1. Introduction

1.1 Background

The internal-combustion engine is the foremost important power source to ensure present and future mobility. At least two questions may rise as a response to such a statement. First, why is the internal-combustion engine the most important power source, and, secondly, why is mobility so important? The second question is mostly a matter of opinion of course, especially when personal mobility is concerned, and a subjective discussion is beyond the nature of this thesis. Nevertheless, mobility is generally regarded as one of the most important signs of freedom and prosperity in modern society. People want to live in the country-side and work in the city, visit family and sporting events (for the sake of sticking to the subject, let us say: motorsports), or go on vacation. They want to be able to travel to places that are beyond walking or cycling distance. Moreover, they want fresh vegetables to be delivered to their local store. Or, to put it in a somewhat double-edged way: We want to be able to get the fuel for our internal-combustion engines at a filling station around the corner. Clearly, to meet all these demands, some kind of transportation is needed and, hence, some kind of power source will be required. This brings these reflections back to the first question: Why is the internal-combustion engine the most important power source to ensure mobility?

The internal-combustion engine was invented over a century ago and its development and application have taken a tremendous flight ever since. It is difficult to imagine modern society without these machines. Internal-combustion engines are found in virtually every passenger car and truck, and in many ships, trains and aircrafts. These efficient power plants are reliable, cheap, small and light. Furthermore, they use fuels that have high specific energy densities and can be easily and safely distributed to the vehicle, and stored in small containers on board. These properties are very advantageous for application of the internal-combustion engine as the power source for road vehicles.

Figure 1.1 : CO₂ emissions from transport, industry and other emitters in Europe since 1971 (Nijkamp, 1995)

However, average engine performance, in terms of efficiency and pollutant emissions, has repercussions extending to the planetary scale. Local environmental concerns include photochemical smog, increased atmospheric carbon-monoxide concentration and toxic depositions. A regional environmental concern is acid deposition. Globally, the potential for climatic warming is a threat. Figure 1.1 shows the development of carbon-dioxide (CO₂) emissions produced by transport, industry and others in Europe over the last decades. Clearly, transport has taken a large growth and became the major emitter of this so-called *greenhouse gas*. Within the transport sector, road transport is responsible for over 80 per cent of the impact in most Western European countries (Nijkamp, 1995). World-wide, nearly every road vehicle operates on a fuel derived from petroleum, which is a limited resource. For the next twenty-five years, petroleum-based fuels are expected to continue their domination of automotive propulsion, but alternative energy sources are already being investigated as a solution to the environmental issue. Alternative sources of propulsive energy having potential include liquefied petroleum gas (LPG), compressed natural gas (CNG), alcohol, bio-fuel, hydrogen, and electricity. However, electricity is not a primary source of energy. It has to be generated through the conversion of chemical, hydro or nuclear energy sources.

A major ally in coping with the pollution and the energy use problems may be found in changes of human behaviour, i.e. the mobility demands must be eased (e.g. Bilderdijk et al., 1993). In addition, technological progress is generally considered as an important means in solving these problems. New technologies may either focus on improving road vehicles or on the development of different concepts of transportation, such as high-speed trains, subterranean systems and hydrogen-fueled aircrafts. Nijkamp (1995) addressed the potential of some of such new technologies and concluded that improved road vehicles have clearly the best opportunities for adoption, especially on a metropolitan scale.

Since the early 1980s, engine evolution is primarily determined by the increasingly-stringent regulations on vehicle exhaust gas emissions. In 1993, the European Union effectuated the so-called EC 93 directive, followed by the more stringent EC 96 in 1996, which regulate the emission of hydro-carbons (HC), nitrogen-oxides (NO_x), carbon-monoxides (CO) and

Emissions	EC 93		EC 96		EC 2000		EC 2005	
	Gasoline = Diesel	Gasoline	Diesel	Gasoline	Diesel	Gasoline	Diesel	
HC	-	-	-	0.20	-	0.10	-	
NO _x	-	-	-	0.15	0.50	0.08	0.25	
HC+NO _x	0.97 (1.13)	0.50	0.70	-	0.56	-	0.30	
CO	2.72 (3.16)	2.20	1.00	2.3	0.64	1.0	0.50	
Particulates	0.14 (0.18)	-	0.08	-	0.05	-	0.025	

Table 1.1 :: European Union emissions regulations (g/km) for passenger cars (directives 93/59/EC, 94/12/EC and EC 2000; EC 2005 was mandated in June 1998; sources: Delphi, 1996 and Exxon, 1998)

particulates, as indicated in Table 1.1. The regulations for the near future (EC 2000 and EC 2005) will not only imply a further reduction of these polluting emissions, but also of CO₂. The emission of this greenhouse gas is proportional to fuel consumption and has increased largely over the past decades, as was already indicated in Figure 1.1. In combination with the ever-increasing fuel prices, this has initiated increased fuel efficiency to be one of the primary objectives in engine development. Globally, many manufacturers are now working on cars that have a fuel consumption of only 3 litres per 100 kilometres. However, increased vehicle mass, due to comfort and safety demands, has caused vehicle specific fuel consumption to rise in recent years. This trend is strengthened by the increasing demand for more engine power.

1.2 Statement of the problem

The area with the most potential for technological development of road vehicles is drive-line optimisation. This may also include development of more or less new drive-line concepts, such as battery-electric vehicles, fuel-cell powered vehicles and hybrid systems. Nevertheless, many drive-line concepts will be based on the internal-combustion engine, because of its beforementioned advantages and the problems that other systems still face.

Although the internal-combustion engine has gone through over a century of very ambitious development, the margin for improvement can still be considered as relatively wide. Regulations, new technologies and marketing constraints require engineers to develop and propose increasingly-sophisticated solutions in order to improve performance even further. An example of the offspring of these conditions is the development of direct-injection gasoline engines, which shows large potential. To cope with the demands, control over combustion is a key objective, but one that is difficult to attain due to the complexity of the processes involved. Basically, these processes include the flow of air and fuel into the cylinder, mixing of air and fuel, ignition, combustion and, thus, formation of exhaust gases. Reduction of engine emissions and fuel consumption can be reached by an improved control

over the degree of homogeneity of the air-fuel mixture, cycle-to-cycle variation, and turbulence intensity as well as large-scale motion at the moment of ignition.

It is generally acknowledged that the in-cylinder fluid motion has large influence on these phenomena. Engine fluid mechanics have been reviewed by various authors, see for instance the work of Arcoumanis and Whitelaw (1987) or the text books of Heywood (1988), Stone (1992) and Urlaub (1995). The general characteristics of in-cylinder flow structures that are common in both gasoline and Diesel type engines can be summarised as:

- unsteady, as a result of the reciprocating piston motion,
- essentially three-dimensional, as a result of the internal engine geometry,
- highly turbulent, with a wide range of time and length scales (see Section 2.1), and
- subject to cycle-to-cycle variations in local flow properties.

From these features it becomes clear that the flow is complex and its interpretation difficult. Separation of large-scale and small-scale flow structures is important for a general understanding of the mechanisms that determine the in-cylinder processes. Large-scale fluid motion is initiated during the intake stroke and is primarily determined by the induction system and combustion chamber geometry. These motions determine the mixing and the transport of the mixture inside the combustion chamber. The induced kinetic energy, present in the large-scale motions, is the source that feeds the generation process of small-scale, or turbulent, fluctuations. The speed of combustion is related to the intensity of these turbulent fluctuations. Mixing of fuel and air is determined by all scales of motion.

Typically, large-scale swirling and tumbling motions are generated during the intake stroke to increase the induced kinetic energy, to improve mixing and to generate higher top-dead-centre (TDC) turbulence levels and faster combustion. This suggests the possibility of controlling the combustion process, and hence engine efficiency and emissions, by tailoring the in-cylinder flow. However, it is often not straightforward what the most desirable flow features are because of the complexity of the processes involved and their strong dependence upon the characteristics of a specific engine. Questions remain concerning: a) the influence of large-scale fluid motion versus turbulence on ignition and combustion, b) the relative attributes of swirl, tumble and other large-scale flow structures, and c) the mechanisms by which large-scale structures break down to generate turbulence. Moreover, as a result of an increase of the induced kinetic energy, discharge efficiency is generally reduced, which results in reduced engine efficiency and power. As a consequence, engine design will always be a compromise, depending on the objectives.

Summarising, in-cylinder fluid motion in internal-combustion engines is one of the most important factors controlling the combustion process. Therefore, a good understanding of,

and an ability to predict, in-cylinder fluid dynamics during the intake and compression strokes is paramount to developing engines that can meet present and future demands. To comply with the demands, less conventional combustion concepts may emerge. Concepts like *lean burn* and *direct gasoline injection* have high potential, although control over the in-cylinder processes is even more critical than for conventional engines, especially at part-load conditions. Due to the complexity of the in-cylinder flow processes, improved understanding can only be obtained through appropriate scientific methods and advanced instrumentation.

The most reliable information about a physical process is often given by actual measurement, although measuring instruments are not free from errors. An experimental investigation involving a complete engine can only be used to assess how identical copies would perform at the same conditions. However, such full-scale tests are, in most cases, prohibitively expensive and often impossible until the final stages of engine development. Moreover, conducting engine measurements often implies serious difficulties and complex measurement techniques may be required. An alternative then is to perform experiments on a simplified model, such as a *steady-flow rig* in which a stationary flow of air is blown through the intake or exhaust ports of an engine cylinder head. The information obtained from such experiments is commonly limited to some kind of measure indicating overall performance of the induction or exhaust system. For example, the angular momentum of the induced flow may be measured. The resulting information must be extrapolated to the complete engine. However, rules for such extrapolation often have only limited validity. Hence, although such practises offer some knowledge about the engine's performance and are often very helpful for optimisation studies, they do not add to the understanding of the processes involved.

In order for engine manufacturers to remain competitive, development lead times must be reduced. In this perspective, mathematical modelling is seen as an alternative technology. An experimentally-validated computational fluid dynamics (CFD) code with the capability of predicting the influence of geometric changes on the in-cylinder processes would significantly reduce the need for iterative experimental testing with subsequent reductions in material costs, facility costs, manpower and project timing. An additional advantage of numerical simulation over experiments is that it offers much more information; the value of many different variables is acquired as a function of time and throughout the combustion chamber, the ports and the manifolds. Experiments usually only offer the, often time-averaged, value of a single variable at a limited number of measuring positions. Hence, computations may facilitate studies to increase the understanding of in-cylinder processes. However, as opposed to experiments, numerical simulations are based on a mathematical model which is an approximate representation of the physics. This modelling must include those aspects that are decisive for the phenomena that are to be studied. The amount of physical detail that can be included in the mathematical model may be limited by incomplete knowledge and by the demands on computational resources.

An appreciation of the strengths and weaknesses of experimental investigation and computer analysis is essential to the proper choice of the appropriate techniques. An optimal prediction effort should be a judicious combination of experiment and computation. The proportions of the two ingredients depend on the nature of the problem, on the objectives of the prediction, and on economic and other constraints of the situation.

1.3 State of the art

Scientific methods can help to increase the understanding of the role of in-cylinder flow on near-TDC flow structures in reciprocating engines. Especially over the last two decades, many researchers have contributed to this understanding. The applied techniques involve both experiments and computations of varying sophistication.

Large-scale in-cylinder flow structures are often characterised by single characteristic non-dimensional numbers, as was discussed in the previous section. Examples of such characteristic numbers are the *Swirl Number* or the *Tumble Number*, which are measures for the net angular momentum about the cylinder axis and an axis normal to the cylinder axis, respectively. These rather general numbers give an indication about the induced kinetic energy, assuming solid-body rotation of the fluid around the indicated axes. An indication of the swirl or tumble production of an engine cylinder head can be easily obtained on a steady-flow rig with a rotating vane or an impulse meter (Yokota et al., 1993). Such techniques are often applied in engine development because their relative simplicity allows a quick analysis of various cylinder head designs.

However, application of such techniques does not contribute to the understanding of the in-cylinder processes. Although there are straightforward flow characteristics in all engines, the precise flow depends on the particular engine under investigation and is much more complex than a single solid-body rotation flow. More sophisticated techniques are needed to study flow details. Such techniques may either be of an experimental or a computational nature and will be discussed below. A complete state-of-the-art review is not attempted, but the aim is rather to give an overview of frequently applied techniques and their development and application in relation to engine performance analysis.

Experimental techniques

Experimental techniques for acquiring detailed flow information often focus on measurement of fluid velocity distributions. Various sophisticated experimental techniques for this purpose have been applied by many researchers to study engine-like flows of varying complexity. The main techniques for detailed engine flow analysis are *hot-wire velocimetry (HWV)*, *laser-*

Doppler velocimetry (LDV), and *particle image velocimetry (PIV)*. All of these techniques have their specific field of application in engine research.

HWV is a measuring technique for determining local fluid velocities, based on the cooling of a thin wire, which is heated by an electrical current. The hot-wire probe must intrude into the fluid, which is often undesirable from a fluid dynamics as well as a constructional point of view. The probe is a delicate instrument, which cannot survive the harsh environment of engine combustion. Therefore, application is mostly limited to steady-flow rigs and motored engines. Furthermore, calibration of the instrument is problematic and most HWVs suffer from directional ambiguity. Since the pioneering work of Semenov (1958), several investigations of in-cylinder flow with HWV have been reported, see for instance the work of Witze (1977).

LDV can overcome many of the problems that HWV faces, but has its own limitations. This measuring technique is based on probing the local fluid velocity with a measuring volume created by crossing two laser beams. Hence, it is a non-perturbing measuring technique, although it may be considered intrusive as a consequence of the modification required to provide optical access to the flow domain. A more elaborate description of LDV is given in Chapter 4 and Appendix C. LDV is clearly the most frequently-used measuring technique for detailed in-cylinder flow analysis. Only part of the publications in this field can be referred to here.

Initially, engine researchers such as Rask (1979) were focusing on the development of this technique under idealised engine-like conditions. Subsequently, model engine configurations were studied in order to gain insight into the basic flow processes. Major contributions were made at Imperial College, where many LDV research projects focused on an axi-symmetric, four-stroke, disc-chamber engine with either a central pipe inlet, an annular port inlet or a port with a reciprocating valve. These model engines were motored at 200 RPM with compression ratios ranging from 3.5 to 6.7 (cf. [Morse et al., 1979; Vafidis, 1984; Bicen et al., 1985]). Optical access was obtained by applying a transparent cylinder wall. Following steps towards more complicated flow structures were the application of shrouded valves (Gosman et al., 1985) and off-centre valves, which essentially render the flow three-dimensional. Arcoumanis et al. (1986) investigated a disc-chamber Diesel engine with off-centre intake port, which was motored at 900 RPM with a more realistic compression ratio of 8.5. Again, optical access was obtained through a transparent cylinder wall. Liou et al. (1984) conducted extensive LDV investigations on the in-cylinder flow for a four-valve cylinder head with a pent-roof combustion chamber. A window in the piston was applied for optical accessibility. Other studies focused on the effect of inlet port geometry on the in-cylinder flow structure by using LDV to analyse the steady flow in engine flow rigs. Brandstätter et al. (1985), Arcoumanis et al. (1988) and Bicen et al. (1985) conducted experiments to obtain the flow around the intake

valve for flat cylinder heads. Höfler and Wigley (1993) measured in-cylinder velocity distributions at similar conditions. Comparative investigations of inlet port flows under steady-state and motoring conditions were conducted by Höfler et al. (1993), amongst others. Important contributions to in-cylinder LDV were made by Lorenz and Prescher (1990) and Bopp et al. (1990) on a fired spark-ignited, four-stroke, disc-chamber engine with a single off-centre intake port, operating at speeds up to 2000 RPM. Optical access was obtained through windows in the cylinder liner and the cylinder head. Through careful design of the velocimeter, they were able to conduct cycle-resolved measurements, yielding information on cyclic variation and turbulence. Hu et al. (1992) managed to correlate in-cylinder flow to performance and emissions characteristics for a four-valve engine, with a pent-roof combustion chamber. Yoo et al. (1995) and Hascher et al. (1997) conducted simultaneous three-component LDV on a prototype four-valve engine, motored at 600 RPM. Dimopoulos and Boulouchos (1997) also performed coincident three-dimensional LDV in a pancake combustion chamber of a two-valve engine, which was motored at speeds between 600 and 1500 RPM. They were able to acquire not only mean velocities, but also Reynolds normal and shear stresses so that isotropy of turbulence could be investigated. Finally, the work of Valentino, Corcione and Seccia (1997) is referred to since they were able to estimate integral and micro time scales from in-cylinder LDV results.

PIV is an instantaneous whole-field measuring technique, as opposed to LDV, which measures the time history of the fluid velocity in a single point. Basically, this technique is based on taking multiple pictures, with short time delays, of a particle-laden flow passing through a laser sheet. The displacement of the particles allows for the calculation of the two-dimensional flow structure and local fluid velocities within the plane of the sheet. Hence, PIV is a very powerful tool for obtaining both qualitative and quantitative information about complex flow structures. However, for accurate quantitative data often LDV is the preferable measuring technique. Both techniques may be used together to obtain maximum information. In recent years, PIV has been applied to engine-like flows by several researchers. Gindele et al. (1997) successfully conducted time-resolved investigations of the unsteady flow inside inlet manifolds at real engine conditions. Brücker (1997) showed how PIV can be used to conduct three-dimensional time-resolved in-cylinder measurements by applying a scanning-drum to shift the laser sheet. Grosjean et al. (1997) analysed the potential of combining LDV and PIV for studying engine-like flow structures.

Computational techniques

Numerical simulation of the flow in engines can be separated into two categories: zero-dimensional or quasi-dimensional, and multi-dimensional modelling. The first category of models essentially deals with the equations of thermodynamics and may include empirical relationships. These models are often capable of outstanding performance for the

investigation of macroscopic balances. Yet for detailed computation of in-cylinder flow structures, most authors agree that essentially multi-dimensional modelling is required that resolves the variations of mass, composition, momentum and energy in all three dimensions. This has been the subject of many research projects over the past two decades, during which a number of numerical methods have been developed.

Multi-dimensional Computational Fluid Dynamics (CFD) is emerging from its research status to become a design tool in automotive industry. However, the assimilation of CFD into the design process, as an engineering tool for design evaluation and optimisation prior to manufacture, requires the validation of its predictive accuracy and the determination of the limits of its application. The ultimate objective of CFD for engine combustion system development is the simulation of all components of engine internal flow under operating conditions. This would reduce the need for extensive flow field investigations with the aid of experimental laser diagnostic methods, which are limited by optical access, measurement time and cost.

Development of numerical simulation methods for in-cylinder flows shows a path similar to that of LDV. Assessment or improvement of the modelling often depended on the application of laser techniques so that experiments could be conducted which were needed for validation purposes. However, computer power has also been a determining factor in the progress of CFD. Naturally, early investigations focused primarily on the development of simulation techniques. Gradual improvements of numerical methods and computer performance allowed application to increasingly-realistic engine flows. Gosman (1985a) gives an overview of the early work that has been done on the simulation of two-dimensional flows in reciprocating engines. The axi-symmetric engine-like configurations used at Imperial College for the development of LDV techniques have been the subject of many computational investigations as well, yielding a large data-base of information that has often been used to test numerical methods (also see Sections 3.2 and 3.3 of this thesis). These test cases have been used extensively, especially for testing turbulence modelling (cf. [El Tahry, 1985a; El Tahry, 1985b; Ahmadi-Befrui and Gosman, 1989]). Watkins et al. (1990) assessed not only turbulence models, but also discretisation schemes by analysing their performance for the case of steady, axi-symmetric flows. Lea and Watkins (1997) published similar investigations for the unsteady cases.

The progress of three-dimensional model computations has been largely determined by limitations on computer power and modelling flexibility, so sweeping assumptions had to be made to simplify the computations. Relatively coarse computational grids were used for idealised geometries with simplified boundary conditions. Henriot et al. (1989) computed the unsteady three-dimensional in-cylinder flow on a 12000 node grid for an engine with an idealised four-valve, pent-roof cylinder head. Intake ports were not modelled; the boundary

conditions at the valve curtain were estimated. Comparison with data taken from LDV showed that some flow trends could be reproduced by the computations. However, the modelling proved to be incapable of correct predictions for a four-valve configuration due to the inaccurate inlet-boundary definitions. Höfler and Wigley (1993) followed a similar strategy to compute and validate steady in-cylinder flows generated by a helical port. Ahmadi-Befrui et al. (1993) also assessed the accuracy of unsteady three-dimensional flow computations for a disc-chamber engine by comparison with LDV data taken at an engine speed of 1000 RPM. Inlet valve boundary conditions were taken from steady-flow experiments and the computational grid contained 13600 nodes. Tu and Fuchs (1992) conducted incompressible flow simulations of the unsteady flow in a disc-chamber with several configurations of a pipe inlet port. More complex intake port configurations were studied by Khalighi et al. (1994) for an otherwise similar configuration. Flow visualisation techniques were used for qualitative validation purposes.

The assumed simplified boundary conditions and idealised geometric configurations are inadequate for the challenge of improving performance of already highly refined engines (Khalighi et al., 1995). In recent years, as computer technology and numerical methods have evolved, flow simulations for more realistic engine geometries have become feasible. The average model size has increased to 100000-500000 computational cells, which is adequate for reliable description of the flow in complex geometries according to Gosman (1985b). Godrie and Zellat (1994) computed the steady flow through production-type intake port-valve-cylinder configurations and validated the results by comparison with in-cylinder LDV data, whereas Krüs (1993b) did similar investigations for Diesel engine heads. Befrui (1994) validated the computed flow through a helical intake port by comparison with LDV data taken at the valve exit. Ntone and Zehr (1993) simulated the flow through Diesel engine exhaust port geometries. Jones and Junday (1995) computed and measured the unsteady flow inside a production-type, four-valve, four-stroke, pent-roof-chamber spark-ignition engine. Still, the latter computations were limited to the chamber volume bounded by the valve curtains. Boundary conditions were taken from HWV. Similar investigations were conducted by Bo et al. (1997) for a Diesel engine. They estimated the valve curtain boundary conditions from steady-flow measurements. Khalighi et al. (1995) conducted similar simulations including the intake ports in the flow domain. As for most other investigations, emphasis has been on low-speed, part-throttle operating conditions.

1.4 Objectives and scope

Advances in experimental and computational techniques enable detailed analysis of in-cylinder processes in realistic engine configurations that thus far were not possible. Improved diagnostics and modelling capabilities have resulted in an enhanced appreciation of the sensitivity of in-cylinder flow and combustion to what had previously been considered to be

secondary geometric effects. Many publications about this subject exist, but the analyses often involve idealised flow cases, as was argued in the previous section. Although three-dimensional computations of unsteady in-cylinder flow processes are currently used as additional development tools by the major engine manufacturers, the number and extent of publications about detailed flow analyses, and validations of such simulation tools with detailed experimental results, at realistic production-type engine conditions, are limited.

The objective of the work presented in this thesis is to contribute to the understanding of in-cylinder flow structures and to present further evidence of the value of sophisticated experimental and computational techniques for modern engine development. This will be achieved by applying detailed experimental techniques and multi-dimensional modelling to production-type engine geometries. Furthermore, the research will assess the accuracy and possible error sources of these techniques.

Due to limited computer resources, the mathematical description of complex fluid dynamics will always include some kind of modelling. If computer codes are to be used for engine development purposes, the implications of such modelling must first be assessed. Ultimately, the codes must be validated for realistic, three-dimensional engine geometries, which has been the topic of several published investigations, as was discussed in the previous section. However, it is very difficult to make definite judgements on the performance of the modelling in such circumstances. The geometric complexity, and the moving piston and valves, make grid generation complex. Furthermore, many investigations involved rather coarse grids, due to limited computer speed, with the inevitable consequence that grid related numerical errors and geometric inaccuracies are introduced. Moreover, it is extremely difficult to obtain high-quality experimental data. Therefore, the present investigations first focus on the validity of the applied modelling techniques by analysing their performance for idealised flow cases. These cases range from the flow over a backward-facing step to the beforementioned axisymmetric in-cylinder flow cases that have been the subject of many published investigations (see for example the work of Lea and Watkins, 1997).

The flow during the intake stroke largely determines the resulting in-cylinder flow and turbulence intensity at the moment of ignition. Hence, the performance of the induction system is of great importance. The various complexities of the flow through intake ports pose a challenge to CFD. Especially turbulence modelling is known to be problematic for prediction of flows with three-dimensional strain-rate variation, strong streamline curvature, favourable and adverse pressure gradients, separation and compressibility effects. Because of these reasons, an important part of the investigation focuses on the three-dimensional flow structures generated in a steady-flow rig for a production-type cylinder head. Another important reason that warrants such an investigation is that steady-flow rig analysis is standard industry procedure for design and evaluation of intake ports. Such analyses involve

the experimental determination of established global performance parameters which present quick, but limited insight into the occurring flow structure. More detailed analysis may yield a better understanding of the flow phenomena and allow for an evaluation of the value of the global performance parameters.

In the present investigation, steady flows are analysed, and experimental and numerical techniques are applied and validated, at several realistic flow conditions. Literature reports about various investigations in which such techniques are applied at similar conditions. However, their scope is often limited to a single valve-lift height and almost invariably to a single mass-flow rate. Moreover, model validation is often based on limited experimental data. The present investigation will assess the robustness of three-dimensional numerical methods at a wider range of steady-flow conditions through comparison with the results of extensive LDV experiments.

Of course, the intake flow plays an important role in the subsequent in-cylinder processes. However, its structure is importantly affected by the motion of the piston and the valves during the intake and compression strokes. This is essentially an unsteady process that can not be studied at steady-flow conditions. Only analysis of the unsteady phenomena can give information about the flow conditions at the end of the compression stroke, after which combustion takes place. The ability to accurately predict the conditions just prior to combustion is of course crucial to the usefulness of a computational method for the simulation of combustion. Especially turbulence affects the rate of combustion because it causes flame wrinkling. If turbulence is not too intensive, the so-called turbulent burning velocity may exceed its laminar counterpart by a factor of 30 to 50. Already in 1940, this concept was formulated by Damköhler (1940, also see Bradley, 1992). Turbulent burning velocities in engines are typically of the order of 10 m/s. However sophisticated the combustion model employed may be, it cannot hope to accurately predict the flame propagation rates and such fine details as the amounts of unburned hydrocarbons and other emissions, if the turbulent flow structure is not correctly predicted.

For this reason, the unsteady flow in a motored engine is investigated. The main focus in this thesis is on in-cylinder LDV experiments. An optically-accessible motored engine is designed and part of the appropriate experimental techniques are developed. Subsequently, in-cylinder flow structures are investigated experimentally so that reliable and detailed data are acquired that can facilitate the validation of numerical modelling of these three-dimensional unsteady flows. Such numerical modelling, and the validation of computation results through comparison with the experimental results, was a major part of the investigation. However, although close to completion, that part of the investigation could not be finished because of time limitations. Therefore, it was decided to not yet report about it in this thesis. The presented work on computing unsteady in-cylinder flows is limited to an axi-symmetric case.

1.5 Outline of the thesis

The nature of in-cylinder flows is addressed in the first part of Chapter 2. The remaining part of that chapter describes the numerical techniques that are used further on for the simulation of various flow cases. The modelling accuracy and its applicability are assessed in Chapter 3 by analysing the performance of the computational method for several simplified flow cases which have distinct engine-like flow features. Also, the value of steady-flow analysis for studying the flow during the intake stroke is assessed. To conclude that chapter, modelling demands for more realistic engine flow simulations are discussed.

The theoretical and practical backgrounds of conducting in-cylinder laser-Doppler velocimetry is described in Chapter 4. Apart from the basic principles of this measuring technique, this chapter deals with the various choices that have to be made to set up reliable and practically-feasible engine experiments. Furthermore, the measuring accuracy is addressed.

Chapter 5 deals with the numerical and experimental analysis of steady-state port-valve cylinder flows as they occur in an engine flow rig for a production-type cylinder head. First, the dedicated test rig and measuring conditions are described. Then, the LDV results are presented and the steady-flow structures are analysed. Subsequently, the numerical simulation results are presented and validated by comparison with the experimentally-acquired data. Finally, the value of the validated computational method is demonstrated through a study of the effects of several cylinder head configurations on the in-cylinder flow field.

The experimental analysis of in-cylinder flow structures during the intake and compression strokes is presented in Chapter 6. The development of an optically-accessible engine and the measuring methodology for these experiments is an important part of this investigation. The acquired time-dependent velocity distributions are presented and their implication is discussed.

Finally, the results of the presented investigation are discussed in Chapter 7 and conclusions are drawn. Furthermore, recommendations for future work are given.

2. Modelling of in-cylinder flows

The computation of complex flow phenomena, such as occurring in internal-combustion engines, requires the mathematical description of all significant properties of the processes by means of a limited number of linear algebraic equations and their solution. For the numerical flow simulations presented in this thesis, a commercial code called *STAR-CD* (Computational Dynamics, 1996) is applied. This code is frequently used in industry for automotive applications. In this chapter, a general description of the computational methods that are applied for the computation of various flow cases are given. First, the nature of the flow phenomena that play a significant role in the current study are evaluated in Section 2.1. Subsequently, the governing equations and additional modelling of the flow physics are described in Sections 2.2 and 2.3. The practice for discretisation of the derived differential equations is discussed in Section 2.4. Finally, prescription of boundary conditions is briefly addressed in Section 2.5.

2.1 Nature of the flow problem

For smooth flows, adjacent layers of fluid slide past each other in an orderly fashion. If the applied boundary conditions do not change with time, such a flow is steady. This regime is called *laminar* flow. However, most of the flow situations occurring in nature enter into a particular form of instability, called *turbulence*. Turbulence is characterised by a multitude of scales in time and space and associated mixing and diffusion that are orders of magnitude stronger than in laminar flows. The state of fluid motion is often characterised by the non-dimensional *Reynolds number* $Re \equiv \vartheta l / \nu$, where ϑ and l represent a characteristic velocity and a characteristic length, respectively, and ν is the kinematic viscosity. Which characteristic scales are used to define Re depends on the phenomena of interest. Below, several independent Reynolds numbers are defined based on the scales of fluid motion that are studied. The Reynolds number characterises the relative importance of inertial forces over viscous forces in the flow. A Reynolds number close to unity indicates a flow predominantly

driven by viscous forces. For large values of Re , the viscous forces will no longer be capable of damping perturbations.

The Reynolds number based on large-scale motion with length scale L and velocity scale U is defined as $Re_L \equiv UL/\nu$. In the laminar flow regime, this large-scale Reynolds number is below a critical value Re_{crit} although laminar flow may still exist for higher values at special conditions such as a flow free from disturbances (Schlichting, 1979). Normally however, the transition to turbulence starts for Reynolds numbers above Re_{crit} . For example, the value of Re_{crit} for a pipe flow is typically of order $2 \cdot 10^3$, when U represents the mean axial velocity and L is given by the pipe diameter. Full turbulence is attained at a Reynolds number somewhere between $2 \cdot 10^3$ and 10^5 , depending on the specific flow case (Versteeg and Malalasekera, 1995). Reynolds numbers may become as high as 10^8 , such as for jet aeroplanes, or even much higher like in atmospheric flows. However, the Reynolds number gives only an indication of flow stability and, thus, the possible occurrence of turbulence. An additional measure to characterise the state of turbulent fluid motion is the turbulence intensity I , which is defined as the ratio between the mean amplitude of the turbulent velocity fluctuations and the mean large-scale velocity. Flows with high Reynolds numbers may well possess a low turbulence intensity, because of high mean velocities, and visa versa.

Turbulent flows reveal rotational flow structures, so-called *turbulent eddies*. The turbulence energy associated with these flow structures spreads over a wide range of length and time scales. The largest eddies present, mostly referred to as *macroscales*, are limited by the boundaries of the turbulent flow domain. Most of the turbulent energy production is associated with these large eddies because they break up and exchange their energy with the just-smaller eddies by a mechanism called *vortex stretching* (see Nieuwstadt, 1992). This results in the structure of the largest eddies being highly directional, or *anisotropic*, and flow dependent. These eddies are effectively inviscid and angular momentum is conserved during vortex stretching. This causes the rotation rate to increase and the radius of the eddy cross-sections to decrease, which results in an increase of the local vorticity. Thus the process creates motions at progressively smaller transverse length scales and also at smaller time scales. This energy cascade process ends at the smallest eddies, mostly characterised by the so-called *Kolmogorov microscales*. The size of these smallest eddies is predominantly determined by the molecular process of viscous dissipation. Work is performed against the action of the viscous stresses, so that the energy associated with the eddy motions is dissipated and converted to thermal internal energy. This dissipation is the cause of increased losses of kinetic energy associated with turbulent flows when compared to laminar flows. The diffusive action of viscosity tends to diminish directionality at small scales. Therefore, the smallest eddies in a turbulent flow are predominantly *isotropically* distributed. The continuous spectrum of turbulent motion between the energy-containing macroscale and the viscosity-damped microscale eddies is called the *inertial subrange*. This spectrum has a nearly universal character and is independent of the macro structures and viscosity (cf.

[Nieuwstadt, 1992; Hallböck, 1996]) according to the so-called *universal equilibrium theory* of Kolmogorov (1941). This theory is based on the assumption that for high Re_L the rate of turbulent energy dissipation per unit mass at the microscales, ε , is only governed by the kinematic viscosity ν and the rate at which these microscales are supplied with energy by the macroscales.

This assumption implies that the Reynolds number of the smallest eddies is equal to unity, which expresses that the viscous forces are preponderant, as was discussed earlier. This Reynolds number is defined as $Re_\eta \equiv \nu\eta/\nu$, based on the microscale length η and the characteristic velocity $v (= \pi\cdot\eta/\tau)$, where τ is the time microscale. Based on this assumption, Kolmogorov introduced the following relations:

$$\eta = \left(\frac{\nu^3}{\varepsilon} \right)^{1/4}, \quad (2.1a)$$

$$\tau = \left(\frac{\nu}{\varepsilon} \right)^{1/2}. \quad (2.1b)$$

$$v = (\nu\varepsilon)^{1/4}. \quad (2.1c)$$

The assumption that the rate at which the small scales are supplied with energy is determined by the energy transfer through the spectrum from large to small scales implies that the dissipation rate ε can be related to the velocity scale U and time scale $T (=L/U)$ of the largest eddies:

$$\varepsilon \sim \frac{U^2}{T} = \frac{U^3}{L}. \quad (2.2)$$

Using large eddy properties to define the dissipation rate ε is permitted at high Reynolds numbers because the rate at which large eddies extract energy from the mean flow is precisely matched by the rate of transfer of energy across the spectrum to small, dissipating eddies. Otherwise, the energy at some scales of turbulence could grow or diminish without limit and that does not occur in practice for flows that are in local equilibrium (Versteeg and Malalasekera, 1995). Substitution of this expression in equations 2.1 yields the following scale relations, which relate the microscales to the macroscale structures:

$$\frac{\eta}{L} \sim \left(\frac{U L}{\nu} \right)^{-3/4} = Re_L^{-3/4}, \quad (2.3a)$$

$$\frac{\tau}{T} \sim \left(\frac{U L}{\nu} \right)^{-1/2} = Re_L^{-1/2}. \quad (2.3b)$$

From this equation it can be seen that the range of the length scales broadens with increasing Reynolds number. Hence, high Reynolds numbers yield 'fine' turbulent structures.

In-cylinder engine flows are almost exclusively turbulent. The confined three-dimensional entrainment and the compression in engines produce high spatial and temporal variation of fluid properties. Moreover, these flows exhibit curvature, rotation and flow separations or reversals. The large-scale in-cylinder eddies that are responsible for producing most of the turbulence during the intake stroke arise from the jet-like flow structure that emerges from the intake ports. The flow velocity in the jet is typically an order of magnitude larger than the piston velocity, and the initial width of the jet is approximately equal to the valve lift. Shear between the jet and the more or less stagnant cylinder contents leads to eddies. The size of these induction-generated eddies is of the order 10^{-2} m since that is a typical value for the valve-lift height for automotive engines. During compression, the eddies relax to the shape of the combustion chamber, resulting in a typical length scale L of 10^{-1} m. The velocity scale U is conveniently associated with the mean piston velocity during the intake stroke, which is of course dependent on the engine speed, but is typically of the order of 10 m/s. Hence, the in-cylinder engine flows of interest in this thesis exhibit large-scale Reynolds numbers in the range of 10^4 - 10^5 . For such high values, the large-scale eddies in engines are dominated by inertia forces and viscous effects are negligible. According to equation 2.3a, such high Reynolds numbers cause the smallest in-cylinder lengths scales to be of the order of 10^{-1} to 10^{-2} mm. Lorenz and Prescher (1990) report that hot-wire velocimetry experiments have shown that the turbulent fluctuations can have frequencies $f(=1/\tau)$ up to 10 kHz. Equation 2.3b indicates the same order of magnitude for the in-cylinder flow during the compression stroke ($U=10^1$ m/s, $L=10^{-1}$ m, $Re_L=10^4$). In the intake jet, much higher frequencies of order 10³ kHz ($U=10^2$ m/s, $L=10^{-2}$ m, $Re_L=10^5$) are suggested by the equations. However, no literature was found that reports of frequencies higher than 10 kHz. This may also be caused by limitations of commonly-applied experimental techniques to measure higher frequencies. Nevertheless, in-cylinder flows indeed exhibit a broad range of length and time scales. Due to their reciprocating behaviour, flows in engines generally have large turbulence intensities, which are of the order of 10%. Hence, in conjunction with relatively high Reynolds numbers, flows in engines may be considered highly turbulent.

2.2 Governing equations

Fluid motion occurs as a consequence of pressure differences between adjacent air masses which are sustained by natural or mechanical forces. This motion is governed by the conservation laws for mass, momentum and energy. The equations describing fluid velocity and pressure distribution were discovered independently more than a century and a half ago by the French engineer Claude Navier (1827) and the Irish mathematician George Stokes

(1845). The system of so-called *Navier-Stokes equations*, supplemented by equations of state and constitutive relations, completely describes flow behaviour (see for instance Patankar, 1980). Hence, any experiment could be accurately duplicated by computations given appropriate computer resources.

For most practical applications, the numerical solution of the governing equations demands spatial discretisation by subdividing the flow domain into a finite number of computational cells and through time-stepping, as will be discussed in more detail in Section 2.4. With so-called *Direct Numerical Simulation (DNS)*, the governing equations are solved on a grid which is sufficiently fine to resolve the flow up to the smallest detail, e.g. the Kolmogorov microscales. According to equations 2.3, the number of computational cells required for three-dimensional DNS is of order $Re_L^{9/4}$, with the number of time steps of order $Re_L^{1/2}$. Hence, the complexity of unsteady computations scales with $Re_L^{11/4}$, meaning that an increase of the Reynolds number by one order of magnitude results in an increase of the computational effort in DNS of nearly three orders. Clearly, the direct numerical representation of all relevant hydrodynamic length and time scales in an engine, even without combustion and sprays, is a formidable task which puts very high demands on computer resources. At present, full DNS can only be conducted for fairly simple flow problems at low Reynolds numbers.

In the future, with increasing computer power, both in speed and memory, simulation of the macroscale turbulent fluctuations, or even the microscale turbulent motion, from the time-dependent Navier-Stokes equations may become feasible for more complex flow problems. Meanwhile, engineers need adequate information about such complex, turbulent flows. As far as the analysis of flows in engines is concerned, there is already much insight to be gained from information about the mean flow properties and their average turbulent fluctuation. This demands computational procedures which can supply such information while avoiding the need to predict the effects of each and every eddy in the flow. As a consequence, the required resolution is reduced. One ultimately relies on mathematical models to condense and digest information, in any realistic case (Khaligi et al., 1995). This is achieved by considering the Reynolds-averaged Navier-Stokes equations supplemented by models for the Reynolds stresses, as will be discussed below.

Reynolds-averaged Navier-Stokes equations

The particular form of instability generated in turbulent flow regimes is characterised by the presence of statistical fluctuations of all flow quantities. The instantaneous quantity $\phi_i(\alpha)$ can be considered as a high-frequency fluctuation $\phi'_i(\alpha)$ superimposed on an average, low-frequency value $\bar{\phi}(\alpha)$, the so-called *Reynolds decomposition*:

$$\phi_i(\alpha) = \bar{\phi}(\alpha) + \phi'_i(\alpha) \quad , \quad (2.4)$$

where α is the crank angle position and i identifies the engine cycle. Under the periodic flow conditions in reciprocating engines, the Reynolds-averaging procedure is a phase averaging:

$$\bar{\phi}(\alpha) = \lim_{I \rightarrow \infty} \frac{1}{I} \sum_{i=1}^I \phi_i(\alpha) \quad . \quad (2.5)$$

For steady-flow conditions, this procedure of course returns to time averaging. The average of the fluctuations $\phi'_i(\alpha)$ is, by definition, zero. Information regarding the fluctuating part of the flow can be obtained from its root-mean-square (RMS) value,

$$\phi'_{RMS}(\alpha) = \sqrt{\lim_{I \rightarrow \infty} \frac{1}{I-1} \sum_{i=1}^I (\phi_i(\alpha) - \bar{\phi}(\alpha))^2} \quad . \quad (2.6)$$

The Reynolds-averaged mass and momentum conservation equations for time-dependent compressible fluid flows are, in Cartesian tensor notation (Warsi, 1981):

$$\frac{\partial \bar{\rho}}{\partial t} + \frac{\partial}{\partial x_j} (\bar{\rho} \bar{u}_j) = 0 \quad , \quad (2.7)$$

$$\frac{\partial}{\partial t} (\bar{\rho} \bar{u}_i) + \frac{\partial}{\partial x_j} (\bar{\rho} \bar{u}_j \bar{u}_i - \tau_{ij} - \tau_{ij}^R) = -\frac{\partial \bar{p}}{\partial x_i} \quad , \quad (2.8)$$

where the fluid velocity components are denoted by u_i for the direction of Cartesian coordinate x_i ($i = 1, 2, 3$), ρ is the density, τ_{ij} and τ_{ij}^R represent the viscous and the Reynolds-stress tensor components, respectively, and p is the static pressure. Repeated subscripts indicate the Einstein summation convention and overbars denote the averaging process. Gravitational buoyancy effects are not taken into account because in-cylinder flow problems are expected to be governed by forced convection.

Note that, apart from the additional τ_{ij}^R terms in the momentum equations, equations 2.7 and 2.8 are identical to the general set of Navier-Stokes equations for unsteady flow (see for instance Patankar, 1980). The additional terms in the Navier-Stokes equations arising from the Reynolds decomposition and the time averaging are the so-called *Reynolds stresses*: three normal stresses $\tau_{ii}^R = -\bar{\rho} \overline{u'_i u'_i}$ and three shear stresses $\tau_{ij}^R = \tau_{ji}^R = -\bar{\rho} \overline{u'_i u'_j}$. In turbulent flows, the normal stresses are always non-zero because they contain squared velocity fluctuations.

