Chapter I

General introduction

1.1 Molecular aggregation

Amphiphilic molecules such as fatty acid salts and phospholipids consist of a polar (hydrophilic) head group and an apolar (hydrophobic) tail. Depending on the nature of the head group, amphiphiles can be anionic, cationic, zwitter-ionic or non-ionic. When dispersed in water at a concentration above the so-called critical micelle concentration (CMC) they can achieve segregation of their hydrophobic portions from the solvent by self-association. This segregation is frequently referred to as the "Hydrophobic Effect"¹. Such aggregates are known as micelles (Figure 1.1). Below the CMC insufficient molecules can associate to achieve an effective elimination of the hydrocarbon-water interface. Consequently, only monomers are observed. Around the CMC, a delicate balance between monomers and micelles occurs which is dictated by the "Hydrophobic Effect". Accordingly, the transition between monomers and micelles is not distinct, but has a broad range. Growth of small micellar spheres or disks can develop ultimately into parallel layers of amphiphiles with the polar head groups located on the outside, the so-called bilayer (Figure 1.1)². The self-association of amphiphiles in aqueous solution into aggregates can readily be accounted for by the "Hydrophobic Effect". However, as in many cases relatively small micelles are preferred, an opposing force has to be present as well, which prevents the growth of the aggregates to larger sizes. Even for the largest possible aggregates (*i.e.*, the bilayer sheet) such a repulsive force must also occur to oppose separation into an entirely separate phase. The opposing force comes primarily from the electrostatic

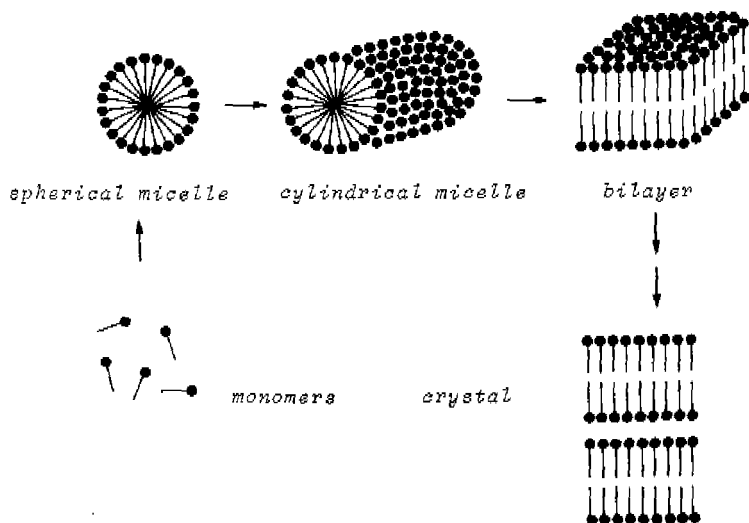

Figure 1.1 Molecular aggregational states.

repulsion between identically charged ionic head groups. In the case of non-ionic detergents, a preference for hydration is involved. In this context it can be envisaged that simple aliphatic alcohols, which form complexes with one another through hydrogen bonds, separate from the aqueous medium as a distinct phase. It should be noted that the "Hydrophobic Effect" induces a *lower* limit to the micelle size, because a minimal number of amphiphiles have to associate with each other to eliminate hydrocarbon-water interactions effectively. Thus micelle formation is necessarily a cooperative process, requiring simultaneous participation by many amphiphiles³. The *upper* limit of the aggregate dimension can be visualized by means of pure geometrical considerations. When the aggregation number increases, the packing between the head groups also increases. The repulsive force acts against too close an approach, thereby keeping the dimension limited. As single stranded amphiphiles form micellar structures under standard conditions, amphiphiles containing two chains mainly

build up bilayer structures¹. Such a number of chains per amphiphile results in half as many head groups as there would be for single stranded surfactants. The average *head group area* will be twice as large as the area per chain. An optimal aggregational state will now be reached not in the micelles but in the bilayers where the head groups become more closely packed. This offers a description without the use of complicated theoretical considerations, why single stranded amphiphiles prefer the micellar state, and phospholipids are mostly found in the bilayer state.

