study originating from NSW were significantly more likely to die or be euthanased if infected with *T. gilletti* or a mixed trypanosome infection [15].

Given the limited understanding of the potential clinical effects of koala infection with trypanosomes, clinically abnormal koalas with trypanosomes identified should receive a full diagnostic work-up to identify any other possible causes of illness or mortality [34].

Clinical pathology

Trypanosome parasitemia is confirmed by examination of fresh or Giemsa-stained blood smears under light microscopy. *Trypanosoma* spp. can be detected extracellularly among the red blood cells [3].

Although reductions in packed cell volume (PCV) were detected in trypanosome-infected koalas in the study by McInnes et al 2011 [15], a causative role for trypanosomes is difficult to establish. Mild anaemia is a common and non-specific clinical sign in diseased koalas which is associated with a range of clinical syndromes, including complicated cystitis, lymphosarcoma and heavy tick infestations [15]. In many cases, the observed reductions in PCV in trypanosome-infected koalas may not be biologically significant. While koalas infected with *T. gilletti* or *T. copemani* demonstrated significantly lower mean PCV than uninfected koalas, no such association was detected for *T. irwini*, and the PCV of *T. gilletti*-infected koalas were still within reference ranges for the species. The very small number of animals which were positive for *T. copemani* in this study (n=6) precludes further interpretation of findings [15].

Anecdotally, there have been a small number of cases where profound anaemia occurs in association with trypanosome parasitaemia. These cases exhibit PCV in the order of 9-12% (normal PCV is 30-40%) with a very strong regenerative response (marked anisocytosis and polychromasia) along with erythroid hyperplasia on bone marrow cytology [33]. These findings are similar to the clinical pathological findings reported for the sentinel koala diagnosed with *T. irwini,* which had a PCV of 9% and haemoglobin of 32g/l (normal range is 88–140g/l) as well as bone marrow erythroid hyperplasia [4].

Pathology

Published description of pathology associated with trypanosome infection in koalas is limited. A post mortem examination of the first koala diagnosed with *T. irwini* revealed pathology in a range of tissues, but it was not clear the extent to which pathology was attributable to trypanosome infection as opposed to co-morbidities [33]. Changes included benign osteochondromas of ribs, haemosiderosis and extramedullary haematopoiesis of the spleen, extreme atrophy of lymphoid tissues, bone marrow hyperplasia, severe necrosis of the liver, nephritis and oxalate nephrosis of the kidneys and pneumonia. Grossly there was marked subcutaneous oedema, large volumes of peritoneal fluid and markedly enlarged mesenteric lymph vessels [4, 35]. The KoRV status of this individual was not described, but he was PCR-positive for *Chlamydia* and had clinical signs of keratoconjunctivitis [33].

Trypanosome-infected koalas which developed neurological signs appeared to have trypanosome life stages present in the liver, central nervous system and choroidal vessels, as well as a lymphocytic/plasmacytic choroiditis [1].

Differential diagnosis

Other causes of poor body condition in koalas include advanced dental disease or tooth wear, poor nutrition, renal disease, chlamydiosis, neoplasia, untreated injuries and opportunistic bacterial and fungal infections. Potential causes of anaemia and low PCV in koalas include blood loss due to trauma, poor nutrition, chronic inflammatory disease, neoplasia, bone marrow dysplasia and ectoparasite infestation [36].

Diagnostic testing

Identification of trypanosomes on blood smears via light microscopy is a relatively insensitive detection method, particularly if parasitaemia levels are low. Molecular methods of detecting trypanosome DNA via PCR are sensitive and commonly utilised for studies of Australian trypanosomes [3-7, 14, 17, 20]. Next generation sequencing methods have been shown to be of greater accuracy than traditional PCR methods for detecting novel and rare trypanosomes in mixed infections in native species [7, 14].

Although most molecular testing is carried out on blood samples, PCR methods have also been used to detect trypanosome DNA in the tissues of Australian vertebrates, including brain, lung, liver and skin. Five out of seven healthy koalas tested positive for trypanosome infection on testing of liver samples using molecular techniques [37].