The turbulent shear stresses are also non-zero and usually very large compared to the corresponding viscous-stress components.

Heat transfer

Heat transfer is provided for through the energy equation, expressed here in terms of the enthalpy h :

$$\frac{\partial}{\partial t}(\bar{\rho} \bar{h}) + \frac{\partial}{\partial x_j}(\bar{\rho} \bar{u}_j \bar{h} + \bar{\rho} \overline{u'_j h'}) + q_j = \frac{\partial \bar{p}}{\partial t} + \bar{u}_j \frac{\partial \bar{p}}{\partial x_j} + \tau_{ij} \frac{\partial \bar{u}_i}{\partial x_j} , \quad (2.9)$$

where q_j represent the heat fluxes.

Equations of state

The enthalpy and the pressure are given by caloric and thermal equations of state, respectively. The enthalpy is defined by

$$h = \int_{T_0}^T c_p dT = c_p(T - T_0) , \quad (2.10)$$

where c_p is the constant-pressure specific heat, which is assumed constant, T is the temperature and T_0 is a reference temperature. Local pressure p is a function of local density and temperature by assuming that the fluid has the properties of an ideal gas, thus

$$p = \frac{\rho R T}{M} , \quad (2.11)$$

where R is the universal gas constant and M represents the average molecular weight.

Constitutive relations

The heat fluxes q_j are assumed to obey Fourier's law:

$$q_j = -k \frac{\partial T}{\partial x_j} , \quad (2.12)$$

where k represents thermal conductivity, which is taken to be constant.

For turbulent flows, u_i , p and other dependent variables, including the viscous stresses τ_{ij} , assume their ensemble-averaged values, giving, for Newtonian fluids (Hinze, 1975)

$$\tau_{ij} = 2\mu s_{ij} - \frac{2}{3}\mu \frac{\partial \bar{u}_k}{\partial x_k} \delta_{ij} \quad , \quad (2.13)$$

where μ is the molecular viscosity, which is assumed constant. The 'Kronecker delta' δ_{ij} is unity when $i = j$ and zero otherwise. The rate of strain s_{ij} is given by

$$s_{ij} = \frac{1}{2} \left(\frac{\partial \bar{u}_i}{\partial x_j} + \frac{\partial \bar{u}_j}{\partial x_i} \right) \quad . \quad (2.14)$$

The unknown Reynolds stresses τ_{ij}^R and turbulent heat fluxes are linked to the mean velocity field via turbulence models to mathematically close the set of Reynolds-averaged Navier-Stokes equations, as will be seen in the following section.

2.3 Modelling of turbulence

Models of turbulence comprise additional differential or algebraic equations that relate the Reynolds stresses and the turbulent heat fluxes to the ensemble-averaged properties of the turbulence field and also provide a framework for computing these properties. This modelling process unavoidably introduces inaccuracies into the solution. Nevertheless, it is the only feasible approach today for the three-dimensional numerical simulation of engine gas flows that must be conducted in a reasonable time-frame and still fulfil the requirement of adequate accuracy and generality for engineering applications.

It is important to stress here the role of turbulence modelling for engine simulations. As for most engineering purposes, it is unnecessary to resolve all details of the turbulent fluctuations. Only the effects of the turbulence on the mean flow and combustion are sought. Engine developers demand models that have wide applicability, are simple and economical to run, have a proven level of accuracy and are available in commercial codes. Two types of mathematical modelling of turbulent flows are distinguished here: *classical modelling*, which employs Reynolds-averaged Navier-Stokes equations, and *Large Eddy Simulation (LES)*.

State of the art

LES is a form of mathematical modelling where space-filtered equations (see for instance Piomelli and Chasnov, 1996), as opposed to Reynolds-averaged equations, are solved for the

mean flow and the largest eddies. As argued in Section 2.1, the largest eddies interact strongly with the mean flow and contain most of the turbulence energy. In LES, only the unresolved small scales are modelled, which are normally less anisotropic and less influenced by the geometry of the flow than the large scales. This encourages optimism about the possibility of constructing models for these small scales that are more universal than those thought of as adequate for the complete turbulence field. Such models are called subgrid-scale models. The mesh size for LES is chosen such that local isotropy can be assumed within the dimensions of each computational cell. Hence, cell size must relate to the length scale of the eddies in the inertial subrange. As a consequence, this approach results in a good model for the main effects of turbulence. With growing computer capacities, the LES technique is becoming an alternative to traditional mathematical modelling, in particular for unsteady flows. However, this technique is still at an early stage of development and reliable application to industrial problems is limited. Many phenomena are still not adequately understood. Therefore, LES is not yet an option for the simulation of realistic engine flows. Anticipated improvements in its understanding and in computer hardware may change this perspective in the near future.

Classical modelling employs Reynolds-averaged Navier-Stokes equations and forms the basis of turbulence computations in most currently-available commercial CFD codes. Flow simulation for realistic engines today almost exclusively depends on this approach. Eddies ranging from macroscales to microscales are included in turbulence models, instead of just for the microscales and the eddies in part of the inertial subrange as is the case for LES. Hence, the fluctuating quantities that are introduced by the Reynolds-averaging must represent all scales of turbulence. The major problem with this type of modelling lies in the difficulty to describe the anisotropy associated with the larger eddies. Most commonly, the models must rely on empiricism, which renders them strongly dependent on the flow case. Typically, the time-scales resolved in classical modelling are one or two orders of magnitude larger than for LES. Appropriate cell sizes may be of similar order or one order larger in each direction. From this point of view, computations with classical modelling are generally considerably less expensive than LES. However, there are a few more aspects that determine the final difference of computational costs. On the one hand, LES computations can be more efficient since commonly explicit solution schemes are applied. Computations with classical modelling mostly involve implicit solution because that allows larger time steps without stability constraints. On the other hand, the computational effort involved with LES is increased because it requires computation through multiple engine cycles to accumulate ensemble-average statistics (Haworth and Jansen, 1996).

In general, classical turbulence models range from the straightforward algebraic *mixing length* models to transport equations for the turbulent kinetic energy and dissipation rates, the so-called k - ϵ models, or to still more complicated models directly computing the Reynolds stresses. Mixing length models attempt to describe the stresses by means of simple algebraic

formulae as a function of position (Versteeg and Malalasekera, 1995). The k - ε model is a more sophisticated, more general and often more accurate, but also less economic, description of turbulence. It allows for the transport of turbulence properties by mean flow and diffusion, and for the production and destruction of turbulence. Two transport equations are solved for, one for the turbulent kinetic energy k and one for the rate of dissipation of turbulent kinetic energy ε . Both the mixing length model and the k - ε models are based on the presumption that there exists an analogy between the action on the mean flow of viscous stresses and Reynolds stresses.

An alternative is to solve transport equations for all six Reynolds stresses in addition to the transport equation for ε , which is called *Reynolds Stress modelling* (RSM). The design of such models is an area of vigorous research and they have not been validated as widely as the mixing length and k - ε models. RSM is not yet capable of predicting complex compressible flows with sufficient accuracy. Moreover, these models must solve seven equations, which gives rise to a substantial increase in computational cost over the two-equation k - ε models. The k - ε models are most commonly used for realistic in-cylinder flow simulations (Khalighi et al., 1995) and are readily available in many commercial flow simulation codes in industry.

Two-equation k - ε turbulence modelling

All turbulence models applied in the investigations that are presented in this thesis are two-equation k - ε models. In k - ε turbulence modelling, the turbulent Reynolds stresses τ_{ij}^R and the turbulent heat fluxes are modelled by gradient-diffusion expressions. Hence, they are described as additional diffusion transport processes. The so-called *turbulent viscosity* μ_t is defined as the turbulent diffusion coefficient and is given by

$$\mu_t = \frac{C_\mu \rho k^2}{\varepsilon} \quad , \quad (2.15)$$

where C_μ is an empirical model coefficient. This is an isotropic entity, which implies that the employed modelling can not describe anisotropy of turbulence.

A number of variants of the k - ε model have been developed over the last decades to give improved descriptions of specific flow phenomena. The empiricism involved in the derivation of some of these models implies that they are best suited for simple flows and, in particular, those flow geometries from which experimental data were used to fix the empirical constants. Every engineer is aware of the dangers of extrapolating an empirical model beyond its data range. Flows in engines are invariably complex and, hence, provide a challenge to these turbulence models. CFD computations of such turbulent flows should never be accepted

without any validation against high-quality experiments. This summarises one of the main objectives of the work reported in this thesis, as was discussed in Chapter 1. Here, three different k - ϵ models for high-Reynolds-number flows are analysed at engine-like conditions: the ‘standard’ k - ϵ model, the Renormalisation Group variant, and the so-called CHEN model. Below, some specific properties of these models are discussed. Extensive model descriptions are given in Appendix A. The model constants of these models were set to their default values, which are also given in the appendix. Optimisation of these constants may yield improved predictions for a specific flow case. Such an optimisation was not attempted here since the present investigation focuses on the general applicability of the models.

The standard k - ϵ model (Launder and Spalding, 1974) relies on two basic assumptions. Firstly, it is based on the assumption that turbulent transport and dissipation of turbulent energy proceed with the same time scale, which is the *dissipation time scale*, k/ϵ . Consequently, small-scale fluctuations will respond instantaneously to large-scale fluctuations, which implies that turbulence is in approximate *equilibrium*. In reality, this appears to be often the case and the success of this model for engineering applications may be due to the fact that many of these flows can be described with only a single time-scale. Secondly, the model assumes isotropy, which is due to the fact that a single turbulent viscosity is used to model all Reynolds stresses, as was seen above. This poses an important problem to the application of this type of turbulence modelling because many engineering applications are anisotropic.

The k - ϵ model performs particularly well in confined flows where the Reynolds shear stresses are dominant. This includes a wide range of flows with industrial engineering applications, which explains the popularity of this model. Ahmadi-Befrui and Gosman (1989) analysed several k - ϵ models and concluded that the version of El Tahry (1983), applied in the present study, is suitable for engine applications. However, the model has problems predicting several flow phenomena. For example, swirling motions and flows with large strain rates are not captured since no description of the effects of streamline curvature on turbulence are included. Unfortunately, flows in engines exhibit such features as a result of the highly curved geometries, the diverging flow through the ports and the volume compression. The standard k - ϵ model is known to be highly diffusive in such cases, which is often attributed to the ϵ -equation. Many variants of the standard model have been developed over the past decades for improved prediction of such flows, such as the RNG and CHEN models.

The Renormalisation Group (RNG) method is a general framework for model building in which the complex dynamics of physical problems are described in terms of so-called *coarse-grained* equations of motion governing the large-scale, long-term behaviour of a system. In analogy with LES, the basic idea of the RNG method as applied to turbulence modelling is the elimination of small-scale eddies from the equations of motion. The RNG turbulence

model is based on the work of Yakhot and Orszag (1986) and Yakhot et al. (1993). The method can describe effects of the small eddies that should be statistically independent of the large-scale motion. In other words, the RNG method gives a theory for the Kolmogorov equilibrium range of turbulence, comprising the inertial range of small-scale eddies. The importance of the RNG approach is that once the inertial range eddies can be accounted for in a quantitatively correct way, coarse-grained equations of motion for the averaged flow quantities at the macroscale of turbulence may be obtained. The main difference of the RNG model compared to the standard k - ε model is an additional term in the dissipation equation, which represents the effect of mean flow distortion on ε (see Appendix A). In regions of large strain rate, the production rate of ε is increased due to this term. This feature of the RNG model may allow for an improved prediction of flow separation and recirculation, which are prominent phenomena occurring in in-cylinder engine flows.

The so-called CHEN k - ε model is based on the work of Chen and Kim (1987). The dissipation time scale, k/ε , is the only turbulence time scale used in closing the ε -equation of the standard k - ε model. In Chen's model, the *production range time scale*, $\rho P/\mu k$, as well as the dissipation time scale, are used in closing the ε -equation. This additional time scale should allow the transfer mechanism of turbulence energy to respond to the mean strain rate more effectively. Again, this has resulted in an additional expression in the dissipation equation, which has a net effect of enhancing turbulent energy dissipation when the turbulence production rate is large (see Appendix A). This expression represents the energy transfer rate from large-scale turbulence to small-scale turbulence controlled by the production range time scale. Numerical test cases presented by Chen and Kim (1987) suggest that this model is more generally applicable than the standard model. Superior performance for flow problems involving rapidly-changing energy production and dissipation rates are attributed to the energy-transfer expression. This expression is expected to suppress an overprediction of turbulent kinetic energy that is characteristic for the standard k - ε model for strong mean shear.

2.4 Discretisation

The previous sections illustrated that the physical phenomena of interest are governed by partial differential equations. A numerical solution of a partial differential equation consists merely of a set of numerical values from which the distribution in space and time of the flow variables can be constructed. In this sense, a numerical method is akin to a laboratory experiment, in which a set of instrument readings enables the experimenter to establish the distribution of the measured quantity in the domain under investigation. The numerical analyst and the laboratory experimentalist both must consent with only a finite number of numerical values as the outcome. However, this number can, at least in principle, be made

large enough for practical purposes. A numerical method treats the values of the flow variables at a finite number of locations and instances in time as its basic unknowns. The numerical method provides a set of algebraic equations for these unknowns.

2.4.1 Finite-volume discretisation of governing equations

The partial differential equations governing the conservation of mass, momentum and energy, presented in Sections 2.2 and 2.3, are discretised by means of the *Finite-Volume Method* (see Gosman et al., 1969, and Patankar, 1980). Thus, the equations are first integrated over a control volume, here chosen as an individual computational cell, and then approximated in terms of the cell-centred nodal values of the flow variables.

For the purpose of finite-volume discretisation, it is convenient to work with the following general coordinate-free, conservative form of the conservation equations:

$$\frac{\partial}{\partial t}(\bar{\rho} \tilde{\phi}) + \text{div}(\bar{\rho} \tilde{u} \tilde{\phi} - \Gamma_{\phi} \text{grad} \tilde{\phi}) = s_{\phi} \quad , \quad (2.16)$$

where \tilde{u} is the Favre-averaged fluid velocity, $\tilde{\phi}$ denotes any of the Favre-averaged dependent variables and Γ_{ϕ} and s_{ϕ} are the associated ‘diffusion’ coefficient and ‘source’ term, respectively. With Favre-averaging, the variable ϕ is decomposed into a mass-weighted quantity $\tilde{\phi}$ and a fluctuation ϕ'' , similar to equation 2.4. The mass-weighted quantity is defined as:

$$\tilde{\phi} = \frac{\overline{\rho \phi}}{\bar{\rho}} \quad . \quad (2.17)$$

Favre-averaging is mathematically preferable over conventional averaging (Sanders, 1994).

An exact form of equation 2.16, valid for an arbitrary time-varying control volume V_p , which is bounded by discrete faces S_j ($j = 1, N_f$) of a computational cell (see Figure 2.1), can be written as (Warsi, 1981)

$$\underbrace{\frac{\partial}{\partial t} \int_{V_p} \bar{\rho} \tilde{\phi} dV}_{T_1} + \underbrace{\sum_j \int_{S_j} (\bar{\rho} \tilde{u}_r \tilde{\phi} - \Gamma_{\phi} \text{grad} \tilde{\phi}) \cdot \bar{n} dS}_{T_2} = \underbrace{\int_{V_p} s_{\phi} dV}_{T_3} \quad , \quad (2.18)$$

where \bar{n} is the surface normal vector and \tilde{u}_r is the velocity of the fluid relative to the velocity of surface S . Here, the Gauss theorem is applied to write term T_2 as a surface integral.

Figure 2.1 : Illustration of a computational cell with centred node P and neighbour cell with centred node N

From here onwards, approximations are introduced. The first term T_1 is discretised as:

$$T_1 \approx \frac{(\bar{\rho} \tilde{\phi} V)_P^n - (\bar{\rho} \tilde{\phi} V)_P^o}{\delta t} , \quad (2.19)$$

where the superscripts n and o refer to 'new' and 'old' time levels respectively, separated by an interval δt . This is a so-called *Euler-backward* time discretisation, which is first-order accurate in time (see f.i. Hirsch, 1988a). For steady-flow problems, which are solved by iteration, the time derivative term T_1 is dispensed entirely. The manual of the CFD code STAR-CD claims that a fully-implicit formulation is used (Computational Dynamics, 1996). This implies that all fluxes and sources in terms T_2 and T_3 prevailing over this interval are taken to have their new-time-level value.

The second term of equation 2.18 is split into separate contributions C_j and D_j due to convection and diffusion, respectively. Each contribution is expressed in terms of average values over cell faces, denoted by the subscript j , thus:

$$T_2 \approx \sum_j (\bar{\rho} \tilde{u}_r \tilde{\phi} \cdot \tilde{n} S)_j^n - \sum_j (\Gamma_\phi \text{grad } \tilde{\phi} \cdot \tilde{n} S)_j^n \equiv \sum_j C_j^n - \sum_j D_j^n . \quad (2.20)$$

The approximation of the convection terms C_j is discussed in Section 2.4.2. The diffusion terms D_j are approximated by face-centred expressions of the form

$$D_j \approx \Gamma_{\phi,j} \left[f_j^l (\tilde{\phi}_N - \tilde{\phi}_P) + \sum_k f_j^k \delta \tilde{\phi}_j^k \right] , \quad (2.21)$$

where the first term within the brackets represents the gradient between P and the neighbouring cell-centred node N , as indicated in Figure 2.1. The second term is an

approximation of the *cross-diffusion* expressed as a summation of $\delta\tilde{\phi}$ over all vertex pairs on face j , with $\delta\tilde{\phi}$ being the difference between the vertex $\tilde{\phi}$ values, which are interpolated from the surrounding nodal values. The cross-diffusion compensates for the gradient not being perpendicular to the interface. Terms f_j are geometrical factors and Γ_{ϕ_j} is the interpolated diffusivity. From a Taylor-series expansion, it can be shown that the approximation of the diffusion terms D_j introduces a truncation error of the order of $(\Delta x)^2$ on uniform, Cartesian grids, where Δx is the distance between two neighbouring cell centres.

The third term of equation 2.18, T_3 , may contain sources and sinks of the transported property, as well as additional flux terms. Fluxes and other gradient-containing terms are approximated in a similar fashion as C_j and D_j , while non-gradient quantities are evaluated using the cell-centred nodal quantities.

2.4.2 Spatial flux discretisation

The manner in which the convective and diffusive fluxes are expressed in terms of nodal ϕ values is one of the key factors determining accuracy and stability, for both steady-state and transient computations. At high Reynolds numbers, flows are often predominantly driven by convection and exhibit large gradients. In other words, the non-dimensional cell *Peclet number* Pe , defined as a measure of the relative magnitudes of convection and diffusion ($Pe = \rho \cdot u_r \cdot \Delta x / \Gamma_{\phi_j}$), is often large. Therefore, the choice of convective flux approximation is important. In what follows, the spatial discretisation schemes that are used in the present investigation are presented and discussed. For this purpose, the C_j factors in equation 2.20 are rewritten as

$$C_j \equiv F_j \tilde{\phi}_j \quad , \quad \text{where } F_j \equiv (\rho \tilde{u}_r \cdot \tilde{n} S)_j \quad (2.22)$$

is the mass flux through face j . The average property value at the face ϕ_j is effectively interpolated from selected nodal values in accordance with the scheme used and as indicated in Figure 2.2. The face values of auxiliary properties such as ρ and Γ are also obtained by linear interpolation. All the difference schemes are one-dimensional.

Upwind differencing

The Upwind Difference (UD) scheme, which was first put forward by Courant, Isaacson and Rees (1952), selects the nearest upwind neighbour value for ϕ_j , thus

Figure 2.2 ∴ Node labelling convention for flux discretisation

$$C_j^{UD} \equiv F_j \begin{cases} \tilde{\phi}_P & , F_j \geq 0 \\ \tilde{\phi}_{N+} & , F_j < 0 \end{cases} \quad (2.23)$$

This scheme applies a ‘zeroth-order’ interpolation, which results in a truncation error of the order of Δx , rendering it only first-order accurate. This form of interpolation preserves the correct physical bounds on ϕ at all conditions, given correct initial and boundary conditions. A major drawback of the scheme is that it gives rise to smearing of gradients, which has come to be known as *numerical diffusion*. Numerical diffusion is large in the case of steep gradients and in multi-dimensional flow problems when the flow is not aligned with the grid lines. In high Reynolds number flows, the numerical diffusion can be large enough to give physically-incorrect results. Numerical diffusion is a form of truncation error that diminishes as the cell sizes are decreased, but of course at an increased cost of computation. An important advantage of the UD scheme is that it is unconditionally stable (Patankar, 1995).

Central differencing

The Central Difference (CD) scheme simply interpolates linearly on the nearest neighbour values, irrespective of the flow direction, giving

$$C_j^{CD} = F_j [f_+ \tilde{\phi}_P + (1 - f_+) \tilde{\phi}_{N+}] \quad (2.24)$$

From a Taylor-series expansion, it can be shown that this scheme has a truncation error of the order of $(\Delta x)^2$ on uniform, Cartesian grids. This order of accuracy would make this scheme ideal for most practical purposes if it were unconditionally stable. Unfortunately, it can be shown that the CD scheme exhibits oscillatory behaviour for $|Pe| > 2$, which is often called *numerical dispersion* (Hirsch, 1988b). In this respect, it is important to note that the cell Peclet number is a combination of fluid properties (ρ and Γ), a flow property (u_r) and a property of the computational grid (Δx). So, for given values of ρ and Γ , it is only possible to

satisfy the condition $lPe \leq 2$ when the velocity is small, hence in diffusion-dominated low Reynolds number flows, or when the grid spacing is small.

Self-filtered central differencing

The very attractive second-order accuracy of the CD scheme has led to the development of several variants that are less dispersive. A famous example is the Hybrid scheme (Spalding, 1972), which basically applies CD for $lPe \leq 2$ and UD otherwise. Unfortunately, this scheme possesses high numerical diffusion for large values of the Peclet number. The Self-Filtered Central Difference (SFCD) scheme, as its name implies, is effectively central differencing with a built-in adaptive filter to remove non-physical extrema whenever they arise. This is achieved by locally blending the CD and UD schemes, thus

$$C_j^{SFCD} = \gamma_j C_j^{CD} + (1 - \gamma_j) C_j^{UD} \quad . \quad (2.25)$$

The face-related weighting factors γ_j ($0 \leq \gamma_j \leq 1$) are evaluated from the local ϕ gradients in a way that the factors are as close to unity as possible in regions of steep gradients. Although the exact algorithm of the scheme has not been published for commercial reasons, its developers assure that the evaluation of the weighting factors is achieved in a similar fashion to the CONDIF scheme, as proposed by Runchal (1987). That scheme only switches to upwind differencing ($\gamma_j = 0$) in case the property gradient has an extremum within the computational cell. Whenever the ratio of the gradients on opposite cell faces exceeds a certain value, the CONDIF scheme blends the CD and UD solutions ($0 < \gamma_j < 1$). As a result, a controlled, but limited, amount of numerical diffusion is introduced, which reduces dispersion. In all other cases, the scheme is unconditionally stable and central differencing is applied ($\gamma_j = 1$). Effectively, this procedure gives the higher accuracy of the CD scheme in areas of limited Peclet number, without becoming unstable in other areas. According to Ziman (1990), the difference between the SFCD and the CONDIF schemes lies in another appreciation of the local-gradient variation. The SFCD scheme, as applied in the present study, promises reduced numerical diffusion without dispersion.

Quadratic upstream interpolation of convective kinematics

The Quadratic Upstream Interpolation of Convective Kinematics (QUICK) scheme of Leonard (1979) fits a parabola through two points upstream and one point downstream to get an interpolation value, giving

$$C_j^{QUICK} = F_j \begin{cases} f_- \tilde{\phi}_{N-} + f_+ \tilde{\phi}_{N+} + (1 - f_- - f_+) \tilde{\phi}_P & , F_j \geq 0 \\ f_{++} \tilde{\phi}_{N++} + f_+ \tilde{\phi}_{N+} + (1 - f_+ - f_{++}) \tilde{\phi}_P & , F_j < 0 \end{cases} \quad (2.26)$$

where f_- , f_+ and f_{++} are quadratic interpolation factors. Since this scheme is based on a quadratic function, its accuracy in terms of the Taylor-series truncation error is of the order of $(\Delta x)^3$ on a uniform, Cartesian mesh. Hence, the QUICK scheme has a higher formal accuracy than the other schemes. In conjunction with the formally second-order accurate description of diffusion, the overall accuracy of the convection-diffusion terms C_j and D_j will only be third order for convection-driven flows. The resultant false diffusion is small, but the scheme is only conditionally stable and may give rise to unbounded solutions (Versteeg and Malalasekera, 1995). Note that more stable variants of the QUICK scheme have been developed, such as the ULTRAQUICK scheme (cf. [Dogge, 1996; Leonard and Mokhtari, 1990; Leonard, 1991]). Nevertheless, only the standard QUICK scheme is applied in the present investigation.

2.4.3 Solution-domain discretisation

Inherent to the finite-volume method is the necessity to discretise the solution domain. A computational grid must be generated that fits the boundary surface of the domain and subdivides its volume into ‘cells’, used for the spatial flux discretisation as was discussed in the previous section. The accuracy of the numerical simulation of complex flows is very much determined by the computational grid structure employed. Simulation of flows in engines puts very high demands on the grid because of the complex three-dimensional geometry and the moving boundaries, i.e. piston and valves.

The grids employed in the current investigation are body-fitted and unstructured. They consist of straight-edged cells of predominantly hexahedral form. Occasionally, triangular prisms occur within an otherwise hexahedra grid at positions where it is not possible or inconvenient to apply hexahedras. The cells are shaped and patched face-to-face in an ‘arbitrary’ manner to fill complex volumes, such as the intake port of a cylinder head or the pent-roof combustion chamber. To increase local resolution, so-called *embedded refinement* is applied, in which one or more existing cells are subdivided while neighbouring cells remain unchanged.

Moving boundaries are represented through grid movement, in which portions of the grid are distorted by ascribing time-varying positions to some or all of the cell vertices. This type of grid movement is sometimes referred to as *Arbitrary Lagrangian-Eulerian*. Of course, the grid motion is not entirely arbitrary because there are limits on the degree of distortion that is tolerated, imposed by accuracy and stability requirements. Grid motion has been accommodated by working from the outset with the general form of the governing differential

equations in an arbitrary moving coordinate frame. The development and solution of the discretised forms of these equations is straightforward within the finite-volume framework, provided that appropriate measures are taken to ensure obedience to an additional equation called the *space conservation law* (Demirdzic and Peric, 1988), which is solved for the moving grid points. This relates the change in cell volume to the coordinate frame velocity. The simultaneous satisfaction of the space conservation law and all other equations of fluid motion facilitates the solution to be obtained on a moving grid.

During the computation of unsteady in-cylinder flow, cells may become extremely distorted, for instance as a result of the large compression ratio of the combustion chamber volume, which is typically 10:1. To prevent this, so-called *cell-layer removal and addition* is applied. The general approach in cell-layer removal is that grid motion is used to cause two opposing pairs of cell faces to become coincident at a specific time step, thereby causing all other faces to collapse to lines or points, upon which the cell can be removed and the grid rearranged. The opposite process is used for cell-layer addition, i.e. a previously-removed cell is made to reappear.

2.4.4 Computation of the flow field

The conservative set of algebraic finite-volume equations resulting from the discretisation practises described in the previous sections are solved to obtain the values of all variables throughout the solution domain. The equation set is closed since there are as many equations as dependent variables for each computational cell. However, there is a difficulty in the computation of the velocity field in an unknown pressure field. The pressure gradient forms a part of the right-hand side of the momentum equations 2.8. Yet, there is no obvious equation for obtaining the pressure. The pressure field is indirectly specified via the continuity equation 2.9 in the sense that when the correct pressure field is substituted into the momentum equations, the resulting velocity field will satisfy the continuity equation. Simultaneous solution of the velocity and pressure field is done by using an initial estimate of the pressure field and applying subsequent pressure and velocity corrections until the velocity field satisfies the continuity equation.

Two different pressure-correction algorithms for the computation of the flow field are employed, namely a variant of the well-established SIMPLE (Semi Implicit Method for Pressure Linked Equations) method (Patankar and Spalding, 1972) and the more recent PISO method (Issa, 1986; Issa et al., 1986; Issa et al., 1991). SIMPLE is used solely for steady-flow computations in an iterative mode, i.e. the time derivative terms are deleted from the finite-volume equations. PISO is applied to unsteady-flow computations.

It can be shown that the simultaneous solution of the flow field and the pressure field may cause unrealistic results when both are computed at the same grid points. Therefore, a so-called *staggered grid* is used, which means that the velocity components are computed for points that lie on the faces of cells instead of the cell-centred nodes, see for instance Patankar (1980).

2.5 Boundary conditions

A set of appropriate boundary conditions is necessary to close the set of coupled non-linear partial differential equations. For the description of most fluid mechanical problems, the boundary conditions can be categorised into the conditions appearing at inlet and outlet planes, impermeable walls and symmetry planes. Symmetry planes denote surfaces at which the normal velocity and normal gradients of all other variables are zero. The other boundary types are discussed below.

Inlet boundaries

For steady-flow problems, the inflow conditions are imposed at so-called inlet boundaries. The quantity specified at the inlet cell faces is either a fixed velocity or a fixed mass flux. The latter case leaves the density to be determined during the course of the computation using boundary pressures obtained by extrapolation from adjacent interior grid node values and the prescribed boundary temperature. Mass flux is then preserved by adjusting the velocity.

Since differential turbulence models are employed, it is necessary to specify the distributions of k and ε . If measurement data of the turbulent normal stresses $\overline{u'_i u'_i}$ are available, the turbulence energy k can be deduced via the relation A.3. In the absence of such data, plausible values can be assigned to u' via estimates of the local turbulence intensity I , here defined as

$$I \equiv \frac{\sqrt{\overline{u'_i u'_i}}}{U} \quad , \quad (2.27)$$

where U is the magnitude of the local velocity at the inlet boundary.

The turbulence dissipation rate ε is seldom measured and must, therefore, usually be estimated. A common way is using the following equation (Hirsch, 1988b):

$$\varepsilon = \frac{C_\mu^{3/4} k^{3/2}}{L} \quad , \quad (2.28)$$

which allows ε to be computed from the value of k and a prescription of the turbulence length scale L . The turbulence length scale is often chosen to be an order of magnitude smaller than the local flow domain size, according to Schlichting (1979).

Outlet boundaries

For obvious reasons, a computational domain is to be isolated from the universe that lies downstream of open flow systems. An outlet-boundary treatment is applied in steady-flow simulations to account for the fluid leaving the domain. At such a boundary, neither the value of ϕ nor its flux are known, but these are not needed if some assumptions are met. The flow is assumed to be outwards-directed everywhere on the boundary. No other conditions need to be known as these are estimated by extrapolating from upstream, on the assumption of zero-gradient along the mesh lines intersecting this surface; a so-called *Neumann condition*. Subsequently, the velocities are adjusted uniformly to give the required flow rate by satisfying overall continuity. The accuracy of the extrapolation is of course dependent on how closely the assumptions resemble physical reality. The outlet boundaries must be located at a position where the possible inaccuracies have only negligible effects on the upstream flow areas of interest.

Impermeable wall boundaries

The modelling of wall boundaries requires particular attention since boundary layers form adjacent to solid walls (Lauder and Spalding, 1974). In these layers, the structure of the turbulence is highly anisotropic and strongly influenced by the presence of the wall. Away from solid walls, the mean velocity gradients are generally moderate due to turbulent mixing, whereas steep mean velocity gradients are formed in the near-wall region because of the no-slip condition at the wall. These gradients lead to associated strong turbulence production and high turbulence levels. Many modelling difficulties are associated with the regions near solid walls due to the anisotropy and strong inhomogeneity.

As was seen in Section 2.1, the Reynolds number based on the large-scale motion is often very large, which implies that inertia forces are overwhelmingly larger than viscous forces. The Reynolds number based on the distance y normal to the wall, $Re_y = \rho U y / \mu$, is also large for the region far from the wall, e.g. $y \approx L$. However, there will be a range of y values, closer to the wall, for which Re_y is of the order of unity implying that there the viscous and inertia forces become of the same order of magnitude. Close to the wall, Re_y approaches zero and the flow is governed by viscous effects, independent of free-stream properties. Based on these considerations, Schlichting (1979) divided the near-wall zone into a laminar sublayer, a buffer layer where laminar and turbulent friction are of the same order of magnitude, and a fully

turbulent zone, called *inertial sublayer*. The multi-layer structure is a universal feature of fully-developed turbulent boundary layers near solid walls.

At impermeable walls, the no-slip condition for the velocity applies. By direct application of the wall-boundary conditions, the boundary layer can be computed by solving the mass, momentum, energy and turbulence equations of the flow within boundary layer. This type of wall region treatment is often referred to as the *two-layer approach*, because of the large number of cells required to describe the boundary flow in such a direct manner. For a discussion of the dimensions of the near-wall cells in such an approach, the non-dimensional distance to the wall y^+ is defined as:

$$y^+ = \frac{\rho u_\tau}{\mu} y \quad , \quad (2.29)$$

where u_τ is the so-called *friction velocity* (see Appendix B). For an accurate description of the boundary layer, the height of the first cell adjacent to the wall should have a y^+ value of the order of 10^{-1} - 10^0 (Fell, 1997). Hence, already for values of u_τ of the order of 10^{-1} m/s, the first cell height should be of the order of 10^{-4} - 10^{-5} m, according to equation 2.29. More realistic conditions demand a cell size that is many orders smaller. Clearly, a huge number of cells is required if the boundary layer is to be modelled this way. Furthermore, such small cell heights may cause serious stability problems as a result of extremely high cell aspect ratios, since the cell length parallel to the wall is typically of the order of 10^{-3} - 10^{-2} m. Because of these considerations, boundary layers are commonly treated in a different manner: by application of so-called *wall functions*. In this approach, the high Reynolds number k - ϵ models are used in conjunction with algebraic representations of the momentum, heat and mass transfer within the boundary layer. These relations prescribe the 'known' distributions of velocity, temperature and turbulence parameters to 'bridge' the boundary layer.

The wall-functions describing these distributions are those of steady-state, fully-developed boundary layers on a flat plate, based on the universal behaviour of near-wall flows for high Reynolds numbers (Versteeg and Malalasekera, 1995). Although it is evident that realistic engine flows usually do not fulfil these requirements, the approach is numerically convenient. Wall functions effectively provide turbulence boundary conditions at the layer's outer edge for solution of the turbulence transport equations in the outer layer. The details of wall-function modelling, as applied in the present investigation, are given in Appendix B.

2.6 Closing remarks

This chapter described the background of the physical and numerical methods that are applied in the computational investigation presented in the following chapters. The precise application for the various flow cases is discussed in those sections, as will their implication on the quality of the flow predictions. The following chapter is focused on the latter issue. The performance of the various numerical methods is analysed for several idealised flow situations, which are, to a certain extent, typical for in-cylinder flows.

3. Accuracy and applicability of the computational method

In order that the numerical simulation of the multi-dimensional flows that occur in internal-combustion engines attain their full potential and have an impact on the understanding of the in-cylinder processes and the design of internal-combustion engines, it is necessary that physical submodels contained in the computational method are sufficiently versatile. Therefore, any submodel in the method should be able to cope with various flow phenomena without the need for further empirical input. This, of course, demands both adequate understanding of the different physical processes occurring in engines as well as their accurate representation. Application of any numerical technique demands awareness of the potential errors which it may embody. Numerical diffusion may arise from the approximations introduced by the chosen scheme for converting partial differential equations into algebraic equations. Truncation errors are caused by spatial and temporal discretisation. Aside from discretisation errors, modelling errors are introduced when the partial differential equations do not match the physics of the flow. One of the important mechanisms that control most physical processes in the combustion chambers of engines is turbulence. Hence, its understanding and prediction is paramount to the success of any computational method. Finally, imposing incorrect boundary and initial conditions may cause erroneous results.

Accuracy and applicability of the computational method can be addressed by investigating simplified flow cases. Such investigations may focus on flow phenomena that are typical for engines, or at least the flow during a specific part of the engine cycle. This strategy allows for a more straightforward analysis of typical flow processes that exist in real engines. Since such cases have been the subject of several experimental and numerical investigations, detailed and accurate data are available through literature. Important flow features occurring during the intake stroke, and also in a steady-flow rig, are flow *separation* and *recirculation*. The flow leaving the intake port will separate from both the edges of the valve and the valve seat, causing a *jet*-like structure to develop. When this occurs in the vicinity of a wall, the flow will subsequently reattach. Between the jet and the wall, a recirculation region will be generated.

To investigate the performance of the computational method for these types of flow structures, a so-called *backward-facing step* is analysed in Section 3.1. Other typical in-cylinder flow structures are so-called *swirling* and *tumbling* motions, indicating a rotary motion around the cylinder axis and one around an axis perpendicular to the cylinder axis, respectively. These types of flow are caused by the interaction of the jet with the walls and the piston. Tumble, flow separation and recirculation have been studied for an axi-symmetric steady-flow engine rig, as is discussed in Section 3.2. Finally, the development of the observed flow structures, and the possible generation of others, is investigated in Section 3.3 for the unsteady flow during intake and compression strokes in an axi-symmetric model engine. The insight gained from these investigations is used to draw conclusions about the best modelling strategy for the simulation of three-dimensional flows in realistic engine geometries, as will be described in the final section of this chapter.

3.1 Backward-facing step

Reattachment of separated turbulent shear layers and flow recirculation occur in many aerodynamic flow cases, such as the flow from the intake port of an engine into the cylinder volume, as was indicated in the previous section. The reattaching shear layer is found in the valve area of engines and occurs on a surface with complex geometry. These aspects are likely to cause strong interaction between the separation and reattachment. Therefore, independent studies of the individual phenomena by itself are difficult. A backward-facing step geometry offers one of the least geometrically-complex separating and reattaching flows, because of the fixed location of separation. The flow over backward-facing steps has been the subject of many experimental and numerical investigations (cf. [Jovic and Driver, 1994; Le and Moin, 1992; Vogel and Eaton, 1985; Jovic, 1996; Clayton, 1994; Limbach, 1997]). As a result, much data is available for validating numerical simulation methods. The performance of the present method has been analysed for the backward-facing step geometry for which Jovic and Driver (1994)¹ conducted laser-Doppler velocimetry (LDV) and Le and Moin (1992)¹ completed direct numerical simulations (DNS) at low-turbulence flow conditions. The Reynolds number of this flow is $Re_h = U_o \cdot h / \nu \approx 5000$, based on the free stream inlet velocity U_o and step height h . Apart from the analysis of that case, the present study also focuses on the performance of the computational method for higher turbulence levels ($Re_h=28000; 75000; 120000$).

¹ These authors are gratefully acknowledged for providing their data.

Figure 3.1 :: Flow characterisation for a backward-facing step geometry

3.1.1 Nature of the flow problem

The backward-facing step geometry is indicated in Figure 3.1 along with a characterisation of typical flow regions. Upstream of the step edge, the flow has the typical characteristics of the flow over a flat plate with an *attached fully-developed boundary layer*. At the step edge, it undergoes a rapid transition and forms a *free shear layer*. A *recirculation region* is formed downstream of the step due to the pressure gradient and the shear. The shear layer attaches to the wall at the so-called *reattachment point*. Downstream of this point, an equilibrium boundary layer develops in the *recovery region*.

3.1.2 Model description

The width of the test section and the applied flow conditioning during the experiments of Jovic and Driver (1994) were such that an assumption of a two-dimensional flow at the central plane is justified. Therefore, only two-dimensional flow computations are required. In the applied three-dimensional numerical simulation method, two-dimensional flows are simulated by applying a single hexahedral cell in the third dimension and forcing symmetry conditions onto the appropriate cell faces.

The domain boundary opposite to the step is a symmetry plane. The chosen expansion ratio of the step geometry, defined as $E_r = (l + h) / l$, is 1.2, while the step height h is 9.6 mm. The measured boundary velocity profile at a distance of three step heights upstream of the step closely resembles that of a standard, fully-developed, turbulent boundary layer (Jovic and Driver, 1994). The equilibrium boundary layer thickness $\delta_{99}/h \approx 1.2$. The free stream inlet velocity U_0 is 7.72 m/s, with a reported turbulence intensity of less than 1%.

In order to obtain appropriate inlet-boundary conditions, the measured velocity distributions are imposed at $x = -3 \cdot h$. However, sensitivity studies for inlet turbulence, mesh density, and Reynolds number, have been conducted for a uniform velocity profile at $x = -10 \cdot h$. For the latter condition, the boundary layer thickness at $x = -3 \cdot h$ was found to be much smaller than observed during the experiments. This difference is due to the effects of special boundary layer trip wires, which were applied in the experiments. The flow is calculated up to $x = 20 \cdot h$ for all cases. The bottom mesh boundaries are modelled as no-slip walls, with wall-functions descriptions for the near-wall region, as discussed in Section 2.5.

In turbulent flows, turbulence parameters must be imposed at the inlet boundary in addition to the velocity distribution. Jovic and Driver (1994) report a free-stream turbulence intensity at $x = -3 \cdot h$ of less than 1%, while no information about inlet turbulence length scale is given. Typically, the length scale is estimated to be $1/10 \cdot l$, which approximates to the boundary-layer thickness. However, when analysing the performance of turbulence models, it is prudent to test the sensitivity of the solution to the inlet-boundary conditions. Therefore, the effects of the variation of the inlet turbulence intensity between 1% and 25%, and of the inlet length scale between $1/30 \cdot l$ and $1/3 \cdot l$ have been studied for both $Re_h = 5000$ and $Re_h = 28000$ by comparison of the computed reattachment lengths. This study showed that the solution is relatively insensitive to the variation of both parameters. Only for large values of the turbulence intensity a significant reduction of the reattachment length is observed. This phenomenon was also observed by Clayton (1994), who conducted computations for a backward-facing step with the same computational method as employed in the present study. He showed that x_R only slightly decreases with increasing inlet turbulence intensity and length scale for $Re_h = 66400$. Because the influence of these inlet turbulence parameters was found to be small, all simulations were conducted with an inlet turbulence intensity of 1% and an inlet length scale of $1/10 \cdot l$, unless indicated otherwise. These parameters are chosen constant over the inlet area, which is of course only valid outside the near-wall region.