These descriptions have shown, that the thermodynamic principles underlying aggregation are conceptually simple: the "Hydrophobic Effect" provides the driving force for aggregation (*i.e.*, a positive entropy change), whereas repulsion between head groups limits the size that a particle can attain. *Both factors* must vary, however, with the particle size. Aggregation is thus shown to be cooperative and non-specific.

1.2 Membranes

Biological activity, particularly the specificity of many metabolic processes, demands molecular order. Aggregation (see Section 1.1) provides one way of ordering molecules and it is a reversible process. The transitions monomer-micelle and micelle-bilayer seem widely accepted as a means of controlling and regulating membrane properties⁴⁻⁸. Phospholipids are the major class of membrane lipids. Other kinds of membrane lipids are glycolipids, triglycerides and cholesterol. In biological membranes, the lipids form a bilayer matrix in which the proteins are embedded or surface bound. Although many biological activities are understood at a pharmacological or biochemical level, the behaviour of the individual membrane components and especially the phospholipids on a molecular basis, is often less well known. In contrast, macroscopic characteristics of the entire membrane have been investigated thoroughly in the past. It was shown that membranes are sheet-like structures of relatively small molecules. They form closed boundaries between compartments of different composition (*i.e.*, the unit membrane, the nuclear membrane and the membranes of

the mitochondria, Golgi-bodies, ribosomes and the endoplasmic reticulum of the living cell). Membranes mainly consist of lipids, proteins and in some cases pigments and carbohydrates. The phospholipid bilayer part of the membrane is highly impermeable to ions and most polar molecules. Permeability of the phospholipid section can only be established at local disturbances of the bilayer orientation, the so-called local micelle formation⁵ and local inverted micelle formation⁶⁻⁹ (*i.e.*, polar discontinuities). In all other cases specific membrane bound proteins mediate distinct functions of the membrane. They serve as pumps, gates, receptors, energy-transducers or enzymes. They can be bound at the surface of the membrane (extrinsic or peripheric proteins) or within the hydrophobic core (intrinsic or integral proteins).

I.3 Membrane fluidity

Only non-covalent interactions, such as hydrophobic *van der Waals* type interactions or electrostatic interactions, keep the membrane components together. From these considerations it will be obvious that the membrane lipids and especially the phospholipids must not be considered as static, but as dynamic membrane components (*i.e.* the "Fluid Mosaic Model")¹⁸, capable of regulating metabolic important processes, such as enzym expression, membrane fusion and transbilayer transport^{8, 10-17}. This dynamic behaviour can also be made plausible by the observations that phospholipid bilayers undergo a phase transition of the hydrophobic core from a relatively viscous fluid (the gel) to a relatively non-viscous fluid (the liquid crystalline) phase at a certain temperature, the so-called phase transition temperature. This temperature is strongly dependent on the nature of the hydrophobic tails and it readily decreases upon higher degrees of unsaturation¹⁹⁻²⁷. Unsaturation induce a disordering, thus eliminating the anti-parallel stacking of the phospholipid chains as compared with the saturated system. Consequently, the transition between the gel and liquid crystalline phase of the unsaturated lipid will occur at a lower temperature. Not only unsaturated phospholipid acyl chains alter the fluidity of

the hydrophobic core of the membrane. Incorporated cholesterol also affects membrane fluidity. Under physiological circumstances, cholesterol induces a profound condensing effect when the phospholipids are in the liquid crystalline state. On the other hand, a liquefying effect occurs for the gel state phospholipids²⁴.