Surveillance and monitoring

There is no coordinated, targeted national program for surveillance of trypanosomes in Australian native wildlife. However, the findings of trypanosomes in samples from wildlife in Australia would be considered interesting and unusual and would therefore be logged in the Wildlife Health Australia national wildlife health information system (eWHIS) as part of national general wildlife surveillance activities [34].

5.13.6 Treatment

There are no specific treatment recommendations for trypanosome infection. Treatment of infected, symptomatic individuals has been attempted using melarsomine dichlorhydrate, but this failed to kill circulating trypanosomes. Imidocarb has also been used in an attempt to clear parasitaemia, but without success [33]. Anecdotal cases where trypanosomiasis has been suspected as the cause of profound, regenerative anaemia have generally been unresponsive to treatment, but a small number have survived with careful nursing, multiple blood transfusions and iron supplementation [33]. Symptomatic therapy based on clinical signs, reduction of stress, and specific treatment for co-infections are indicated [1].

5.13.7 Prevention and control

There are no identified methods of prevention or control of trypanosome infection in koalas. Prevention and control of trypanosome infection in general depends on breaking the cycle of transmission, which in turn requires knowledge of competent vectors [34]. Limiting

exposure to vectors is unlikely to be feasible in wild koalas, but may be indicated as part of a general reduction of stressors and vectors for disease spread in captivity and rehabilitation.

Appendix 6 Suggested Leaders and Participants for Recommendations

Table 23 List of koala stakeholder organisations and groups assigned in the "Leaders and participants of recommendations" exercise. See Appendix 2.4.3 Assignment of leaders and participants to recommendations for further details.

Abbreviation used in Table 24	Stakeholder organisation or group
ARWH	Australian Registry of Wildlife Health
Govt	Government agencies (commonwealth, state, territory and local government)
KHH	Koala Health Hub, Uni Sydney
Land mngr	Private land managers
NKMP	Nat Koala Monitoring Program
NKRT	National Koala Recovery Team
Public	General public
Rehab	Rehabilitators
Trad Owners	Traditional owners
Unis Other	Other universities and researchers
WHA	Wildlife Health Australia
WL care orgs	Wildlife care organisations
WL charity & adv	Wildlife charities and advocacy groups
WL vets	Wildlife veterinary personnel
Zoos	Zoos

Table 24 "Leaders" and "Participants" assigned to high priority recommendations

Votes for leaders and participants were tallied for each recommendation. The range of tallied votes is divided into three bands (top, middle and lower thirds). Tallied number of votes in the top band are indicated by the darkest colours, tallied number of votes in the middle band are indicated by mid-range colours and tallied number of votes in the bottom band are indicated by the lightest colours.

Recommendation		ARWH	Govt	KHH	Land mngr	NKMP	NKRT	Public	Rehab	Trad Owners	Unis other	WHA	WL care orgs	WL charity & adv	WL vets	Zoos
General																
G1 Recognise and prioritise habitat preservation, restoration and revegetation as key mitigators of disease risk.	LEADER															
	PARTICIPANT															
G2 Maintain or increase koala population size and genetic diversity.	LEADER															
	PARTICIPANT															
G3 Improve national population estimates; ongoing population health monitoring for koalas.	LEADER															
	PARTICIPANT															
G4 Undertake a national population and habitat viability analysis for koalas.	LEADER															
	PARTICIPANT															
G5 Develop national data sets on causes of illness & death in free-living koalas.	LEADER															
	PARTICIPANT															
G6 A national shareable system for capturing health & disease data (captive, wild and rehabilitation).	LEADER															
	PARTICIPANT															