3.1.3 Simulation results

The results of various computations will be used to analyse the performance of the computational method. Focus will be on grid sensitivity, the performance of the three $k-\epsilon$ turbulence models and the performance of the UD, SFCD and QUICK difference schemes.

Grid sensitivity

According to Clayton (1994), the reattachment length x_R is slowest to converge to a grid size independent solution and can, therefore, be used as the criterion for selection of an appropriate number of cells. To study grid dependency, the total number of cells was varied

Figure 3.2 : Variation of reattachment length x_R with the number of cells and the applied turbulence model for the flow over a backward-facing step ($Re_h=5000$ and $Re_h=28000$)

between 1565 and 32400. Figure 3.2 shows the variation of the reattachment length with the number of cells for the three turbulence models: the standard k- ϵ model and its RNG and CHEN variants, which are described in Section 2.3 and Appendix A. The reattachment length was determined as the location at which the mean axial velocity u is equal to zero at the first grid point away from the wall, normalised to the step height h . Jovic and Driver (1994) conducted visualisation experiments and found the reattachment length to be 6.0 ± 0.15 for the present case. The DNS conducted by Le and Moin (1992) indicated a value of 6.1, using the same definition for x_R as presently applied. The results indicate that the number of cells must be at least 5000 to generate results of reasonable accuracy. However, this is clearly not sufficient for a grid-independent solution, for which at least 15000 cells are required. This conclusion is confirmed by the findings of Clayton (1994) for $Re_h = 66400$. In view of computational cost and the fact that the present investigation is focused on comparing variations of the computational method rather than obtaining absolute values, the following analyses have been conducted on a grid containing 7900 cells.

In-cylinder flows in engines may have a Reynolds number of the order of 10^4 - 10^5 , as is discussed in Section 2.1. In order to justify choosing a relatively low Reynolds number of 5000 for the present study of the flow over a backward-facing step, the influence of higher Reynolds numbers was analysed. Figure 3.3 shows the dependence of the reattachment length on Re_h for the three turbulence models. Clearly, the solutions are nearly insensitive to Re_h . The applied turbulence modelling, for instance, is of much larger influence on the solution than the Reynolds number. Therefore, a value of 5000 for the Reynolds number is considered appropriate for the present analysis.

Figure 3.3 : variation of reattachment length with the Reynolds number and the employed turbulence model for the flow over a backward-facing step (7900 cells)

Effects of applied turbulence model

The computed reattachment length is highly dependent on the applied two-equation turbulence model, as is seen in Figures 3.2 and 3.3. For the specific case considered, the CHEN k- ϵ model accurately predicts the measured reattachment length ($x_R = 6.0$). The standard model underpredicts ($x_R = 4.62$), whereas the RNG variant causes a considerable overprediction ($x_R = 7.12$). Similar observations concerning the performance of the standard model and the CHEN model are reported by Chen and Kim (1987).

For a more detailed validation of the results, predicted distributions of the mean axial velocity and Reynolds stress at five stations downstream of the step are analysed and compared to the data from the experiments and the DNS. Figure 3.4 shows these distributions for the three turbulence models. Although the standard model underpredicts the reattachment length, it performs remarkably well in the prediction of the mean axial velocity throughout the domain (see Figure 3.4a). Clearly, all three models perform well in predicting the mean axial velocity at $x = 4 \cdot h$, which is in the recirculation region. The width of the recirculation bubble in the direction normal to the wall is captured correctly by all models, resulting in an almost perfect prediction of the main stream profile. These findings are in contradiction with the results of Clayton (1994), who found that both the standard and the RNG model underpredict the bubble width. Further downstream at $x = 6 \cdot h$, the RNG and CHEN models start to deviate considerably from the experimental data and from the DNS results. This station is exactly at the reattachment point found in the experiments. As a consequence, a small error in the predicted location of the reattachment point may yield large discrepancies. This is the case for the CHEN model. The large backflow which is observed for the RNG model at this station is

Figure 3.4 :: Axial mean velocity (a) and Reynolds-stress (b) distributions at the inlet boundary and five stations downstream of the backward-facing step ($x = 4h, 6h, 10h, 15h$ and $19h$) for $Re_h = 5000$: performance of three k- ϵ models (Upwind Differencing, 7900 cells) compared to experiments and DNS

in accordance with the overestimation of the recirculation length. Generally, the predictions around the reattachment point may be expected to be greatly in error because of the flow characteristics at this point.

Downstream of the reattachment point, the profiles for the RNG and CHEN models become similar. They still exhibit considerable discrepancies with the experiments in the near-wall region. However, these discrepancies become smaller further downstream as the boundary layer develops in the recovery region. In the area between the step and a point well beyond the reattachment point, turbulence production and dissipation are not in local equilibrium. This

invalidates the use of wall functions for which a fully-developed boundary layer is assumed. This is likely the main cause of the observed deviations of the simulation results from the experimental data in the near-wall region. Further downstream in the recovery region, the boundary layer will start to approach a fully-developed state and, hence, the wall-function description will be closer to reality. This explains the observed improved agreement in that area. Nevertheless, the recovery region for the RNG and CHEN models is apparently much larger than that for the standard $k-\varepsilon$ model. The zero-gradient outlet-boundary condition at $x = 20 \cdot h$ is not expected to have an influence on this observation, since the gradients in the axial mean velocity and the Reynolds-stress were indeed found to be near zero at this boundary.

Figure 3.4b gives distributions of the axial Reynolds-stress $\overline{u'u'}$ (see Section 2.2). The computational method gives as output a value for the total turbulent kinetic energy k , which is independent of the coordinate direction since the $k-\varepsilon$ models assume isotropic turbulence. Therefore, the axial Reynolds-stress is defined as $\overline{u'u'} = 2 \cdot k / 3$, according to equation A.3. The predicted distributions of this variable show tendencies similar to those observed for the mean velocity. However, the agreement with the experimental data is generally less good. Again, the standard $k-\varepsilon$ model clearly performs better than the other turbulence models. Both the width and the intensity of the large turbulent structures are captured by this model. A comparison of the present results, attained on a grid with 7900 cells, with the results for a fine grid of 32400 cells learns that only a minor grid size dependency exists; due to blurring, computations on the coarser grid predict a somewhat wider and more intense recirculation region, as is indicated in Figure 3.4 at $x = 4 \cdot h$. The other models underpredict the turbulence intensity in the recirculation region, although the mean velocity and, hence, turbulence-generating velocity gradients are predicted correctly. The width of the recovery region downstream of the reattachment point is underestimated by these models in a similar fashion as observed for the mean axial velocity predictions. The behaviour of both the RNG and the CHEN model is likely to be a result of the additional terms in the ε -equations A.10 and A.14 that distinguish these models from the standard model. These terms are expected to enhance turbulent energy dissipation in distorted areas. Apparently, this produces too much dissipation for the present case with the present setting of the model constants. The RNG model produces a Reynolds-stress profile at $x = 4 \cdot h$ which is excessively low in amplitude and skewed away from the wall, perhaps because dissipation near the wall is enhanced by the strain there.

The results that Chen and Kim (1987) presented for their own turbulence model in comparison with the standard model for another backward-facing step flow case clearly indicate improved predictions with the CHEN model, both for the mean velocities as well as the Reynolds-stresses. In their investigation, the standard model produces an overshoot of turbulent kinetic energy in the area just downstream of the step, whereas the CHEN model is much closer to the experimental data as a result of the enhanced turbulent energy dissipation

in areas of high shear that is associated with this model. The present results clearly show similar tendencies where the discrepancies between the solutions for both models are concerned. However, the standard model is closer to the experimental data for the present flow case. Apparently, energy dissipation is overpredicted by the CHEN model for this case. These observations show that the performance of empirical models, like these $k-\varepsilon$ turbulence models, is sensitive to the specific case investigated, even for relatively straightforward flow problems like a backward-facing step.

Effects of difference scheme

Computations have been conducted with the UD, SFCD and QUICK difference schemes, which are described in Section 2.4.2. Apparently, the applied difference scheme has no significant influence on the reattachment length since the various predictions were found to be within 3% of each other. The computed distributions of axial mean velocity and axial Reynolds-stress are presented in Figure 3.5 for all three schemes with the use of the standard $k-\varepsilon$ turbulence model. Clearly, only minor differences between the various solutions exist. The observations indicate that no significant benefits are to be gained by applying the higher-order, and thus more expensive, schemes instead of first-order accurate upwind differencing. Of course, this conclusion only holds for this relatively simple two-dimensional flow case which exhibits only limited gradients. Moreover, the higher-order schemes may still give good results on coarser computational grids, whereas low-order schemes would fail.

3.2 Axi-symmetric steady-flow rig

An axi-symmetric steady-flow over a single valve into an open-ended cylinder was investigated to study the performance of the computational method for predicting the flow during the intake stroke of an engine. The intake flow is a crucial aspect of flow management in internal-combustion engines, contributing much to the nature of the turbulent flow during combustion. Of course, the unsteady and three-dimensional nature of real engine intake flows are important. Nevertheless, its main features are reproduced by the present axi-symmetric steady-flow case, which exhibits tumble, flow separation and recirculation. The case has the advantage of simplicity and, hence, allows for a first assessment of these flow phenomena without the extra computational overhead of unsteady three-dimensional flow computations. Similar flow cases have been the subject of several published investigations. Most studies are based on the flow rig for which the Imperial College group conducted extensive LDV experiments. These experimental data, taken from Bicen (1985) and Watkins et al. (1990), are used for comparison with the present computational results.

Figure 3.5: Axial mean velocity (a) and Reynolds-stress (b) distributions at the inlet boundary and five stations downstream of the backward-facing step ($x = 4h, 6h, 10h, 15h$ and $19h$) for $Re_h = 5000$: performance of three difference schemes (standard $k-\epsilon$ model, 7900 cells) compared to experiments and DNS

3.2.1 Model description

The steady-flow geometry is given in Figure 3.6. The stationary valve is positioned at the centre of the open-ended cylinder and has a lift h of 6 mm. The valve diameter d is 33 mm, so that the non-dimensional lift $h/d = 0.18$. The valve angle is 45° . The induced mass-flow rate is 12 kg/h, which corresponds to the mean flow rate during the intake stroke of a real engine at a speed of 200 rpm, similar to the model engine investigated in Section 3.3. As a consequence, the Reynolds number Re_h , based on the valve lift h and the inlet velocity U_{inlet} ,

Figure 3.6 : Axi-symmetric steady-flow rig geometry

is approximately 1700. The cylinder bore B is 74 mm and its length L was chosen to be 200 mm in agreement with Watkins et al. (1990).

Although the experiments involved a three-dimensional flow domain, measurements were taken in a single plane because of assumed axi-symmetry of the flow. Of course, no axi-symmetry exists in reality due to the effects of flow instabilities. Nevertheless, the flow will predominantly be axi-symmetric since no swirling motions are induced. The objectives of the present investigation, being the assessment of the performance of various variants of the computational method at typical intake flow conditions, justifies axi-symmetric flow modelling.

The intake port is not accounted for, similar to Watkins et al. (1990). Instead, an inlet boundary is defined at the so-called *valve curtain* (see Figure 3.6). Lea and Watkins (1997) indicate that imposition of an experimentally-determined inlet flow distribution may yield a much better description of the subsequent in-cylinder flow, compared to imposition of a uniform distribution. However, they also showed that one such distribution measured on one flow rig could not be transferred to another flow case. Indeed, they report a case that was computed more accurately when a uniform distribution was assumed at the inlet. Because of these observations, and since there are no measured inlet velocity distributions available for the present case, it was decided to compromise and accept a uniform velocity distribution.

The axial and radial components of the mean velocity at this boundary are obtained by assuming that the flow enters at the valve seat angle of 45° . Turbulence intensity was set to 10% and the inlet length scale was one-third of the valve lift. All computations have been carried out on an axi-symmetric grid similar to the one applied by Watkins et al. (1990). The grid contains 101×61 cells in axial and radial direction, with 13 cells spanning the valve curtain.

Figure 3.7 :: Vector plot impression of the numerically-simulated mean velocity of the steady-flow through an axis-symmetric flow rig ($Re_n = 1700$, RNG model, QUICK scheme, 5836 cells)

3.2.2 Simulation results

Figure 3.7 shows a vector plot impression of the computed mean velocity field close to the cylinder head. The dominant flow feature is the oblique impingement of the intake jet on the cylinder wall. A major part of the air flows directly from the jet towards the open end of the cylinder. Also, a large recirculation region behind the valve develops due to shear between the jet and the stagnant air in the cylinder. Additionally, a smaller recirculating vortex in the corner between the cylinder head and the cylinder wall is generated due to the separation of the jet from the valve seat.

Figure 3.8 shows the axial mean and RMS velocity distributions at $z = 6$ mm, which coincides with the valve edge, and at $z = 15$ mm for the UD, SFCD and QUICK difference schemes. Since both stations are close to the cylinder head, the intake jet is the dominant flow feature. As a consequence, the flow is convection dominated. It is in such a flow that differences between the solutions for the different schemes may be observed since the employed schemes are used to discretise the convective terms of the various equations (see Section 2.4.2). The UD scheme gives first-order accuracy, while SFCD is accurate up to the second order. The QUICK scheme is third-order accurate, although being not unconditionally-stable like both other schemes.

For the mean flow, use of higher-order difference schemes reduces the computed spread of the intake jet, as can be seen from the results for the SFCD scheme and, in particular, for the QUICK scheme at $z = 15$ mm. This is due to a reduction of the numerical diffusion. Moreover, the QUICK scheme is capable of capturing more flow detail, such as the S-bend in the mean velocity distribution at $z = 6$ mm. As for the prediction of flow turbulence, all three schemes produce similar amounts of turbulence. Again, the QUICK scheme performs best,

Figure 3.8 :: Axial mean (a, c) and RMS velocity (b, d) distributions at $z=6$ mm and $z=15$ mm: performance of difference schemes for the steady axi-symmetric flow case ($Re_h = 2400$, standard $k-\epsilon$ model, 5836 cells)

closely followed by the SFCD scheme. Both schemes produce slightly more pronounced peaks of RMS velocities at the edges of the jet. The more diffusive UD scheme produces a more smeared turbulence distribution. All present observations made for the QUICK scheme confirm the findings of Watkins et al. (1990).

Figure 3.9 :: Axial (a) and RMS (b) velocity distributions at $z=15$ mm: performance of $k-\epsilon$ turbulence models for the steady axi-symmetric flow case ($Re_h = 2400$, QUICK scheme, 5835 cells)

The performance of the standard $k-\epsilon$ model and its RNG and CHEN variants are evaluated based on the results at $z = 15$ mm, as presented in Figure 3.9. Closer to the cylinder head, the three models produce almost identical solutions. The results show that the prediction of the intake jet structure is only mildly sensitive to the choice of turbulence model. However, considerable dependency is observed in the recirculation regions near the wall and in the wake of the valve. The CHEN model produces a slightly larger backflow in the near-wall region than the RNG variant. The standard model obviously predicts the smallest size of this recirculation region, which corresponds with the findings for the backward-facing step case in Section 3.1. However, the much larger recirculation region observed for that case with the RNG model, when compared with the CHEN model, is not repeated here. The standard model produces the largest backflow in the wake of the valve. Both other models perform similar to each other.

3.2.3 Experimental validation of numerical simulation results

Figures 3.8 and 3.9 include the experimental data for this steady-flow case. Comparison of the various simulation results with these data allows for an assessment of the accuracy of the numerical solutions.

The intake jet strength is considerably underpredicted at both the $z = 6$ mm and the $z = 15$ mm stations. The strength of the corner vortex (see the top left corner of Figure 3.7) between the jet and the cylinder head is captured well, as can be seen from the results at $z = 6$ mm. At $z = 15$ mm, the experiments still indicate a large backflow at the wall, whereas the simulations suggest that the jet is about to attach to the wall, or has indeed done so for the UD scheme. Apparently, the size of this vortex is largely underpredicted. On the other hand, the strength of the recirculating vortex in the wake of the valve (see Figure 3.7) is considerably overpredicted. Both the axial and radial mean velocity, of which only the former is shown in the figures, are much higher than their measured counterparts. Obviously, the reduced size of the corner vortex and the increased strength of the larger wake vortex are closely related because of mass conservation over a cross section of the flow domain.

The impingement of the jet on the cylinder wall creates a complex structure of shear and normal stresses, implying high levels of turbulence, which will be anisotropically distributed. The $k-\varepsilon$ model assumes isotropy. Nevertheless, the RMS results indicate that the correct order of magnitude of the Reynolds stresses is predicted. Moreover, peaks are predicted at their correct positions, which is of course closely related to the correct prediction of the width of the jet, as was observed above. However, peak strength is generally underpredicted. The RNG and CHEN $k-\varepsilon$ models produce improved predictions over the standard model, but only to a moderate extent. The improvements are a result of the extra turbulent energy dissipation in areas of such high shear, which is associated with these models (see Section 2.3).

3.3 Axi-symmetric model engine

Due to the reciprocating character of internal-combustion engines, in-cylinder flows are much more complex than the steady flows studied thus far. In this section, an axi-symmetric model engine is investigated in order to gain insight into the occurring flow phenomena and the performance of the computational method at such conditions. Furthermore, comparison of this unsteady-flow case and the steady-flow case described in the previous section allows for an assessment of the utility of using steady-flow approximations for analysing in-cylinder flow structures during the intake stroke. This is important with respect to the use of three-dimensional steady-flow rigs, such as the one that is investigated in Chapter 5.

Performance of computational methods has most frequently been assessed against experimental data obtained from axi-symmetric model engines with centrally located valves, similar to the steady-flow rig studied in the previous section. Such geometries, although idealised, still exhibit many of the flow phenomena existing in real engines, and, thus, allow for the modelling to be assessed without the extra overheads of three-dimensional numerical simulations. The bulk of these data have been collected at Imperial College from transparent

Figure 3.10 : Geometry of the axi-symmetric model engine

model engines operating at low speeds and low compression ratios, using laser-Doppler velocimetry (cf. [Bicen, 1983; Arcoumanis et al., 1983; Vafidis, 1984; Bicen, et al., 1985]). These data have been used for many validation studies. Perhaps the major work undertaken in this area was that of Ahmadi-Befrui and Gosman (1989). Recently, Lea and Watkins (1997) published a comprehensive study focusing on the performance of higher-order difference schemes and turbulence modelling. An engine similar to one of the Imperial College engines is considered here.

3.3.1 Nature of the flow problem

The engine geometry is indicated in Figure 3.10. The engine has a flat cylinder head and a flat piston face, thus ensuring no squish effects during compression. Moreover, swirling motions do not occur due to the axi-symmetry. The flow from the valve area during the intake stroke will form a jet-like structure, similar to the one observed in the previous section for the axi-symmetric steady-flow case. In the present unsteady-flow case however, the jet may not only interact with the cylinder wall, but also with the piston face. As a consequence, an extensive tumbling motion will be induced. A corner vortex in between the intake jet and the cylinder head, similar to the one observed for the steady-flow case, is to be expected. The motion of the piston during the final stages of the intake stroke and during the compression stroke imposes external forces on the induced air that determine the final flow structure at the end of compression. Combustion is not included in this study.

The valve is used for both air intake and exhaust purposes. As a consequence, the valve opens at the start of the intake stroke immediately after it was closed during the later stages of the preceding exhaust stroke. In fact, the valve motion is modelled in a way that it does not close completely due to an overlap of the intake and exhaust lift diagrams.

Figure 3.11 ∴ Illustration of the computation grid for the unsteady axis-symmetric model engine at 90 °CA after TDC of the intake stroke

3.3.2 Model description

The engine speed was taken to be 200 RPM and the applied compression ratio is 3.5. The cylinder bore B and the stroke S are 75.4 mm and 94.0 mm, respectively, while the connecting rod has a length of 363.5 mm. The centrally-positioned valve has an outer diameter d of 34.0 mm with a valve angle of 60°. The maximum valve lift h is 8.0 mm. The Reynolds number Re_h , based on the valve-lift height, is of the order of 10000 for this case. The computations presented here have been guided by the results of Lea and Watkins (1997).

Lea and Watkins investigated the grid sensitivity by analysing 30×30 , 45×45 , and 60×60 cell grids, with 5 cells spanning the valve curtain (see Figure 3.10). They concluded that simulations with the 45×45 grid gave sufficiently-accurate results. A limited grid sensitivity study with the present method yielded a similar conclusion, showing only some moderate grid sensitivity during early stages of the intake stroke. Figure 3.11 illustrates the present grid at 90 degrees of crank angle (°CA) after TDC (*top dead centre*) of the intake stroke. Valve and piston motion are accommodated through expansion and contraction in axial direction of the cell volumes covering the valve curtain and the cells between the cylinder head and the piston face, respectively. Subsequent cell layers were removed from the computation during compression and added during expansion to prevent cell aspect ratios from becoming too high, which may introduce inaccuracies or convergence problems, and to save unnecessary computing time (see also Section 2.4.3). Lea and Watkins used the same approach, although they did not remove and add piston cell layers and, hence, the number of cells between the cylinder head and the piston face was always 40. In the present case, this number varies between 50 for BDC (*bottom dead centre*) and 40 for TDC piston position. Although Lea and Watkins indicate that 5 cells spanning the valve curtain in its fully-open position is sufficient, the present computations are conducted with an 8-cell curtain discretisation. The number of cells in radial direction was set to 45, similar to the grid employed by Lea and Watkins. The time step applied throughout every engine cycle during all computations was equivalent to $\frac{1}{4}$ °CA, which is sufficiently accurate according to the findings of Lea and Watkins. Because

a three-dimensional simulation method is applied, a single cell is used in the third coordinate direction with symmetry conditions imposed on the top and bottom surfaces. An axis-symmetric solution is obtained through appropriate definition of these single cells, as is indicated in Figure 3.11.

3.3.3 Boundary and initial conditions

At solid surfaces, such as the cylinder wall, the cylinder head, the piston and the valve, appropriate boundary conditions are imposed via 'wall functions', as discussed in Section 2.5. Symmetry conditions are imposed at the cylinder axis.

For an accurate simulation of the flow through the port during the intake and exhaust strokes, the port must be included in the computational domain up to a location where imposition of only a pressure boundary condition is sufficient to close the set of equations. In such a case, the motion of the piston is the driving force which determines the flow through the port. However, the port is not included in either the present computations, nor in the computations performed by Lea and Watkins (1997). Alternatively, appropriate boundary conditions are imposed at the valve curtain. Since the pressure at this boundary is unknown, the flow rate during the intake and the exhaust strokes must be prescribed. Lea and Watkins calculated the flow rate through the valve curtain using a quasi-steady relationship (Heywood, 1988) based on discharge coefficients measured on a steady-flow rig for different valve-lift heights. For the present case, such data are given by Bicen (1983). With that relationship, the flow rate can be approximated from the pressure difference between the in-cylinder volume and the ambient air. Unfortunately, straightforward application of such a method in the present investigation led to numerical instabilities, which resulted in diverged solutions.

Alternatively, the present computations were conducted with a constant-velocity definition at the valve curtain. For this purpose, the temporal distribution of the velocity at the curtain during the intake stroke was calculated by assuming that the flow rate responds instantly, and without dissipation, to the piston motion. At low engine speeds, this is considered a good approximation of reality. The mean piston velocity V_p is 0.63 m/s at an engine speed of 200 RPM. Furthermore, a uniform velocity distribution at the valve curtain was assumed, similar to Lea and Watkins (1997). The latter assumption was accepted for the same reasons as described in Section 3.2 for the steady-flow case. Figure 3.12a shows that the thus calculated velocity is more or less constant during the intake stroke. In view of the other large assumptions to be made, approximating the calculated distribution by its mean value was considered acceptable. The velocity at the valve curtain was set to this value.

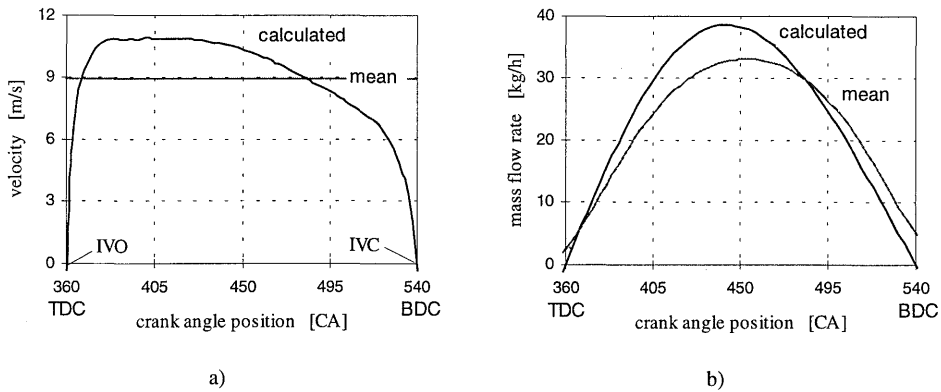

Figure 3.12 : Calculated and applied fluid velocity (a) and mass-flow rate (b) distributions at inlet boundary (IVO: 360 °CA; IVC: 540 °CA)

To determine the time-dependent boundary conditions at the valve curtain, the valve lift as a function of crank angle must be specified. Since this information could not be retrieved from the available literature, arbitrary valve lift diagrams and valve timing were chosen. These diagrams were taken from the engine studied in Chapter 6, adequately scaled to meet the maximum lift condition of 8 mm and to limit the duration of valve opening to 180 °CA. The inlet valve opens at the exact moment that the outlet valve closes, which is at TDC. Here, the valve is said to be open for lift heights above 1 mm and closed below that value.

Figure 3.12b gives the temporal distribution of the imposed mass-flow rate. Clearly, the distributions based on the calculated velocity and the one based on the mean velocity are similar. Generally, the flow rate is under-estimated during the early stages of the intake stroke, while an over-estimation exists at the later stages. For the purpose of comparing the relative performance of computational method variants, the present description of the inlet conditions is assumed appropriate. The axial and radial components of the mean velocity are set by assuming that the flow enters at the valve seat angle of 60°. Turbulence properties at the inlet boundary were taken from Lea and Watkins (1997). Turbulence intensity was set to 2 % of the local incoming mean kinetic energy and the inlet turbulent mixing length was assumed to be one-third of the maximum valve lift. Wall temperatures were set to 360 K.

The numerical flow simulations are supposed to be a representation of the flow in a stationary motored engine. For correct predictions, an adequate initial field at the start of the intake stroke is required. Since no such information is available, a zero-velocity initial field is imposed. This does not reflect reality. Therefore, the computations are initially marched through one full 720 °CA engine cycle to provide more realistic initial conditions for the start

Figure 3.13 :: Comparison of numerically simulated first and second-cycle mean axial velocity at 36 °CA after TDC of intake employing the SFCD scheme and the standard $k-\epsilon$ modelling ($z=15$ mm, $Re_h=10000$)

of the second intake stroke. These conditions are assumed to be accurate enough since Lea and Watkins (1997) state that, using $k-\epsilon$ turbulence modelling, third-cycle simulations without swirl are virtually identical to second-cycle results. Figure 3.13 shows results during an early stage of the intake stroke of first and second cycle simulations employing the SFCD scheme. The results clearly indicate that a considerable sensitivity to the initial field exists. When compared to the first cycle simulation, the flow during the second cycle shows a less intense intake jet that is closer to the cylinder wall. Consequently, the corner vortex is smaller and considerably stronger.

3.3.4 Simulation results

The numerically-simulated in-cylinder flow is visualised in Figure 3.14 by means of velocity vector plots at selected crank angle positions. At 36 °CA after TDC of the intake stroke (396 °CA), the intake jet is clearly present and has attached to the opposite cylinder wall. The jet separates at the valve seat and produces a recirculating vortex near the corner formed by the cylinder wall and the cylinder head. A second, tumbling motion is formed in the wake of the valve due to shear between the jet and the stagnant air in the cylinder, and through interaction of the jet with the cylinder wall and the piston. This flow structure is retained at mid-intake stroke until which the jet remains attached to the wall over its full length. After that, the jet separates from the wall downstream of the attachment point, as can be seen from the vector plot for 492 °CA. Consequently, a third tumbling motion near the piston face is formed. All of the three prominent motions are quickly dissipated during the early stages of the compression stroke (588 °CA). Near the end of the compression stroke (684 °CA), no explicit large-scale flow structures exist for the present flow case.

Figure 3.14 :: Numerically simulated flow fields at 36 °CA, 132 °CA, 228 °CA and 324 °CA after TDC of the intake stroke (SFCD scheme, standard $k-\varepsilon$ model, 2nd cycle, $Re_h \approx 10000$)

The performance of the 'standard' $k-\varepsilon$ turbulence model and the RNG and CHEN variants is assessed through comparison of the computed distributions of the axial mean velocity and the axial RMS velocity. Such distributions are plotted in Figure 3.15 for several cross sections at 396 °CA, 450 °CA and 684 °CA. At 396 °CA, the simulations with all three models give results that are virtually identical, similar to the steady-flow case. The dependence of the predicted axial RMS velocity on the turbulence model also holds a trend similar to the steady-flow case. Again the standard $k-\varepsilon$ model predicts the largest turbulent fluctuations in the jet structure. No significantly-different solutions are observed in the wake of the valve where turbulent fluctuations are nearly absent. At 450 °CA, while the intake valve lift is at its maximum, all turbulence models still perform similar.

The flow structure near TDC of compression (684 °CA) is most important for the analysis of the engine performance since that is just prior to the start of combustion. The results presented in Figure 3.15 indicate that a nearly uniform distribution of axial mean velocity exists close to the piston face at this stage, which is again almost identical for all three turbulence models. Closer to the cylinder head, still a weak recirculating motion is predicted. Here, significantly different solutions for the three turbulence models are found. The CHEN model and, to a lesser extent, also the RNG model predict a considerably stronger recirculation than the standard $k-\varepsilon$ model. Nevertheless, the prediction of the RMS velocity field is similar for all three models.

Figure 3.15 :: Axial mean velocity (a, c, e) and axial RMS velocity (b, d, f) distributions at 36 °CA, 90 °CA and 324 °CA after TDC of the intake stroke; Comparison of results of numerical simulation with the three $k-\epsilon$ models (SFCD scheme) and experimental results ($Re_h = 10000$)

The simulation results that are shown in Figure 3.15 were computed with the SFCD difference scheme. Unfortunately, the higher-order QUICK scheme did not converge for the present flow case. Results of numerical simulations with the first-order accurate UD scheme showed moderate differences with the results obtained with the SFCD scheme. Although the jet strengths are similar, SFCD predictions indicate a smaller jet which attaches earlier to the cylinder wall. The observed differences of jet-prediction are explained by the fact that higher-order schemes offer reduced numerical diffusion, as was discussed before.

3.3.5 Experimental validation of numerical simulation results

Although a comparison of the results of the numerical simulations and the experimental results is hampered by the assumptions made about the inlet-boundary definition, still a general assessment of the accuracy of the computational methods is possible. Figure 3.15 includes the experimental results for the presently-investigated flow case.

During early stages of the intake stroke (396 °CA and 450 °CA), the most important flow structures are captured. However, the intake jet is predicted slightly too far away from the cylinder wall. Furthermore, the jet strength is clearly underpredicted, which can be explained from the approximate inlet-boundary definition. At this stage of the intake stroke, the imposed fixed velocity at the valve curtain is too low, as was seen from Figure 3.12. The degree of underprediction of the jet strength is of the same order of magnitude as this underestimation of the inlet velocity. Consequently, the strength of the recirculation near the cylinder wall and in the wake of the valve are also underpredicted. The turbulence intensity is largely underpredicted at these stages of the engine cycle.

At the later stages of the compression stroke (684 °CA), a good agreement between computational and experimental results exists close to the piston face. Here, the measured axial velocity distribution is nearly perfectly predicted by the computational method. Closer to the cylinder head, the agreement is found to be much worse because the computational method still predicts recirculation unlike the experimental results. Moreover, the numerical simulations indicate considerably higher fluid velocities. Nevertheless, the distribution and intensity of the RMS velocities throughout the cylinder volume are almost perfectly captured by the computational method.

3.3.6 Utility of steady-flow analysis

Steady-flow analysis by means of engine flow rigs is often used to study the in-cylinder flow phenomena in engines. It allows for a more straightforward approach than analysis of the unsteady flows in real engines, both from an experimental and a computational point of view.

Figure 3.16 :: Vector plots of the numerically simulated in-cylinder flow field at 36 °CA and 90 °CA after TDC of the intake stroke and the steady-flow solution, simulated with identical boundary conditions.

Comparison of the computational results of the present unsteady-flow case with those of the steady-flow case studied in the previous section allows for an assessment of the utility of such an approach.

By their nature, steady-flow approximations can at best yield insight into the in-cylinder flow during the intake stroke. Figure 3.16 shows velocity vector plots of the present unsteady-flow simulations at 36 °CA and 90 °CA after TDC of the intake stroke. Also, the results of an additional steady-flow simulation with boundary conditions identical to the unsteady-flow case are plotted. Clearly, the general flow features that are found close to the cylinder head are similar for all three results. Further downstream, the solution at 36 °CA after TDC (396 °CA) differs because of the presence of the piston. The separation of the intake jet from the cylinder wall, as seen at 90 °CA after TDC (450 °CA), does not occur in the steady-flow solution because of the absence of the piston and a different pressure level. Figure 3.17 shows the axial mean velocity distributions at a cross-section close to the cylinder head, thus allowing for a quantitative comparison of both flow cases. Apparently, the position and the strength of the intake jet as well as of the corner vortex are captured by the steady-flow model.

From these results, it is concluded that the steady-flow case is a fair representation of the unsteady in-cylinder flow during the early stages of the intake stroke. The most accurate

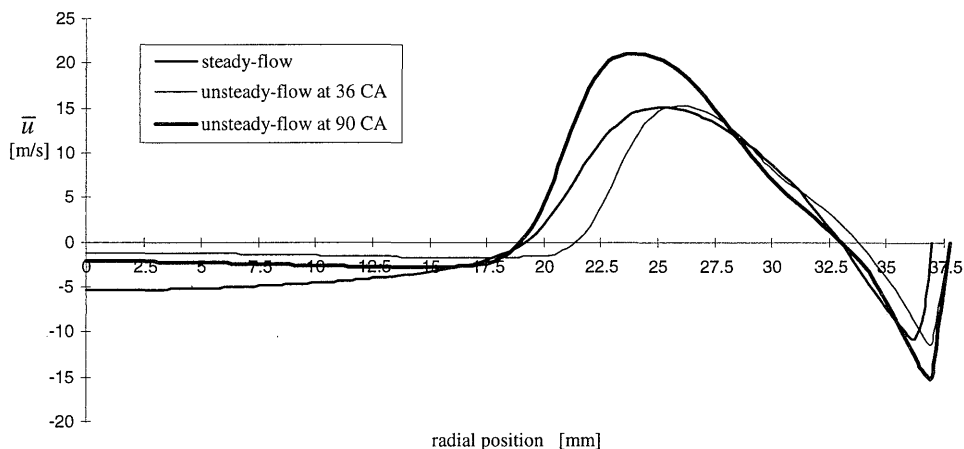

Figure 3.17 :: Distributions of the numerically-simulated axial mean velocity obtained for the steady-flow case and for the unsteady-flow case at 36 °CA and 90 °CA ($z=15$ mm, SFCD scheme, standard $k-\epsilon$ model)

representation lies somewhere in between 36 °CA and 90 °CA after TDC. The presently-achieved accuracy is considered high enough to allow for application of steady-flow models for first assessments of the performance of intake port designs. However, the present axis-symmetric flow cases are highly simplified models of real engines, which involve complex three-dimensional flow structures. Hence, the utility of steady-flow modelling (see Chapter 5) for studying in-cylinder flow phenomena during the intake stroke must be proven at such conditions.

3.4 Conclusions and discussion

The in-cylinder flow of production-type engines, is much more complex than the idealised flow cases studied in this chapter. Moreover, such flows are essentially three-dimensional due to the complexity of the geometries involved. Although the flow is also unsteady of course, the flow during early stages of the intake stroke may be characterised by a steady flow through a port-valve-cylinder configuration, as was concluded in Section 3.3.6. Such a configuration is the subject of an experimental as well as computational investigation in Chapter 5. Apparently, the computational method is capable of predicting the main flow features of the two-dimensional and axi-symmetric cases studied in the previous sections. However, the relative strength of the various flow structures is not always captured. Below, the implications of the insight gained from studying these simplified flow cases on the simulation of more realistic flows is discussed. First, the appropriate size of the computational grid will be discussed, after which turbulence models and difference schemes are addressed.

Appropriate computational grid size

The flow cases studied in the previous sections involve dimensions similar to the steady-flow rig studied in Chapter 5. The grid sensitivity studies performed for the backward-facing step indicated that a solution more or less indifferent to grid refinement is attained for grid sizes of approximately 15000 cells. In view of the size of the computational domain, this implies an average cell size of approximately 1 % of domain diameter for this $Re_L = 5000$ case with wall-function modelling. The $Re_L = 28000$ case that was also investigated, and the $Re_L = 66400$ case of Clayton (1994), lead to the same conclusion. Similarly, both the steady and the unsteady axi-symmetric flow cases analysed in Sections 3.2 and 3.3 imply sufficient grid density for an average cell size of 1-2 % of the cylinder bore, while Re_L is of order 10000. For all three cases, the Reynolds number based on the cell size is of order 10^3 .

Although no solid conclusions about grid size can be deduced from this limited information, using a maximum cell Reynolds number of 10^3 seems to be a good first guess. Of course, the exact grid size for obtaining grid independent solutions can only be obtained through appropriate grid sensitivity studies. The cell size may be varied throughout the solution domain to reduce the number of cells while still satisfying the cell Reynolds number requirement.

Choice of turbulence model

All $k-\varepsilon$ turbulence models performed well in predicting flows similar to those occurring during the early stages of the intake stroke. In general, it was found that this type of turbulence modelling performs remarkably well in such flows, provided there is no significant swirl. This is due to the assumption of isotropically-distributed turbulence which is associated with this type of modelling. Swirl introduces considerable anisotropy. Unfortunately from this point of view, the three-dimensional steady-flow rig analysed in Chapter 5 does exhibit a considerable amount of swirl. Hence, it remains to be seen to what extent $k-\varepsilon$ models are capable of predicting such flows.

For the backward-facing step, the standard $k-\varepsilon$ model surprisingly performs superior to the RNG and CHEN variants because turbulent energy dissipation is overpredicted by the latter models. Furthermore, it was found for that case that the performance of the turbulence models relative to each other is apparently insensitive to grid size and Reynolds number, which gives confidence in the generality of the findings. For the axi-symmetric steady-flow rig, the RNG and CHEN models perform considerably better than the standard model at flow conditions involving high shear, such as occurring in jet flows and recirculation regions. Almost identical performance of the three models is observed during the intake stroke of the axi-symmetric model engine. However, during the later stages of the compression stroke, significant differences in the prediction of the flow structure close to the cylinder head were

found. Generally, the RNG and CHEN models predict similar or smaller mean Reynolds-stresses compared to the standard $k-\varepsilon$ turbulence model. This appears to be a result of the additional terms in the ε -equation of these models that enhance turbulent energy dissipation in regions of high shear. Although the RNG model produces significantly more energy dissipation than the CHEN model for the backward-facing step case, both models performed similar to each other for the other cases. Hence, no solid conclusions can be drawn about the differences between these two models.

Apparently, increased turbulent energy dissipation in areas of large strain is no guarantee for obtaining an improved prediction, as was seen for the backward-facing step where this resulted in less agreement with experimental data. As a consequence, no general conclusion can be drawn about which of the three turbulence models performs best at a given situation. One model may be preferable for one flow phenomenon, while a different model performs best for another. A three-dimensional steady-flow rig exhibits many different flow phenomena. Therefore, the performance of all three models is analysed for the three-dimensional steady-flow rig in Chapter 5 in order to investigate the best overall performance.

Choice of difference scheme

The investigation of the axi-symmetric steady-flow case showed that higher-order difference schemes produce significantly less numerical diffusion in steep-gradient flows, such as the jet-flow structure. Compared to the solutions obtained with the UD scheme, the QUICK scheme and, to a lesser extent, also the SFCD scheme produced stronger and somewhat sharper peaks in the velocity distributions and an associated increased intensity of turbulence. Similar performance was found for the axi-symmetric model engine. For that case however, the simulations with the QUICK scheme were found to diverge. The reduced numerical diffusion found for higher-order schemes of course came at an increased computational cost. Higher-order schemes were found to be much less advantageous throughout the backward-facing step flow domain and outside the jet area for the axi-symmetric cases. This may partly be because there less-strong gradients occur. However, grid sensitivity studies did not include a variation of the difference schemes. Higher-order schemes may be capable of producing similarly-good results on coarser grids and may for that reason be preferable over low-order schemes.

Generally, higher-order difference schemes are to be preferred. However, reduction of computational cost, or convergence and stability problems associated with the QUICK scheme, may be a reason to choose lower-order difference schemes for more complex flow problems.

4. Application of laser-Doppler velocimetry to engines

The objective of the experimental investigation described in this thesis is twofold. Firstly, the experiments should give enough information for studying the occurring flow phenomena. Secondly, this information must allow for a proper validation of numerical simulation methods. Such a validation is described in Section 5.4 for the steady-flow rig, based on the results of the experiments reported in Section 5.2. Although not reported in this thesis, the in-cylinder flow experiments for the motored engine, presented in Chapter 6, serve for validation purposes of the numerical simulations of the unsteady-flow fields.

Experimental analysis of internal-combustion engine performance can be done with a wide range of techniques. For the purposes of the present investigation, detailed flow data must be acquired. Such experimental data must not only yield a qualitative impression, but also quantitative information is required since it must serve as a validation means. Ultimately, complete validation of the numerical method would demand each new flow simulation to be validated separately by experimental determination of the instantaneous values of all independent flow quantities throughout the whole flow domain. Clearly, such an approach is not feasible nor sensible. However, accurate information about velocity distributions at a limited number of well-chosen positions, and for several well-chosen flow cases, can already give insight into the predictive capabilities of the numerical simulation method. If reliable performance is thus proven, part of the optimisation during the development phase of an engine can be done through computations alone. In the final stages, experiments can be conducted to determine the quantitative engine performance and possibly optimise for aspects that are not predicted accurately enough by the simulation method. Concluding, the main objective for the present experimental investigation is to acquire a maximum amount of high-quality information on the flow structures by means of a limited number of experiments.