From these points of view, it will be valuable to investigate fluidity as a contributing factor for regulating several membrane functions. A clear definition of the meaning of the term fluidity is hard to offer. Several types of motion (inter- and intramolecular) have to be considered to contribute to membrane fluidity, such as lipid exchange between the bilayer and the surrounding medium. However, this process is very slow (average exchange time of the order of 24 hrs.), and thus hardly contributes. Another slow process is the interchange of lipid molecules between the outside and inside of the bilayer: transverse diffusion or "flip-flop" (Figure 1.2), with an average interchange time of the order of minutes. In contrast to these kinds of motion, the lateral diffusion of lipid molecules in the plane of the bilayer is a fast process (correlation time $\sim 10^{-8}$ s). Besides this latter process, fluidity also depends upon uncorrelated and correlated molecular processes generated by the coherence with neighbouring lipids (the correlated process is frequently referred to as the "Correlated Molecular Ordering")²⁹. Examples of the former type are conformational changes between *anti* and *gauche* and rotations about individual bonds. Examples of the latter type are correlated phenomena such as intermolecular packing, kink-diffusion and axial rotation of the entire phospholipid chains³⁰⁻³⁴. It should be realized, however, that these molecular processes might not be entirely independent of each other. For example, diminishing the coherence between neighbouring chains will induce more kinks within and/or less packing between the lipid molecules, which in turn influences rates and types of intramolecular mobilities.

I.4 Mixed micelles and mixed bilayers as model membranes

Just as ordinary micelles, phospholipid membranes are

miscible with various kinds of substrates possessing hydrophobic groups (see Section 1.2)¹. Non-amphiphilic substrates such as cholesterol and proteins only penetrate the phospholipid bilayer; while amphiphiles can also induce for instance former mentioned polar discontinuities, due to their nature to adopt micellar structures. As is generally accepted, mixed micelles/bilayers play an important role in the process of cell-division, cell-fusion, reconstitution of biomembranes and they also act as pharmaceutical drug carriers^{9, 35-36}. All natural occurring membranes are mixed aggregates, containing different types of lipids and proteins. Knowledge of the fluidity of simple mixed aggregates can offer a relevant contribution to the elucidation of specific interactions between biomembrane phospholipids and their substrates. Model studies are most conveniently carried out on simple well-defined systems.

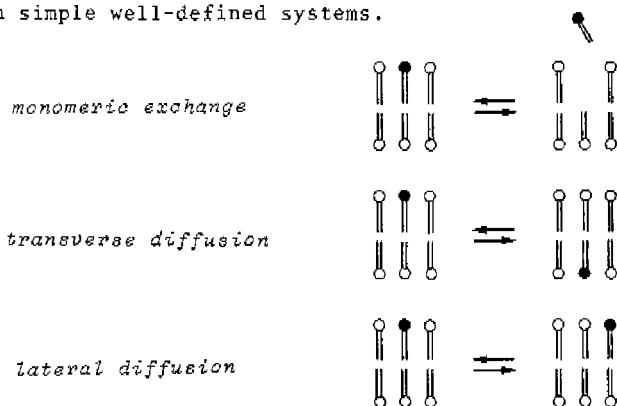

Figure 1.2 Exchange processes within the bilayer.

1.5 Scope of this thesis

In the past decade, many biophysical studies have been performed on model systems of biomembranes, by means of a wide variety of analytical methods, such as ESR-, NMR-, IR-, Raman and Fluorescence spectroscopy, Differential Scanning Calorimetry, X-ray and Neutron Diffraction³⁴. The subject of this thesis is to apply ¹³C NMR spectroscopy in particular to investigate the fluidity, caused by interactions between

neighbouring constituents, of mixed micelles and bilayers of phospholipids and their substrates (for instance fatty acid derivatives and cholesterol) on a molecular basis. Moreover, the applicability of ^{13}C NMR spectroscopy in this particular field of research is extended. Attention will be paid to the extent that incorporation of substrates modulate the intermolecular packing, the intramolecular conformational equilibria and mobilities of the components of the mixed aggregates.