Recommendation		ARWH	Govt	KHH	Land mngr	NKMP	NKRT	Public	Rehab	Trad Owners	Unis other	WHA	WL care orgs	WL charity & adv	WL vets	Zoos
G7 National approach to diagnosis, triage, investigation, treatment, care & recordkeeping of koalas.	LEADER															
	PARTICIPANT															
G8 National post-release identification and monitoring protocols.	LEADER															
	PARTICIPANT															
G9 Best practice training for veterinary professionals & rehabilitators in care & treatment of diseased koalas.	LEADER															
	PARTICIPANT															
1. Chlamydia																
1.1 Develop national protocols for triage and assessment of koalas with *Chlamydia* infection.	LEADER															
	PARTICIPANT															
1.2 Support pharmacokinetic and clinical studies for treatment of *Chlamydia* infection.	LEADER															
	PARTICIPANT															
1.3 Develop nationally-agreed guidelines for diagnostic testing for *Chlamydia*.	LEADER															
	PARTICIPANT															
1.4 Develop *Chlamydia*-specific biosecurity protocols for koalas.	LEADER															
	PARTICIPANT															

Recommendation		ARWH	Govt	KHH	Land mngr	NKMP	NKRT	Public	Rehab	Trad Owners	Unis other	WHA	WL care orgs	WL charity & adv	WL vets	Zoos
2. Koala retrovirus																
2.1 Continue research into KoRV; focus on determining the extent to which it causes disease.	LEADER															
	PARTICIPANT															
2.2 Quantify proviral and viral KoRV load and develop protocols to incorporate KoRV status into koala management.	LEADER															
	PARTICIPANT															
2.3 Develop guidelines for biosecurity, control and prevention of KoRV risk in koala management & movement.	LEADER															
	PARTICIPANT															
3. Heat stress																
3.1 Identify and map koala populations likely to be susceptible to heat events.	LEADER															
	PARTICIPANT															
3.2 Develop early intervention and emergency response protocols for koala populations during extreme heat events.	LEADER															
	PARTICIPANT															
3.3 Develop protocols for assessment and treatment of heat stressed koalas.	LEADER															
	PARTICIPANT															
3.4 Conserve quality, quantity, connectivity and complexity of koala habitat and refugia, to provide thermal protection.	LEADER															
	PARTICIPANT															

Recommendation		ARWH	Govt	KHH	Land mngr	NKMP	NKRT	Public	Rehab	Trad Owners	Unis other	WHA	WL care orgs	WL charity & adv	WL vets	Zoos
3.5 Strengthen regulatory controls against clearing and development in koala habitat.	LEADER															
	PARTICIPANT															
4. Predator trauma																
4.1 Study community education for reducing dog encounters, and strategies for dog control.	LEADER															
	PARTICIPANT															
4.2 Educate dog owners on responsible and "koala-friendly" dog ownership.	LEADER															
	PARTICIPANT															
4.3 Develop national monitoring for koalas following rehabilitation and release.	LEADER															
	PARTICIPANT															
5. Thermal burns																
5.1 Develop protocols for triage and assessment, treatment and rehabilitation of fire-affected koalas.	LEADER															
	PARTICIPANT															
5.2 Incorporate protocols for first responder intervention and response for koalas into fire emergency response planning.	LEADER															
	PARTICIPANT															
5.3 Continue studies to understand the impacts of the 2019-2020 fire events on koalas.	LEADER															
	PARTICIPANT															

Recommendation		ARWH	Govt	KHH	Land mngr	NKMP	NKRT	Public	Rehab	Trad Owners	Unis other	WHA	WL care orgs	WL charity & adv	WL vets	Zoos
5.4 Train rehabilitators and vets during “peacetime” in incident management and safe access to fire fields.	LEADER															
	PARTICIPANT															
5.5 Develop monitoring protocols for koalas following rehabilitation and release.	LEADER															
	PARTICIPANT															
6. Cryptococcosis																
6.1 Develop national guidelines for the diagnosis, prevention and treatment of cryptococcal disease.	LEADER															
	PARTICIPANT															
6.2 Develop protocols for recording and communicating diagnosis of cryptococcal disease and map 'hot spots'.	LEADER															
	PARTICIPANT															
7. Vehicle trauma																
7.1 Incorporate considerations of koala ecology and behaviour into road planning and design.	LEADER															
	PARTICIPANT															
7.2 Develop best-practice strategies and guidelines to reduce koala motor vehicle trauma in "black spots".	LEADER															
	PARTICIPANT															
7.3 Investigate the effectiveness of vehicle strike prevention strategies.	LEADER															
	PARTICIPANT															