Accurately-acquired velocity distributions are appropriate for such a quantitative analysis of flow structures. Laser-Doppler Velocimetry (LDV) is a proper technique for this purpose and

has often been applied for analysis of engine-like flow structures, as was discussed in Section 1.3. The use of LDV requires knowledge of optics, wave theory, fluid dynamics, two-phase flows, signal and data analysis, and statistics. This wide and diverse range of topics makes it difficult to grasp all details of the technique, which is often underestimated. LDV will always demand skilled and experienced operators and experiment designers if reliable and accurate measurements are to be conducted. Moreover, internal-combustion engines are probably one of the most demanding environments for this technique. The statement of Riethmuller (1977) is still applicable:

*“Know-how is perhaps the Leitmotiv of laser-Doppler velocimetry.
Whatever optical design is used, whatever electronic processing is fitted,
the satisfactory use of LDV depends essentially on the know-how of the operator”.*

Therefore, this chapter will focus on the characteristics of LDV and its specific application to engines, while the specific choices made for the presently-conducted experiments are discussed in Chapters 5 and 6. First, the set-up of an LDV system, with all its elements, is described. After that, scattering particles are considered. Subsequently, signal processing and data processing are addressed. Finally, the accuracy of the LDV technique is discussed.

4.1 LDV set-up

Laser-Doppler Velocimetry is a method characterised by the use of laser light and the *Doppler effect* for non-perturbing measurements of the local, instantaneous velocity of particles suspended in a flow. Of course, since it is the particle velocity which is measured, the relationship between the particle and the fluid velocity must be known if the fluid velocity is to be evaluated. The start of what could be called modern laser velocimetry goes back to the measurements of Yeh and Cummins (1964). In the late sixties, several laboratories pursued this technique and a number of different optical configurations were proposed during these earlier days of LDV. There are now several manufacturers of sophisticated laser velocimeter systems.

The velocimeter that Yeh and Cummins developed was of the so-called *reference beam* type. A major advancement in optical configurations for LDV was the invention of the so-called *dual-beam systems*. Extensive descriptions of both systems have been provided by Durst, Melling and Whitelaw (1976) and Adrian (1983). Due to their flexibility and superior performance in particle-rare fluids, dual-beam systems are generally preferred in modern laser velocimetry of complex gaseous flows. Such a system is applied for the current experiments and its principles are briefly discussed in Appendix C, along with the basic principles of LDV.

Figure 4.1 :: Dual-beam velocimeter set-up

Here, only the essential equation of a dual-beam LDV system is given:

$$f_D = V_x \frac{2 \sin\left(\frac{1}{2}\theta\right)}{\lambda} \quad (4.1)$$

where f_D is the so-called Doppler frequency, θ denotes the crossing angle of the laser beams and V_x is a velocity component. From this equation it becomes apparent that a local velocity component can be determined through measurement of the frequency of the laser light scattered by a particle.

Figure 4.1 shows a typical dual-beam velocimeter set-up, which includes a *laser*, a *frequency shifter*, *projection optics* for forming the fringe pattern in the *measuring volume*, *receiving optics* and a *photomultiplier* for capturing the light scattered by the particles, and, finally, a *signal processor* for deriving fluid velocity data. Below, the laser, the optical elements and the photomultiplier of an LDV set-up are discussed. Signal processing is addressed in Section 4.3.

Laser

The measuring volume is the optical transducer of an LDV system. It can be considered as an ellipsoidal volume containing a fringe pattern parallel to the major axis, as is explained in Appendix C. A high-contrast parallel fringe pattern can only be formed from the complete interference of two co-linearly polarised coherent light beams with plane wave fronts of equal intensity. Laser beams can meet these demands.

Almost invariably, Argon-Ion lasers are used to provide sufficient power at different wavelengths (476, 488, and 514.5 nm). These lasers give high signal quality at high velocities and allow detection of small particles. The lasers are operated in the so-called TEM₀₀ mode, which yields an output light beam with a Gaussian intensity distribution. For a description of

the typical properties of Gaussian beams and their effects in LDV systems, the reader is referred to Absil (1995).

However, the assumption that these lasers operate ideally in the Gaussian or TEM₀₀ mode is a major source of error. If lasers are operated for maximum power, they often will run a multi-mode, which means that other cavity modes are excited as well. The beam will then exhibit a non-Gaussian transverse intensity distribution and a beam divergence exceeding that of the fundamental TEM₀₀ mode. To prevent this from occurring, the bore diameter of the intracavity aperture can be chosen such that only the TEM₀₀ mode, which has the smallest beam size and divergence, is not constricted. Wigley (1987) performed simple free jet experiments to quantify the effects of mode noise on laser velocimetry. He showed that correct laser operation may double the data rate and increase spatial resolution. Furthermore, an increased validation rate was observed, which stems from a more efficient operation of the signal processor with signals having true Gaussian profiles.

Optical elements

Projection and receiving optics have totally different roles and should be designed accordingly. A projector handles high power, small aperture, linearly-polarised, Gaussian beams while a receiver handles very low power, large aperture, depolarised, non-Gaussian beams.

A frequency shifter can be considered as a part of the projector and is primarily used to allow for discrimination of the velocity sign as is discussed in Appendix C. However, frequency shifting has a second major advantage because it increases the dynamic range and accuracy of the velocimeter. Since small measuring volumes are required for high spatial resolution in high speed flows, the number of fringes formed is low. Adding a pre-shift to one of the laser beams leads to a moving fringe pattern. As a consequence, the number of fringes observed when a particle travels through the measuring volume is increased. Hence, the Doppler signal contains more cycles, which results in a higher data rate and improved visibility.

The velocimeter relies on the interference of two crossing coherent light beams of equal intensity. These beams can be obtained by splitting the single beam of a laser. An acousto-optic *Bragg cell* is used for both beam splitting and frequency shifting one of the beams. In such a device, the incoming beam is partly diffracted. Appropriate apertures are used to isolate the zeroth-order and first-order diffracted beams. The latter is frequency shifted over 40 MHz. When the Bragg cell is optimally aligned, it will split the light equally between the zeroth and first order of diffraction.

Basically, the projection optics consists of a single lens for focusing both laser beams to create a measuring volume (see Figure 4.1). Usually, also some kind of system for aligning the laser beams is included. In the present investigations, the DANTEC 60X80 fibre-optic system with an optional *beam expander* is applied.

The receiving optics can be located wherever scattered light can be received from the measuring volume. Receiving the scattered light in forward direction is favourable and yields the highest signal-to-noise ratio, as is discussed in Section 4.2.1. Forward-scattered light is often 100 to 1000 times more intense than back-scattered light, although it depends highly on the type and size of the scatterers. Such an arrangement is referred to as the *forward-scatter mode*.

Since the projector and the receiver will be on opposite sides of the test section in forward-scatter mode, optical access at both sides of the test section is required and all optics must be mounted on a large traversing system. The *on-axis back-scattering* optical arrangement has the advantage that the transmitting lens can also be used for the collection of the scattered light, resulting in compact systems which can be easily traversed and optical-accessibility requirements can be minimised.

According to the fringe model, as explained in Appendix C, the measuring volume is determined by the intersection region of the crossing laser beams. When the fringe model is combined with the Gaussian characteristics of the laser beams, the approximate size of the measuring volume can be defined by assuming that no measurable signals can be obtained when the intensity is below $1/e^2$ of its value in the centre of the measuring volume. The width d_m , length l_m and height h_m of the ellipsoidal measuring volume, indicated in Figure C.3b, are given by:

$$d_m = \frac{d_{e^{-2}}}{\cos\left(\frac{1}{2}\theta\right)}, \quad (4.2)$$

$$l_m = \frac{d_{e^{-2}}}{\sin\left(\frac{1}{2}\theta\right)}, \quad (4.3)$$

$$h_m = d_{e^{-2}}, \quad (4.4)$$

where $d_{e^{-2}}$ denotes the waist diameter of the focused laser beams.

The width d_m of the measuring volume is typically in the order of 0.1 mm and its length is between 0.5 and 3.0 mm. Decreased measuring volume sizes can be obtained from decreasing the focal length f of the focusing lens, and from increasing the beam intersection angle θ and the input waist. The latter two options can be achieved by placing a *beam expander* in front of

the focusing lens. In such a device, which consists of a negative and a positive lens, the beam is expanded and the beam separation distance is increased. Beam expanders are characterised by the so-called *expansion ratio* E , which is defined as the ratio of the outgoing and the incoming beam waist diameters. When an expander is used, the waist of the focused beam is given by

$$d_{e^{-2}} = \frac{4 f \lambda}{\pi E D_{e^{-2}}} , \quad (4.5)$$

where $D_{e^{-2}}$ is the waist diameter before expansion and λ is the wave length of the laser light. As a result of the increased beam separation on the focusing lens, the beam intersection angle is now given by

$$\theta = 2 \arctan \left(\frac{E d}{2 f} \right) , \quad (4.6)$$

where d is the separation distance of the beams before expansion. By substituting these expressions into equations 4.2 and 4.3 it can be deduced that the width d_m of the measuring volume decreases proportional to the expansion ratio, and its length l_m decreases proportional to the square of the expansion ratio. The use of a beam expander will increase the signal strength and the measuring accuracy, since the smaller measuring volume size will lead to a higher light intensity at the focal plane. However, the total number of fringes, given by

$$N_{fr} = \frac{d_m}{d_f} , \quad (4.7)$$

decreases due to beam expansion, which may diminish the visibility of fast moving particles. As stated earlier, frequency shifting helps to increase visibility, because it increases the number of observed fringes. Furthermore, beam expansion introduces a greater susceptibility to misalignment of the beams. For a more complete analysis of the effects of misalignment, the reader is referred to Absil (1995).

Usually, the receiver consists of a lens, or a combination of lenses, and a small aperture, called *pin hole*, in front of the photodetector. The function of the receiving lens and pin hole combination is to delimit the region from which scattered light is received to the cross-over region of the beams, or just a part of it. Moreover, light scattered from other sources such as background light and extraneous radiation from light flare and reflections at the test section windows is blocked off. The length of the effective measuring volume can be reduced by viewing the scattered light from aside (Absil, 1995), which is referred to as *off-axis light*

collection. However, this requires careful alignment of the receiving optics because the prominent maxima in the scattering diagram must be found, as will be seen in Section 4.2.1.

Photomultiplier

The function of the photomultiplier is to convert the scattered radiation collected by the receiving optics to an electrical signal. Especially during in-cylinder flow measurements, low light levels are experienced. Photomultipliers have a high sensitivity and are, therefore, almost exclusively preferred for LDV in gaseous flows.

A photomultiplier is a vacuum tube containing a photocathode, a dynode chain and an anode. The semi-conductor material in the cathode will emit electrons when being hit by photons. These primary electrons strike the first dynode which emits multiple secondary electrons for each electron striking it. By means of a high-voltage power system, a potential gradient is maintained across the dynode chain. The secondary electrons are accelerated towards subsequent dynodes. Repeating this cascade process through the dynode chain results in an amplification of the current. The anode, which forms the end of the dynode chain, collects the electrons and converts them into a voltage. At best, photomultipliers have a bandwidth of $2 \cdot 10^8$ Hz. In general, this limitation is caused by the variation of the travelling time of the secondary electrons through the dynode chain. The frequency of the incident light, which is of $O(10^{14})$, is not recorded by the photomultiplier. The Doppler frequency f_D however, will be recorded since it is of $O(10^6-10^8)$. Hence, a photomultiplier acts like a low-pass filter. For a more detailed description of photomultiplier tubes, the reader is referred to textbooks such as the one by Durst et al. (1976).

4.2 Scattering particles

Clearly, scattering particles play an important role in LDV. They are the basic source of the Doppler signal, and their importance in the overall performance of an LDV system should not be underestimated. They can have more influence on the quality of the signal than any other component of the system. Below, general light scattering, particle characteristics and particle materials and generation methods are addressed.

4.2.1 Light scattering

Whenever a light beam passes through an inhomogeneous medium, light will be scattered by the natural particles present in the fluid, like dust, but also by the fluid molecules. Light scatterers which are much smaller than the wavelength of the incident beam, such as

Figure 4.2 : Polar plot of a typical scattered light distribution for micron-sized particles (Absil, 1995). Note the logarithmic scale.

molecules and atoms, result in so-called *Rayleigh scattering*. In practice it is found that this type of scattering is too weak to generate measurable signals for LDV applications. The so-called *scattering cross section* of a particle is defined as the ratio of the power of the light scattered in all directions to the intensity of the light incident on the particle. For dipole scatterers, such as molecules, the light power scales with d^6 (Ruck, 1990), where d is the equivalent diameter of the scatterer. Consequently, the scattering cross-section of molecules is 10^{21} times smaller than micron-sized particles (Durst et al., 1976). Scattering by micron-sized particles, which are larger than the wavelength of the laser light, obeys the *Mie scattering theory* (Mie, 1908), and the scattered light power scales with d^2 . A typical distribution of the scattered light intensity for micron-sized particles is shown in Figure 4.2.

The scattering properties of micron-sized particles are very sensitive to size, refractive index, and scattering angle, so it is difficult to make straightforward statements about their general behaviour. On average, the following inferences are valid (Adrian, 1983): (1) the intensity of the scattered light increases proportional to the square of the particle diameter; (2) backward-scattering signal-intensity is very weak compared to forward-scattering for the 0.5 to 20 μm range; and (3) high ratios of the particle refractive index to the fluid refractive index yield better scattering, which is often the case when measuring in air.

4.2.2 Seeding

Durst et al. (1976) indicate an atmospheric concentration of $2 \cdot 10^8$ micron-sized particles per cubic meter, which is 10 to 100 times too small for laser-Doppler velocimetry with low laser powers, especially for backward scattering. Only when using high laser power, forward-scattering signals may be obtained from natural particles without seeding. Hence, dependent on the application and the optical set-up, external particles must be entrained in the flow. But also because of the relatively broad size-distribution of natural particles, it is desirable to seed

the flow with external particles of known size so that the effects of the less suitable natural particles are overwhelmed. Adding particles to a flow is commonly referred to as *seeding*.

Although the presence of particles in the investigated fluid is essential to laser-Doppler velocimetry, there is comparatively little published information relating to this specific application (cf. [Witze and Baritaud, 1986; Van Peer, 1997]). Seeding is of special importance for engine applications. Perhaps in no other field of laser velocimetry are such high demands put on the choice of seeding and its introduction into the air flow. In order to obtain satisfactory results in an optical flow measurement, it is necessary to take into account the seeding requirements when the experiment is designed. The main property requirements for scattering particles are:

- ability to accurately follow the flow up to the highest frequencies of fluctuation,
- good light scattering properties,
- limited fouling of windows and test sections,
- cheap, non-toxic, non-volatile, non-corrosive, non-abrasive, and chemically-inactive, and
- convenient generation at sufficient rate and with the desired size distribution.

The most important requirement is that the particles must be able to follow the paths of the fluid particles up to the highest frequencies of flow fluctuation that are of interest to the investigation. In engines, these frequencies typically run up to 10 kHz (Lorenz and Prescher, 1990). All particles must satisfy this requirement because otherwise erroneous results may occur. The fluid dynamic behaviour of particles suspended in a moving fluid depends on the particle size and shape, which affect the drag force, and on the relative density of the particle to the fluid. In air flows, the ratio of particle density to air density is typically of the order of 10^3 . Several authors have derived approximate equations to describe the relative motion of particles suspended in air flow, see for instance Ruck (1990) or Lading et al. (1994). These equations provide an indication of the maximum acceptable particle size at given flow conditions.

The particle size distribution is as important as its mean value. For reliable experiments, all particles must be smaller than the maximum acceptable diameter. But also particles that are too small can cause problems since they do not produce a measurable Doppler signal, but add to the background noise. Errors caused by particles that are either too large or too small are referred to as *particle lag bias* (Absil, 1995), which can be considerable when the flow experiences large velocity gradients such as near the inlet valve during the intake stroke.

4.2.3 Seeding materials and generation

For successful measurements, aerosols must be produced with the demanded mean diameter and a narrow diameter distribution; ideally a δ -function. Seeding generation for in-cylinder velocimetry falls into two main categories: atomisation of liquids and fluidisation for dispersion of solids. In general, generation at a steady rate and uniform size becomes more difficult as the flow rate increases.

Atomisation is frequently applied, especially for cold flows, because it is an easily-controlled process and generally produces a distribution of droplets in the size range of 0.5 to 5 microns. For in-cylinder engine investigations, oil-mist seeding can be advantageous from a lubrication and lifetime point of view, but its drawback is that oil films may collect on the optical windows or be deposited there by centrifugal forces. Although the films may be transparent, irregular refraction through them will degrade the fringe pattern and hence lead to low data rates or spurious data. In cases where window fouling is not too much of a problem, oil-mist seeding gives good data rates, especially for forward-scattering because of the transparent nature of droplets. Typical atomisers are the so-called *blast atomiser* (Durst et al., 1976) and nebulisers such as used in respiratory medicine. Droplet concentrations of 10^{10} particles per cubic meter are common after atomisation, which is sufficient for most back-scattering LDV experiments. During the experiments presented in Chapters 5 and 6, sunflower oil droplets, generated with a blast atomiser, have been used in cases where window fouling is not problematic and frequencies of fluctuation remain below 1 kHz. Approximate calculations performed by Durst et al. (1976) indicate that droplets smaller than $2.6 \mu\text{m}$ are required to follow such flow fluctuations. According to Durst et al. (1976) and Krebs (1986), a mean droplet size of $1 \mu\text{m}$ can be obtained from atomisation. Therefore, the majority of droplets is expected to meet the size requirement.

For engine investigations, solid seeding is often required because the high engine compression ratios produce sufficiently high in-cylinder temperatures to vaporise oil-mist seeding. Furthermore, solid seeding allows smaller particle sizes and can result in an improved visibility for back-scattering configurations due to a higher reflection coefficient. Solid particles must be fluidised and often a so-called *fluidised bed* is used, see for instance Lorenz and Prescher (1990). Witze and Baritaud (1986) and Van Peer (1997) list typical solid seed materials and describe their applicability. Some of these materials have single particle sizes in the sub-micron range. However, such small particles exhibit high inter-particle attractive forces causing agglomerates to be formed. Energy is required to break these bonds. A fluidised bed is not an efficient device for breaking these agglomerates so it must be followed by a cyclone to remove too large particles before they are introduced into the engine. Many velocimetrists also report adding some kind of additive to the seeding material in order to reduce hygroscopicity (Lorenz and Prescher, 1990). Additionally, an adsorption air dryer and a heater may be installed in the air supply for this purpose.

For in-cylinder velocimetry, often TiO_2 particles are used which are commercially available in monodisperse samples for various particle sizes. These solid, white-coloured particles have good back-scattering performance. Krebs (1986) showed that this seeding material can have a mean particle size as small as 200 nm. According to approximate calculations by Durst et al. (1976), such small particles are capable of following turbulent fluctuations of over 10 kHz with 99% accuracy, whereas micron-sized TiO_2 particles are still able to follow frequencies of 1 kHz. The TiO_2 particles tend to agglomerate and experience high static electricity, resulting in window fouling and possible damage to the engine when these hard agglomerates collect between the piston and the cylinder liner. Therefore, appropriate measures must be taken. TiO_2 particles have been reported to give good signal quality and data rates for in-cylinder measurements, see for instance Lorenz and Prescher (1990). This type of seeding is used for the LDV experiments in the cylinder of the motored engine, as presented in Chapter 6. During these experiments, the particles are wetted and suspended in a volatile liquid, usually ethanol. An ultra-sonic mixing bath is used to break down the agglomerates. The resulting suspension is subsequently atomised. The air shearing atomisation process also contributes to breaking down agglomerates. The liquid part of the aerosol then vaporises to leave behind a cloud of separate solid particles. Although the actual size distribution of the thus generated particles was not measured, particle sizes in the sub-micron range are claimed by experts (e.g. Wigley, 1987).

Tobacco smoke can also be used as seeding for measuring highly turbulent flows since it has mean particle sizes in the sub-micron range (Merzkirch, 1974). Similar to the smallest TiO_2 particles, smoke particles can also accurately follow fluctuations with a frequency of the order of 10 kHz. This type of seeding was applied for a part of the steady-flow rig experiments described in Chapter 5. Generation of tobacco smoke at a steady and sufficiently-large rate, and of constant quality, is not straightforward. Therefore, a dedicated smoke generator was developed. Figure 4.3 shows a schematic drawing and a photograph of this generator. Cigars are combusted in a Perspex cylinder. An air flow is pumped through the cigars to supply oxygen and to transport the thus generated smoke towards the test section. The cigars are contained in holes which are drilled in a steel plate. The amount of smoke generated is set by adjusting the air flow rate and varying the number of cigars. Although up to 16 cigars can be combusted simultaneously in the present configuration, three or four cigars are sufficient for most applications. Unused holes are blocked. The cigars are ignited with a lighter by removing the top part of the cylinder and sucking air through the cigars with a pump. Several filters are applied to exclude substances from the smoke that are liable to contaminate the test sections. Cigarettes, shag tobacco or insense can also be used instead of cigars.

The air flow in engine intake manifolds can be highly streamlined and, hence, there is little mixing of added seeding particles with the fluid. Care must be taken to introduce the seeding in a way such that it passes through the measuring volume. Mixing the seeding with the intake air in a large plenum or using a special mixing device in front of the air intake system

Figure 4.3 : Schematic drawing and photograph of the smoke generator

is a sound practice. Ideally, introduction of seeding should not perturb the induction flow and particles should be evenly distributed in the flow.

4.3 Signal processing

LDV signal processors determine the Doppler frequency from the Doppler signal. Several different types of processors have been developed over the years, each using specific analysis and validation techniques. The experiments presented in this thesis are primarily conducted using a so-called *Burst Spectrum Analyser* (BSA).

The DANTEC Burst Spectrum Analyser 55N21 Enhanced is the latest update of the signal processor that was introduced in 1987 (cf. [Lading, 1987; and Caspersen, 1992]). As the name indicates, the BSA performs a spectrum analysis of the Doppler signal. The Doppler frequency is defined by the position of the peak in the spectrum. Contrary to a so-called *counter processor*, which only uses the signal information around zero-crossings, the BSA uses the complete Doppler signal. Another benefit of spectral analysis is that it is relatively insensitive to *white noise* contributions. Since white noise has a flat spectrum, the position of the Doppler peak will hardly be affected. However, other noise spectra also may occur, which can still introduce erroneous effects (Van Maanen, 1993). The block diagram of Figure 4.4 illustrates the two signal paths of the BSA. The upper path shows the *burst detector* and the circuitry for measurement of *burst arrival time* and *burst transit time*. The lower path represents the *spectrum analyser*. Both the burst detector and the spectrum analyser are discussed below in more detail.

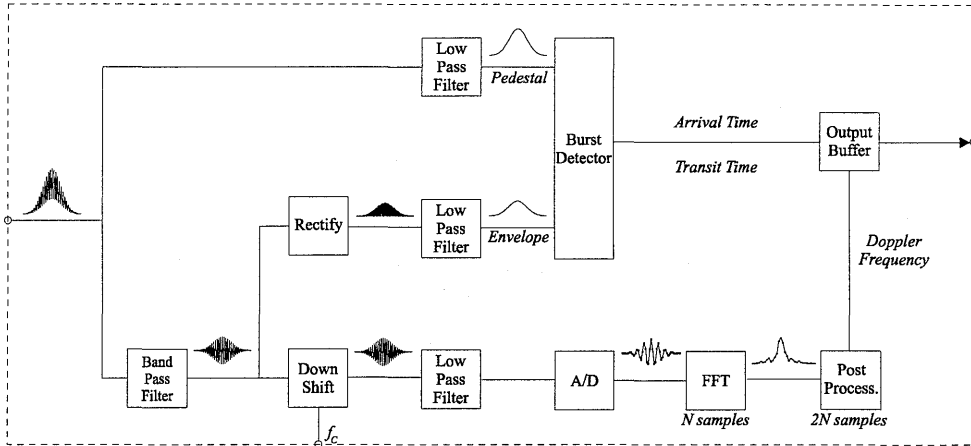

Figure 4.4 :: Block diagram of DANTEC Burst Spectrum Analyser

Burst Detector

The burst detector determines whether a signal is actually a Doppler signal or background noise. The Doppler burst is low-pass (LP) filtered to obtain the signal pedestal. Furthermore, the band-pass filtered burst is rectified and then low-pass filtered to give the signal envelope. Burst detection can be based on the pedestal, the envelope, or a combination of both exceeding a certain threshold. In the following, it is assumed that both the pedestal and the envelope are used.

In case of high data rates, individual bursts may overlap and quasi-continuous signals will be recorded. The BSA has the capability to process such signal, the so-called *Continuous mode*. In this mode, sampling is controlled by a signal formed by dividing the sample clock by N and multiplying it by a duty cycle. For as long as the burst detector indicates that Doppler signals are present, N input samples are stored in the input buffer and the arrival time is recorded at the positive-going edge of the sampling signal.

Alternatively, the BSA may be operated in the so-called *Burst mode*, in which individual bursts are processed. In this mode, the burst detector is provided with a number of increasing thresholds for the pedestal and the envelope. Input sampling is started when either one exceeds the first threshold. Simultaneously, the arrival time is registered and the transit time counter is started. The sampling is restarted when the envelope exceeds a higher threshold. This procedure ensures that the part of the burst with the largest amplitude is used for the frequency determination. The transit time counter is stopped when the pedestal and envelope decrease below another threshold.

Spectrum analyser

Spectrum analysis consists of three separate stages: preprocessing, fast Fourier transformation, and postprocessing, which are discussed below.

The band-pass (BP) filter removes all frequency components outside the range of interest, thus maximising the signal-to-noise ratio. In the spectrum analyser, the filtered signals are then passed through a mixer unit, which shifts the frequency spectrum down by the *centre frequency* f_c to improve the resolution in the computed spectrum. Both the average expected centre frequency and the frequency *bandwidth* B_w must be carefully set by the velocimetrist. This usually involves an iterative procedure of testing. Especially for engine experiments, the optimum setting is not straightforward because commonly large temporal and spatial fluctuations of fluid velocity and turbulence intensity occur.

The low-pass (LP) filtered complex mixed signal is subsequently digitised by an A/D converter through sampling at regular time intervals T_s . The *record length* N , which is defined as the number of samples per burst, can be set to 8, 16, 32, or 64, dependent on the burst length. The record length will always be a compromise between accuracy and validation ratio and should be approximately equal to the shortest expected transit time multiplied by the *sampling frequency* f_s . The resolution in the frequency domain is $\Delta f = f_s/N = 1/NT_s$. Hence, the resolution of the power spectrum can be improved by increasing the record length or decreasing the sampling frequency. However, to prevent aliasing, the sampling frequency must be at least twice the highest appearing frequency, which is known as the Nyquist criterion. Sensible signal reconstruction may even demand a sampling frequency as high as 2π times the highest frequency (Van Maanen, 1993). Since the frequency range of the BSA extends to 120 MHz, meeting such a criterion requires extremely high sampling rates. Therefore, the signal spectrum is first shifted down to the base band, as indicated above. Consequently, the sampling frequency can be considerably reduced since it can be taken of the order of the bandwidth. In the BSA, the sampling frequency is fixed at 1.5 times the bandwidth. Hence, the resolution of the computed spectrum equals $1.5 \cdot B_w/N$.

When a burst is detected, the sampled signal is stored in a buffer and subsequently processed by the fast Fourier transform (FFT) processor, which performs a discrete Fourier transform (DFT) on the record of N samples. The input clock frequency is 5 MHz, but the number of input samples is doubled by applying a *zero-filling technique* (Bendat and Piersol, 1986). This fast hardwired FFT processor can handle mean data rates of 78 to 625 kHz, depending on the record length. However, the first-in, first-out (FIFO) buffer allows peak data rates that are considerably larger than the mean data rates accepted by the FFT.

The *post processor* determines the maximum in the measured spectrum by fitting a 'sinc' curve through the maximum frequency sample and its two neighbouring samples. A 'sinc'

function represents the spectrum of a signal with frequency f which is multiplied by a rectangular window of duration T and is given by: $\text{sinc}(\pi f T) = \sin(\pi f T) / \pi f T$. By applying the zero-filling technique in the FFT, the resolution of the calculated spectrum is doubled to $\Delta f_n = f_s / 2N$ without affecting the shape of the spectrum. This allows a better estimate of the position of the maximum in the spectrum.

The post processor also validates the measured spectrum by comparing the magnitude of the two highest peaks in the spectrum. Bursts are validated if the global maximum exceeds the largest local maximum at least four times. After validation, the measured Doppler frequency is sent to the *output buffer* (see Figure 4.4), together with the arrival time (t) and the transit time measured by the burst detector.

During steady-flow experiments, the internal clock of the BSA is used to set the arrival time of a burst. In the case of a reciprocating engine however, the arrival time is given by the crank angle position, which is measured through external triggering with a crank shaft encoder. In this way, a precise determination of the position is achieved even though the angular velocity of the engine is not constant.

4.4 Data processing

In a typical steady-flow situation, it is convenient to decompose the measured instantaneous fluid velocity $u(t)$ into a mean velocity \bar{u} , a turbulent fluctuation $u'_{urb.}(t)$, a bias u'_{bias} and a statistical error $u'_{error}(t)$,

$$u(t) = \bar{u} + u'_{urb.}(t) + u'_{bias} + u'_{error}(t) \quad , \quad (4.8)$$

The mean is a simple time average, which is unambiguous and physically meaningful; no real problems of concept or definition exist. Within a reciprocating engine however, the fluid motions are time-dependent because of its inherent cyclic nature. Therefore, it is common to apply phase averaging to define the instantaneous mean velocity as a function of crank angle,

$$\bar{u}_{PA}(\alpha) = \bar{u}(\alpha) + u'_{bias}(\alpha) = \frac{1}{N_C} \sum_{i=1}^{N_C} u_i(\alpha) \quad , \quad (4.9)$$

where $u_i(\alpha)$ is the instantaneous velocity at crank angle α during the i -th cycle of measurement, while N_C indicates the total number of cycles that are measured. The subscript *PA* indicates phase averaging. The phase-averaged mean velocity includes the measurement bias because of the systematic nature of this error source.

The root-mean-squared (RMS) value of the turbulent velocity fluctuation then follows

$$u'_{PA}(\alpha) = \sqrt{\frac{\sum_{i=1}^{N_C} (u_i(\alpha) - \bar{u}_{PA}(\alpha))^2}{N_C - 1}}, \quad (4.10)$$

when assuming the statistical error $u'_{error}(\alpha)$ to be insignificant. This of course introduces an approximation into the analysis of turbulent fluctuations in an engine. The measurement bias $u'_{bias}(\alpha)$ has no influence on this RMS value since it is included in $\bar{u}_{PA}(\alpha)$.

It is important to realise that the instantaneous velocity at crank angle α may not be the same for each cycle. Consequently, the use of a phase average to separate $u'_{urb.}(\alpha)$ out of $u_i(\alpha)$ introduces a further approximation. When cycle-to-cycle variation is taken into consideration, the measured instantaneous velocity can be expressed as

$$u_i(\alpha) = \bar{u}_{PA}(\alpha) + u'_{urb.}(\alpha) + u'_{i,cycle}(\alpha) + u'_{error}(\alpha), \quad (4.11)$$

where $u'_{i,cycle}(\alpha)$ is the velocity fluctuation due to cycle-to-cycle variation at crank angle α during engine cycle i . Here, the turbulent fluctuations and the measurement bias and error are assumed to be independent of the engine cycle. There is a problem of defining the $u'_{i,cycle}(\alpha)$ term or, alternatively, of defining $\bar{u}_i(\alpha) = \bar{u}_{PA} + u'_{i,cycle}(\alpha)$. In order to account for cycle-to-cycle variations, a nearly continuous velocity record is required such that every single cycle can be processed.

The data acquired in the present study do not satisfy this requirement. Consequently, fluctuations due to turbulence and due to cycle-to-cycle variation can not be separated. The magnitude and importance of cycle-to-cycle contamination of turbulence are unclear for the present case. Therefore, the term *RMS velocity fluctuations* is used to indicate both contributions. When analysing turbulence intensity from $u'_{PA}(\alpha)$, the existence of cycle-to-cycle variation must be taken into account.

Due to the random arrival time of scattering particles at the measuring volume, LDV can be considered a random sampling procedure of a continuous signal. Therefore, the mean velocity is estimated by ensemble-averaging over a crank angle window $\Delta\alpha$ about position α . If the value of $\Delta\alpha$ is too large, this may introduce a so-called *crank angle broadening* error. According to Morse et al. (1979), crank angle broadening only slightly affects mean velocities, but RMS velocity fluctuations may become overestimated during periods of high fluid acceleration.

The ensemble-averaged mean velocity and the RMS velocity fluctuation are subject to statistical uncertainty since they are calculated from a limited number of velocity measurements. Turbulent fluctuations, cycle-to-cycle variations and statistical errors are assumed to have Gaussian distributions. Then, the error in the RMS value is inversely proportional to the square root of the number of samples N . Consequently, the error in the mean velocity estimate is proportional to the relative RMS fluctuation, normalised by the mean, divided by the square root of N . This is known as the *central limit theorem* of statistics (Chatfield, 1983). Additionally, the measurement bias $u'_{bias}(\alpha)$ introduces a shift to the mean that is independent of N . Of course, both $u'_{bias}(\alpha)$ and $u'_{error}(\alpha)$ must be as small as possible to improve accuracy. The following section discusses the error sources that are related to the LDV technique and how they can be minimised.

4.5 Error sources of LDV

It often turns out to be surprisingly simple to design and build an LDV optical set-up and to create a measuring volume that produces 'measurable' Doppler signals. Often, one may be apt to put up with the rather easily obtained Doppler signals without making further attempts at improving the signal quality. However, due to the complexity of LDV and its numerous error sources, such an approach yields unreliable results. Below, the most important error sources are discussed. Furthermore, noise reduction and signal enhancement techniques will be briefly addressed.

The ideal dual-beam LDV signal is obtained when all background light, spurious heterodyne signals, and electronic noise are negligible, and a single scattering particle resides at the centre of the measuring volume, where the illuminating beams, assumed to be of equal power, have maximum intensities. In such a case, a recorded signal will only contain information about the local fluid velocity component. Unfortunately, a number of erroneous effects will affect the measurement results. For an elaborate analysis of LDV error sources the reader is referred to the literature (cf. [Absil, 1995; Durst et al., 1976; Van Maanen, 1993; Ruck, 1990]). The most important sources of measurement bias and error are discussed below:

- Random *shot noise* is generated in the photomultiplier. Shot noise is an intrinsic part of the random photo-emission process (Lading et al., 1994, and Durst et al., 1976) and imposes a fundamental limit upon the maximum attainable signal-to-noise ratio. Shot noise is usually directly proportional to the mean photocurrent.
- Part of the shot noise originates from background illumination, which is caused by light reflections or flare light, light scattering from particles passing only one of the laser beams, or even ambient light. This is a major difficulty in performing LDV in engines. Background illumination is detrimental in that it contributes nothing to the signal power

while it increases the shot-noise power. Very substantial improvements of the signal-to-noise ratio can be achieved by using a small pinhole for spatial filtering, as stated in Section 4.1, and by taking the precautions that will be stated below.

- The fringes will not be parallel when the beam waists are not both in the focal plane of the transmitter lens because of the Gaussian and diverging nature of the focused laser beams (Lading et al., 1994). Such a fringe gradient will result in incorrect RMS values since the measured Doppler frequency is dependent on the particle position in the measuring volume. Checking the crossing of both beams is done by expanding the beams with a lens with a small focal length placed at the measuring volume and projecting them onto a screen. As the lens is moved along the optical axis of the beams, the expanded beam images can be seen to subsequently converge and diverge. Accurate overlap of the beams is obtained when, at the intersection point, both images converge into a single spot.
- The finite size of the measuring volume combined with the presence of a strong velocity gradient in the mean velocity flow field renders the assumption of constant mean velocity throughout the measuring volume invalid. As a consequence, the probability density function of the measured velocities broadens, causing too high measured RMS values. However, the ensemble-averaged velocity is not necessarily false, it should merely be interpreted as a spatially-integrated value over the measuring volume. Therefore, the spatial resolution of the measuring volume should be carefully tuned to the scales occurring in the flow. In engines, high velocity gradients occur near the intake valve during the intake stroke.
- An important error is the *particle lag bias* due to particle inertia, which is discussed in Section 4.2.2. Careful analysis of the particle size distribution is important to minimise this error source.
- The scattered light power for particles that are small compared to the fringe spacing will be relatively low, which results in a low signal-to-noise ratio. Again, optimisation of the particle size distribution minimises this error source.
- In highly turbulent flows, the measured velocity probability distribution becomes biased towards higher velocities. More high-speed particles are observed, because the volume flux through the measuring volume is proportional to the local fluid velocity. This effect is commonly referred to as *velocity* or *sampling bias* and will scale with the in-cylinder turbulence intensity, which is of course crank angle dependent.
- The amplitude and visibility of the Doppler signals increase with decreasing particle velocity, because more photons are scattered. This so-called *amplitude* or *signal-to-noise ratio bias* shifts the measured velocity probability distribution towards lower velocities when measuring turbulent flows. Hence, this effect may partly compensate for the velocity bias. Smaller measuring volume size and lower seeding concentration may reduce this effect.
- Scattered light from multiple particles, whether inside or outside the measuring volume, may lead to phase-jumps or other spurious heterodyne signals. Although most processors

are equipped with means to prevent such signals from validation, no complete elimination of this error can be guaranteed. Hence, the measuring volume size and the seeding concentration must again be minimised.

- Particle visibility decreases with increasing particle size, because the integrated scattered light intensity over the particle is never zero (Absil, 1995). This will cause e_{min} , as defined in Figure C.4 of Appendix C, to rise. Moreover, visibility will vanish for particles of the same size as the fringe spacing. The integrated intensity remains constant throughout the measuring volume in that case, because the particle will always cover a bright and a dark fringe.
- *Thermal noise* is caused by thermal movements of electrons in the semi-conductor material of the photomultiplier. However, in case of a photomultiplier with internal gain, thermal noise is often dominated by shot noise (Lading et al., 1994).

Furthermore, signal power depends on:

- The light intensity in the measuring volume. Light intensity can be increased by reducing the measuring volume size. This can be achieved by employing a beam expander, as discussed in Section 4.1. Alternatively, higher laser power may be used. However, laser power is limited by the maximum attainable power of a TEM₀₀ mode beam and the losses in the transmitting optics, which can be especially large when a fibre-optic system is used.
- The light collection angle and the size of the cone defined by the aperture of the receiving lens and its focal length f_R (see Figure 4.1). Compared to back-scatter signals, observing the scattered light in forward direction can significantly improve signal power when particles of micron-size are used, as was discussed in Section 4.1. Furthermore, signal power will be increased when using lenses with larger aperture and smaller focal length.
- The scattering efficiency of the particles. Signal strength can be increased significantly by optimising particle size (Absil, 1995) and particle refractive index.

Signal rate and quality are obviously complex functions of the mechanical geometry, the flow field, the seeding density, the optical system and the signal processor. Nevertheless, accepting or rejecting a measurement result often relies heavily on the subjective judgement and experience of the operator. This person will have a subjective approach to first finding the signal, and, secondly, finding a strategy for optimising the signal quality, i.e. the data and validation rates. This usually involves a gradual reduction in detector and amplifier gains until noise sources are no longer processed. Moreover, the velocimetrist must be keen on setting the correct filter bandwidth on the processor, which determines the range of valid Doppler frequencies. For example, a too narrow setting may cause a velocity range of interest to be skipped.

Reducing the background light is the most appropriate way to reduce noise and to improve signal quality. Primarily, background light is caused by reflection of the incident beams on walls and windows. Surface treatment of walls must receive much attention. Blackening, anodising, polishing, using anti-reflective coatings or transparent inserts are most popular. Furthermore, stray light may be blocked with black tape before it enters the receiving optics. Placing a pinhole far away from the receiving lens will also prevent much of the flare light from being collected because it introduces spatial filtering.

Windows must be cleaned regularly to reduce background noise as a result of flare light. Seeding density should be kept as low as possible to reduce window fouling and background light scattered by particles outside the measuring volume, and to reduce the chance of multiple particles in the measuring volume.

4.6 Closing remarks

In this chapter, the backgrounds of laser-Doppler velocimetry for application in engines were discussed in a general sense. Clearly, this measurement technique is capable of providing the demanded information of the in-cylinder fluid motion. Nevertheless, its application to acquire reliable results is not straightforward, especially not for complex flow cases. The application of this technique to steady-flow rigs and a motored engine is described in Chapters 5 and 6, respectively. There, also quantitative estimations of measurement errors are given.

5. Computational and experimental analysis of steady port-valve-cylinder flows

At part load, pollutant formation can be limited by improved homogeneity of the air-fuel mixture and reduced cycle-to-cycle variation. This requires an enhanced turbulent kinetic energy during combustion, which can be reached by creating large-scale in-cylinder motion, such as swirl and tumble, during the intake stroke. Such large-scale motions break down during the compression stroke. With a single intake port, swirl is the main choice, whereas almost any combination of swirl and tumble can be generated with multiple intake ports. However, inducing large-scale motions usually results in a reduced discharge efficiency. Consequently, the design of cylinder heads must always be a compromise.

Cylinder heads of modern engines involve up to three intake and two exhaust ports. Multiple intake ports are not necessarily symmetrically-shaped and may have individual lift diagrams. In order to allow multiple valves to be positioned in the head, often a so-called *pent-roof combustion chamber* is applied. An overview of the geometric properties of cylinder head designs is given by Schäfer et al. (1997). The most common lay-out of cylinder heads for production-type spark-ignition engines is one with two intake ports on one side of a pent roof, and two exhaust ports on the other side, with a single centrally-positioned spark plug. An example of such a cylinder head is shown in Figure 5.1. It was taken from a Rotax D605 0.6 litre single-cylinder engine and is the subject of the investigation presented in the current chapter and in Chapter 6.

From the abovementioned properties of modern cylinder heads, it may become clear that the flow that is induced in the cylinder of production-type engines is much more complex than the idealised flow cases studied in Chapter 3. Moreover, the flow is essentially three-dimensional. To design cylinder heads, industrial engine designers need tools to study induced flow structures, and their effect on the combustion process. Although in reality the flows are unsteady, often steady-flow rigs are used to study the flow structures that occur during the early stages of the intake stroke. In such a steady-flow rig, a cylinder head is

Figure 5.1 :: The Rotax cylinder head

Figure 5.2 :: Cross-section of the steady-flow rig

mounted on top of a dummy cylinder and air is blown through the intake port, along the valve, into the cylinder volume, and, finally, out of the open end of the cylinder. The valve is fixed at a given lift height as indicated in Figure 5.2. Of course, such a set-up is merely a model of reality, but its advantage is the relative simplicity of the configurations compared to a complete engine. The comparison of steady and unsteady axi-symmetric flow cases in Section 3.3.6 showed that steady-flow analysis can yield valuable insight into the flow during the early stages of the intake stroke.