At this point it is essential to notice which motions can contribute on the ^{13}C NMR time scale. These can be divided into three classes: motions within the molecules, motions of the entire molecules and motions of the molecular aggregate. Only small amplitude, high frequency bond rotations such as *anti-gauche* rotations and kink diffusion build up the first class. The second class surrounds molecular motions, which have already been mentioned (see Section I.3), such as axial rotation, rigid body motions and lateral diffusion. Other types of motion such as "flip-flop" and interbilayer exchange are normally too slow to be detected by means of ^{13}C NMR spectroscopy. The third class represents motions of the entire aggregate, such as tumbling of bilayer sheets or bilayer fragments. The extent to which these types contribute mainly depends on the size of the fragment. On the ^{13}C NMR time scale of observation large fragments tumble too slow to affect the former defined fluidity (see Section I.3). From these considerations it is shown unambiguously that ^{13}C NMR spectroscopy is a most valuable tool to investigate membrane fluidity. In the subsequent chapters the following points regarding fluidization of the membrane will be discussed in detail. Chapter II will deal with a concept which distinguishes changes in intermolecular packing from changes in intramolecular conformational equilibria as contributors to the fluidization of the hydrophobic interior. Mixed micelles of saturated fatty acid salts of variable chain lengths will serve as subject of investigation. In Chapter III this concept is applied to mixed micelles of short-chain lecithins and saturated hydrocarbon compounds which differ in *n*-alkyl chain lengths.

As for the hydrophobic region, results were obtained similar to the mixed micelles of the fatty acid salts. For the hydrophilic head group region the function of molecular mobility is introduced. It will be shown that the multiplicity of the carbon resonances of the methyls of the cationic site are highly influenced by the rate of motion of the $\text{CH}_2\text{-}\overset{\delta+}{\text{N}}$ site around the $\text{CH}_2\text{-CH}_2$ head group bond. In Chapter IV the principles of packing, conformations and head group mobility are extended towards bilayer structures. Mixed-vesicle systems of long-chain phospholipids and *n*-alkyl trimethylammonium bromides of different chain lengths are studied. A dynamic picture is offered for lysis of the bilayer when raising the concentration of the lytic *n*-alkyl compounds to ca. one equiv. Contrary to the decrease of the particle size upon lysis, in Chapter V inclusion of cholesterol is studied to monitor the effects of increasing particle sizes, and concomitant increasing aggregational densities¹ (*i.e.* packing), on the fluidity of the hydrophobic and hydrophilic region of the bilayer structure. For both types of intercalations (*i.e.* cholesterol and the lytic compounds), it will be shown that the surrounding phospholipids possess an intrinsic property which acts against disruption of the bilayer: the lecithins reduce the degrees of freedom of the disturbing substrates. Chapter VI surveys the effects optically active *n*-alkyl quaternary nitrogen substrates have on the fluidity within the chiral phospholipid bilayer, and *vice versa*. It is demonstrated that the chiral substrate is pressed between the surrounding chiral lecithins. Analogous to the single stranded lytic compounds, it results in conformational changes of the chain of the chiral substrate, as monitored by ¹³C NMR. Moreover, the chirality of the head groups of the substrate is affected, as detected by CD spectroscopy. Finally, Chapter VII describes the fluidity changes in the flat bilayer orientation of phospholipids upon intercalation of former mentioned *n*-alkyl trimethylammonium bromides. Analogous to the vesicular dispersions, also for the flat bilayer dispersions the intrinsic property of the lecithins of reducing the degrees of freedom of the lytic compounds is again

demonstrated by means of relaxation data. These relaxation data are obtained by means of a new NMR technique for anisotropic systems: the ^{13}C -CPMAS experiment.

CHAPTER II

A ^{13}C NMR study of mixed micelles. Variation of interchain distances and conformational equilibria

II.1 Introduction

Short-chain lecithins exist as large micellar aggregates in water above a given critical micelle concentration (CMC). The CMC depends on the fatty acyl chain length¹. Lipid micelles and mixed micelles of lipids and fatty acid derivatives are of biological interest. They introduce the so-called polar discontinuities within the phospholipid bilayer, thereby altering the permeability of the cell membrane for vital compounds^{2,3}. They also play an essential role in the process of cell division^{2,4}. Furthermore, the large rate of hydrolysis of lecithins by phospholipases occurs also in the micellar state^{5,6}. It is generally presumed, that conformational changes in the head groups and/or the lipid chains as well as their relative orientations and order, are of importance for the physical chemistry of the lecithins^{3,7}.