Recommendation		ARWH	Govt	KHH	Land mngr	NKMP	NKRT	Public	Rehab	Trad Owners	Unis other	WHA	WL care orgs	WL charity & adv	WL vets	Zoos
7.4 Identify "black spots" for koala MVA and focus mitigation efforts in these areas.	LEADER															
	PARTICIPANT															
8. Neoplasia																
8.1 Investigate the role of host genetics in the development of neoplasia.	LEADER															
	PARTICIPANT															
8.2 Further investigate association between neoplasia and KoRV.	LEADER															
	PARTICIPANT															
9. Sarcoptic mange																
9.1 Investigate the epidemiology of sarcoptic mange in koalas.	LEADER															
	PARTICIPANT															
9.2 Collect records of clinical signs and response to treatment of sarcoptic mange.	LEADER															
	PARTICIPANT															
9.3 Investigate the pharmacokinetics of mange treatments in koalas.	LEADER															
	PARTICIPANT															

Recommendation		ARWH	Govt	KHH	Land mngr	NKMP	NKRT	Public	Rehab	Trad Owners	Unis other	WHA	WL care orgs	WL charity & adv	WL vets	Zoos
10. Oxalate Nephrosis																
10.1 Protect koala habitat, conserve refugia and improve the hydration of koala food.	LEADER															
	PARTICIPANT															
10.2 Investigate the causes of ON in koalas including genetics, infections and co-morbidities.	LEADER															
	PARTICIPANT															
10.3 Support water retention and availability in koala environments.	LEADER															
	PARTICIPANT															

Appendix 7 Common and Taxonomic Names of Species

Taxonomic names for the species mentioned in this report are listed in Table 25.

Table 25 Taxonomic names of animal species mentioned in KDRA report

Common Name	Taxonomic Name
Banded hare-wallaby	*Lagostrophus fasciatus*
Bare-nosed wombat	*Vombatus ursinus*
Black flying-fox	*Pteropus alecto*
Black-tufted marmoset	*Callithrix penicillata*
Brush-tailed bettong	*Bettongia penicillata*
Brush-tailed rock-wallaby	*Petrogale penicillata*
Burrowing bettong	*Bettongia lesueur*
Bush rat	*Rattus fuscipes*
Carpet python	*Morelia spilota*
Chamois	*Rupicapra*
Chuditch	*Dasyurus geoffroii*
Common brush-tailed possum	*Trichosurus vulpecula*
Dingo	*Canis familiaris dingo*
Domestic cat	*Felis catus*
Domestic dog	*Canis familiaris*
Eastern bettong	*Bettongia gaimardi*
Eastern grey kangaroo	*Macropus giganteus*
Eastern quoll	*Dasyurus viverrinus*
Red fox	*Vulpes*
Gilbert's potoroo	*Potorous gilbertii*
Gould's wattled bat	*Chalinolobus gouldii*
Grassland melomys	*Melomys burtoni*
Koala	*Phascolarctos cinereus*
Lace monitor	*Varanus varius*
Lesser long-eared bat	*Nyctophilus geoffroyi*
Little red flying-fox	*Pteropus scapulatus*
Northern brown bandicoot	*Isoodon macrourus*
Quenda	*Isoodon fusciventer*
Quokka	*Setonix brachyurus*
Red kangaroo	*Osphranter rufus*
Shark Bay bandicoot	*Perameles bougainville*
Southern hairy-nosed wombat	*Lasiorhinus latifrons*
Spotted-tailed quoll	*Dasyurus maculatus*
Swamp wallaby	*Wallabia bicolor*
Tammar wallaby	*Macropus eugenii*
Tasmanian devil	*Sarcophilus harrisii*
Western grey kangaroo	*Macropus fuliginosus*
Yellow-footed rock-wallaby	*Petrogale xanthopus*