It is common industrial practice to conduct experiments in which global numbers are determined that characterise the flow. For example, such numbers may relate to the discharge efficiency or the strength of an induced swirling motion. However, such general characterisations yield only limited information about the induced flow structures. More detailed analyses are required to enhance insight into the global performance as well as the flow details. Such analyses may be either of an experimental or a computational nature. Additionally, the validation of CFD simulations for steady flows can be considered as a prerequisite to prove the feasibility of time-dependent numerical simulations of in-cylinder flows during an engine cycle. Detailed experimental data is required for such a validation.

In this chapter, the steady flows in several port-valve-cylinder configurations are investigated through LDV experiments and three-dimensional computations. Of course, many papers have been published on the issue of experimental and computational analyses of steady flows, as was discussed in Section 1.3. LDV experiments on similar flow cases have been conducted since the early days of this measuring technique. Initially, mainly axi-symmetric flow cases were studied, similar to the one described in Section 3.2. As computer power and simulation techniques evolved, three-dimensional flow problems started to become feasible. Because the

geometric complexity of production-type cylinder heads drastically complicates domain discretisation, CFD and LDV validation for such configurations started much later, see for instance Krüs (1993) and Godrie and Zellat (1994). Most such validations of CFD codes typically involve only a single (moderate) mass-flow rate and a single (maximum) valve-lift height. A soundly-based validation should include a range of realistic flow phenomena. Furthermore, it should include strong velocity-gradient conditions since these occur in reality and are especially demanding on discretisation schemes, computational grids and turbulence modelling.

In the following sections, first the nature of the steady-flow cases is reviewed. Subsequently, both the experimental and computational analyses are described. With the data acquired from these analyses, the validation of the numerical method is then addressed. The thus validated modelling is used for a more elaborate study of steady port-valve-cylinder flows to demonstrate the use of numerical simulations. A concluding discussion is given in the final section.

5.1 Nature of steady port-valve-cylinder flows

Complex flow structures occur in the port-valve region. First the flow impinges on the valve stem. Then it is directed towards the valve region, before jetting into the cylinder. The structure of the final jetting flow depends heavily on the port shape, the valve-lift height and the flow conditions. The air motion leaving the intake port will induce in-cylinder flow structures such as swirl, tumble and recirculating vortices. Most viscous and turbulent losses occur in the port-valve region.

The nature of the flow in a steady-flow rig largely depends on the geometric lay-out of the port-valve-cylinder configuration. Especially the shape of the port is important. Most commonly, straight ports or ports with a helical shape are used. Helical ports cause the intake flow to swirl even before it enters the cylinder volume. They are applied in cases where high swirl intensities are needed, such as in Diesel engines. Most frequently however, straight ports are applied, especially in spark-ignited engines. During the period of large valve lift, the induced air exits the valve area predominantly in a direction along the axis of the port. This is due to the shape of such ports and due to inertial forces. Consequently, a directed, *jet-like* flow is introduced, as is indicated in Figure 5.3. The Rotax D605 cylinder head has two straight intake ports (see Figure 5.2). The head and its ports are symmetrical. However, during the present steady-flow investigation, only one of the two intake ports is used so that a non-symmetric configuration exists. This configuration was chosen because it allows for the investigation of swirl, which is one of the options for organising the in-cylinder fluid motion. Swirl develops because of the impingement of the intake jet at the opposite cylinder wall at a non-perpendicular angle.

Figure 5.3 ∴ Characterisation of in-cylinder flow fields in the steady-flow rig for maximum (a) and small valve lift height (b).

The flow that resides inside the cylinder volume after closure of the intake valve is determined mainly by the intake flow during the period of large valve lift because the largest amount of air is induced in that period. Therefore, the maximum valve-lift height is of most interest to the analysis of steady intake flows. Here, a maximum lift of 9.7 mm is applied. When the valve lift is smaller, the influence of the shape of the intake port on the induced flow structure reduces because the flow is obstructed more by the valve. This results in a more or less uniform flow around the valve and, consequently, in different in-cylinder flow phenomena, as is indicated in Figure 5.3b. Of course, the flow rate during small valve opening is relatively low and usually has only a limited influence on the resulting in-cylinder flow after valve closure. Nevertheless, it may play a decisive role in how a flow starts to develop during the early stages of the valve opening. Moreover, the different flow phenomena of such a configuration offer additional realistic test cases to examine the robustness of the numerical simulation method. For these reasons, a second valve lift of 1.9 mm is investigated.

Apart from the geometry and the valve-lift height, the mass-flow rate through the system is another important parameter that determines the flow structure in a steady-flow rig. In an engine, the flow rate through the port depends on the piston speed at a certain moment in time and on the discharge efficiency of the port. Generally, flow rates will be high for large valve opening, and vice versa. Two mass-flow rates per valve-lift height are investigated in this study. Firstly, an moderate mass-flow rate of 70 kg/h, which corresponds to the average flow during the intake stroke at an engine speed of 1500 RPM, is applied for both valve positions. Secondly, a valve-lift dependent realistic rate is applied. Estimates of these flow rates were based on the results of time-dependent LDV experiments conducted in the intake manifold of an engine motored at 1500 RPM (see Section 6.5). The applied flow rates are 30 kg/h and 219 kg/h for the small and large valve lift configurations, respectively. Hence, moderate as well as extreme flow cases are considered. The Reynolds number Re_{inlet} , based on the port diameter and the flow rate, varies between 16000 and 120000 for these four cases. Table 5.1 summarises the cases considered.

CASE	I	II	III	IV
flow rate [kg/h]	30	70	70	219
valve lift [mm]	1.9	1.9	9.7	9.7
Re_{inlet} [-]	~16000	~38000	~38000	~120000

Table 5.1 : Definition of the mass-flow rates and valve-lift heights for the four steady-flow cases investigated

5.2 Experimental analysis

In this section, the experimental analyses of the flows through all four flow-rig configurations are described. Firstly, the objectives of the experiments are discussed, after which the dedicated test rig and the experimental set-up are described. Subsequently, LDV data taken in the manifold and in the cylinder volume are presented and discussed in separate subsections.

5.2.1 Objectives of experiments

The primary objective of the experiments is the acquisition of quantitative data that can serve as a validation means for computations. For this purpose, it is appropriate to collect velocity distributions in the intake manifold and in the cylinder volume. Laser-Doppler velocimetry is an appropriate experimental technique for obtaining accurate flow data. Since this technique involves single point measurements, it is not feasible to acquire data with a high spatial resolution within a reasonable time frame. For the purpose of validation of computational methods however, a limited number of measurements at well-distributed positions can already offer valuable insight. An optimal set of in-cylinder measurements includes measuring positions throughout the cylinder volume, with an emphasis on the area near the cylinder head. In that area, the flow is expected to be most unstructured and, hence, most demanding on the numerical simulation method.

Because of these considerations, in-cylinder measuring positions were chosen to be located on four planes parallel to the cylinder head, at distances of approximately $1/10 \cdot D$, $1/4 \cdot D$, $1/2 \cdot D$ and $1/1 \cdot D$ from the head, where D is the cylinder bore. On each plane, measurements make up four lines, separated by 45° (see lines A, B, C and D in Figure 5.4). Along each of these measurement lines, 25 measuring positions are located, individually separated by 4 mm.

In addition to in-cylinder measurements, also velocity data were acquired in the intake manifold. Such data can be used to verify boundary conditions. These measurements are located at approximately 110 mm upstream of the valve curtain. There, measurements were taken along a straight line through the centre of the intake pipe, perpendicular to its axis.

Figure 5.4 :: Definition of measuring positions for the in-cylinder LDV experiments on the steady-flow rig

5.2.2 Experimental set-up

A test rig was developed for the purpose of the LDV experiments. A schematic representation of the experimental set-up is presented in Figure 5.5. A steady flow of air is blown through the intake port and the dummy cylinder into open air. The cylinder has an internal diameter D of 99 mm with a length of $2 \cdot D$ and is made of Pyrex glass, thus allowing optical access to its inner volume. The air flow through the system was provided by a 7 bar air supply. The flow rate is adjusted with the use of butterfly valves and a blow-by facility.

Care was taken to design the intake system such that well-developed flow profiles exist at the start of the intake port. Swirling components were eliminated by application of a flow straightener. A circular straight pipe with a length of more than 60 times the internal diameter was mounted between the straightener and the intake port. The pipe radius R is 17 mm. A Pyrex-glass test section allows for LDV at the end of the pipe. The design of this test section was such that smooth transitions to the pipe and the cylinder head could be assured, so that no significant flow disturbances were introduced.

This set-up allows forward-scattering light collection since the projection optics can be at one side of the test sections, while the receiving optics are at the opposite side, as is indicated in the figure for the case of the in-cylinder flow experiments. The set-up for the manifold experiments is similar. The cylinder head was blackened to reduce signal noise originating from flare light. With the one-component LDV set-up, both axial and tangential velocity components were acquired by rotation of the projection optics. The majority of the experiments were conducted with a DANTEC BSA 50N21 Enhanced Burst-Spectrum-Analyser, which is described in Section 4.3. Due to high signal rate, individual bursts could not be identified at a sufficient rate. Therefore, the analyser was operated in the so-called Continuous mode.

Figure 5.5 : Schematic representation of the experimental set-up of the steady-flow rig

Optical alignment

The beam intersection angle θ is $4.00 \pm 0.07^\circ$, which was determined through measurement of the coordinates of the beam spots according to the method described in Appendix C. A 2W Argon-Ion laser with a wave length λ of 488 nm was used. The waist diameter D_{e-2} of the laser beams before focusing is 1.35 mm, while the focal length f of the focusing lens is 310 mm. No beam expander is applied. From equation C.5 it follows that the fringe spacing d_f is $6.99 \pm 0.11 \mu\text{m}$ for this configuration. According to equations 4.2 - 4.6, the diameter d_m and length l_m of the intersection volume of the laser beams are 0.14 mm and 4.1 mm, respectively. The effective size of the measuring volume is reduced by application of an off-axis forward-scatter alignment and a pinhole aperture in the receiving optics. An angle of $43 \pm 1^\circ$ with the forward-scattering direction was found to be an optimal compromise between the data rate and the measuring volume size (see Section 4.2.1). Thus, the effective length of the measuring volume was limited to approximately 0.2 mm.

Positioning of the measuring volume

Both the projection optics and the receiving optics are mounted on a traversing system with which the measuring volume can be positioned at any given location in the cylinder volume. Together with the use of fibre-optics, this resulted in a flexible, easy-to-use system. The traversing system represents a cylindrical coordinate system with its frame of reference at the cylinder axis. As a consequence, the centre lines of both the projection optics and the receiving optics are always perpendicular to the cylinder wall in tangential direction. This has the advantage of straightforward alignment and, more importantly, the alignment between the laser and the receiving optics will not shift when the measuring volume is traversed. The latter is true because both the laser beams and the scattered light, which is collected by the receiving optics, remain at a constant angle to the cylinder wall during traversal.

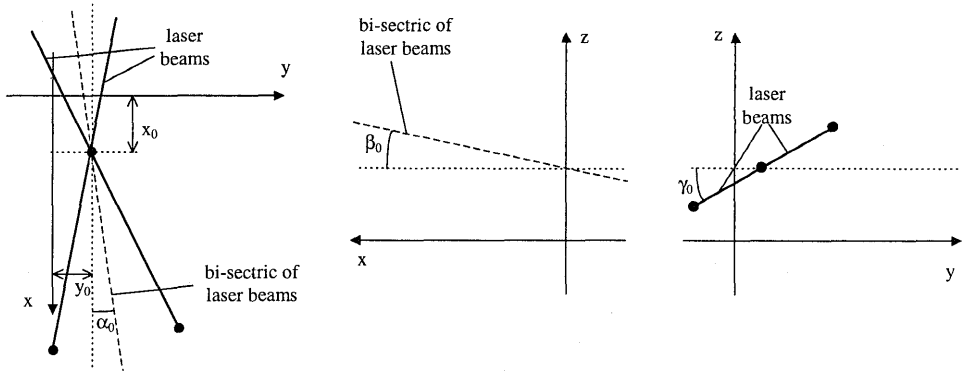

Figure 5.6 : Definition of calibration angles and displacements of the frame of reference of the traversing system with respect to the cylinder frame of reference

Theunissen (1994) and Van den Hurk (1996) described the employed procedures for aligning the frame of reference of the traversing system with the frame of reference of the cylinder or the intake pipe. The accuracy of these procedures is presented below with reference to the definition of calibration angles and displacements given in Figure 5.6. The maximum inaccuracy of the position of the frame of reference is 0.2 mm and 0.05 mm for the x_0 and y_0 displacements and 0.1° , 0.1° and 1.7° for the α_0 , β_0 and γ_0 calibration angles, respectively. With respect to this frame of reference, the measuring volume can be positioned with maximum inaccuracies of 0.05 mm and 0.5° in the radial and tangential direction, respectively. The axial position is determined through absolute measurement, which has an accuracy of 0.5 mm.

Seeding

When conducting LDV in turbulent flows, the seeding particles must be able to follow the flow up to the highest frequencies of turbulent fluctuation. Equation 2.1b gives an expression for the time scale τ of the smallest turbulent eddies, based on Kolmogorov's assumption that these motions are dominated by viscous dissipation. Thus, the highest frequency of fluctuation is defined as

$$f = \frac{1}{\tau} = \left(\frac{\nu}{\varepsilon} \right)^{-1/2} \quad (5.1)$$

With equations 2.27, 2.28, and A.3, the rate of turbulent energy dissipation ε is expressed as

$$\varepsilon = \frac{C_\mu^{3/4} U^3 I^3}{\sqrt{8} L} \quad (5.2)$$

CASE	I	II	III	IV
flow rate [kg/h]	30	70	70	219
manifold frequency [kHz]	0.1	0.3	0.3	1.7
in-cylinder frequency [kHz]	< 1	< 1	< 1	< 10

Table 5.2 : Frequency estimations for the flow in the manifold and the cylinder of the four steady-flow cases

where I represents the turbulence intensity, U is the magnitude of the mean velocity and L is the mixing length. These quantities can be estimated for the region upstream of the intake port. Similar to the inlet-boundary definition for the computations (see Section 5.3.2), turbulence intensity is set to 2.5% and the mixing length is of the order of 10% of the pipe diameter. The mean velocity is determined by dividing the flow rate by the pipe cross-sectional area. With equations 5.1 and 5.2, the highest occurring frequencies of fluctuation in this manifold area can now be estimated and are given in Table 5.2 for the four cases considered. The turbulence intensity is expected to increase and the mixing length will decrease when the flow enters the cylinder volume, which indicates a rise of turbulence dissipation rate ε according to equation 5.2. However, the frequency of fluctuation is expected to rise only modestly in view of the definition of equation 5.1. For cases I to III, in-cylinder frequencies are expected to be lower than 1 kHz, while those for case IV should not exceed 10 kHz (Table 5.2).

Sunflower oil droplets are applied as scattering particles for the measurements in the intake pipe and for part of the in-cylinder measurements of cases II and III. All these cases exhibit maximum frequencies of fluctuation below 1 kHz, as was seen above. Atomised sunflower-oil droplets are small enough to follow these fluctuations, as was discussed in Section 4.2.3. However, for the in-cylinder measurements this seeding material generally caused too much window fouling. Application of other seeding materials was problematic because of their often toxic nature and because the test rig was designed as an open system. For that reason, the measurements of cases II and III were also partly conducted by using merely the particles naturally available in the supplied air flow as scatterers. Despite the drawbacks of such a procedure, most importantly being low particle concentration and non-uniform size distribution, it proved to be an acceptable method at the given circumstances. Erroneous data due to the non-uniform size distribution are largely prevented because of the ability of the signal processor to reject Doppler bursts of particles that are too large. The resulting decrease in signal-to-noise ratio was acceptable since good overall signal quality was obtained with this type of seeding because of the off-axis forward-scattering mode of light collection. Tobacco-smoke seeding was used for the in-cylinder experiments of cases I and IV. This type of seeding can follow the high-frequency fluctuations of case IV, as was discussed in Section 4.2.3. High data rates of 10-35 kHz were obtained with good signal quality and almost no fouling of the test sections.

5.2.3 Accuracy and reproducibility

In-cylinder LDV experiments were conducted for all four flow cases indicated in Table 5.1 with the above-described experimental set-up. In this section, first the accuracy and reproducibility of the measurement data are discussed. After that, some total-error estimates are given.

Accuracy

For steady flows of course no cycle-to-cycle variation exists. Hence, the average magnitude of the turbulent velocity fluctuations may be estimated by the RMS values, as discussed in Section 4.4. Nevertheless, various erroneous effects may add to the acquired values and, thus, lead to an overestimation of the turbulence. Although appropriate measures were taken to minimise measurement errors, according to Section 4.5, no total exclusion of errors can be achieved. Two types of measurement error are identified: statistical error and bias.

The statistical errors that are expected to be important in the present case include velocity gradient broadening and statistical sampling inaccuracy. Before the effects of velocity gradient broadening can be estimated, first the maximum velocity gradient must be known. A posteriori, it was found from the measurement data that velocity gradients predominantly occur in radial direction and have maxima of the order of 5 m/s per millimetre. The finite size of the measuring volume in that direction, 0.2 mm according Section 5.2.2, introduces velocity gradient broadening, which results in an inherent RMS velocity fluctuation of the order of 0.5 m/s. Velocity gradient broadening is insignificant in areas away from the sharp velocity peaks, which mainly occur at the edges of the intake jet. The accuracy of the estimated mean velocity improves with the square root of the number of samples, as discussed in Section 4.4. Since 5000 to 15000 validated Doppler bursts were collected at each measuring position, the statistical sampling inaccuracy is improved by a factor of the order of 10^2 . Consequently, the error in the mean velocity estimates due to velocity gradient broadening is of the order of 0.005 m/s. Hence, statistical errors are rendered insignificant for the present conditions.

Additionally to statistical errors, measurement bias may be introduced. Section 4.5 explains that so-called velocity and amplitude bias are inherent to most LDV experiments. The contributions of these error sources may be of the order of 1 % of the mean velocity (cf. [Ruck, 1990; Absil, 1995]). However, both effects may partly compensate for each other. Some of the many publications that deal with these forms of measurement bias are in contradiction. Moreover, many theoretical correction methods were proven to be in disagreement with experimental results (Ruck, 1990). Since both forms of measurement bias may partly compensate for each other, their total effects are neglected in the present investigation. For the present case, the following sources of measurement bias are considered

significant: uncertainty in the position of the measuring volume, inaccuracy of the average imposed flow rate, and inaccuracy in the determination of the beam angle.

The effect of positioning inaccuracies on measured velocity data can be derived from the information given in Section 5.2.2. The maximum occurring velocity gradient in the investigated flows is of the order of 5 m/s per millimetre displacement in radial direction, as was seen above. The maximum position inaccuracy in that direction is $0.2 + 0.05 = 0.25$ mm. Consequently, positioning inaccuracies may cause a measurement bias at the edges of velocity peaks as high as 1.25 m/s. Bias due to displacement in axial direction is considerably smaller because of the mild velocity gradients occurring in that direction on the measurement planes. Furthermore, it can be shown that the error as a result of inaccurate calibration angles is always smaller than 0.05 %.

During the experiments, the flow rate was determined by measuring the pressure drop over a calibrated orifice with a Druck DPI601 pressure transducer, which has an accuracy of 0.075%. Unsteadiness of the air supply caused a considerably larger variation of flow rate during the experiments. These fluctuations have periods much larger than the duration of an individual measurement and are, therefore, considered to only introduce measurement bias. A total inaccuracy due to mass-flow rate setting of up to 2 % is introduced. According to Appendix C, the error due to inaccuracy in the determination of the beam angle is of the order of 1.7 % of the velocity estimate. Since velocities of the order of 50 m/s may occur at extreme flow conditions in the intake jet, the error introduced by inaccuracies in the flow rate and in the beam angle may approach 2 m/s. The total measurement bias, including inaccuracy of position, is estimated to have a maximum of 3 m/s. Unfortunately, measurement bias is not improved by increasing the number of samples since it is a systematical error, as opposed to statistical errors. RMS velocity fluctuations are not significantly affected by measurement bias.

Reproducibility

Reproducibility of measurement results is checked in two different manners. Firstly, several independent measurements of the same velocity distribution are compared. Secondly, measurement lines A, B, C and D cross at the cylinder centre line (see Figure 5.4). The correspondence of the various measured axial velocities at these positions is also analysed.

Figure 5.7 shows the results of four independent data sets taken along the same measurement line at supposedly-identical conditions. Since all data are close to the mean velocity distribution, an accurate reproducibility of the flow structures is indicated. The observed differences are believed to be a result of measurement bias, since statistical errors are expected to be insignificant as a result of the number of acquired samples, as was discussed

Figure 5.7 :: Accurate reproducibility of steady-flow experiments, illustrated by four independent measurements (symbols) of the tangential velocity compared to their mean (solid line) (valve lift: 9.7 mm; mass-flow rate: 70 kg/h; $Re_h \approx 9500$; measurement line A; $1/2 \cdot D$)

Figure 5.8 :: Problematic reproducibility of steady-flow experiments along measurement line D, illustrated by two independent measurements of axial velocity (valve lift: 1.9 mm; mass-flow rate: 70 kg/h; $Re_h \approx 9500$; $1/2 \cdot D$)

above. The average absolute deviation from the mean distribution is as small as 0.2 m/s. The maximum deviation that occurs in the complete data set is 1.7 m/s. This result confirms the correctness of the above-made considerations about measurement bias, although the observed maximum deviation is only half of the estimated value.

On each measurement plane, the axial velocity at the cylinder centre was measured on four independent occasions, i.e. for measurement lines A, B, C and D. The correspondence of these data is analysed for all four measurement planes at the conditions of flow case III. From this data set, an average absolute deviation from the mean velocity of 0.5 m/s is found. The maximum deviation occurs close to the cylinder head and has a value of 2.8 m/s. Again, the latter observation is in agreement with the maximum bias estimation made above, especially since the maximum deviations occur close to the cylinder head at a position where the intake jet produces extreme flow conditions.

In general, the reproducibility of the measurements along lines D for small valve-lift height proved to be problematic. This is illustrated by the two independently-measured velocity distributions along this line presented in Figure 5.8, which are clearly different. These problems are caused by the flow approaching symmetry for this valve lift, as is indicated by the flow characterisation in Figure 5.3. Measurement line D is near to the plane of symmetry. Hence, small deviations of the measuring volume position or of the position of the symmetry plane can have a large effect on the measured velocity distribution.

Total-error estimates

The total measurement error is believed to be dominated by bias, which may be as high as 3 m/s for extreme flow conditions. However, the average value of the measurement bias seen from measurements to be an order of magnitude smaller, which indicates high accuracy. Because of these findings, mean velocity distributions will be plotted without confidence intervals in the following section.

5.2.4 Measurement results

First, the measured velocity profiles in the manifold are given and compared to theoretical predictions. Subsequently, examples of the measured in-cylinder velocity distributions are presented and a characterisation of the in-cylinder flow structures is attempted.

Manifold velocity distributions

Radial distributions of the axial velocity were collected in the intake manifold at a distance of 38 mm upstream from the start of the cylinder head, which is approximately 110 mm upstream from the valve curtain. Because axi-symmetry is assumed, measurements make up a single, horizontal line through the centre of the intake pipe, perpendicular to its axis. For each measuring position, 15000 validated Doppler bursts were acquired to allow for the calculation of a mean and RMS value of the velocity. Measurement spacing was very small, typically 0.1-0.2 mm. Flow cases I, III and IV were investigated. Additionally, a flow of 30 kg/h was studied at the end of the intake pipe while the cylinder head was removed.

Figure 5.9 shows the results for the four cases. The measured velocities are normalised by the maximum occurring velocity U_{max} , the radial position is normalised by R . Additionally, predicted velocity distributions are plotted. These predictions are due to Nikuradse (1932), who found that the following empirical relation gives a good approximation of fully-developed flow profiles in smooth pipes:

$$\frac{u}{U_{max}} = \left(1 - \frac{y}{R}\right)^{\frac{1}{n}}, \quad (5.3)$$

where the exponent n varies slightly with the Reynolds number, based on the pipe diameter. According to Table 5.1, this Reynolds number for the free-stream case and flow case I is 16000, for which Nikuradse (1932) suggests a value of $n = 6.0$. Flow cases III and IV have Reynolds numbers of 38000 and 120000, which implicates $n = 6.6$ and $n = 7.0$, respectively.

Figure 5.9 :: Measured (fat line) axial velocity distributions (normalised by U_{max}) in the intake pipe compared to predictions (thin line) according to Nikuradse (1932) for four steady-flow configurations

The velocity distribution for the unobstructed case is smooth and close to the prediction, although there exists no perfect agreement. The mean turbulence intensity I , defined as the mean ratio of the local RMS value and the magnitude of the local mean velocity, is 12.5 % for this case. The measured distribution for flow case I (flow rate: 30 kg/h; valve lift: 1.9 mm) shows considerable fluctuations and is generally overpredicted by the empirical relation. The mean turbulence intensity was found to be 15.2 %. The only difference between these two cases is the absence of the cylinder head in the free-stream case. Apparently, the intake port, or rather the small valve lift, has considerable effect upstream in the intake pipe for flow case I.

Flow case III (70 kg/h; 9.7 mm) gives again a smooth velocity distribution, which is reasonably close to the prediction. Apparently, no significant upstream influence of the now wide open valve is experienced for this moderate flow rate case. The mean turbulence intensity has dropped to 10.6 % for this case, which is considerably lower than the value for

the unobstructed case. This is a remarkable observation because generally turbulence intensity is not expected to decrease when a valve is added downstream. At best, no differences are observed. Otherwise, a rise of the turbulence intensity is more likely, as was seen for flow case I. Apparently, the increased mass-flow rate of case III or the flow obstruction introduced by the valve cause a decrease of turbulence intensity, when compared to the unobstructed case. The more extreme flow case IV is only slightly less smooth, compared to case III. The only difference between both flow cases is the flow rate, while valve-lift heights are the same. Remarkable for this case is the clearer deviation from the predicted shape of the flow distribution. Turbulence intensity is now 12.3 %, which is considerably higher than for case III.

Note that the deviation of the measured distribution from the predictions close to the walls may be a result of the finite size of the measuring volume. This results in inclusion of zero-velocity wall signals in the collected signal, which became apparent since the average signal validation percentage dropped from 17 % in the pipe core to 1 % near the wall. Although the validation procedure of the signal processor eliminates most unwanted signals, it is not perfect. Hence, some of the signals may be erroneous.

The velocity distributions are generally close to the fully-developed state and, thus, appropriate for the present investigations. The acquired data is used in Section 5.3.4 to verify the inlet-boundary conditions for the numerical simulations.

In-cylinder velocity distributions and characterisation of flow structures

Axial and tangential velocity distributions were acquired at the in-cylinder measuring positions indicated in Section 5.2.1 for all four flow cases. A total of 3200 data sets was obtained. Figure 5.10 shows two examples of measured mean velocity distributions. Bands representing two times the RMS value are drawn around the mean values to indicate the 95 %-confidence interval of a single measurement.

Figure 5.10a gives the axial velocity distribution close to the cylinder head for a moderate mass-flow rate and maximum valve lift (flow case III). For this large valve lift, a jet stream leaves the intake port with a flow direction along the port axis, as was discussed in Section 5.1. This jet flows along the cylinder head before interacting with the opposite cylinder wall and being deflected in both tangential and axial direction. The latter is observed by the axial velocity peak at $r = -48$ mm. However, not all air exits the port exclusively in the direction of the port axis. The part of the induced air that exits in a perpendicular direction likely has an angle relative to the cylinder axis that approximates to the valve angle, which is 45° . Hence, this flow has a considerable axial velocity component close to the head, which

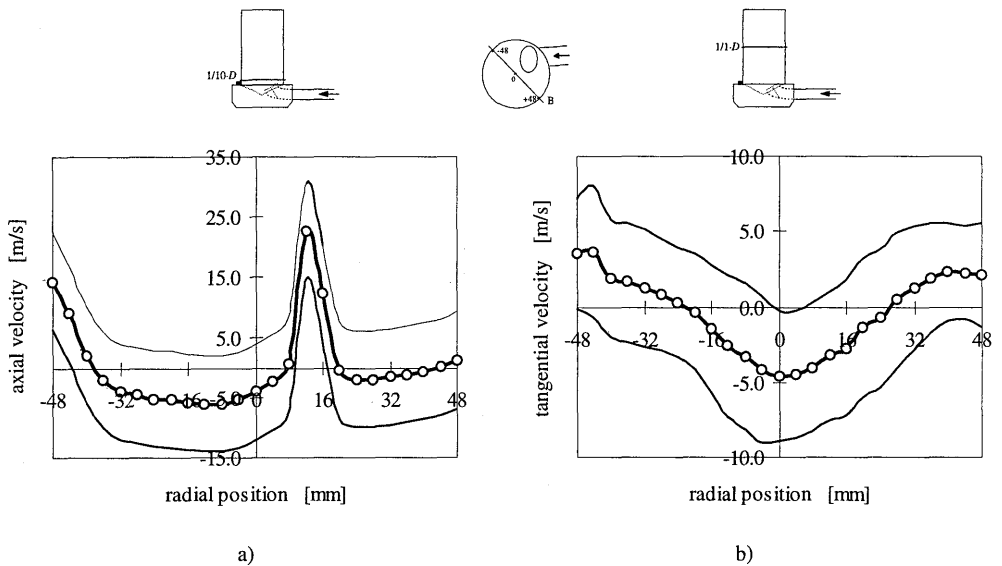

Figure 5.10 :: Examples of measured mean in-cylinder velocity distributions with $2 \times \text{RMS}$ band: a) axial velocity (flow rate: 70 kg/h; valve lift: 9.7 mm; measurement line B; $1/10\text{-}D$ from head) and b) tangential velocity (30 kg/h; 1.9 mm; line B; $1/1\text{-}D$)

can be observed in Figure 5.10a as the peak around $r = 12$ mm. In between both observed velocity peaks, backflow is observed, which indicates a recirculation region.

Figure 5.10b shows a tangential velocity distribution at a relatively large distance from the cylinder head for flow case I, which implies a low flow rate and small valve lift. According to Section 5.1, such a flow situation is likely to approach symmetry. The measurement results confirm this expectation. Velocity peaks are observed near both opposite walls, whereas flow reversal occurs at the centre of the cylinder. This clearly indicates two counter-rotating swirling motions, similar to the flow indicated in Figure 5.3. More measurement results are presented in Section 5.4 together with computational results.

The in-cylinder flow structures are visualised in Figure 5.11, based on the limited set of acquired data. For each of the flow cases investigated, the measured tangential velocity distributions have been studied to arrive at a qualitative impression of the horizontal flow structures in each measuring plane. Similarly, the vertical flow structures on a plane through the measurement lines A are visualised, based on the measured axial velocity distributions.

For cases I and II (low and moderate flow rate, small valve-lift height), no explicit flow structures can be derived close to the cylinder head. Further downstream, the two counter-rotating swirling motions, as discussed above, become apparent. In the vertical plane, large

Figure 5.11 : Flow characterisation for the four steady-flow cases based on LDV data, visualised in the four horizontal measurement planes ($1/10 \cdot D$, $1/4 \cdot D$, $1/2 \cdot D$, $1/1 \cdot D$) and the vertical plane through measurement lines A.

recirculating motions are suggested by the LDV data. For flow cases III and IV (moderate and large flow rate, maximum valve lift), swirling motions at the wall are seen throughout the cylinder. Downstream of the cylinder head, the swirling motion appears to occupy the whole in-cylinder space. For case IV, the axis of rotation does not coincide with the cylinder axis, as can be seen in the figure at $1/1 \cdot D$. The flow structure in the core of the cylinder, close to the head, can again not explicitly be characterised based on the limited number of measuring positions. In the vertical plane, recirculating motions close to the cylinder head are observed. The amount of data does not allow the determination of the detailed structures and their positions.

5.3 Computational analysis

While the previous section describes the experimental analysis of steady flows in engine rigs, in this section the computational analysis of this type of flows is addressed. First, the generation of the computational grid and the prescription of boundary conditions are described in separate sections. Subsequently, some of the computed flow fields are presented and discussed. Finally, the performance of various modelling choices is analysed.

5.3.1 Computational grid

For the spatial discretisation of the three-dimensional flow domain, surface data of the geometry of the engine head were required. These data were acquired by taking three-dimensional coordinate measurements. These measurements involved the scanning of many cross-sections of the intake port and the combustion chamber with a measuring probe, a Mitutoyo AE-122. Scanning the pent-roof combustion chamber is more or less straightforward, but the intake port poses problems due to the fact that it is difficult to probe internal geometries. Therefore, the intake port was molded with a silicon-based elastomere¹. The mold accurately reflects the interior shape of the port and was used instead of the real port for coordinate measurements. The set of measured coordinates was subsequently transformed into appropriate surface data for the grid generation process with the use of cubic interpolation techniques.

Due to the three-dimensional nature of the flows, the required number of cells rises vigorously compared to that of the two-dimensional flow cases studied in Chapter 3. Direct Numerical Simulation (DNS) of steady three-dimensional flows requires a number of cells of the order of $Re_L^{9/4}$, as was seen in Section 2.2. Since the flows considered exhibit Reynolds numbers in the range of 10^4 - 10^5 , this would imply a number of cells of the order of 10^{10} . Clearly, DNS for this case is in no way feasible. For practicable computation of three-dimensional flows, the number of cells usually is a compromise between accuracy of solution and computation time. Ideally, a grid size is needed for which grid refinement would give no significantly different results for the quantities of interest.

The discussion about appropriate grid sizes in Section 3.4 concludes that an average cell size of 1 % of the characteristic domain size is often sufficient, which implies a Reynolds number, based on the cell size, of the order of 10^3 . In view of the volume of the computation domain for the three-dimensional steady-flow rig, the 1 %-rule would imply a total of well over 1.5

¹ The molding material is called Sta-Seal and was acquired from Detax Karl Huber GmbH & Co.KG, Erlangen.

million cells. However, the fluid velocities vary throughout the domain. For example, very high velocities are encountered through the valve gap, while velocities near the open end of the cylinder are much lower. If the local cell Reynolds number is to be of order 10^3 , the cell size may vary inversely proportional to the local fluid velocity. Hence, a non-uniform grid may be applied to reduce the number of cells. Moreover, cell aspect ratios different from unity are acceptable at positions where spatial gradients exhibit directional dependency. For example, this is the case in the valve area. The major problem in generating an optimal grid according to these guidelines is of course the fact that the flow structures are not known. Therefore, a more or less intuitive approach is demanded. Ideally, subsequent iterative grid refinement studies should be conducted to analyse grid sensitivity.

Due to the complexity of the grid generation process for the present cases, it is not feasible to generate a full range of grids with different numbers of cells to allow for an elaborate grid sensitivity study. Therefore, a single grid was generated based on the considerations made above and on expectations of the flow structures. By applying these strategies, a grid was generated for the present configuration that holds nearly $2 \cdot 10^5$ cells. Figure 5.12 gives some impressions of this grid. The flow domain can be subdivided into three main areas: the intake port, the area around the valve and inside the pent-roof 'combustion chamber', and the remaining part of the cylinder volume. Obviously, the smallest cells are located in the port and, especially, in the valve area since that is where the largest fluid velocities and velocity gradients are to be expected. As a result of the complex, three-dimensional geometry of the flow domain, the grid can no longer be rectangular; body-fitted cell distributions are required. The geometry is such that the grid can only be composed out of multiple grid blocks, which are indicated by the areas of different shades of grey in the figures. Air enters the flow domain at an inlet boundary located at the start of the intake port. Outlet-boundary conditions are defined at the end of the cylinder.

In a comparable study of three-dimensional port-valve-cylinder flows, Godrie and Zellat (1994) analysed grid sensitivity for a flow case similar to case III of the present study, although at an even lower flow rate. They compared results for grids with cell numbers of 42500 and 340000, where the latter was obtained by dividing each cell of the coarser grid into eight cells. Only slight changes in the velocity profiles were found. Hence, the coarse grid seems to give sufficiently-accurate results for that case. The present study involves also higher flow rates and a smaller lift height (see Table 5.1). Therefore, local fluid velocities and gradients will be considerably higher than for the case investigated by Godrie and Zellat. In order for the cell Reynolds number to remain the same, the number of cells should be accordingly larger. This is further evidence for the appropriateness of the grid size of 200000 cells. A limited grid sensitivity study is discussed in Section 5.3.4.

Figure 5.12 :: Impressions of the flow domain and the computational grid for the steady-flow rig simulations with maximum valve lift (number of cells: 199003)

5.3.2 Boundary conditions

Apart from the standard wall-boundary definition with wall functions (see Section 2.5), the flow of air into, and out of the computational domain must be modelled. Inlet-boundary conditions are imposed at the start of the intake port, whereas an outlet boundary is defined at the bottom part of the cylinder volume, as indicated in Figure 5.12.

Inlet-boundary conditions can either be specified by imposing fixed velocity components or a fixed mass-flow rate at the inlet cell faces. Initially, fixed flow rate definitions are applied. The effect of imposition of measured velocity distributions at the inlet is analysed in Section 5.3.4. The inlet density is determined during the course of the computations using boundary pressures obtained by extrapolation from adjacent interior grid node values and the prescribed temperature. Inlet-boundary turbulence intensity is initially set to 2.5 %, while the characteristic length scale was assumed to be 10 % of the intake port diameter. The effects of variation of these turbulence parameter settings are also discussed in Section 5.3.4.

The method of defining outlet-boundary conditions was described in Section 2.5 and primarily involves the assumption that all quantities have zero-gradient distributions perpendicular to the boundary. Moreover, the flow is assumed to be outwards directed everywhere on the boundary. The boundary should be at a position in the flow where these assumptions closely correspond to physical reality, or at least have no significant influence on the solution in the area of interest. In the present study, interest focuses on the top cylinder volume, close to the cylinder head. The flow further downstream than the BDC piston position in a real engine is of less interest. In this position, the piston is at a distance of the order of $1 \cdot D$ from the cylinder head. Therefore, the outlet boundary was initially positioned at $2 \cdot D$, similar to the open end of the cylinder used during the experiments. The sensitivity of the flow upstream of $1 \cdot D$ to this boundary position is addressed in Section 5.3.4. The reference pressure needed to close the set of equations is prescribed at the outlet boundary since that is the only position where pressure is known without measurement. By good approximation, atmospheric pressure conditions may be assumed at this boundary.

5.3.3 Computation of in-cylinder flows

The steady-state port-valve-cylinder flows of cases I to IV were simulated using the computational grid described above. As a convergence criterion for all computations, the normalised absolute residual sum was set to a maximum of 10^{-3} . All computations are run in single precision since double precision computations gave no significantly different results.

Two of the four flow cases are visualised in Figure 5.13 by means of stream ribbons along the paths of massless particles and by means of velocity vector plots. Figure 5.13a shows the flow for case III (flow rate: 70 kg/h, valve lift: 9.7 mm). The jet stream that was predicted for large valve lifts, as discussed in Section 5.1, is clearly shown. Interaction of the jet with the opposite wall results in a large-scale swirling motion. Air leaving the valve area in other directions predominantly results in a large recirculating vortex below the valve. For small valve lift case II (70 kg/h, 1.9 mm), the computed flow structure is very different as is seen in Figure 5.13b. The flow leaving the valve area is more or less uniformly distributed around the valve. Interaction with the cylinder wall results in two counter-rotating swirling motions. This behaviour agrees with the experimental observations (see Figure 5.11).

5.3.4 Modelling sensitivity

A number of assumptions were made that are not necessarily straightforward. Therefore, it is important to investigate the sensitivity of the solution to a number of modelling aspects. This section subsequently focuses on grid size dependency, the effects of the inlet-boundary and the outlet-boundary definition, and the choice of turbulence model and difference scheme. All investigations involve flow case III (mass-flow rate: 70 kg/h, valve lift: 9.7 mm) while employing of the standard $k-\varepsilon$ turbulence model and the UD difference scheme, unless indicated otherwise.

Grid size dependency

A grid containing $2 \cdot 10^5$ cells was generated, as discussed in Section 5.3.1. The distribution of the cell size and the cell shape was primarily directed by intuitive considerations about the flow structures. The effort involved in grid generation and the limited computer power made a detailed grid sensitivity study with a full range of grid sizes impracticable. A limited study was conducted in which the top cylinder area was refined by dividing cell edges in axial and radial direction by two. The largest gradients occur in this area as a result of the interaction of the air jetting into the cylinder volume and cylinder contents. Hence, this area may be expected to be particularly sensitive to numerical diffusion due to a too coarse grid. The refinement practise resulted in an increase of the grid size to nearly $2.5 \cdot 10^5$ cells. Thus, the area in which the flow jets from the valve area into the cylinder volume is resolved with a considerably higher resolution.

Differences observed between results of numerical simulations on both grids are small, while the computations with the refined grid increased the computation time by about 50 %. Only some moderately-higher peak velocity predictions are encountered in the centre of the top cylinder area. Figure 5.14 shows a typical axial velocity distribution close to the cylinder

Figure 5.13 :: Visualisation of three-dimensional flow field through ribbon plots and vector plots on a plane through the centre of the intake port. Computed steady-flow fields for a mass-flow rate of 70 kg/h and a valve-lift height of a) 9.7 mm (flow case III) and b) 1.9 mm (flow case II)

Figure 5.14 :: Comparison of the axial velocity distribution, computed on the original grid (thin line) and on the refined grid (fat line) for flow case III (70 kg/h, 9.7 mm, line B, 1/10-D)

Figure 5.15 :: Comparison of the tangential velocity distribution, computed for two inlet-boundary definitions: fixed mass-flow rate (thin line) and prescribed-velocity distribution (fat line) for flow case IV (219 kg/h, 9.7 mm, line C, 1/4-D)

head. Only a slight increase of the peak around radial position $r = 12$ mm is seen. This peak is a result of part of the air leaving the valve area from aside, as was seen earlier. The axial velocity peak at the wall is not affected. This peak is due to the interaction of the intake jet with the opposite wall and may be considered to be most decisive in the development of the flow structure further downstream of the head. In view of these findings, the original grid is assumed to be an appropriate compromise between accuracy of solution and computation time. Therefore, all other investigations are conducted with the $2 \cdot 10^5$ cells grid.