Recently, much work has been done explaining the acyl chain conformation of long-chain lecithins in different aggregational states^{8,9} (see Figure 2.1). The *sn*-1 chain is orientated perpendicular to the bilayer surface and the *sn*-2 chain is bent at the C-2 carbon atom and runs from thereon parallel with the *sn*-1 chain^{8,9}. In order to gain more insight into the conformational behaviour of phospholipids, Roberts *et al.*¹⁰ applied ^1H NMR techniques to several lecithins in different mixed micelles. The observed magnetic nonequivalences of the four α -protons of the *sn*-1 and *sn*-2 chain were explained in terms of different conformational equilibria for the two chains⁸. Because of the difference in effective lengths of the *sn*-1 and *sn*-2 chains, lecithin micelles as such qualify as *mixed micelles* to a certain extent¹¹.

Figure 2.1 Average orientation of lecithin head groups and the conformational nonequivalence of lecithin acyl chains in lipid aggregates⁸⁻¹⁰.

On the other hand, single micelles of simple detergents are studied frequently by means of a wide variety of physical methods¹². A number of discrepancies, notably about the CMC, still exists between the different analytical methods^{13,14}. More details regarding dynamics and conformational equilibria of the acyl chains have been reported by Lindman *et al.*^{13,15,16}. Topics as solubilization and aggregation numbers were also included using ¹³C NMR¹⁷. Specific statements regarding mixed micelles of C₁₄TAB and C₁₆TAB¹⁸ were reported¹⁷. The difference in chain lengths of the partners in these mixed micelles is of the same order of magnitude as that which might prevail in phospholipid micelles (with *nominally* equal *sn*-1 and *sn*-2 chain lengths)¹⁹. The different chemical shifts of the terminal methyls of the C₁₄TAB and the C₁₆TAB constituents were explained in terms of increased chain folding of the longer chain near the apolar end. A similar explanation had been offered previously for the solubilization of *n*-decanol in sodium octanoate micelles¹⁷.

In our opinion, alternative descriptions involving the occurrence of chain separation and, consequently, changes in *van der Waals* solvent effects on the chain should be considered as well. A recent publication by Roberts *et al.*²⁰ concerning

^{13}C NMR of simple phospholipid micelles did not take into account either solvent effects or the model descriptions of Lindman *et al.*¹⁷ regarding mixed micelles. In the following Sections it will be discussed that conformational changes as well as changes in packing contribute to the ^{13}C NMR chemical shifts of the hydrocarbon region of mixed micelles of salts of fatty acids with different chain lengths.

II.2 Results

^{13}C NMR chemical shifts of the micelles have been assigned by combining literature data^{16,17} and relative relaxation data, assuming that T_1 -values increase towards the apolar end^{21,22,23}. Results are presented in Table II.1. When mixed micelles are formed, the ^{13}C NMR chemical shifts of the constituent chains change with respect to the single micelles (see Table II.2). When the potassium dodecanoate solution was diluted from 1.5 M to 0.15 M, no changes in chemical shift were observed. It indicates, that no changes in aggregation numbers occur in this concentration range¹³.

II.3 Single micelles as reference solutions for the mixed-micellar solutions

For the hexanoate NMR measurements indicate the formation of aggregates of ca. five molecules of amphiphile in water¹³. Other experimental methods really indicate the formation of micelles with larger aggregational numbers¹⁴. The octanoate forms micelles with an average aggregation number of ca. seventeen^{13,24}, while the dodecanoate forms much larger micelles. Previous reports^{12,25} revealed no appreciable interaction of water with the hydrophobic core of closely packed surfactant micelles such as sodium dodecanoate^{26,27}. Contradictory results have been shown to be due to deficiencies in the analytical procedures^{28,29}.

The ^{13}C NMR chemical shifts (see Table II.1) of the ω -methyl groups fall roughly into three groups: 14.00 ppm for the hexanoate, 14.18 ppm (± 0.01) for the heptanoate and the octanoate, and 14.25 ppm for the nonanoate, the decanoate and the dodecanoate micelles. Similar observations, albeit with

larger discrepancies (due to non-negligible through bond δ -effects of the polar head group in the hexanoate chain) can be made for the $\omega-1$ methylene chemical shifts.