Effects of inlet-boundary definition

The effect of the inlet-boundary definition was studied for flow cases I (30 kg/h, 1.9 mm), III (70 kg/h, 9.7 mm) and IV (219 kg/h, 9.7 mm). In general, the mass-flow rate through the inlet cross-section is fixed, which resulted in more or less uniform velocity distributions at the inlet boundary. Alternatively, measured velocity distributions were prescribed as fixed inlet conditions. For the latter definition, LDV data was taken at the position of the boundary. These measurement results, which are presented in Section 5.2.4, showed that in reality the distribution of the inlet velocity is not uniform. However, computational results showed that the in-cylinder flow field is not significantly affected by the change of inlet-boundary definition for cases I and III. Flow case IV, which has an extreme flow rate, shows some moderate differences between both solutions, but the characteristic flow structures are not changed significantly. This is illustrated in Figure 5.15, which shows one of the most extreme examples of the observed differences.

Figure 5.16 :: Comparison of a) axial velocity distribution and b) RMS velocity distribution computed for inlet turbulence intensities of 2.5 % (thinnest line), 8 % (thin line) and 25 % (fat line) for flow case IV (219 kg/h, 9.7 mm, measurement line B, 1/4-D from head)

Turbulence intensity at the inlet boundary was initially set to 2.5 % as is frequently reported in literature. However, as measurement results became available, it became apparent that a higher value is more appropriate (see Section 5.2.4). Therefore, the sensitivity of the in-cylinder solution to variation of inlet turbulence intensity was investigated for the extreme case IV (219 kg/h, 9.7 mm). This flow case was chosen because it was expected to be the most sensitive to these variations, in analogy with the findings above. Apart from the 2.5 % case, also 8 % and 25 % turbulence intensity cases were evaluated. Only moderate differences between the solutions for 2.5 % and 8 % were observed. The 25 % case was chosen to investigate if an unrealistically high inlet turbulence intensity can have significant effect on the fluid motion. Indeed the results indicate a considerably-larger influence. However, the general flow structures still remain unaffected.

Differences in mean velocity are especially seen at peaks near the intake valve, which become less intense with rising inlet turbulence intensity, as can be seen from the example given in Figure 5.16a. Apparently, turbulent dissipation is considerably increased with increasing inlet turbulence intensity. Figure 5.16b shows that the RMS velocities are affected considerably more than the mean velocity. This effect is predominantly seen close to the cylinder head. Further downstream, the influence of the inlet turbulence intensity on the in-cylinder turbulent velocity fluctuations is reduced.

Concluding, the computations were proven to be rather insensitive to inlet-boundary definition. Significant influences are only seen for the extreme flow case IV and for extreme settings of turbulence intensity.

Figure 5.17 :: Comparison of solutions for an outlet-boundary definition at $2 \cdot D$ (thin line) and at $4 \cdot D$ (fat line): a) axial (case III, line C, $1/4 \cdot D$) and b) tangential velocity distribution (case III, line C, $1/2 \cdot D$)

Effects of outlet-boundary definition

The outlet boundary must be located at a position where the assumptions that are associated with this type of boundary condition are close enough to physical reality, as was discussed in Section 5.3.2. The current location is at a distance of $2 \cdot D$ from the cylinder head. In order to investigate the sensitivity of the solution to this boundary location, a second computation was conducted in which the outlet boundary was located at a distance of $4 \cdot D$. Two characteristic results are shown in Figure 5.17. The $2 \cdot D$ case was taken to be appropriate since no large differences were observed and as it is the set-up which was used during the experiments.

Effects of turbulence model

The standard $k-\epsilon$ turbulence model and its RNG and CHEN variants are described in Section 2.3 and Appendix A. In Chapter 3, these models were evaluated for simplified flow conditions. Although the latter two models were shown to produce more turbulent energy dissipation compared to the standard model, no decisive conclusions could be drawn about what model is favourable for a specific flow situation. This is even more difficult for the presently-investigated three-dimensional flow cases since these include a combination of many different flow phenomena. Therefore, all three models are evaluated again for this case. Moreover, the solutions for these models are compared to a computation with prescribed turbulent viscosity μ_t . Hence, no turbulence transport equations are solved during the latter computations. This is done to investigate the effectiveness of the applied turbulence modelling. Computations with one of the $k-\epsilon$ models indicate average μ_t values of the order of

Figure 5.18 : Comparison of axial (top) and tangential (bottom) velocity distributions for the three turbulence models (fat lines) and a computation with constant turbulent viscosity, $\mu_t = \mu$ (thin line): at a distance of $1/4 \cdot D$ (a) and $1/1 \cdot D$ (b) from the cylinder head (measurement line C, 70 kg/h , 9.7 mm)

$1-10 \cdot \mu$, while peak values run up to close to $300 \cdot \mu$, where μ is the molecular viscosity. Therefore, constant turbulent viscosity flow fields were computed for $\mu_t = \mu$ and $\mu_t = 100 \cdot \mu$.

Some typical results of the computations are presented in Figure 5.18. Generally, the three $k-\epsilon$ models perform very similar throughout the solution domain. No distinct differences between the three solutions were found. Especially predictions of the peaks are very similar. Any differences must be due to the additional terms in the ϵ -equations of the RNG and CHEN models (see equations A.10 and A.14) and the slightly different values of the model constants. The additional terms should enhance turbulent energy dissipation in regions of high shear, as was argued in Section 2.3. However, this does not become apparent from observing the differences between the solutions for the cases that were studied.

The solutions for the constant turbulent viscosity definition show clear differences with the results for the $k-\epsilon$ models as can be seen from the results for $\mu_t = \mu$, which are given in

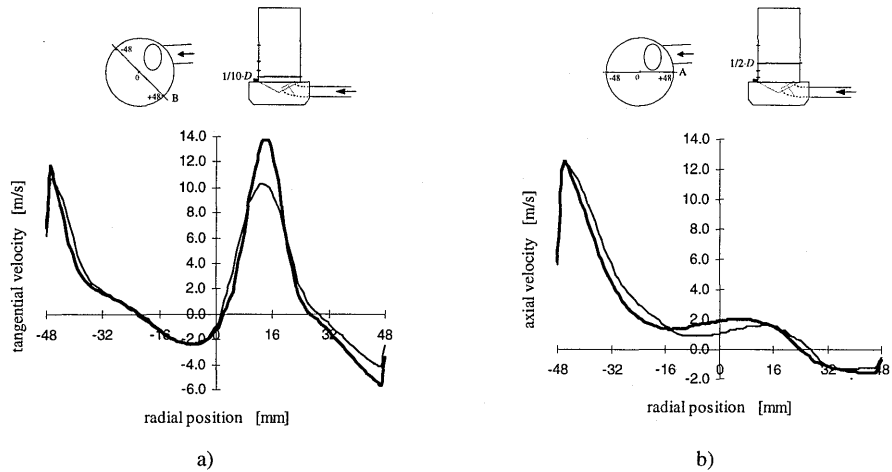

Figure 5.19 :: Comparison of computation results with UD (thin line) and SFCD (fat line) difference schemes: tangential velocity (a) at line B and height $1/10-D$, and axial velocity (b) at line A and height $1/2-D$ (70 kg/h, 9.7 mm)

Figure 5.18. Nevertheless, although these solutions exhibit considerably more variations, the general flow features are already captured. Although the computation for $\mu_t = 100 \cdot \mu$ gave different results compared to the $\mu_t = \mu$ case, both cases performed similarly when compared to the computations with the $k-\epsilon$ models. These results prove that the $k-\epsilon$ models are effective for the presently-investigated flow cases since they are closer to reality than the results obtained with constant turbulent viscosity.

Effects of difference scheme

Three difference schemes of varying order of accuracy were employed in the preliminary investigations of Chapter 3: UD, SFCD and QUICK. These schemes are described in Section 2.4.2. Generally, higher-order schemes give improved performance at increased cost of computation. However, it was shown that the low-order schemes, such as UD, are often capable of predictions close to those of a higher-order scheme. Of course, this depends on the complexity of the specific flow case considered and the employed computational grid. Here, the UD and SFCD schemes are analysed for the three-dimensional steady-flow case III (70 kg/h, 0.97 mm). Unfortunately, convergence for the QUICK scheme was not attained for this complex flow case, similar to the axi-symmetric model engine investigated in Section 3.3. This scheme is only conditionally stable, as was discussed in Section 2.4.2.

Some typical results of computations with the UD and SFCD schemes are given in Figure 5.19. Differences relate to a better prediction of the intake jet by the SFCD scheme, which is up to second-order accurate. This can be seen from the higher and narrower peaks in

the predicted tangential velocity distribution, plotted in Figure 5.19a. Nevertheless, the UD scheme produces only moderately-deteriorated predictions of the velocity peaks and performs almost identical in other regions. Moreover, the position of the velocity peaks seems almost unaffected by the type of difference scheme. Of course, the differences in the prediction of the jet will affect the flow structures further downstream in the cylinder. This can be seen in Figure 5.19b, which shows an axial velocity distribution at a distance of $1/2 \cdot D$ from the cylinder head. However, the differences in this area are even smaller than in the intake jet area.

5.4 Validation of computations with experimental data

Following the experimental and the computational analyses of steady port-valve-cylinder flows, now the accuracy of the computational results can be assessed through comparison with the acquired experimental data. This section focuses on the validation of the numerical simulation method employing the standard $k-\varepsilon$ turbulence model and the UD difference scheme on the $2 \cdot 10^5$ cells grid. Fixed mass-flow rate conditions are applied at the inlet boundary and the outlet boundary is positioned at a distance of $2 \cdot D$ of the cylinder head.

Mean velocity

The experimental data that were acquired include mean axial and tangential velocity distributions at 16 measurement lines throughout the cylinder volume for the four flow cases listed in Table 5.1. Moreover, RMS distributions were obtained which yield information about the local turbulence. Hence, a comprehensive set of detailed data is available to validate the computational method. In this section, only a very limited part of the data can be presented in detail.

Figure 5.20 shows the axial and tangential velocity distributions at a position close to the cylinder head for each of the four cases. The flow close to the head may be very demanding on the numerical simulation because large gradients are to be expected due to the existence of the intake jet and the subsequent shear and recirculation. Similar data are presented in Figure 5.21 for a position further downstream of the head, where the flow may be expected to become much smoother. Measurement data is plotted as mean velocity distributions.

Both figures give the flow data along measurement lines B (see Figure 5.4), which are taken to be representative of all data. Along these lines, the most important flow phenomena are apparent, such as velocity peaks close to the head that occur as a result of the air jetting into the cylinder volume. Further downstream, these lines offer the most insight since they are perpendicular to the symmetry plane between the counter-rotating swirling motions occurring

Figure 5.20 :: Comparison of computed (fat line) and measured (dotted line) axial (a) and tangential (b) velocity distributions for flow cases I to IV (measurement line B at 1/10-D from cylinder head)

Figure 5.21 : Comparison of computed (fat line) and measured (dotted line) axial (a) and tangential (b) velocity distributions for flow cases I to IV (measurement line B at $1/10 \cdot D$ from cylinder head)

in the small valve lift cases. There, large differences can be observed for the tangential velocities at measurement line D for flow cases I and II. However, these are a result of this line nearly coinciding with the symmetry plane. Hence, small deviations may have large effects on the solution in such a case, as was discussed earlier.

Comparison of the computational and experimental data for flow case I (30 kg/h, 1.9 mm) learns that all main flow phenomena are captured by the computational method. Although there are some discrepancies, the overall agreement is good, on a qualitative as well as on a quantitative level. The computational data is close to the experimental results.

Although the agreement for flow case II (70 kg/h, 1.9 mm) is not as good as for case I, it may still be considered fairly good. Basically, large discrepancies are only found for the tangential velocity close to the cylinder head. Otherwise, most flow structures were captured. The similarity between cases I and II concerning the flow structures close to the head leads to the belief that the observed differences may be a result of measurement error. Indeed, bad signal quality was encountered during these measurements for which no solid explanation exists. No attempt was made to repeat these measurements since flow case II is likely to be the most unrealistic of all cases and, therefore, less decisive for the validation of the computations than the other cases. This case combines the moderate mass-flow rate of 70 kg/h with a small valve-lift height of 1.9 mm. That value of flow rate is much higher than common flow rates during the period of the intake stroke in which the valve opening is so small (see Section 6.5). The other three flow cases either involve realistic flow rates (cases I and IV) or a moderate flow rate (case III).

Large valve lift case III (70 kg/h, 9.7 mm) exhibits flow phenomena that are clearly different from those observed in the previous two cases, as was already seen in Section 5.3.3 from the experimental data. An explicit jet structure is present close to the head, which results in a single swirling motion further downstream. Moreover, a large recirculation region occurs behind the valve. The intake jet is the cause of the velocity peaks close to the wall and around radial position $r = 12$ mm, seen in Figure 5.20. The computational method accurately predicts the position of these peaks. However, the computed peaks are smeared, which can be seen from the lower peak height and wider peak basis. This is likely caused by a combination of two aspects. Firstly, numerical diffusion is introduced by the spatial discretisation in combination with the properties of the difference scheme. Higher-order differencing can improve the peak prediction, as was seen in the previous section. Secondly, the assumption of isotropy of turbulence included in the $k-\epsilon$ model is certainly incorrect in the jet area, where a highly-directed flow and large shear exist. This causes the jet to spread too fast resulting in the observed phenomena. The inaccuracies in the jet prediction may also play a role in the differences observed further downstream. However, the swirl is captured reasonably well.

Figure 5.22 :: Comparison of computed (fat line) and measured (dotted) turbulent velocity distributions for a) flow case I (30 kg/h, 1.9 mm) and b) flow case IV (219 kg/h, 9.7 mm) (measurement line B at 1/10-D from cylinder head). Note the scaling differences.

Flow case IV has a much larger flow rate (219 kg/h) than case III. This aspect is reflected in much higher fluid velocities, as can be seen in the figures. Again, the width of the velocity peaks close to the cylinder is overpredicted. However, also an overprediction of the peak height is observed for this case. No decisive explanation for this observation can be given on the basis of the presently-available experimental data. However, it is most likely that the air jets into the cylinder at a somewhat different angle and position than indicated by the computational results. Apart from the overpredicted peak velocities, the computational method performs well for this case since all large-scale flow structures are captured.

Turbulent velocity fluctuations

Turbulence prediction is validated through comparison of the computed and measured turbulent velocities of which examples are plotted in Figure 5.22. The turbulent velocity is defined as the square root of the turbulent kinetic energy k . Since the radial velocity component was not measured, the turbulent energy is obtained from equation A.3 by assuming isotropy of turbulence. Thus, the radial velocity fluctuation is taken to be equal to the mean of the other two components. Hence,

$$k = \frac{3}{4}(\overline{v'v'} + \overline{w'w'}) \quad , \quad (5.4)$$

where v' and w' are taken to be the RMS values of the tangential and axial velocity components. Although the flows are not expected to exhibit isotropy of turbulence in reality,

this practise is considered appropriate since the turbulence modelling is based on the same assumption. Naturally, the assumption has a damping effect on the differences between the results of the numerical simulations and the experiments.

Comparison of the data learns that the predicted turbulent velocity is of the correct order of magnitude, although it is almost always clearly lower than the measured value. The latter finding may be a result of the measured RMS velocities being not solely due to turbulent fluctuations, but also prone to measurement errors. Increasing discrepancies near the walls, such as observed in Figure 5.22a, are partly caused by measurement errors due to increased background noise close to solid surfaces.

5.5 Computational study of port-valve-cylinder flows

From the validation study above, it is concluded that the modelling is sufficiently accurate to investigate different configurations. In this section, the effects on the in-cylinder flow of a variation of the valve-lift height and of the intake port direction are studied to illustrate the utility of the computations.

Effects of valve-lift height

The modelling was validated for two valve-lift heights, namely 1.9 and 9.7 mm. The effects of valve lift on the in-cylinder flow will now be analysed in more detail for four lift heights: 1.9 mm, 4.8 mm, 7.3 mm and 9.7 mm. All cases are computed for the moderate mass-flow rate of 70 kg/h to allow for a more straightforward comparison. However, a study to optimise the intake port may demand lift-dependent flow rates to be analysed.

The solutions for these four flow cases are visualised in Figure 5.23. The largest valve openings cause a dominant swirling motion occupying most of the in-cylinder space. This motion is induced by the highly directed jet flow leaving the intake port. When the valve closes, the directionality is quickly reduced. Already at a lift height of 7.3 mm, a considerable amount of the induced air starts to exit the valve area from aside and even from the backside. This causes a second axial flow structure to develop, which is predominantly axially-directed for this lift height. The large recirculating vortex behind the valve, which was present at maximum valve opening, is already considerably reduced in strength and size. As the valve closes further to 4.8 mm, the second flow structure develops into a swirling motion with a direction of rotation opposite to that of the first swirl. The valve is still half open at this stage. Yet a further reduction of the lift height does not importantly change the flow structure. Only very close to the cylinder head some changes occur as can be seen from the tangential velocity plots: the flow becomes even more symmetrical.

Figure 5.23 :: Ribbon plots of the computed in-cylinder flow field and vector plots of the tangential velocity at heights of $1/10 \cdot D$, $1/4 \cdot D$, $1/2 \cdot D$ and $1/1 \cdot D$ for valve lift ranging from 1.9 mm to 9.7 mm (flow rate: 70 kg/h)

The vector plots show that the two counter-rotating swirling motions at 1.9 mm valve lift are already formed very close to the cylinder head and remain virtually unchanged along the length of the cylinder. The single swirl at maximum lift is formed much further downstream. Moreover, the centre of swirl does not coincide with the centre of the cylinder. Close to the head, the large valve lift cases exhibit more complex flow phenomena.

The computations indicate that the centre of swirl does not coincide with the centre of the cylinder. A swirl measurement using a swirl meter or an impulse meter would never give this information because of the assumed solid-body rotation centred at the cylinder axis. Hence, such techniques yield an incomplete impression of the angular momentum. Nevertheless, the so-called *swirl number* S is a frequently-used measure to characterise the induced kinetic energy. The swirl number is defined according to Heywood (1988) as:

$$S = \frac{8T}{\dot{m} D v_0} \quad , \quad (5.5)$$

where \dot{m} is the air mass-flow rate and D is the cylinder diameter. A characteristic velocity v_0 is derived from the pressure drop across the valve using Bernoulli's equation for incompressible, isentropic, steady flows,

$$v_0 = \sqrt{\frac{2(P_0 - P_c)}{\rho}} \quad , \quad (5.6)$$

where P_0 and P_c refer to the upstream stagnation pressure and the cylinder pressure, respectively, and ρ is the air density. The incompressible flow equation is used since the difference with the compressible flow equation is usually small (Heywood, 1988). The 'impulse meter' torque T for cross-section A is defined as

$$T = \int_A \rho r V_{tan.} V_{axial} dA \quad , \quad (5.7)$$

where $V_{tan.}$ and V_{axial} are the tangential and axial velocity components, respectively. Thus, the swirl number can be calculated from the computed data for each axial position in the cylinder. Impulse meter experiments are usually conducted for a single position, mostly $1.75 \cdot D$ downstream of the cylinder head.

Figure 5.24 :: Swirl number versus normalised axial cylinder position for the four different valve-lift heights (flow rate: 70 kg/h)

Here, the swirl number is considered along the length of the cylinder. The swirl number distributions for the four valve-lift heights are presented in Figure 5.24. Obviously, the swirl number rises with the ‘opening’ of the inlet valve. For small valve-lift heights, virtually no total angular momentum is present due to the approximate symmetry of the flow in the cylinder. The angular momentum represented by the two counter-rotating motions cancels in the integration process. For large valve opening however, the fact that predominantly a single swirling motion exists results in a large swirl number. The valve lifts of 7.3 and 9.7 mm result in a much larger swirl number along the length of the cylinder, although the flow is far from a single swirling motion within the first $1/2 \cdot D$ from the head, as was seen in Figure 5.23. Apparently, a high swirl number does not necessarily imply a single swirling flow. Therefore, the phrase ‘swirl number’ is somewhat deceiving. It merely gives an impression of the angular momentum with respect to the cylinder axis, no information about the flow structure is gained. The swirl number is observed to decrease with the axial position, which is likely due to the effects of friction and turbulent dissipation.

Effects of port direction

To illustrate the effect that intake port design and orientation can have on the induced flow, three different port orientations are studied in this section. In addition to the configuration with the original Rotax cylinder head, two other configurations in which the intake port has been rotated around the valve axis by 45° in each direction are considered. Easy grid generation was facilitated by the rotational-symmetric orientation of the cells in the valve area such that the complete port grid could be rotated. Thus, the configurations considered are a tangentially-directed port, the original port and a radially-directed port as is illustrated by the top view images in Figure 5.25.

Figure 5.25 :: Ribbon plot of computed in-cylinder flow field and vector plots of tangential velocity at heights of 1/10-D, 1/2-D and 1/1-D for tangential, original and radial intake port directions (flow rate: 70 kg/h, lift height: 9.7 mm)

Figure 5.26 :: Swirl number versus the normalised axial cylinder position for three different intake port orientations (flow rate: 70 kg/h)

Computations for these three configurations were performed with a mass-flow rate of 70 kg/h to reflect average flow conditions. The maximum valve-lift height of 9.7 mm was applied since, in real engines, the vast majority of the air is induced during the period of large valve lift. The computed flow fields are also visualised in Figure 5.25 by means of three-dimensional ribbon plots and vector plots of the velocity at three different cross-sections of the cylinder. The tangential port produces a vigorously-swirling motion with the centre of rotation closer to the centre of the cylinder than found for the original port. Furthermore, the ratio of the angular and the axial momentum has increased, which can be seen from the pitching angle of the ribbons in Figure 5.25. This observation is confirmed by the swirl number distribution for this case, which is given in Figure 5.26. Compared to the original case, the swirl number has increased by a factor of approximately 2.5.

The radially-directed port produces a more or less symmetrical flow structure, much like the one observed in the previous section for the original port at small valve lift. Again, two counter-rotating swirling motions are produced. Although the swirl pitching angle is considerably lower than for the original low-valve-lift case (see Figure 5.25), the swirl number is much higher. Apparently, the integration involved in the calculation of the swirl number does not cancel out both motions as was seen previously for that case. This is caused by a less-perfect symmetry, which is illustrated by the vector plots. This is further evidence of the observation that the swirl number should be used with proper care. Another remarkable thing about the flow produced by the radially-directed port is the direction of rotation of the swirling motions. Since the valve is wide open a strong intake jet leaves the intake port in radial direction and impinges more or less perpendicular onto the opposite cylinder wall. Intuitively, one might be apt to assume that this jet will split more or less equally and cause two counter-rotating motions with directions of rotation opposite to those actually formed in the numerical simulations. In reality, the intake jet forms a recirculation region behind the

valve and the two counter-rotating motions are induced by the air leaving the valve area from aside.

5.6 Conclusions and discussion

An off-axis LDV set-up was applied to acquire detailed velocity data throughout the cylinder volume of a steady-flow rig for four flow configurations. These data allow for a characterisation of the in-cylinder flow, as was seen in Section 5.2.4. Such practises yield much more insight into the existing flow structures than can be obtained from general non-dimensional numbers, such as the Swirl number, that are often used to characterise engine flows. However, although a large data set was collected during the present experiments, conclusive descriptions of the flow details would demand a higher spatial resolution of the measuring positions. The number of positions required to enhance detail is estimated to be at least an order of magnitude larger than used here. Such a resolution is feasible, but in view of the time involved with the present manually-controlled experiments, such an approach would demand an automated LDV set-up. Alternatively, a judicious combination of LDV with a whole-field measuring technique, such as PIV (see Section 1.3), may be ideal. The optical accessibility of the flow-rig cylinder volume may allow for a relatively straightforward application of PIV.

The higher spatial resolution that is required to yield a more complete flow description indicates a definite need for the numerical simulation of the steady flow in engine flow rigs. Before a specific computational method can be applied to study flow phenomena, it must be validated for this type of flow. For such a validation, quantitative experimental data of local fluid velocities and turbulence are required. Acquiring such data was the primary objective of the present experiments. For that purpose, the presently-applied measuring technique has been demonstrated to be appropriate.

The validity of the present computational method for the simulation of three-dimensional steady flows in production-type engine flow rigs has been proven through comparison of the computational results with the LDV results. From the results presented in Section 5.4, it is concluded that the computations perform remarkably good in view of the modelling assumptions. In this respect, the assumption of isotropic distribution of turbulence, which is implied in the $k-\epsilon$ turbulence model, is important. This assumption generally causes a smearing effect on flow phenomena such as swirl, high-shear flow at the edges of jets, and recirculation. Nevertheless, the present validation study shows that still a good general description of flows that clearly exhibit such phenomena can be obtained. This observation confirms the findings of similar studies (cf. [Godrie and Zellat, 1994; Krüs, 1993]). The 'standard' $k-\epsilon$ model was compared to the RNG and CHEN variants. Despite the differences

between the three turbulence models, their overall performance was found to be similar at the investigated steady-flow conditions. Hence, no apparent reason exists to abandon the standard model in favour of the other models for the computation of the present flow types.

The proven level of accuracy of the computational method may be considered sufficient for many applications, especially for comparative studies of the flow performance of cylinder head designs. Such studies can provide improved insight in the flow phenomena that occur. The present investigation shows that the method is applicable for a wide range of realistic steady-flow conditions since it was validated for a variation of valve-lift height and of flow rate. The use of the validated computational method was demonstrated through a study of flow phenomena for several flow rig configurations (see Section 5.5). Although not all details are captured, already much insight is gained from such studies. Of course, there still remain differences between the computational and experimental data. Applying higher-order difference schemes can produce moderately-improved predictions. However, if accuracy of prediction is to be increased significantly, an alternative manner of turbulence modelling may be required. Unfortunately, the current state of development of such methods, and the accompanying extra computational costs, are still the limiting factors for general industrial application (see Section 2.3).

6. Experimental analysis of in-cylinder flows during intake and compression strokes

Steady-flow analysis can be very valuable for acquiring information about the flow structures induced during the early stages of the intake stroke and for comparing the performance of different cylinder head designs, as was seen in the preceding chapters. However, no insight is gained as to how the flow structures break down during the remaining part of the intake stroke and, more importantly, during compression. Ultimately, only transient analysis can yield detailed information about the flow field and turbulence intensity distribution prior to, and during, combustion.

Many studies have revealed that in-cylinder flows are complex. Because of their highly-turbulent nature, these flows are not easily quantified. However, LDV experiments and CFD simulations can be powerful tools for acquiring such information and for increasing the understanding of the flow phenomena. Although both types of analyses have been performed by other researchers in the past, as was indicated by the review presented in Section 1.3, they are still no straightforward practises. Moreover, the number of publications of detailed validation studies of unsteady in-cylinder flow computations for production-type engine geometries is still very limited. The present study focuses on the LDV analysis of the unsteady flow in a motored engine. This investigation serves three purposes. Firstly, the complexity of designing a practicable test rig and of conducting LDV under such conditions are assessed. Secondly, the acquired data must allow for an analysis of in-cylinder flow structures. Finally, the data is to be used for a future validation study of computational methods for three-dimensional unsteady flows.

Several demands were put upon the dedicated engine that was developed as part of the present investigation. A primary demand is that it must represent the general features of production-type, spark-ignited, passenger-car engines. Furthermore, it must allow for optical access of the combustion chamber to facilitate not only the LDV experiments, but also visualisation studies of the flame propagation in planes perpendicular to the cylinder axis.

Consequently, the engine is also to be operated under firing conditions, although it is motored during the present investigation. The engine must be able to run at engine speeds of at least 2500 RPM, and preferably at much higher speeds during future investigations. For the present preliminary investigations, it was chosen to run a full-throttle operation at engine speeds of 1000 and 1500 RPM.

The Rotax D605 four-stroke spark-ignition engine again forms the basis of the investigation, similar to the steady-flow analyses in Chapter 5. This 0.6-litre single-cylinder engine is applied in motorcycles and has a bore D of 97 mm and a stroke S of 81 mm, which are maintained in the present investigation because they represent the dimensions of many modern passenger-car engines. The original compression ratio of 11.0 was reduced to 10.5, which is a realistic value. This reduction was partly due to a different design of the piston crown for the purpose of the optical-access, as is discussed in the following section. The original engine was designed for high-performance motorcycle application. Consequently, its intake and exhaust manifolds were laid out for maximum performance at high engine speeds, which resulted in very short intake and exhaust runners. Passenger car engines run at much lower engine speeds and, moreover, involve multiple cylinders. Therefore, the original manifolds are not appropriate for the present investigation. The applied manifolds involve much longer runners to facilitate more realistic performance at lower engine speeds. However, their design remains more or less arbitrary since the effects of multiple cylinders can not be simulated in a single-cylinder configuration. The Rotax cylinder head (see Figure 5.1) has a design similar to most production-type engines, as was discussed in the introduction to the previous chapter. Two intake and two exhaust ports are positioned in a pent-roof combustion chamber with a valve angle of 40° . In the present analyses, all ports are included in the configuration, whereas only a single intake port was used in the steady-flow analyses of the previous chapter. Consequently, a more or less symmetrical configuration exists, which is likely to suppress the occurrence of a single swirling motion. Rather, tumble is to be expected due to the interaction of the induced air with the cylinder wall and the piston. Tumbling flow structures are often favoured in the design of similar configurations.

The LDV experiments focus on determining both in-manifold and in-cylinder velocity distributions. A major difficulty in conducting in-cylinder LDV experiments is that a dedicated test engine is required. Basically, an engine with an optically-accessible combustion chamber is to be designed. This engine must be placed in a test rig that allows the engine to be operated and monitored under well-defined conditions. Severe demands complicate the design of such an experimental set-up, as is seen below. The design of the optically-accessible motored engine, the LDV set-up and the complete test rig design are addressed in separate sections. Subsequently, the experimental analyses of both in-manifold and in-cylinder flow structures are discussed. Some concluding remarks are presented in the final section.

6.1 Design of an optically-accessible engine

In-cylinder LDV requires optical access to the combustion chamber through some kind of window. Deciding on the location of that window is often the major compromise in the whole design of the experimental set-up. From an optics point of view, its requirements are: large diameter, flat, thin, no bubbles or striations, high transmission, low reflection, and applicable for high laser-power densities (Wigley, 1987). The engineering point of view demands: small diameter, thick, high strength, low stress mount, resistance to thermal gradients, vibration, abrasion and pressure differential, easy to maintain and to clean, and low cost. Furthermore, the window should flush fit into the flow geometry so as to preserve flow fidelity.

In general, windows can either be mounted in the cylinder head, in the cylinder liner or in the piston. The demand for future flame visualisation with the present engine in a plane perpendicular to the cylinder axis demands a window in either the head or the piston. Geometric limitations and considerations about deterioration of flow fidelity render the first option impossible for the presently-applied cylinder head. Because of these considerations, a piston-based window is favourable. Piston-based windows can have diameters approaching the cylinder bore and, thus, facilitate easy access to most of the in-cylinder volume including the area close to and in between the valves. Consequently, the important intake jet leaving the port areas can be studied with this set-up. Velocity components parallel to the cylinder head can be measured through a piston based window. Hence, scanning an axial line yields information about the existence of tumble, which is thought to be important here, as was discussed above. Horizontal scans may be conducted to gain insight about the possible existence of swirling motions. Unfortunately, axial velocity components can not be obtained with a window in the piston. That would demand a window in the cylinder liner. This was considered an acceptable drawback because tangential and radial components were expected to yield already great insight and allow for validations studies of computational results.

Figure 6.1 shows a drawing of the single-cylinder engine which was designed and used during the present investigations. The dedicated piston contains a window with an optically-effective diameter of 75 mm. The window is 25 mm thick in order to also withstand the in-cylinder pressures at firing conditions on a later occasion. The window is mounted in the piston in a manner such that it experiences low and uniform stresses. Although production-type pistons may exhibit more complex shapes, a flat piston face was accepted for the present phenomenological investigation. A fixed mirror at an angle of 45° to the cylinder axis is needed below the piston window for the sideways deflection of the incoming laser beams and the outgoing scattered light. This demands an extended piston which is open at two sides. Effectively, a top and a bottom piston are applied in between which the mirror is mounted. The top piston is used for compressing and sealing off the in-cylinder fluid, similar to a regular piston. The bottom piston seals off the crank case and is connected to the crank by a connecting rod of length 140 mm. Both pistons are interconnected by two lobes. The top and

Figure 6.1 :: Drawing of the optically-accessible engine

bottom part of the piston reciprocate in the extended cylinder liner. The liner temperature is conditioned through a water mantle between the liner and the cylinder body. Both the liner and the cylinder body have two holes. The mirror passes through one of the holes, while the other hole facilitates the optical access. The mirror is mounted to the cylinder body by means of dedicated axial traversing and rotating systems.

Oil-lubrication is applied to reduce engine wear, especially of the piston and the cylinder liner. A major problem of oil lubrication in optically-accessible engines is window fouling. Moreover, the piston and the cylinder liner may be damaged by the piston rings or when an abrasive seeding material is applied that accumulates in the oil. Therefore, an advanced lubrication system was developed. This system is based on the controlled injection of filtered oil at the positions where needed, whereas excessive oil is subsequently removed so that

Figure 6.2 :: Lift diagrams of exhaust and intake valves as used for the motored test engine

window fouling is minimised. Hence, the lubrication oil is continuously refreshed so that contamination by seeding particles is prevented.

The top part of the piston is lubricated through eight injection holes in the cylinder liner, located just below the bottom dead centre (BDC) position of the piston's oil scrape ring. The holes, which are 0.5 mm in diameter, are equally divided around the perimeter of the cylinder. The amount of oil that is injected and the frequency of injection are controlled by a single injector. The injected oil is spread on the cylinder surface through the reciprocating motion of the piston rings. Excessive oil runs down the cylinder wall and accumulates on a ring located below the BDC position of the piston. The collected oil is removed from the ring by means of a pressure difference over eight larger holes in the cylinder liner. The bottom part of the piston is lubricated by means of controlled oil injection at the crank and big-end bearings of the original Rotax lubrication system. Through centrifugal forces, oil droplets are slung onto the cylinder wall, after which the oil is again spread on the cylinder liner by the piston rings. The crank case is kept at a lower pressure than the ambient air above the bottom piston part to reduce the chance that oil droplets become air born and, thus, to minimise mirror fouling. Optimisation of the top and bottom oil injection systems resulted in a configuration which is virtually free from window and mirror fouling by lubrication oil, whilst the piston is lubricated sufficiently to ensure a reasonable life time expectancy. However, the optimisation has not been a straightforward process and required delicate fine-tuning.

The Rotax head is mounted on top of the cylinder. The valve train, for which excessive oil lubrication is applied, is driven by the crank. Both intake valves and both exhaust valves are driven by cams with identical profiles with a maximum valve lift of 9.5 mm. The valve lift diagrams¹ are plotted in Figure 6.2. Inlet valve opening coincides with outlet valve closure,

¹ The applied cam profiles are given by the D159 type of Kent Cam Ltd., England

which is at TDC of the intake stroke. Here, the valves are said to be open for lift heights over 1 mm and closed below. The valves are open during 228 °CA, which is appropriate for automotive engines of this type. Of course, such engines are commonly operated at higher engine speeds than is the case in the present preliminary investigation. Consequently, a considerable part of the air induced during intake stroke (360-540 °CA) is expected to be forced back into the intake manifold during the early stages of the compression stroke since the inlet valve is not yet closed at that stage.

6.2 LDV set-up

The design of an LDV set-up for in-cylinder unsteady-flow measurements is much more complex than for the steady-flow rig discussed in Chapter 5. This is due to the unsteadiness and the limited optical access. Since a single window in the piston is applied, the incoming laser beams and the outgoing scattered light must follow the same optical path, which implies a back-scattering LDV set-up. In the following sub-sections, the optics of the applied set-up, the positioning of the measuring volume in the combustion chamber and the seeding of the flow are addressed.

6.2.1 Optics

Figure 6.3 gives a schematic representation of the LDV set-up designed for the in-cylinder flow measurements. A Spectra-Physics Stabilite 2017 2W Argon-Ion laser is used to generate a monochromatic light beam with a wave length λ of 514.5 nm. The Bragg cell splits the laser beam and preshifts one of the beams over 40 MHz. Fibre-optics is used to direct the laser beams to the test rig. The DANTEC 60X80 fibre-optic probe and a lens with a focal length f of 500 mm are applied to focus both beams. A beam expander with an expansion ratio E of 1.98 is used to improve spatial resolution. The beam waist before expansion D_{e-2} is 1.35 mm. The beams are deflected by the mirror and enter the combustion chamber through the piston-based window. The mirror consists of an optically flat glass plate on which a thin film of aluminium vapour was deposited. Scattered light is again collected by the fibre-optic probe. The cone of light collection has an angle of 4.5° around the back-scattering direction. The collected light is fed to a photomultiplier by means of a glass fibre. The BSA is used for signal processing (see Section 4.3).

The signal strength collected in back-scattering direction is generally much lower than in forward direction (see Section 4.2.1). Therefore, it is important to minimise background noise

Figure 6.3 :: Schematic representation of the LDV set-up

due to reflections. For that reason, special window materials, Herasil[®] and Suprasil^{®1}, are applied with the present set-up to provide sufficiently-low scattering. Suprasil[®] proved to perform superior to Herasil[®] because it contains even less impurities. Nevertheless, Herasil[®] was applied during most of the in-cylinder experiments because of availability reasons. Additionally, all surfaces inside the engine that may reflect flare light were blackened for a further reduction of background noise.

6.2.2 Positioning and optical alignment

The use of fibre-optics allows for a flexible set-up. The fibre-optic probe is mounted on a manually-controlled XYZ-traversing system with an electronic position determination facility. This system represents a Cartesian positioning system for the measuring volume in the combustion chamber, which is aligned parallel and perpendicular to the cylinder axis. The accuracy of the traversing system is 0.005 mm for each coordinate axis.

Establishing a frame of reference in an enclosed volume such as the combustion chamber is not straightforward. Here, the following method is used. A thin metal film with an aperture is placed in the cylinder head at the position of the central spark plug, perpendicular to the cylinder axis. The aperture has a diameter of 50 μm , which is significantly smaller than the focused beam waists. The fibre-optic probe is traversed to a position where the light of both

¹ The Herasil[®] and Suprasil[®] windows were acquired from Haraeus Quarzglas GmbH, Hanau.

laser beams passes through the aperture. This is observed through the projection of the beam spots on a screen at a few meters distance of the aperture. Through small adjustments of all three coordinates, the intensity of both spots is maximised under the constraint that they must have identical intensity. Only then, the centre of the measuring volume coincides with the centre of the aperture. Analysis proved that this state could be achieved with great accuracy through visual observation. Subsequently, the measuring volume is traversed from the aperture to the desired frame of reference. The position of the aperture relative to the frame of reference is known through accurate coordinate measurements. The inaccuracy of the described method for establishing the frame of reference has a maximum of 0.02 mm for each coordinate axis.

The flexibility of the XYZ-positioning system is somewhat limited because of the limited size of the mirror and of the holes in the cylinder body and liner. One of the laser beams may be blocked by the cylinder body or fall outside the mirror when the measuring volume is to be placed close to the cylinder wall. The beam separation at the location of the hole is of the order of 40 mm. For such cases, the mirror can be traversed and rotated to establish another frame of reference (see Figure 6.1). Relative to that frame of reference, again the XYZ-traversing system can be used. The optical alignment of the laser beams to form a measuring volume can be done outside the engine when the bi-sectoric of the laser beams is perpendicular the window. Although the measuring volume is no longer at the focal length of the focusing lens due to beam refraction on the surfaces of the 25 mm thick window, it will remain well-aligned under these conditions. In case of mirror rotation, the bi-sectoric of the beams is not perpendicular to the window. Then, optical alignment must be done inside the engine because both beams are refracted unequally by the window. To facilitate easy alignment, the cylinder head must be removed. During the present preliminary experiments, all measuring positions are located in the core of the cylinder as will be discussed in Section 6.6, for which no mirror rotation was needed.

Because of the back-scattering set-up, a relatively long measuring volume is obtained. Nevertheless, application of a beam expander and a large beam intersection angle of $9.00 \pm 0.07^\circ$ (see Appendix C) resulted in reasonable dimensions. According to equations 4.2 to 4.6, the diameter d_m and the length l_m of the measuring volume are 0.123 mm and 1.55 mm, respectively. Significant velocity gradient broadening may be introduced because of the relatively large measuring volume length l_m . This and other aspects of the measuring accuracy are assessed in Section 6.4. From equation D.5 it follows that the fringe spacing d_f for this case is $3.28 \pm 0.11 \mu\text{m}$.

6.2.3 Seeding

Strong requirements are put on the choice of seeding for unsteady in-cylinder flow experiments. The seeding particles must be able to follow the highly-turbulent flow. Frequencies of fluctuation of the order of 10 kHz have been reported in the literature (see Lorenz and Prescher, 1990). Generally, particle sizes in the sub-micron range are needed to satisfy this requirement. Furthermore, the seeding must have good back-scattering efficiency for application with the present LDV set-up. To allow for sufficiently-long measuring durations, window fouling due to deposition of seeding particles must be minimised. Additionally, the seeding material must not damage the engine.

After an extensive analysis of seeding materials and generation methods (see Van Peer, 1997), TiO₂ was found to be an adequate seeding material for the present in-cylinder flow investigation. This seeding material satisfies the above requirements. Particles with a size in the sub-micron range are generated as described in Section 4.2.3. Although TiO₂ can be very abrasive, engine wear could be minimised through optimisation of the oil lubrication system as described in the previous section.

Tobacco smoke was used for the measurements inside the intake manifold. Section 4.2.3. describes the generation method. No significant window contamination problems were encountered because the flow in the manifold is predominantly aligned with the pipe walls. A high signal-to-noise ratio was achieved with processing in the Continuous mode of the BSA.

6.3 Test rig design

An engine test rig for LDV experiments is much more than only an optically-accessible engine and an LDV set-up. The engine must be operated at well-controlled conditions. Figure 6.4 gives a schematic representation of the complete test rig as it was designed for the present investigation. Below, systems for flow conditioning, engine conditioning and engine monitoring are described in separate sections. The final section deals with the functionality of the complete test rig.