Corresponding shift differences are observed for carboxylic acids in chloroform. However, these compounds may form inverse micelles in this solvent. A comparative study was also carried out for solutions of n -alkyl TABs¹¹ in chloroform and water (below the CMC for the latter solvent). The results indicate clearly that the variation within a homologous series of the ^{13}C NMR shifts of inverse micelles and of monomers do not differ significantly. Solutions of n -alkanes do not show a comparable behaviour³⁰. Therefore, it is suggested that the observed shift differences for the methyl carbons of the alkanolate micelles indicate the formation of three different micellar solutions. The reason for the differences between n -alkanes and substituted derivatives over such long distances must be due to the propagation of conformational perturbations caused by the substituents. Through bond substituent effects

^aMixing ratios (m/m) are defined as the quotient of the concentrations of the dodecanoate and the shorter amphiphile.

^bSpectral assignments of the C-4, C-5, C-6 and C-8 atoms of the C₁₁ chain were impossible because of overlapping signals, just as the carbons corresponding to the vacancies in the table. About the C-2 and C-3 effects of the C₁₁ surfactant in its mixed micelles, one can only speculate. Small deviations in the basicity may bring about these divergences on the chemical shift differences.

are measurable only over small distances (maximally five C-C bonds) and thus can hardly contribute. The fact that comparable shift differences are found in the inverse micelles and in the monomers of the fatty acid salts indicates that conformational freedom is not significantly impaired in the latter.

II.4 Theoretical considerations and model description for the mixed-micellar solutions

In Figure 2.2a, the conventional picture of a micelle is presented, according to the classical *Hartley-model*³¹. However, the rodlike shape of the surfactant chains is *not* meant to represent *all-extended* conformations. It is only presented in this way to demonstrate that, on a time averaged basis, all monomers forming the micelle will be equivalent. This also pertains to the number and positions of *gauche* conformers³⁰.

Recently, theoretical descriptions of micelles have been put forward by *Dill* and *Flory*³² and *Pratt*³³. These descriptions are based on a space lattice model combined with *Monte Carlo* type simulations. In the former case, a cubic lattice is used without weighing different chain conformations according to their different energies. In the latter model a diamond lattice is combined with weighing based on a number of interaction energies between head groups and chains, both intra- and intermolecular. In these two respects, the *Pratt model* seems more realistic than the model of *Flory*. Both descriptions share the disadvantage of not being able to accommodate chain conformations of the crank shaft type as proposed many times for lipid bilayers³⁴ and polymer chains³⁵. Even in other simulations these "kinks" are also taken into account³⁶. Further arguments against the theory of *Dill* and *Flory* are found in the data of *Zemb* and *Chachaty*³⁷. The latter showed that the experimental data of *Cabane*³⁸, to which *Dill* refers in a more recent paper³⁹, were unreliable. *Zemb* and *Chachaty* indicated that the paramagnetic relaxation data of *Cabane* did not depend on the absolute rate of internal motions of the micellar particle.

Figure 2.2 Model for mixed-micelle formation: a) the C_{11} single micelle; b) the mixed micelle for the 1:1 mixing ratio; c) the mixed micelle for the 1:2 mixing ratio; the methyle of the long and short surfactants are denoted as w_1 and w_s , respectively. At constant conformational equilibria of the C_{11} chains upon mixing, intramicellar cavities (shaded areas) decrease in dimension upon elongation of the acyl chain length of the short surfactant (see Figure 2.2b) and increase upon lowering the mixing ratio (see Figure 2.2c). Open circles represent the head groups of the short soaps and full circles represent the head groups of the long (C_{11}) amphiphiles; the dimensions are not correct. Only a schematic representation is offered. Rod-like shapes of the acyl chains do not represent all-extended conformations. The actual conformational behaviour can be viewed for instance as follows:

or any other conformation in which kinks are confined to certain non-neighbour layers. In reality, the assembled kinks will move in time about the longitudinal directions of the chains. Kinks in the shorter amphiphiles in mixed-micellar systems also have the above-mentioned requirements. The motional freedom in the w_s-w_1 part of the longer chains may be larger.