Flow conditioning

Pressure waves are induced in intake manifolds as a result of the opening and the closing of the valves. Manifolds are often designed in such a way that these pressure waves can help to increase the amount of air induced into the cylinders. The exact structure of the field of pressure waves depends on many aspects such as the engine speed, the number of cylinders and the length of the runners. As a single-cylinder engine is studied in the present investigation, the design of the intake manifold is more or less arbitrary. For reasons of

Figure 6.4 ∴ Schematic representation of the test rig

simplicity, two straight pipes are mounted in front of the intake ports. Both the port diameter and the internal pipe diameter are identical so that a smooth flow is guaranteed. Here, a manifold length of 1100 mm, including the intake port, is used. The pipes end in a 220 litre settling tank. Air trumpets are mounted at this end of each pipe. Hence, a smooth flow into the pipes is ensured so that no arbitrary vortices are generated because of separation at the pipe edges. This has the advantage of allowing for a more straightforward computational modelling of the manifold flow conditions. When no upstream-generated vortices are present, there exists no need to compute the flow from the tank into the pipes. Prescribed-pressure boundary conditions at a cross-section of the pipes may suffice in such a case.

Part of the fresh air supply is pumped through the seeding generator, which is described in Section 4.2.3. A blow-by valve allows for fine-tuning of the flow rate through the generator. The generator consists of a reservoir containing an emulsion of TiO_2 particles in ethanol. An ultra-sonic bath is used to break up particle agglomerates. Air is pumped through the reservoir and exits through two nebulisers, thus forming a spray of small droplets. This flow of air and droplets reenters the main flow in front of the air trumpets. On their way to the engine, the ethanol droplets evaporate, leaving behind a cloud of individual TiO_2 particles. The distance between the seeding generator and the engine was gradually increased to find maximum signal quality. At such conditions, the distance is expected to be long enough for the droplets to evaporate and short enough to prevent the particles from again forming agglomerates.

A 12-litre settling tank is used in the exhaust system to merge the flow from both exhaust ports into a single exhaust pipe. Two separate pipes are mounted between each of the exhaust ports and the tank. Similar to the intake manifold, pipe lengths of 1100 mm, inclusive of the exhaust ports, are employed.

Engine conditioning

The present study is limited to flow investigations during the intake and compression strokes, which is more or less equivalent to the period between the opening of the intake ports and the start of combustion. Under the assumption that the flow during that period of an engine cycle is unaffected by the combustion process of the preceding cycle, the test engine can be operated at motored conditions. Since there is no combustion, the engine must be externally-driven by an electromotor. From an LDV point of view, such motored conditions are preferable over fired-engine operation since it offers a less harsh environment for this sensitive measuring technique. For example, window contamination is an even larger problem at firing conditions because of the presence of the combustion products, such as particulates. An 11 kW DC electromotor is applied to drive the optically-accessible engine via a drive belt.

A single-cylinder engine will exhibit angular velocity fluctuations as a result of the compression and expansion processes. Although this is a phenomenon common to any engine, the fluctuations must not be too large. A flywheel was mounted to the crank to smoothen these fluctuations. Thus, the variation in engine speed was measured to have an acceptable value of the order of 5 % at 1000 RPM. At higher engine speeds, the variations are reduced due to increased momentum.

Two further engine conditioning systems are to be distinguished. Firstly, a controlled engine-heating system is used. Water is pumped through the engine at a constant rate. A thermostat controls the heating system, which is used to keep the engine at a constant temperature of 80 °C. Secondly, individual lubrication systems are used for the valve train, for the upper piston part, and for the lower piston part and crank case, as described in more detail in Section 6.1. Two separate systems remove the excessive oil at the top piston part and the oil mist from the crank case.

Engine monitoring

A crank shaft encoder provides the corresponding crank angle position of each velocity measurement. The encoder has a resolution of 0.1 °CA and offers an additional pulse at top dead centre (TDC) of both the compression and exhaust strokes. To discriminate between these strokes, an additional sensor at the cam shaft is applied. Thus, a pulse at TDC of the

Figure 6.5 :: The test rig for LDV in the motored engine

exhaust stroke is obtained. This pulse is used to reset the crank angle counter. The engine speed is measured with a hand-held tachometer which has an accuracy of approximately 5 RPM. Drift of mean engine speed was restricted to under 5 RPM during a period of several hours of operation.

The settling tank smoothens the reciprocating air flow through the engine. As a result, the flow through a gas counter, which is mounted upstream of the tank, is always directed towards the tank. This is necessary since this gas counter can not discriminate between flow directions. Moreover, pressure fluctuations must be reduced to prevent damage of the counter's bearings. The gas counter allows the flow rate through the engine to be monitored and, more importantly, with that the engine's discharge coefficient can be determined, as indicated in the following section. Together with measurement data of the local pressure P_{GC} and temperature T_{GC} , the flow rate data can be used to derive the mass-flow rate.

Test rig functionality

Figure 6.5 shows a photograph of the test rig. The optically-accessible engine is seen in the centre of the picture. The fibre-optic probe in the front is positioned for in-cylinder LDV measurements. In the background, the intake pipes and the large, white settling tank can be distinguished.

The engine successfully passed tests to determine whether it can be operated at the demanded speed of up to 2500 RPM. Although it is likely capable of running at higher speeds, no attempt was yet made to test that since, during the current investigation, the engine was only operated at lower speeds. After careful optimisation of the oil lubrication systems (see Section 6.1), engine wear was found to be very limited. The volumetric discharge efficiency (Heywood, 1988) of the entire intake system was analysed from gas counter data and found to be 74 % at 1000 RPM and 75 % at 1500 RPM. These values are considered realistic, especially since the intake manifold was not optimised and the valve train is laid out for maximum performance at higher engine speeds.

Window fouling due to seeding deposition can quickly increase background noise which deteriorates signal quality. However, cleaning in-cylinder windows is laborious. Although window fouling does occur for the present set-up, its rate was so low that good signal quality was attained even after over six hours of operation without window cleaning. This is a remarkable result, since many velocimetrists have reported much shorter cleaning intervals. An effective operation duration of the order of ten minutes is apparently more common. The presently-achieved low fouling-rate is a result of proper system design. Firstly, the applied seeding generation process prevents the TiO_2 particles from forming agglomerates that are too large to follow the flow and may, consequently, deposit on the window. Secondly, free lubrication oil droplets are prevented through careful design of the lubrication system. Such oil droplets can deposit onto the window and, thus, increase light flare. Moreover, the oil may retain seeding particles that otherwise would have been blown away from the window. In addition to these measures to minimise window fouling, the cleaning interval could be extended through application of the signal analyser in Burst mode, which is explained in Section 4.3. That way, good quality of the validated velocity data could be obtained for measurements taken through a heavily-contaminated window. This Burst mode of operation imposes high demands on the quality of a Doppler burst. As a consequence, most noisy signals are not validated. Only at the later stages of a measuring period, as window contamination becomes more severe, a reduction of the data rate is observed, which is a result of the decreased validation ratio of the signal processor.

The probe traversing system and the engine are both rigidly connected to the floor of the laboratory. Consequently, vibrations of both elements relative to each other are largely prevented. This is important for the positioning accuracy of the measuring volume. Relative displacements were found to be less than 0.1 mm for each coordinate direction. Of course, these inaccuracies add to the effective measuring volume size. Nevertheless, they are considered satisfactorily small in view of the total length l_m of the measuring volume, which is 1.55 mm, according Section 6.2.2.

6.4 Measuring accuracy and reproducibility

The experimental set-up described in Sections 6.1 to 6.3 was used to measure temporal and spatial velocity distributions. In this section, first the accuracy and reproducibility of the measurement data are discussed. After that, some total-error estimates are given.

Accuracy

Measured velocity data of unsteady engine flows may be considered as an addition of several contributions, as was discussed in Section 4.4. Apart from turbulent fluctuations and cycle-to-cycle variations relative to a mean velocity, also statistical errors and measurement bias are encountered. Again, although appropriate measures are taken to minimise measurement errors by appreciation of the methods discussed in Section 4.5, no total exclusion of errors can be achieved. This is even more problematic for the present case than for the previously-investigated steady-flow rig because of the application of back-scattering LDV in an enclosed space and due to the unsteadiness of the flow. Application of a back-scattering set-up implies a low intensity of the observed scattered light, while reflections at walls and due to window fouling increase background noise. Hence, the signal-to-noise ratio (SNR) is often dramatically smaller than in a forward-scattering set-up.

Because of the low mean SNR, the in-cylinder LDV experiments were conducted by application of the Burst mode setting of the analyser, which only validates individual bursts of high quality (see Section 4.3). Thus, accurate data were obtained, but, consequently, at the cost of low data rates. With a typical data rate of 0.1 kHz, acquiring cycle-resolved data proved to be impossible. Consequently, the individual contributions of cycle-to-cycle variations and turbulent fluctuations could not be discriminated. Both contributions are captured in a phase-averaged RMS value, similar to equation 4.10. The instantaneous mean fluid velocities are expressed as phase-averaged means, according to equation 4.9. Statistical measurement errors add to the RMS value, while measurement bias adds to the mean velocity. The extent of both types of measurement error is discussed below.

Various phenomena can contribute to the total statistical error. Here, velocity gradient broadening and crank angle broadening are considered important sources of statistical error. Velocity gradient broadening occurs in areas of large spatial gradient as a result of the finite size of the measuring volume. In the present case, the length of the measuring volume l_m is relatively large, 1.55 mm (see Section 6.2.2). The effective length is increased to a maximum of 1.75 mm because of engine vibrations, as was discussed in the previous section. Consequently, considerable velocity gradient broadening may be introduced since large gradients occur, especially at the edges of the jet flow leaving the valve area during the intake

stroke. Local gradients are found to be as high as 8 m/s per millimetre. Hence, the contribution to the RMS value in these areas is of the order of $8 \times (1.75 / 2) \approx 7$ m/s. Crank angle broadening, on the other hand, occurs when the temporal gradient at a specific measuring position is large. It is a result of the averaging process over a crank angle window, as discussed in Section 6.6.2. Here, crank angle windows of up to 10 °CA are applied. Maximum observed temporal gradient is of the order of 0.2 m/s per crank angle degree. Consequently, the increase of RMS value due to crank angle broadening may be as large as $0.2 \times (10 / 2) \approx 1$ m/s.

The size of the confidence interval of the mean velocity estimate due to statistical measurement errors decreases proportionally to the square root of the number $N(\alpha)$ of samples at a certain crank angle position α , according to the central limit theorem discussed in Section 4.4. The total number of velocity samples N taken at each in-cylinder measuring position is 20000 to 30000 for the complete engine cycle of 720 °CA. If a crank angle window of 10 °CA is used to determine a phase-average, $N(\alpha)$ is typically of the order of $25000 \times (10 / 720) \approx 350$. Consequently, the RMS value of the statistical error in the mean velocity estimate due to velocity and crank angle broadening is reduced to a maximum of $\sqrt{(7^2 + 1^2)} / \sqrt{N(\alpha)} \approx 0.4$ m/s in areas of steep spatial and temporal gradients. Outside steep gradients, the RMS value is at least an order of magnitude smaller and, hence, insignificant.

Measurement bias in the present investigation is expected to be a result of inaccuracies of the engine speed, of the beam angle and of the position of the measuring volume. The maximum error in establishing a desired engine speed is 10 RPM, according to Section 6.3. This implies a relative error of 1 % at an engine speed of 1000 RPM. For such small deviations, local fluid velocities may be considered proportional to the engine speed. Hence, the maximum velocity bias due to this source of error is also 1 %. The beam angle is measured with the procedure described in Appendix C. Hence, the maximum inaccuracy introduced is 1.7 % of the local mean velocity. Since velocities of the order of 50 m/s may occur under extreme flow conditions in the intake jet, the bias introduced by inaccuracies of engine speed and beam angle may be as large as $50 \times (1 + 1.7) / 100 \approx 1.3$ m/s. Inaccuracies in the positioning of the measuring volume are very small. According to Section 6.2.2, the maximum total inaccuracy is $0.02 + 0.005 \approx 0.025$ mm per coordinate axis, which is an addition of the error involved in establishing a frame of reference and the inaccuracy of the traversing system. With a maximum velocity gradient of 8 m/s per millimetre, the error due to this source has a maximum of 0.2 m/s. Concluding, the measurement bias is expected to have a maximum of the order of $1.3 + 0.2 \approx 1.5$ m/s. However, the average absolute bias is expected to be considerably smaller, similar to the observations made for the accuracy of the steady-flow rig experiments, as discussed in Section 5.2.3.

Reproducibility

Reproducibility of measurement results is checked based on two repeated experiments. Firstly, two independent sets of measurements are compared to analyse the average total measurement error. Secondly, two successively acquired, and thus dependent sets are observed, which allow for a comparison free of bias.

Figure 6.6 shows two distributions of the velocity during the first 90 °CA of the compression stroke at in-cylinder measuring position 10 (see Section 6.6.1 and Appendix D). Both distributions are measured under similar conditions and at the same measuring position. They are considered largely independent since the most important operating conditions, such as the position of the measuring volume, were re-established before the second measurement. The number of samples per crank angle window for the measurements indicated as line A in the figure is of the order of 100, whereas line B represents the mean of approximately 4000 samples. Hence, according to the above-estimated measurement accuracy, measurements A may be subject to a statistical error with a maximum of $\sqrt{(7^2 + 1^2)} / \sqrt{100} \approx 0.7$ m/s, while measurements B may be considered virtually free of statistical error. Indeed, the considerable statistical error of measurements A is seen from the less smooth distribution. In addition to statistical errors, both measurements are subject to bias, which was estimated above to be of the order of 1.5 m/s in areas of steep gradients. The mean absolute difference between the means of both measurement sets is 0.67 m/s, which is, as expected, considerably smaller than the above-made estimates. This confirms the appropriateness of those estimates since those indicate a maximum occurring in areas of steep gradients, while the flow at the current measuring position exhibits relatively weak gradients.

The mean velocity distributions of two dependent experiments are given in Figure 6.7 for measuring position 14. The dependency is due to the fact that both experiments were conducted immediately after one another, without modification of the measuring conditions such as the position of the measuring volume and the engine speed. Both experiments had an averaging time of under three minutes. Because of the dependency, the difference between both results is considered free of bias. The number of samples per crank angle window is of the order of 3000 for both experiments. Hence, according to the estimates made above, the statistical error of both experiments is approximately $\sqrt{(7^2 + 1^2)} / \sqrt{3000} \approx 0.13$ m/s in areas of steep gradients. However, the actual statistical error may be expected to be much lower since no steep gradients exist at the measuring position, which is confirmed by the smoothness of both velocity distributions. Hence, the difference between both experiments should be free from measurement bias as well as statistical error. Nevertheless, a small, but significant mean absolute difference of 0.18 m/s is found. The uniformity of both distributions suggests the existence of a small bias, for which no solid explanation was found.

Figure 6.6 :: Reproducibility of in-cylinder flow experiments, illustrated by two independent mean velocity distributions (measuring position 10, 1000 RPM)

Figure 6.7 :: Reproducibility of in-cylinder flow experiments, illustrated by two dependent mean velocity distributions taken under identical conditions (measuring position 14, 1000 RPM). Note the scaling differences with figure 6.6.

Total-error estimates

Summarising, the total measurement error is believed to be dominated by measurement bias, which may be as high as 1.5 m/s under extreme flow conditions. Additionally, an average statistical error of the order of 0.4 m/s is expected. The mean measurement error outside areas of steep gradients was seen to be considerably smaller.

6.5 Manifold flow measurements

LDV experiments were conducted at the end of one of the intake manifold pipes of the optically-accessible engine. A back-scattering set-up, similar to the set-up for the in-cylinder flow measurements, was applied to determine the distribution of the axial velocity component at a distance of approximately 120 mm upstream of the inlet valve (see Figure 6.8). A Pyrex cylinder is mounted between the intake pipe and the cylinder head to facilitate optical access. Engine speed was set to 1500 RPM. Measuring positions were located on a vertical line through the centre of the pipe, parallel to the cylinder axis. At each measuring position, an average of 60000 validated velocity samples were taken. Tobacco smoke, generated according to the method described in Section 4.2.3, was used for seeding purposes. No significant window fouling problems were encountered because the flow direction of the smoke particles is predominantly parallel to the wall.

The majority of measuring positions was located on the vertical line between the pipe centre and the top wall because of symmetry considerations. However, this symmetry may only be assumed in case of an undisturbed flow. To analyse the symmetry, a number of measurements

Figure 6.8 :: Schematic representation of the LDV set-up for manifold measurements

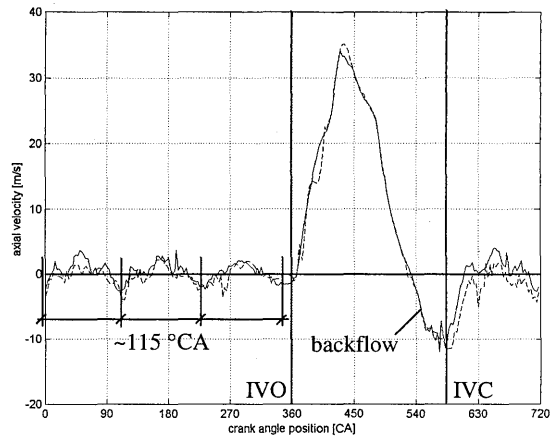

Figure 6.9 :: Two axial velocity distributions in the manifold at $r/R = 0.67$, measured at the top and bottom half of a vertical line through the pipe centre at an engine speed of 1500 RPM

were taken on the opposite vertical line, between the pipe centre and the bottom wall. Comparison of velocity distributions in the top and bottom part of the pipe, taken at the same radial position, allows for an assessment of flow symmetry. Figure 6.9 shows typical distributions for the radial positions $r/R = 0.67$, where R is the pipe radius of 17 mm. Clearly, both distributions are very similar. Consequently, the vertical axial velocity distribution may be assumed to be symmetrical.

The measured velocity distributions, illustrated by the examples given in Figure 6.9, indicate a flow towards the cylinder immediately after inlet valve opening (IVO). During the intake stroke (360 °CA-540 °CA), a large amount of air is induced into the cylinder volume with peak velocities of up to 35 m/s. At the end of the intake stroke, the velocity at the measuring location switches sign and, subsequently, a considerable backflow is observed during the early stages of the compression stroke. This is due to the motion of the piston which forces air out of the cylinder volume into the manifold until inlet valve closure (IVC). Subsequently, the axial velocity in the manifold exhibits fluctuations which have a period of approximately 115 °CA. These fluctuations indicate pressure waves that run up and down the intake pipes with a velocity close to the speed of sound c . Such pressure waves are due to the opening and closing of the valve and due to pressure differences over the valve as a result of the piston motion. A compression wave travels to the start of the pipe, which is assumed to be an open end because of the large volume of the settling tank (see Figure 6.4). By good approximation (Stone, 1992), the pressure wave reflects as an expansion wave. At the measuring location, this is observed as negative axial velocities. The expansion wave reflects at the closed valve and returns to the open end, where it reflects as a compression wave. This results in positive

Figure 6.10 : Measured axial velocity distribution 120 mm upstream of the inlet valve at an engine speed of 1500 RPM (data measured at the top part of the pipe is mirrored to visualise the complete flow profile)

axial velocities at the measuring location. Consequently, the period of the observed fluctuations must be equal to four times the length of the intake pipe divided by the speed of sound. This is true by good approximation for the present configuration, motored at 1500 RPM.

Figure 6.10 shows a three-dimensional plot of the axial velocity in the intake manifold as a function of the crank angle position and the normalised radial position. Clearly, a uniform profile is observed throughout the engine cycle. No measurements were conducted in the horizontal plane. However, previous experiments at similar conditions also indicated fully-developed, symmetrical velocity profiles on a horizontal measurement line. Because of those results and the present results, the axial velocity distribution is expected to be rotational symmetric.

Temporal and spatial integration of the measured velocity distributions over the pipe cross-sectional area gives an estimate of the amount of air induced into the engine during a single engine cycle. For the abovementioned reasons, rotational symmetry is assumed. Moreover, the flow through both intake pipes is assumed identical, which was not proven since measurements were only conducted in one of the two pipes. Nevertheless, this assumption

Figure 6.11 :: Top and side views indicating the location of the four in-cylinder measurement lines

appears justified since a high level of symmetry of the in-cylinder motion exists, as is seen in the following section. For the present case, a discharge efficiency of approximately 83 % is calculated while assuming rotational symmetry. Flow measurements under similar conditions with the gas counter indicate an actual discharge efficiency of 75 % at an engine speed of 1500 RPM, as was discussed in Section 6.3. The discrepancies with the presently-found value are attributed to measurement bias and the assumption of rotational symmetry of the velocity distribution, which may not be perfect.

6.6 In-cylinder flow measurements

The objectives of the in-cylinder LDV experiments presented in this section are twofold. Firstly, it is a test for proving that reliable and accurate in-cylinder velocity data can be acquired with the designed experimental set-up and the applied techniques. Secondly, the experiments must offer data that allow for an analysis of the flow structures and for a validation of computational results. Because of limitations of available time, only a limited number of measurements have been conducted for a single operating condition.

6.6.1 Measuring conditions and positions

A number of full-cycle velocity measurements were conducted at an engine speed of 1000 RPM. The measuring positions were carefully chosen so that a maximum amount of information is acquired. Measurements are taken along four lines, two axial lines and two lines perpendicular to the cylinder axis, as is indicated in Figure 6.11. The coordinates of the measuring positions are given in Appendix D. Only a single velocity component, directed according to the arrows indicated in the figure, is acquired.

Measurement line I was chosen because it may visualise a possible tumbling motion that is caused by the interaction of the intake jet with the cylinder wall and the piston face. Measurement line IV is also used to study the possible tumbling motion. Furthermore, this line gives an axial cut through the jet of one of the intake ports. The highest spatial resolution is applied at the top part of this line because of the expected steep velocity gradients in the jet. The existence of symmetry can be analysed from the data acquired along measurement lines II and III. The former is located in between the inlet and exhaust valves, whereas the latter is approximately halfway between the TDC and the bottom-dead-centre (BDC) piston position. Additionally, line II allows the structure of the intake jet to be analysed in the plane perpendicular to the cylinder axis. Measurement line III gives information about the existence or absence of swirl.

Typically, 20000 to 30000 velocity samples were taken at each measuring position to improve the statistical sampling accuracy, as was discussed in Section 6.4. The number of engine revolutions involved in these measurements varied between 2000 and 15000, dependent on the data rate obtained at a specific measuring position. The validated data rate is primarily determined by the amount of background noise. Close to walls, more noise is experienced. Moreover, many of the measurements are located at a position that may be blocked by the piston or a valve during a certain period of the engine cycle. Of course, no data is collected during such periods and, hence, acquiring the intended total number of samples involves more engine cycles.

6.6.2 Data processing

With each velocity sample, the moment of occurrence is determined from the crank-shaft-encoder signal. In view of the phase-averaging process, crank angle registration is restarted each time the piston reaches the TDC position of the compression stroke. Figure 6.12a shows a typical plot of the raw velocity data versus the crank angle position. The velocity distributions are nicely illustrated by this figure. To extract quantitative estimates, data processing as described in Section 4.4 is needed. However, here a pre-processing step is required. As can be seen from the velocity-histogram plotted in Figure 6.12b, a prominent peak at zero velocity occurs. The measuring position for which these data are plotted is relatively close to the cylinder head wall. As a consequence, it is likely that the zero-velocity peak originates from the outer region of the measuring volume where light scatters on that wall. Obviously, such signals contaminate the fluid velocity estimate. Therefore, the peak was excluded from the data set by straightforward deletion all samples in a small band around zero velocity. The resulting data set is plotted in Figure 6.13. From that set, the phase-averaged mean and its RMS value are calculated. Figure 6.13c shows the mean velocity distribution with an RMS band around it. A single velocity sample has a probability of 65%

of being within this band. Deviation from the mean velocity distribution is due to turbulence, cycle-to-cycle variation and statistical measurement error, as was discussed in Section 6.4.

At some of the measuring positions, peculiar spots of high velocity data are observed near TDC piston position. Figure 6.14 gives an example of this phenomenon, which results in additional peaks in the velocity histogram. The fact that these spots only occur near TDC leads to the believe that they originate from reflections on the piston. However, the observed velocities can not be correlated to piston motion. In fact, only velocity components perpendicular to the piston motion are measured with the applied LDV set-up. Although no solid explanation for this phenomenon was found, it is clear that it does not represent a flow property. Therefore, the spots were removed in a similar fashion as the zero velocity samples,

indicated above. The resulting data set is visualised in Figure 6.15. The data presented in Figures 6.14 and 6.15 were taken at a position halfway down the cylinder axis. Consequently, the piston blocks the measuring volume during large periods of the engine cycle, as is nicely illustrated by the raw data distributions.

Since the obtained data rate is too low for a cycle-resolved velocity analysis, the data of many subsequent cycles is used to obtain phase-averaged velocity distributions. The raw data set gives a noisy distribution as a result of velocity fluctuations due to turbulence, cycle-to-cycle variation and measurement error. Some kind of algorithm is required to smoothen the velocity distribution. Here, the data are averaged over a certain crank angle window to obtain the velocity at the crank angle position at the centre of the window. Consequently, high-frequency velocity fluctuations are suppressed and a smoother distribution is obtained. This effect is enhanced with increasing window size. However, the difficulty lies in choosing an appropriate window size, which must be high enough to obtain a smooth distribution, but it must not eliminate velocity fluctuations which represent the physical nature of an average engine cycle. The ultimate choice depends on the locally-achieved data rate, which can vary largely during the engine cycle. Thus, crank angle windows of up to 10 °CA are needed for the presently-acquired data. Alternative methods, such as signal reconstruction from a filtered Fourier transform, or the even more sophisticated Savitzki-Golay method (Press et al., 1992), were seen to perform equally good to the crank-angle averaging for the present data set.

6.6.3 Results and discussion

The acquired velocity data allows for a temporal as well as a spatial analysis of the in-cylinder flow structures. Below, first a temporal-velocity distribution at a single position is analysed. Subsequently, spatial flow structures at specific crank angle positions are studied.

Temporal-velocity distributions

Figure 6.16 again shows the mean velocity distribution at the centre of measurement line II (also see Figure 6.13), which was chosen because it allows both the intake and exhaust flows to be studied. For that purpose, the moments of opening and closing of the intake and exhaust valves are indicated in the figure.

At intake valve opening (IVO), first negative velocities are observed, which indicates a backflow of in-cylinder air into the intake port as a result of a pressure difference. However, as a result of the piston motion, the velocity quickly switches sign and a prominent flow into

Figure 6.16 ∴ Mean velocity distribution with a 1xRMS band acquired at measuring position 27 (centre of line II)

the cylinder volume develops. During the later stages of intake valve opening, again some backflow into the intake port occurs. This is most likely due to the piston having passed BDC (540 °CA) and again moving towards the cylinder head. After inlet valve closure (IVC), again positive velocities were measured, which may indicate the presence of a large-scale tumbling motion induced by the vigorous intake flow. This tumble weakens as the piston starts to approach TDC of compression (720 °CA). Around exhaust valve opening (EVO), the velocity again switches sign indicating a flow from the exhaust port into the cylinder volume. Apparently, the in-cylinder pressure is considerably lower than the exhaust manifold pressure at that moment, which is a result of the volumetric efficiency of the intake system. The inflow condition persists until the exhaust valve approaches its maximum lift. After that, a nearly-constant, positive velocity indicates a flow of air from the cylinder volume into the exhaust system.

Proper care must be taken when the RMS value of the velocity data is to be analysed as an indication of turbulence intensity since it also contains cycle-to-cycle variation and statistical measurement error. A more or less constant RMS value during most parts of the engine cycle is found, which is shown by the width of the band around the mean velocity distribution in Figure 6.16. The increase observed at the peak of the intake flow (around 420 °CA) is likely due to an increase of turbulent fluctuations as a result of the shear at the edges of the intake jet. The increased RMS estimate around 135 °CA, is expected to be due to sampling inaccuracy since a relatively small number of velocity samples was obtained at that position. Moreover, the deletion of the zero-velocity peak, as indicated in Figure 6.13, causes an additional decrease of the number of samples.

Spatial-velocity distributions

Spatial flow structures are studied on the basis of the measurement results along the lines I to IV, as indicated in Figure 6.11. The results are plotted in Figures 6.17 to 6.20 for various crank angle positions during the intake and compression strokes. Along with the LDV results, some conjectures of the in-cylinder flow structures are plotted. For the axial measurement lines I and IV, the position of the piston is also plotted.

The velocity distribution along the cylinder axis, as shown in Figure 6.17 for line I, indicates the existence of a strong intake jet, especially during the mid-stages of the intake stroke (450 °CA). Interaction of this jet with the cylinder wall and the piston face apparently results in a large tumbling motion occupying most of the in-cylinder volume. The generation of a tumbling flow structure and its subsequent dissipation during the compression stroke were also seen from the numerical flow simulations for the axi-symmetric model engine reported in Section 3.3.

However, for that case the tumble is of course quite differently shaped as a result of the axi-symmetry. The tumbling motion in that model engine was dissipated very early in the compression stroke, whereas the tumble observed in the present case persists until at least mid-stages of the compression stroke (630 °CA). Only at the later stages of compression (675 °CA), a clear tumbling motion is no longer observed. In both cases, the break-up of tumble is due to an increase of shear and turbulent dissipation as a result of the compression. The delayed break-up observed for the present case is likely due to the different shape of the combustion chamber. The present pent-roof chamber facilitates the existence of a tumbling structure much longer than the pancake combustion chamber of the model engine.

Figure 6.17 : Measured velocity distributions along measurement line I at 450, 540, 630 and 675 °CA after TDC of compression, arrows indicate conjectured flow structures (IVO: 360 °CA; IVC: 588 °CA)

The velocity distribution along measurement line II gives a cross-section, perpendicular to the cylinder axis, of the flow leaving the valve areas (see Figure 6.18). This measurement line lies 5 mm above the plane intersecting the cylinder head and the cylinder. At small valve opening, the intake flow is not yet observed at this position. Nevertheless, at 405 °CA, a strong central intake jet is observed, which is likely emerging from the small gap in between the two intake valves. The effects of the air leaving the intake ports in a direction more or less parallel to the port axes are not observed at this stage because the measuring position is still located in the wake of the valve. As the valves approach maximum lift height (450 °CA), these effects become apparent. Two direct jets have been added to the central jet. This inflow structure remains intact until the later stages of the intake stroke (495-540 °CA), although its strength is reduced due to the closing of the valves. After closure of the valve, an almost uniform velocity distribution is observed (630 °CA). This is likely caused by the tumbling motion which was observed above from the data taken at measurement line I (see Figure 6.17). At the later stages of the compression stroke (675 °CA), the only significant velocities are found at the centre of the cylinder. It should be noted that all flow structures exhibit a high degree of

Figure 6.18 ∴ Measured velocity distributions along measurement line II at 405, 450, 495, 540, 630 and 680 °CA after TDC of compression, dashed lines and arrows indicate conjectured flow structures (IVO: 360 °CA; IVC: 588 °CA)

symmetry, throughout the intake and compression strokes. The observed plane of flow symmetry approximately coincides with the plane of symmetry of the cylinder head.

The observations may lead to the believe that the two direct jets and the single central jet induce a single tumbling motion, similar to the axi-symmetric model engine studied in Section 3.3, that persists until the later stages of the compression stroke. However, the data

Figure 6.19 ∴ Measured velocity distributions along measurement line III at 450, 540, 585 and 630 °CA after TDC of compression, dashed lines and arrows indicate conjectured flow structures (IVO: 360 °CA; IVC: 588 °CA)

taken at measurement line III, which is half way between the TDC and the BDC piston positions, suggest a much more complex flow structure, as indicated by Figure 6.19. Already at the mid-stages of the intake stroke (450 °CA), steep velocity gradients are observed at this position. The observed flow direction at the centre of the cylinder is opposite to that in the outer regions. This indicates the existence of two counter-rotating swirling motions. These structures persist well into the compression stroke (585 °CA). Again, the flow structures clearly indicate symmetry, similar to the observations made above. At the mid-stages of the compression stroke (630 °CA), the swirling motions have become much less apparent, but that is likely due to the piston having almost reached the measurement line at this stage.

The indication that a single tumbling motion does not exist outside the symmetry plane is confirmed by the velocity distributions found at axial measurement line IV, which is at the centre of one of the presumed swirling motions (see Figure 6.20). Again, a strong intake jet is observed close to the cylinder head, which emerges directly from the intake port. During the second half of the intake stroke (495 °CA), a layered flow with steep gradients is observed

Figure 6.20 : Measured velocity distributions along measurement line IV at 450, 495, 540, 585, 630 and 675 °CA after TDC of compression, arrows indicate conjectured flow structures (IVO: 360 °CA; IVC: 588 °CA)

above the piston face. However, no subsequent tumbling motion is observed. Apparently, tumble only exists at the symmetry plane (Figure 6.17). That tumbling motion is induced by the central intake jet emerging from the gap in between the two valves, as seen in Figure 6.18. The jets that emerge directly from the intake ports apparently induce two counter-rotating swirling motions.

6.7 Conclusions and discussion

A dedicated optically-accessible engine was designed and built for the experimental investigation of unsteady in-cylinder flow structures, as is described in Section 6.1. This engine facilitates back-scattering LDV through a piston-based window. Although presently operated and tested at motored conditions, the engine was designed to also allow for fired operation. Through proper design, it was proven possible to apply oil-lubrication while the generally-encountered problems of window and mirror fouling were largely minimised. The present engine can be operated for several consecutive hours without cleaning. Moreover, engine wear was seen to be minimal. Special positioning systems for the optics enable radial and tangential velocity components to be measured throughout a major part of the combustion chamber. TiO_2 particles, generated as described in Section 4.2.3, were successfully applied as scatterers for the LDV experiments.

Conducting in-cylinder velocity measurements with a back-scattering LDV configuration was proven possible. The flow analyses given in Section 6.6 showed that much insight into the temporal and spatial in-cylinder flow structures can already be gained from a relatively small number of measurements. The observed flow structures are clearly not straightforward. The three-dimensional nature of modern reciprocating engines implies the in-cylinder air motion to be considerably more complex than, for instance, of the axi-symmetric model engine (Section 3.3). Despite the insight gained from the experimental results, more data is needed to draw definite conclusions. Such data may be obtained from additional LDV experiments. Alternatively, multi-dimensional techniques such as PIV may be applied to check whether flow descriptions that are constructed on the basis of the LDV results are correct. However, practicable experiments can not reveal all flow details. Consequently, again a definite need for validated computational methods exists in order to obtain a more complete flow description. The experimental data obtained in the present investigation may already offer a validation means for computational results. Ultimate validation should involve a larger data set for the present and other operating conditions, such as operation at different engine speeds and engine loads. The present investigations proved that such data can be obtained in a quantitative and reliable manner with the test rig and experimental techniques used in this study.

Unfortunately, the observed data rates were too low to allow for the discrimination of the effects of turbulence and of cycle-to-cycle variation. An LDV set-up with scattered light collection in forward or sideward direction is expected to yield much higher data rates. Application of such a configuration puts considerable demands on the design of the engine. However, small windows in the cylinder liner may be feasible and would not only facilitate sideward light-collection, but additionally allow for LDV of axial velocity components. Moreover, it allows for the application of an in-cylinder laser sheet in order to facilitate PIV experiments. Alternatively, preliminary investigations on the feasible data rates with forward-

scattering could be analysed with a set-up involving a window in one of the three spark plug holes of the cylinder head. This practise is recommended as the next step because its realisation is relatively straightforward and it may already yield valuable information. Although such a window would be very small, it is expected to enable forward-scattering LDV along an axial line in the combustion chamber.

7. Concluding discussion

The objective of the present investigation was to contribute to the understanding of in-cylinder fluid motion in modern internal-combustion engines and to present further evidence of the value of sophisticated experimental and computational techniques for engine research and development. Below, the most important conclusions of this study are summarised and recommendations for future investigations are presented. Finally, some closing remarks are put forward.

Conclusions

Numerical simulations of the steady flow in an axi-symmetric rig and the unsteady flow in an axi-symmetric model engine showed that steady-flow analysis can yield valuable insight into the flow structures induced during the early stages of the intake stroke (Section 3.3). Such steady-flow analyses can either be experimental or computational. Successful LDV experiments were conducted on the steady flow in an engine flow rig for a modern four-valve cylinder head at several combinations of valve-lift height and mass-flow rate (Section 5.2). A computational method for the simulation of the three-dimensional steady flows in this engine rig was thoroughly validated with the acquired experimental data (Section 5.4). It was concluded that the computational method produces good predictions of the large-scale in-cylinder fluid motion, despite the associated assumptions, such as isotropic distribution of turbulence. Comparison of the performances of the 'standard' k - ϵ turbulence model and its RNG and CHEN variants led to the conclusion that there exists no apparent reason to abandon the standard model for the simulation of these flow types. It was demonstrated that validated computational methods can be used for enlightening comparative studies of the performance of different intake port designs (Section 5.5).

The flow structures induced during the early stages of the intake stroke are altered during the remaining part of the intake stroke and during the compression stroke. This process is essentially unsteady. For the experimental investigation of such unsteady flows, a production-

type, optically-accessible, single-cylinder, spark-ignition engine was developed which facilitates in-cylinder LDV at motored as well as fired conditions (Sections 6.1 to 6.3). Through optimisation of the oil-lubrication systems and the seeding properties, window fouling was minimised such that reliable experiments can be conducted during several hours of operation without window cleaning. Successful in-cylinder and in-manifold velocity measurements were conducted with a back-scattering LDV set-up (Sections 6.5 and 6.6). It was shown that the data acquired at a limited number of measuring positions can already contribute to the understanding of the complex flow structures occurring in engines. This was demonstrated by the finding that the investigated in-cylinder flow does not exhibit a predominantly tumbling air motion, as might be expected for a symmetrical engine geometry with two directed intake ports and a pent-roof combustion chamber. In fact, a combination of tumble and two counter-rotating swirling motions was observed. Apart from adding to the understanding of in-cylinder flows, the acquired experimental data can be used to validate numerical simulations of these unsteady flows.

In general, the investigation of the steady and unsteady in-cylinder flows has shown that LDV and CFD are powerful tools for modern engine research and development. These techniques can offer insight into the flow that can not be given by less-sophisticated methods.

Recommendations

The present LDV experiments at the motored engine are merely preliminary. A larger data set should be taken at the presently-considered conditions as well as at other conditions, such as different engine speeds and engine loads. Such data would allow for a more elaborate analysis of in-cylinder flow structures. However, the results of the LDV experiments for the engine flow rigs as well as for the motored engine indicated that a high spatial measuring resolution is required to allow for conclusive descriptions of the in-cylinder flow structures. A judicious combination of LDV and a whole-field measuring technique, such as PIV, is considered ideal for this purpose. Therefore, application of PIV to both the flow rig and the real engine is recommended for future studies.

The demand for high spatial resolution, and the effort and cost involved with designing test rigs and conducting reliable experiments, indicate a definite need for numerical simulations. The value and validity of a computational method for the steady flows in engine rigs has been shown in this thesis. The numerical simulation of the unsteady flow in the motored engine, and its experimental validation with the acquired data, could not be completed within the present investigation. It is recommended that this study is finished so that the accuracy of such simulations can be assessed. A validated computational method can help to understand how the complex flow structures, like the ones that were observed from the experimental data, arise and develop during the engine cycle. Furthermore, comparison of numerical

simulations of the steady flow in the rigs and the unsteady flow during the intake stroke of the real engine will allow for a further assessment of the value of steady-flow analysis at realistic engine conditions.

Unfortunately, the data rates attained for the unsteady-flow measurements with the present set-up are too low to allow for the discrimination of the effects of turbulence and cycle-to-cycle variation. Therefore, it is recommended that these effects are studied through application of a forward-scattering LDV set-up, which is expected to yield much higher data rates (Section 6.7).

Closure

The present investigation learns that LDV and CFD of the flow in realistic engine geometries remain the domain of specialists. The costs and time involved to complete such analyses is high. While there remains room for improvement and further validation, engine design through application of these techniques is technically viable today and provides detailed insight into the in-cylinder processes. It is not anticipated that CFD will ever replace experiments, but rather that there will be an evolving blend of CFD and measurements. The computational capability to fully resolve all relevant hydrodynamic length and time scales in the engine, even without combustion and sprays, is not foreseen for the near future. Continued work on modelling of turbulence, on improved computational methodologies, as well as further automation of grid generation techniques for complex flow geometries will allow for improved accuracy and a more efficient application of CFD.

Finally, it is important to bear in mind that experiments of complex physical systems are subject to difficulties analogous to those experienced in computations. Experimental diagnostics, as models, generally are developed and calibrated in simple, controllable configurations. Application of highly sensitive techniques, such as LDV, on complex realistic problems is never straightforward. Thus, in comparing computation and measurement of flows in realistic engine configurations, it is appropriate to view the exercise as one of reconciliation between computation and measurement rather than as one of validation of a computational method.

Appendices

A. Turbulence modelling

Three different k - ε turbulence models were applied in the present investigation: the 'standard' model, and its Renormalisation Group (RNG) and CHEN variants. Below, the essence of k - ε turbulence models is described. Subsequently, the individual model equations and their specific properties are presented.

Constitutive relations for turbulent stresses and heat fluxes

The k - ε modelling assumes that the turbulent Reynolds stresses τ_{ij}^R and the turbulent scalar fluxes are linked to the ensemble-averaged flow properties in an analogous fashion to their laminar counterparts, the viscous stresses τ_{ij} (Launder and Spalding, 1974):

$$\tau_{ij}^R = -\rho \overline{u'_i u'_j} = 2 \mu_t s_{ij} - \frac{2}{3} \left(\mu_t \frac{\partial \bar{u}_k}{\partial x_k} + \rho k \right) \delta_{ij} \quad , \quad (\text{A.1})$$

$$-\rho \overline{u'_j h'} = -\frac{\mu_t}{\sigma_{h,t}} \frac{\partial \bar{h}}{\partial x_j} \quad , \quad (\text{A.2})$$

where the turbulent Prandtl number $\sigma_{h,t}$ is defined as $\mu_t \cdot c_p / k_t$, with k_t being the turbulent thermal conductivity coefficient. The turbulent kinetic energy k is defined as

$$k \equiv \frac{\overline{u'_i u'_i}}{2} \quad . \quad (\text{A.3})$$

The last term in equation A.1 is introduced to ensure consistency with equation A.3 for $i=j$, since τ_{ii}^R is equal to minus twice the turbulent kinetic energy per unit volume ρk (Hirsch, 1988b).

The quantity μ_t represents the so-called *turbulent viscosity*. The turbulent Reynolds stresses and turbulent heat fluxes are modelled by gradient-diffusion expressions. Hence, they are described as additional diffusion transport processes, with μ_t being the turbulent diffusion coefficient. The idea of turbulent viscosity is based on the notion of the momentum transfer in a turbulent flow being dominated by the mixing caused by the large energy-containing turbulent eddies. The first ideas along these lines seem to have been proposed by Boussinesq (1877). Therefore, this approach is known as the *Boussinesq hypothesis*. The turbulent viscosity μ_t is linked to k and ε by assuming proportionality to the product of a characteristic velocity fluctuation and length scale of the energy containing motions. These scales are defined as $U \equiv k^{1/2}$ and $L \equiv k^{3/2}/\varepsilon$, respectively. Hence, the turbulent viscosity is given by

$$\mu_t = \frac{C_\mu \rho k^2}{\varepsilon} \quad , \quad (\text{A.4})$$

where C_μ is an empirical model coefficient. This is an isotropic entity, which implies that all modelling based on the constitutive relations of equations A.1 and A.2 can not describe anisotropy of turbulence.

The turbulent energy dissipation rate ε is modelled as (Launder and Spalding, 1974; Nieuwstadt, 1992; Yakhot et al., 1992):

$$\varepsilon = \frac{\mu}{\rho} \overline{\left(\frac{\partial u'_i}{\partial x_j} \right)^2} \quad . \quad (\text{A.5})$$

Standard k- ε model equations

The 'standard' k - ε model (Launder and Spalding, 1974) is used in this study in a high Reynolds number form and in conjunction with algebraic 'law-of-the-wall' representations of flow properties within boundary layers, as is discussed in Appendix B. Basically, the derivation of transport equations for turbulence energy k and turbulence dissipation rate ε is based on the Navier-Stokes equation for the velocity fluctuations u'_i . These equations are obtained by subtracting the Reynolds-averaged Navier-Stokes equations from the full Navier-Stokes equations. The transport equations for k and ε can then be found by application of equations A.3 and A.5.

Table A.1 : Empirical coefficients applied for the standard k - ε turbulence model

The equation that is applied for compressible flows in the present investigations is given by El Tahry (1983):

$$\underbrace{\frac{\partial}{\partial t}(\bar{\rho} k)}_{T_1} + \underbrace{\frac{\partial}{\partial x_j} \left(\rho \bar{u}_j k - \frac{\mu_{eff}}{\sigma_k} \frac{\partial k}{\partial x_j} \right)}_{T_2-T_3} = \underbrace{\frac{\mu_r P}{T_4}} - \underbrace{\bar{\rho} \varepsilon}_{T_5} - \underbrace{\frac{2}{3} \left(\mu_r \frac{\partial \bar{u}_i}{\partial x_i} + \bar{\rho} k \right) \frac{\partial \bar{u}_i}{\partial x_i}}_{T_6}, \quad (A.6)$$

where the turbulence production P is defined as

$$P \equiv 2 s_{ij} \frac{\partial \bar{u}_i}{\partial x_j}, \quad (A.7)$$

while σ_k is an empirical coefficient. The effective viscosity μ_{eff} is defined as

$$\mu_{eff} \equiv \mu + \mu_t. \quad (A.8)$$

For high Reynolds numbers, this effective viscosity is dominated by the turbulent viscosity μ_t , given by equation A.4. Transport of the turbulence dissipation rate ε follows from:

$$\underbrace{\frac{\partial}{\partial t}(\bar{\rho} \varepsilon)}_{T_1} + \underbrace{\frac{\partial}{\partial x_j} \left(\rho \bar{u}_j \varepsilon - \frac{\mu_{eff}}{\sigma_\varepsilon} \frac{\partial \varepsilon}{\partial x_j} \right)}_{T_2-T_3} = \underbrace{C_{\varepsilon 1} \frac{\varepsilon}{k} \left[\mu_t P - \frac{2}{3} \left(\mu_t \frac{\partial \bar{u}_i}{\partial x_i} + \rho k \right) \frac{\partial \bar{u}_i}{\partial x_i} \right]}_{T_4} - \underbrace{C_{\varepsilon 2} \rho \frac{\varepsilon^2}{k}}_{T_5} - \underbrace{C_{\varepsilon 4} \rho \frac{\partial \bar{u}_i}{\partial x_i}}_{T_6}, \quad (A.9)$$

where σ_ε , $C_{\varepsilon 1}$, $C_{\varepsilon 2}$ and $C_{\varepsilon 4}$ are empirical coefficients whose values are given in Table A.1, along with C_μ and σ_k .

The first term T_1 of both the equations A.6 and A.9 represents the rate of change of k or ε . Terms T_2 and T_3 account for transport of k or ε by convection and diffusion, respectively. The first term on the right-hand side of both equations, T_4 , gives the production rate of k or ε by shear and normal stresses, which is fed by macroscale destruction of the mean flow kinetic

energy. The negative-signed term T_5 represents the destruction rate of k or ε through microscale viscous dissipation. Production and destruction of turbulent kinetic energy k are always closely linked. The dissipation rate ε is large where production of k is large. The model equation for ε assumes that its production and destruction terms are proportional to those of the k -equation. Adoption of such forms ensures that ε increases rapidly when k increases rapidly and that it decreases sufficiently fast to avoid non-physical negative values of turbulent kinetic energy if k decreases (Versteeg and Malalasekera, 1995). The factor ε/k , which represents the inverse of the *dissipation time scale*, renders the production and destruction terms dimensionally correct in the ε -equation. The final term, T_6 , describes amplification or attenuation due to compressibility effects.

RNG k - ε model equations

The RNG turbulence model is based on the work of Yakhot and Orszag (1986) and Yakhot et. al. (1993). The procedure is as follows: first, a narrow band of the smallest energy containing eddies is removed by expressing their effects in terms of larger scale motions and an increased effective viscosity. As a result, the effective Reynolds number of the system decreases. This process is repeated in an iterative manner, so that more and more scales of motion are removed from the dynamics to a point where the remaining scales are all resolvable. The removal of only the smallest scales gives rise to so-called *subgrid-scale* models, in a similar fashion to LES. In the limit, as successively-larger scales are removed, a model equivalent to the standard k - ε model is recovered.

Through the scale-elimination procedure, RNG theory develops an equation for the variation of the effective viscosity μ_{eff} with the eddy length scale l . Thus, a formula is obtained with which $\mu_{eff}(l)$ is interpolated between the molecular viscosity μ for the Kolmogorov microscale $l = \eta$ and the high-Reynolds-number limit of $l = L \gg \eta$. The detailed mathematics of the RNG k - ε model is highly abstruse. Here, only the resulting model equations are quoted. The RNG transport equation of turbulence energy is equal to that of the standard k - ε model as given by equation A.6. Transport of turbulence dissipation rate is as follows:

$$\underbrace{\frac{\partial}{\partial t}(\bar{\rho}\varepsilon)}_{T_1} + \underbrace{\frac{\partial}{\partial x_j} \left(\bar{\rho} u_j \varepsilon - \frac{\mu_{eff}}{\sigma_\varepsilon} \frac{\partial \varepsilon}{\partial x_j} \right)}_{T_2-T_3} = \underbrace{C_{\varepsilon 1} \frac{\varepsilon}{k} \left[\mu_t P - \frac{2}{3} \left(\mu_t \frac{\partial \bar{u}_i}{\partial x_i} + \bar{\rho} k \right) \frac{\partial \bar{u}_i}{\partial x_i} \right]}_{T_4} \quad (A.10)$$

$$- \underbrace{C_{\varepsilon 2} \bar{\rho} \frac{\varepsilon^2}{k}}_{T_5} - \underbrace{C_{\varepsilon 4} \bar{\rho} \frac{\partial \bar{u}_i}{\partial x_i}}_{T_6} - \underbrace{\frac{C_\mu \eta^3 (1 - \eta/\eta_0)}{1 + \beta \eta^3} \bar{\rho} \frac{\varepsilon^2}{k}}_{T_7} ,$$

Table A.2 : Empirical coefficients applied in the RNG k - ε turbulence model

where η_0 and β are empirical model constants given in Table A.2. The non-dimensional strain rate η is defined as

$$\eta \equiv S \frac{k}{\varepsilon} \quad , \quad (\text{A.11})$$

$$S \equiv \sqrt{2 s_{ij} s_{ij}} \quad . \quad (\text{A.12})$$

Apart from the values of the model constants, which are also given in Table A.2, terms T_1 to T_6 in equation A.10 are identical to those of the ε -equation of the standard model. Notable about the RNG derivation is that the values of the constants are calculated explicitly, whereas the constants of the standard model have an empirical nature.

The additional last term in the dissipation rate equation, compared to the standard k - ε model, represents the effect of mean flow distortion on ε (Rodi, 1979) and, in the form written in equation A.10, it may be interpreted as an addition to term T_5 . Indeed, in regions of small strain rate η , this term tends to increase the destruction rate of ε . Nevertheless, μ_{eff} is still typically smaller than its value in the standard theory due to the lower value of $C_{\varepsilon 2}$. In regions of large strain rate, the sign of term T_7 is changed and its effect is one of increased production rate of ε , which becomes more apparent when it is rewritten in a similar fashion to production term T_4 :

$$T_7 = \frac{\eta(1-\eta/\eta_0)}{1+\beta\eta^3} \frac{\varepsilon}{k} \mu_i P \quad . \quad (\text{A.13})$$

As a consequence, the effective viscosity μ_{eff} , as given by equation A.4, is decreased even more. This feature of the RNG model may allow for an improved prediction of flow separation and recirculation, which are prominent phenomena occurring in in-cylinder engine flows. The model, as originally proposed, does not take explicit account of compressibility effects. However, in the presently-applied modelling these effects are modelled as in the standard k - ε model.

Table A.3 :: Empirical coefficients applied in the CHEN k - ε turbulence model

CHEN's k - ε model equations

The so-called CHEN k - ε model is based on the work of Chen and Kim (1987). The dissipation time scale, k/ε , is the only turbulence time scale used in closing the ε -equation of the standard k - ε model. In Chen's model, the *production range time scale*, $\rho P/\mu_t k$, as well as the dissipation time scale, are used in closing the ε -equation. This additional time scale should allow the transfer mechanism of turbulence energy to respond to the mean strain rate more effectively. This has resulted in an additional term, T_7 , in the ε equation:

$$\underbrace{\frac{\partial}{\partial t}(\bar{\rho}\varepsilon)}_{T_1} + \underbrace{\frac{\partial}{\partial x_j} \left(\bar{\rho} \bar{u}_j \varepsilon - \frac{\mu_{\text{eff}}}{\sigma_\varepsilon} \frac{\partial \varepsilon}{\partial x_j} \right)}_{T_2-T_3} = \underbrace{C_{\varepsilon 1} \frac{\varepsilon}{k} \left[\mu_t P - \frac{2}{3} \left(\mu_t \frac{\partial \bar{u}_i}{\partial x_i} + \bar{\rho} k \right) \frac{\partial \bar{u}_i}{\partial x_i} \right]}_{T_4} - \underbrace{C_{\varepsilon 2} \bar{\rho} \frac{\varepsilon^2}{k}}_{T_5} - \underbrace{C_{\varepsilon 4} \bar{\rho} \frac{\partial \bar{u}_i}{\partial x_i}}_{T_6} + \underbrace{C_{\varepsilon 5} \frac{\mu_t^2 P^2}{\bar{\rho} k}}_{T_7}, \quad (\text{A.14})$$

where $C_{\varepsilon 5}$ is an additional empirical coefficient, which is given in Table A.3 along with the other model constants. Again, compressibility effects are modelled as in the standard k - ε model.

Terms 1 to 6 are again similar to the corresponding terms in the standard model equations. The net effect of term T_7 is to enhance turbulent energy dissipation when the turbulence production rate is large. This expression represents the energy transfer rate from large-scale turbulence to small-scale turbulence controlled by both the dissipation rate time scale and the production range time scale, as becomes more obvious when it is again written in a similar fashion to term T_4 :

$$T_7 = C_{\varepsilon 5} \frac{\mu_t P}{\rho k} \mu_t P \quad (\text{A.15})$$

B. Modelling of near-wall region

For the discussion of the flow model in the near-wall region, first, non-dimensional quantities that characterise flow properties within the boundary layer are introduced. The non-dimensional distance normal to the wall, y^+ , is defined as

$$y^+ = \frac{\rho u_\tau}{\mu} y \quad , \quad (\text{B.1})$$

where y is the normal distance to the wall. The so-called *friction velocity* u_τ is given by

$$u_\tau = \sqrt{\frac{\tau_w}{\rho}} \quad . \quad (\text{B.2})$$

The wall shear stress τ_w can be written as

$$\tau_w = \mu_t \left. \frac{\partial u}{\partial y} \right|_{y=0} \quad , \quad (\text{B.3})$$

where μ_t is the turbulent viscosity as given in equation A.4. Under the assumption of one-dimensional equilibrium flow in the boundary layer, the local turbulence production rate is balanced by the local dissipation rate. Hence, terms T_4 and T_5 of the k -equation A.6 are equal. Moreover, only a single non-zero shear stress τ_{ij} exists, which is approximately constant throughout the boundary layer and, therefore, equal to the wall shear stress τ_w . It can be shown that the turbulence kinetic energy k , in its non-dimensional form, is then given by

$$k^+ = C_\mu^{-1/2} \quad , \quad \text{where } k^+ \equiv \frac{k \rho}{\tau_w} \quad . \quad (\text{B.4})$$

When substituting these expressions into equation B.1, the non-dimensional distance to the wall can be rewritten as

$$y^+ = \frac{\rho C_\mu^{1/4} \sqrt{k} y}{\mu} \quad (\text{B.5})$$

In accordance with equation B.1, the non-dimensional velocity u^+ and temperature T^+ are defined as

$$u^+ = \frac{(u - u_w)}{u_\tau} \quad , \quad \text{and} \quad (\text{B.6})$$

$$T^+ = \frac{\rho(T - T_w)u_\tau c_p}{F_{T,w}} \quad , \quad (\text{B.7})$$

where u is the tangential fluid velocity, u_w is the wall velocity, which allows for the representation of moving walls, T_w is the wall temperature and $F_{T,w}$ is the wall heat flux.

In the present investigation, so-called *wall-function modelling* is applied, which prescribes the velocity and temperature distributions in the near-wall region. The expressions giving the velocity distributions in terms of the normal distance y^+ , commonly known as the *law of the wall*, are given by (Launder and Spalding, 1974):

$$u^+ = \begin{cases} y^+ & , \quad y^+ \leq y_m^+ \\ \frac{1}{\kappa} \ln(E y^+) & , \quad y^+ > y_m^+ \end{cases} \quad (\text{B.8})$$

A value of 9.0 was assigned to the profile shape factor E , whereas the 'von Kármán' coefficient κ is 0.42, 0.4 and 0.415 for the standard k - ϵ model and the RNG and CHEN variants, respectively. In the wall-function approach, the buffer layer (Schlichting, 1979) is usually not taken into account. The value of y_m^+ is defined as that distance from the wall at which the linear velocity profile of the laminar sublayer ($\mu_t \ll \mu$) meets the logarithmic profile of the fully turbulent inertial sublayer ($\mu_t \gg \mu$). Hence, it must satisfy the equation:

$$y_m^+ - \frac{1}{\kappa} \ln(E y_m^+) = 0 \quad (\text{B.9})$$

Temperature distributions in boundary layers are given by:

$$T^+ = \begin{cases} \sigma_{T,t} y^+ & , \quad y^+ \leq y_m^+ \\ \sigma_{T,t} \left(u^+ + P \left(\frac{\sigma_T}{\sigma_{T,t}} \right) \right) & , \quad y^+ > y_m^+ \end{cases} \quad (\text{B.10})$$

where u^+ is given by equation B.8, $\sigma_T (= \mu c_p / \Gamma_T$; Γ_T is the thermal conductivity) is the molecular Prandtl number and $\sigma_{T,t}$ is the turbulent Prandtl number. Finally, P is a non-dimensional sub-layer resistance factor dependent on the ratio of the molecular and the turbulent Prandtl numbers given, for impermeable, smooth walls, by Jayatilaka (1969).

C. Basic principles of Laser-Doppler Velocimetry

The experiments presented in Chapters 5 and 6 involve laser-Doppler velocimetry (LDV). The specific application of this measuring technique to engines is addressed in Chapter 4. In this appendix, its basic principles are described. First the mere essence of LDV is discussed: the Doppler effect. Subsequently, the dual-beam method, the so-called *fringe model*, which is helpful for understanding LDV, and signal characteristics are briefly explained. Finally, a method to prevent directional ambiguity is described.

Doppler effect

As the name indicates, the basic physical principle involved in LDV is the Doppler effect. In LDV the change of frequency of an incident laser beam is caused by the movement of small particles scattering the light. A laser is used as the light source because it generates coherent, monochromatic light waves. Furthermore, a laser can provide a light beam so intense that even micron-sized particles scatter measurable amounts of radiation. Figure C.1 shows a particle, moving at velocity \vec{v} , which is illuminated by a laser beam of frequency f_i and wavelength λ directed along unit vector \vec{e}_i . A detector, located in the direction of unit vector \vec{e}_s , will receive scattered light of frequency f_s which, as a result of the Doppler effect, differs from that of the incident beam. This frequency difference is firstly caused by the particle having a velocity component in the direction of the beam causing it to receive the wavefronts at a faster or slower rate than f_i . Secondly, the particle has a velocity component relative to the detector which causes either compression or stretching of the wavefronts as the particle scatters the wave in the direction of the detector. The frequency of the scattered radiation received by the detector can be written as

$$f_s = \frac{c}{\lambda} \frac{(c - \vec{v} \cdot \vec{e}_i)}{(c - \vec{v} \cdot \vec{e}_s)} \quad (C.1)$$

Figure C.1 : Operating principle of LDV: a particle moving at velocity \vec{v} , illuminated by a laser beam with frequency f_i .

Since the particle velocity $|\vec{v}|$ is usually much smaller than the speed of light ($|\vec{v}| \ll c$), the Doppler shift f_D , which is defined as the difference between the frequency of the scattered radiation and that of the incident radiation, can be approximated by

$$f_D = f_s - f_i \approx \frac{\vec{v} \cdot (\vec{e}_s - \vec{e}_i)}{\lambda} \quad (C.2)$$

Expression C.2 indicates that the Doppler shift depends linearly on the velocity of the scattering particle, which is one of the favourable features of LDV. The Doppler shift is furthermore determined by the scattering geometry, i.e. by the angle between the wave source and the detector. The geometric layout is defined by the angles ϕ and α , which denote the scattering angle and the angle between the velocity vector and the vector $(\vec{e}_s - \vec{e}_i)$, as indicated in Figure C.1. The Doppler shift can also be written as

$$f_D \approx \frac{2|\vec{v}|}{\lambda} \sin\left(\frac{1}{2}\phi\right) \cos(\alpha) \quad (C.3)$$

From this relationship it is evident that the velocity component $|\vec{v}|\cos(\alpha)$ can be obtained if the Doppler frequency is known.

Dual-beam method

Unfortunately, the direct measurement of the frequency shift poses a problem. The wavelength of most visible light is of the order of 500 nm. With the speed of light being $3 \cdot 10^8$ m/s, this yields a light frequency f_i of $6 \cdot 10^{14}$ Hz. From equation C.3 it can be seen that the Doppler shift is only of the order of 10^6 - 10^8 Hz at typical in-cylinder gas velocities, i.e. below 100 m/s. Since the scattered light has a frequency that is shifted relative to the frequency f_i of the incident laser light, a detector with resolution better than 10^{-8} is needed to

Figure C.2 :: Operating principle of an LDV: the dual-beam method

measure the Doppler shift with some accuracy. No such high resolution detection systems are available.

In most practical LDV systems for engine flow measurements, the problem of limited detection resolution is overcome by using an optical heterodyne detection technique, which means that two light waves having slightly different frequencies f_1 and f_2 are mixed on a *square-law detector*. After passing through a low-pass filter, the output signal of such a detector oscillates with the frequency difference ($f_1 - f_2$).

In a dual-beam velocimeter, light of two laser beams of the same wavelength is scattered by a particle moving through their crossing region and subsequently mixed on a photodetector. Its principle of operation is illustrated in Figure C.2. Both scattered beams are Doppler shifted and have slightly different frequencies f_{s1} and f_{s2} . Due to its limited resolution, the photodetector operates as a low pass filter and will, hence, only respond to the frequency difference. This difference is used to determine the local fluid velocity component. From equation C.3 it can be derived that the Doppler frequency for this system can be written as

$$f_D = f_{s1} - f_{s2} = \frac{\vec{v} \cdot (\vec{e}_{i2} - \vec{e}_{i1})}{\lambda} = V_x \frac{2 \sin(\frac{1}{2}\theta)}{\lambda}, \quad (\text{C.4})$$

where θ denotes the crossing angle of the beams and V_x is the velocity component lying in the plane of the crossing beams, perpendicular to their bisector. A great advantage of the dual-beam method is that the Doppler shift is independent of the scattering direction. Consequently, the Doppler shift does not vary across the surface of the photodetector and is independent of the detector's location. Hence, the angular aperture of the collecting optics can be as large as desired to ensure much scattered radiation to be collected, providing strong and high signal-to-noise ratio signals.

Figure C.3 :: Fringe model: a) superposition of two laser beams yields a pattern of interference fringes, b) the measuring volume is ellipsoidal (Courtesy of TSI)

Fringe model

The principle of operation of dual-beam LDV can also be explained in terms of the *interference fringe model*, as proposed by Rudd (1969). This model provides an easily visualised picture as well as a basis for both qualitative and quantitative analyses of a number of features of laser-Doppler signals. However, the fringe model should be used with proper care, because it is a simplification of reality.

Two coherent light beams having plane wave fronts, as would be present in the waist region of two Gaussian beams, intersect at an angle θ . This yields a pattern of plane interference fringes, when observing the intersection area with a square-law detector, as indicated in Figure C.3a. The distance between the intensity maxima is called the *fringe spacing* d_f and is proportional to the wavelength of the light and inversely proportional to the half-angle between the two beams,

$$d_f = \frac{\lambda}{2 \sin(\frac{1}{2}\theta)} \quad (C.5)$$

A particle that passes through such a fringe pattern will scatter laser light of varying intensity. These light intensity variations are detected by a photomultiplier. The frequency of the resulting signal is proportional to the perpendicular component of the particle velocity V_x and inversely proportional to the fringe spacing. It can be shown that this frequency is exactly that determined from the analysis based on Doppler considerations. From equations C.4 and C.5 it is derived that

$$f_{crossing} = \frac{V_x}{d_f} = V_x \frac{2 \sin(\frac{1}{2}\theta)}{\lambda} \approx f_D \quad (C.6)$$

When the fringe model is combined with the Gaussian behaviour of the interfering beams, a more complete picture of the LDV system is obtained. The effective probe volume is ellipsoidal in shape, using $1/e^2$ of the peak intensity to define its boundaries. Thus, the probe volume for dual-beam systems can be visualised as a set of parallel fringe planes occupying an ellipsoidal volume at the beam intersection point, as indicated in Figure C.3b. The effective probe volume is usually referred to as the *measuring volume*.

The fringe model assumes plane wavefronts throughout the measuring volume. This is correct by good approximation when both beams cross at their waists. Before or after the beam waists, wavefronts are spherical. The effects of improper alignment of the beams can be readily visualised by the fringe model, because in that case spherical rather than plane wavefronts interfere. The resulting fringe surfaces are distorted and are no longer parallel planes. Particles with the same velocity, but passing through different parts of the probe volume, will consequently produce different Doppler frequencies (Durst, 1976).

The particle velocity can be calculated with equation C.6 from the measured Doppler frequency if the fringe spacing d_f is known. The accuracy of the calculated velocity is directly related to the accuracy with which d_f is determined. Several methods for the determination exist and are evaluated by Absil (1995). In the present study, the fringe spacing is determined indirectly from the measurement of the beam intersection angle θ . This is done by projection of the beams on a screen at a large distance behind the measuring volume and determination of the coordinates of the beam spots. The applied method is described in more detail by Theunissen (1994). The accuracy of the thus determined fringe spacing was found to be 1.7%, which is acceptable for the present investigation.

Signal characteristics

Figure C.4 shows a typical Doppler burst. This signal is prone to bias errors and noise contributions, as is seen in Section 4.5. The strength and quality of the signal are defined by the *pedestal height* e_p and the *envelope* or *Doppler height* e_E , as indicated in the figure. The ratio of the envelope height to the pedestal height is called the *visibility* or *modulation depth* of the signal and is defined as:

$$\bar{V} = \frac{e_E}{e_p} = \frac{e_{\max} - e_{\min}}{e_{\max} + e_{\min}} \quad (C.7)$$

Figure C.4 :: Typical Doppler burst

where e_{max} and e_{min} are defined according to Figure C.4. The visibility is a complex function of particle size, particle refractive index and the optical parameters of the LDV system, and can be approximated from Mie's theory (see section 4.2.1). In terms of the fringe model, large visibility implies completely 'dark' fringes, because then the pedestal height is low. Clearly, the Doppler burst of Figure C.4 does not exhibit maximum visibility, since e_{min} is non-zero. This may for instance be caused by unequal intensity of the two laser beams, but also particles that are too large will cause the visibility to decrease. Fringe contrast and the intensity distribution profile across the fringe pattern are found to be the most important parameters for judging the capability and applicability of a laser-Doppler velocimeter (Wigley, 1987). Finally, the *signal-to-noise ratio* of dual-beam LDV systems is defined as the ratio of signal power to noise power.

Directional ambiguity

From the properties of heterodyning, it follows that the Doppler shift recorded by the detector depends on the magnitude of the scattering particle velocity, but not on its direction, as can be seen from equation C.4. A measured Doppler frequency may be generated by a particle moving in forward direction at velocity $+V$, or by a particle moving in reverse direction, i.e. at velocity $-V$. Hence, conventional LDV suffers from directional ambiguity.

The introduction of a *frequency shifter* can overcome this sign ambiguity problem. The principle of this technique is to apply a constant frequency shift f_{shift} to one of the incident beams. Consequently, the fringe pattern will appear to move at a constant velocity, which is proportional to f_{shift} . The resulting frequency difference is then given by:

$$f_D = f_{s1} - f_{s2} \approx f_{shift} + \frac{\vec{v} \cdot (\vec{e}_{i2} - \vec{e}_{i1})}{\lambda} \quad (C.8)$$

Hence, the frequency shift provides a fixed off-set of the linear frequency versus velocity relationship. A zero velocity no longer corresponds to a zero Doppler frequency, but yields a frequency equal to f_{shift} . Negative velocities will generate frequencies below f_{shift} and positive velocities result in frequencies higher than f_{shift} . Consequently, the ambiguity is removed since Doppler frequencies can now be related uniquely to one specific velocity. Furthermore, a stationary particle will now yield a measurable signal.

D. Measuring positions of motored-engine experiments

The in-cylinder measurements conducted in the motored engine, as presented in Chapter 6, are located on four individual lines. The exact coordinates of the measuring positions are given in the Table D.1 below.

Summary

In this thesis, a study of in-cylinder fluid motion in modern internal-combustion engines through experiments as well as computations is described. The objective of the investigation was to contribute to the understanding of such complex flows and to present further evidence of the value of sophisticated experimental and computational techniques for engine research and development.

The employed mathematical flow modelling consists of a set of Reynolds-Averaged Navier-Stokes equations complemented with transport equations for the turbulence parameters k and ϵ . The equations are numerically solved using a finite-volume method within the commercial STAR-CD package. Engine flows are very complex since they exhibit many different flow phenomena and are three-dimensional, highly turbulent and time-dependent. Because of that complexity, the accuracy and applicability of the computational method was first assessed for simplified flow cases exhibiting flow phenomena that are typical for real engines. The study includes the flow over a backward-facing step, the steady flow through an axi-symmetric engine flow rig and the unsteady flow in an axi-symmetric model engine. Comparison with experimental data, obtained from literature, demonstrated that the main flow structures are captured by the computational method. The numerical simulations of the steady and the unsteady flow in the axi-symmetric engine configurations showed that steady-flow analysis can yield valuable insight into the flow structures induced during the early stages of the intake stroke.

Therefore, the flow structures occurring at realistic engine conditions during the intake stroke have been studied by means of an experimental and computational assessment of the steady flow in several engine flow rig configurations. Successful in-cylinder and in-manifold LDV (laser-Doppler velocimetry) experiments were conducted for a production-type cylinder head. An off-axis forward-scattering LDV set-up was applied to acquire an extensive data set of axial and tangential velocity components at several combinations of valve-lift height and mass-flow rate. Additionally, these three-dimensional steady flows were numerically

simulated and the simulation results were thoroughly validated with the acquired experimental data. The computational method was found to produce good predictions of the large-scale in-cylinder fluid motion, despite the associated assumptions, such as isotropic distribution of turbulence. Comparison of the performances of the standard $k-\epsilon$ turbulence model and its RNG and CHEN variants led to the conclusion that there exists no apparent reason to prefer the latter models over the standard model for the simulation of these flow types. It was demonstrated that the validated computational method can be used for enlightening comparative studies of the performance of different intake port designs. Moreover, it was shown that global measures, like the swirl number, give very limited and sometimes deceiving information about the in-cylinder air motion.

For the experimental investigation of realistic unsteady in-cylinder flows during the intake and compression strokes, a production-type, optically-accessible, single-cylinder, four-valve, spark-ignition engine was developed. Through optimisation of the oil-lubrication systems and the seeding properties, window contamination was minimised such that reliable LDV experiments can be conducted during several hours of operation without window cleaning. TiO_2 particles were used as scatterers and a method was developed to prevent the particles from forming agglomerates. The engine was placed in a dedicated test rig which allows for air and engine conditioning. Successful in-cylinder and in-manifold velocity measurements were conducted at motored conditions with a back-scattering LDV set-up. It was shown that the data acquired at a limited number of measuring positions can already contribute to the understanding of the complex flow structures occurring in engines. In-cylinder flow structures were shown to be far from straightforward. For example, instead of a predominantly tumbling in-cylinder air motion, which may be expected for the investigated configuration, a complex combination of tumble and two counter-rotating swirling motions was observed.

In general, the investigation of the steady and unsteady in-cylinder flows has proven that LDV and CFD are powerful tools for modern engine research and development. These techniques can offer insight into the flow that can not be given by less sophisticated methods. However, application of these techniques is time-consuming and costly, and demands specialised knowledge.

Samenvatting

Dit proefschrift beschrijft een onderzoek naar de luchtbeweging in de cilinderruimte van moderne verbrandingsmotoren. De doelstelling van het onderzoek was het begrip van dergelijke complexe stromingen te vergroten en de waarde van diepgaande experimentele en numerieke technieken voor onderzoek en ontwikkeling van motoren aan te tonen.

De toegepaste mathematische stromingsmodellering bestaat uit een set Reynolds-gemiddelde Navier-Stokes-vergelijkingen, aangevuld met transportvergelijkingen voor de turbulentieparameters k en ϵ . De vergelijkingen worden numeriek opgelost met een eindige volume methode, zoals geïmplementeerd in het commerciële simulatiepakket STAR-CD. Stromingen in motoren zijn zeer complex omdat een verscheidenheid aan stromingsfenomenen optreedt, die bovendien essentieel drie-dimensionaal, hoog turbulent en tijdsafhankelijk zijn. Vanwege deze complexiteit zijn eerst de nauwkeurigheid en de toepasbaarheid van de berekeningsmethode onderzocht aan de hand van een aantal vereenvoudigde voorbeelden van stromingsfenomenen die typisch zijn voor motoren. Dit vooronderzoek omvatte de stroming tussen twee platen met een stapvormige verbreding, de stationaire stroming in een doorgeblazen axi-symmetrische motorconfiguratie en de instationaire stroming in een axi-symmetrische modelmotor. Vergelijking met uit literatuur verkregen experimentele gegevens heeft aangetoond dat de belangrijkste stromingsfenomenen kunnen worden voorspeld met de berekeningsmethode. De numerieke simulaties van de stationaire en instationaire stromingen in de axi-symmetrische motorconfiguraties zijn met elkaar vergeleken. Hieruit bleek dat de analyse van stationaire stromingen waardevolle inzichten kan verschaffen in de stromingsfenomenen welke ontstaan gedurende de beginperiode van de inlaatslag van een motor.

Dergelijke stromingsfenomenen zijn bestudeerd voor realistische motorcondities door middel van experimentele analyses en numerieke simulaties. Hierbij werd een stationair luchtdebiet door het inlaatkanaal van een moderne cilinderkop in een cilinder met open einde geblazen. Succesvolle LDA (laser-Doppler Anemometrie) experimenten zijn uitgevoerd in de cilinder-ruimte en in het inlaatkanaal. Axiale en tangentiële snelheidscomponenten zijn gemeten op

een groot aantal posities voor diverse configuraties, waarbij de massastroom van de lucht en de lighthoogte van de inlaatklep werden gevarieerd. Numerieke simulaties van deze drie-dimensionale stationaire stromingen zijn uitgevoerd en de resultaten zijn gevalideerd aan de hand van de experimentele resultaten. Ondanks de soms grove aannamen, zoals isotropie van turbulentie, is de berekeningsmethode in staat goede voorspellingen van de grootschalige luchtbewegingen in de cilinder te produceren. Uit een vergelijking van het standaard $k-\epsilon$ turbulentiemodel met de RNG en CHEN varianten is gebleken dat voor de simulatie van dit soort stromingen geen reden bestaat om de laatstgenoemde modellen te verkiezen boven het standaard model. Tenslotte is aangetoond dat de gevalideerde berekeningsmethode kan worden gebruikt voor de vergelijking van de stromingseigenschappen van verschillende ontwerpen van een inlaatpoort. Hieruit bleek ondermeer dat globale maten, zoals het swirlgetal, een zeer beperkt en soms misleidend beeld geven van de werkelijke stromingen in de verbrandingsruimte.

Voor de experimentele analyse van realistische, instationaire stromingen in de verbrandingsruimte gedurende de inlaat- en de compressieslag is een moderne, optisch-toegankelijke, vier-kleps, één-cilinder Ottomotor ontwikkeld. Door optimalisatie van het oliesmeringssysteem en van de seedingeigenschappen kon de vervuiling van de vensters tot een minimum worden beperkt. Betrouwbare LDA experimenten kunnen gedurende meerdere uren zonder reiniging van de vensters worden uitgevoerd. Als seeding worden voornamelijk TiO_2 deeltjes gebruikt. Veel aandacht is besteed aan de kwaliteit van deze deeltjes. De motor is opgenomen in een speciale proefopstelling waarin de lucht en de motor kunnen worden geconditioneerd. Snelheidsmetingen zijn uitgevoerd in de cilinderruimte en in een inlaatkanaal. Hierbij werd een zogenaamde 'back-scattering' LDA-opstelling toegepast. De motor werd tijdens deze experimenten gesleept. Aan de hand van de experimentele resultaten is aangetoond dat snelheidsmetingen op een beperkt aantal meetposities al kunnen bijdragen tot een beter begrip van de complexe stromingsfenomenen in motoren. Interessante stromingsfenomenen zijn waargenomen welke verre van vanzelfsprekend bleken te zijn. Zo is bijvoorbeeld een complexe combinatie van een tumble-structuur en twee swirl-structuren waargenomen in plaats van een te verwachten enkelvoudige tumble-beweging in de gehele verbrandingsruimte.

Algemeen kan worden geconcludeerd dat door middel van de analyses van de stationaire en instationaire stromingen is aangetoond dat LDA en CFD krachtige gereedschappen zijn voor hedendaags onderzoek en ontwikkeling van verbrandingsmotoren. Deze technieken bieden inzichten in de stromingseigenschappen welke niet kunnen worden verkregen met minder gedetailleerde methoden. Toepassing van deze technieken is echter tijdrovend en kostbaar. Bovendien vraagt het specialistische kennis.

Nawoord

Zo..... het is zover, voor jullie ligt mijn proefschrift! Hoewel, proefschrift? Waarom heet het eigenlijk een *proefschrift*? Jullie denken toch niet dat ik dit nóg een keer ga doen, hè? Ik ben blij dat ik het gedaan heb hoor, maar er staat toch niet straks iemand op om te zeggen: *Zo, en nu echt*. Nee, dat zal wel niet. Maar het blijft toch een raar woord: *proefschrift*. Zou het misschien iets met het woord *beproeving* te maken hebben?

Tijdens mijn studie Werktuigbouwkunde heb ik mogen *proeven* aan verscheidene aspecten van toegepast wetenschappelijk onderzoek, zowel van experimentele als numerieke aard. Beiden trokken me bijzonder aan. In 1993 kreeg ik de mogelijkheid om na mijn afstuderen een promotieonderzoek te gaan doen waarbij ik me zowel op hoogwaardige experimentele technieken als gedetailleerde numerieke simulaties zou kunnen gaan richten. En bovendien ook nog eens op het gebied van stromingen in verbrandingsmotoren. Ik was er dan ook erg enthousiast over. En dat ben ik nog. De breedte en de diepgang van het onderzoek hebben er echter wel toe geleid dat het een bijzonder zware taak was. Misschien wel te zwaar. Het heeft er echter in geresulteerd dat ik erg veel heb geleerd op wetenschappelijk gebied, en daarnaast zeker ook op menselijk en organisatorisch gebied. Het waren namelijk woelige tijden, waarin de sectie Verbrandingsmotoren veel veranderingen doormaakte. Gelukkig hebben die veranderingen ertoe geleid dat de sectie nu weer een krachtige positie aan het innemen is.

Veel is bereikt in het genoemde promotieonderzoek en dat is zeker niet alleen mijn verdienste. Een groot aantal mensen hebben bijgedragen tot dit succes. Het is me dan ook een groot genoegen dat ik hier de kans heb om hen te bedanken. Maar waar moet ik beginnen? Laat ik beginnen met Pieter Blom, Onno van den Hurk, Madan Bindraban, Wout de Boer en Larry de Graaf, diegenen zonder wie de experimenten niet mogelijk waren geweest. Pieter en Onno hebben als eindstudenten (Pieter later ook nog als medewerker) een zeer waardevolle bijdrage geleverd door zich met grote inzet op de LDA experimenten te richten. Dat moest vaak onder niet ideale arbeidsomstandigheden gebeuren. Daarnaast heb ik met beiden vruchtbare discussies kunnen voeren. Als constructeur heeft Wout ervoor gezorgd dat de bijzonder complexe *proefopstellingen* zijn ontwikkeld. Met zijn nooit aflatende gedrevenheid en enthousiasme heeft Madan, samen met Wout, ervoor gezorgd dat die *proefopstellingen* op

een kwalitatief hoogstaande wijze werden gerealiseerd. Larry heeft gezorgd voor een prima ondersteuning op onder andere het gebied van instrumentatie.

Grote dank gaat uit naar de leden van mijn promotiecommissie. Ondanks dat hij pas in een laat stadium bij het onderzoek betrokken raakte, heeft prof.dr.ir. Rik Baert, mijn eerste promotor, nog een zeer positieve invloed kunnen uitoefenen. Ik heb veel van hem geleerd en ik waardeer zijn eerlijkheid en rechtlijnigheid. Bijzondere bewondering heb ik voor mijn tweede promotor, prof.dr.ir. Anton van Steenhoven, als wetenschapper en als mens. Hij heeft me enorm gesteund en gestimuleerd en hij heeft er vaak voor gezorgd dat ik de zaken weer duidelijk zag. Zonder hem waren vele dingen anders gelopen. Dr.ir. Bart Somers, mijn copromotor, heeft vooral tijdens de laatste periode waardevolle ondersteuning geboden. Zo was hij een gewillig slachtoffer om de eerste versies van mijn *proefschrift* te corrigeren, waarna we vaak tijdrovende discussies hadden. Prof.dr.ir. Harry Hoeijmakers wil ik danken voor de opmerkelijke grondigheid waarmee hij mijn *proefschrift* heeft gecorrigeerd. Al zijn opmerkingen waren waardevol. Als laatste lid van mijn kerncommissie noem ik dr.ir. Cees van der Geld. Hem dank ik voor zijn opmerkingen, maar vooral ook voor zijn enthousiasme. Daarnaast dank ik natuurlijk de overige leden van mijn promotiecommissie: prof.dr.ir. R. Sierens, prof.ir. D. Stapersma, prof.dr. J.J. ter Meulen en prof.dr.ir. M.J.W. Schouten. Hoewel hij geen deel uitmaakt van de commissie, zijn de discussies met dr.ir. Rob Bastiaans tijdens het schrijven van mijn *proefschrift* vaak zeer verhelderend geweest.

Graag bedank ik ook mijn collega promovendi Ard, Daan, Dirk, Gerry, Jack en Silvan voor hun ondersteuning en adviezen, de vruchtbare discussies en de prettige sfeer. Ik ben blij dat ik kan zeggen dat ik ze allemaal als goede vrienden beschouw. Daarnaast dank ik Rian Tielemans en Marjan Dijk, twee bijzondere vrouwen, en de rest van sectie Werktuigkundige Energietechnologie (WET) voor de steun en de uitermate fijne sfeer.

Om uiteenlopende redenen ben ik dank verschuldigd aan prof.dr.ir. Dick van Campen, Gemmy Crombags, Henk Krüs, Roel Luppens, Berry van Peer, Marcel Theunissen, Roel Wessels en Dr. Graham Wigley. Uiteraard dank ik ook de Stichting voor de Technische Wetenschappen voor de financiële ondersteuning van het onderzoek. Verder ben ik natuurlijk dankbaar voor de steun die ik van mijn vrienden heb mogen ondervinden.

Als laatste en meest belangrijke bedank ik mijn moeder uit de grond van mijn hart voor de ongelooflijke steun en liefde. Ik heb oneindig veel respect en waardering voor haar en ben enorm trots dat ik haar zoon ben.

Bedankt allemaal!

Bas.

Eindhoven, 23 oktober 1998.

Curriculum vitae

Bas van den Heuvel

- 17 March, 1968 Born in Eindhoven, The Netherlands.
- 1981 - 1987 Pre-university education (VWO), Eckart College, Eindhoven.
- 1987 - 1993 Education in Mechanical Engineering at the Eindhoven University of Technology. Both the graduation and training projects dealt with Automotive Engineering. The graduation project focused on the numerical optimisation of rear-axle suspensions for heavy-duty trucks. The training project dealt with the experimental analysis of the acoustic behaviour of an air intake system for truck engines.
- 1993 - 1998 PhD project at the Laboratory for Internal-Combustion Engines of the Eindhoven University of Technology. This project dealt with the computational and experimental analysis of in-cylinder flows for production-type internal-combustion engines. The results of this investigation are reported in the present thesis.
- 1998 - today Post-Doctoral fellow at the Laboratory for Internal-Combustion Engines of the Eindhoven University of Technology.