With regard to the single micelles (see Section II.3), consideration of lattice models instead of conventional micelles would not influence the discussion of our NMR results. However, the lattice model representation is rather convenient to visualize the model of *mixed* micelles of fatty acid soaps of different acyl chain lengths (see Figure 2.3a). A number of facts can be deduced.

Figure 2.3 Lattice model representation after Dill and Flory³²; a) twodimensional representation of the cross section of a cylindrical micelle. Lattice sites, each containing ca. 3.6 methylene groups³², are indicated. Head groups are situated in the outer layer. The figure is not meant to reproduce a time-averaged basis, but rather a momentaneous view; b) twodimensional representation of the cross section of a cylindrical mixed micelle, analogous to a).

First, with complete filling of all outer lattice sites by chain segments (it is more appropriate to consider methylene groups rather than chain segments³², as this is more realistic from a practical point of view), the long amphiphile chains would have to assume lateral displacements (*gauche* conformations in reality) at or very close to the ω_s carbon atom, which should lead to open lattice sites in the center of the micelle. Under the assumption of complete filling, however, this results in smaller micelle diameters³². This conforms to the strategy taken by, e.g., Lindman *et al.*¹⁷. Secondly, without complete filling³², open lattice sites are created between two adjacent long chains (between the ω_{s+1} carbons). These vacancies or cavities "move" in time over a complete layer parallel to the

aqueous interface occupied by the polar head groups³², thus creating larger *average* distances between the long chains. The same occurs for layers farther inside the micellar core, *but to a lesser extent* (see Figure 2.3b). Thirdly, the number of lattice sites within a given layer could be adapted for mixed micelles compared with the single micelles. So complete filling over all lattice sites is maintained. These sites, however, have to possess larger dimensions. This would lead to essentially the same consequences and conclusions as in the second case (*vide supra*).

We are thus left with two basically different possibilities: increased "folding" (with respect to their single micelles) of the long chains in the mixed micelles (*vide supra*: the first consequence) or rather constant conformational equilibria of the long chains (with respect to their single micelles) leading to larger average interchain distances (*vide supra*: the second and third consequence). Both processes would lead to increased shielding for the $\omega_s - \omega_1$ parts of the long-chain surfactant molecules but with *different relative magnitudes*. A detailed interpretation in terms of ¹³C NMR chemical shifts can therefore be offered. The shieldings, concomitant with *gauche* conformations in the acyl chains, are given in Table II.3a. These values are derived from literature data^{30,40-43}. Shieldings arising from *increased interchain distances* should reflect the relative sensitivities or site factors of the methyl and the various methylene groups^{44,45}. In practice, this means that relatively large effects are observed for the methyl signals³⁰: ca. three times larger as compared with methylene carbon signals (for different methylenes, the variance of the extra interchain distances along the direction of the chains would have to be considered as well, in theory).

The consequences of the model presented here in terms of ¹³C NMR chemical shift differences can be summarized as follows (see also Figure 2.2b and Figure 2.2c). Shielding effects are to be expected for the ω_1 through the ω_{s+1} carbon atoms of the *n*-C₁ chains, caused by decreasing *van der Waals* interactions and increasing contributions of *gauche* conformations. These effects will be enhanced upon

solubilization of more short chain amphiphile (Figure 2.2b and 2.2c). If only decreasing *van der Waals* interactions participate upon mixed-micelle formation without conformational changes, it is possible to offer the contributions to the chemical shift changes purely from geometrical considerations. The methyl carbons of the short soap molecules will approach the ω_{s+1} carbons of the longer $n-C_{11}$ chain. Consequently, a maximal shielding will appear at or near the ω_{s+2} carbon of the $n-C_{11}$. Furthermore, there will be a gradient of shielding, decreasing towards the terminal methyl carbon of the long surfactant. When the concentration of the short chain amphiphile is raised, the changes for the $\omega_s - \omega_1$ part of the dodecanoate molecules will be larger, but it is expected that the maximum effects remain on the same carbons of the long chains. This is borne out by our results. In addition, the possibility of a maximum solubility of the shorter soap molecules into the longer soap micelles always has to be taken into account. For the short-chain soap molecules, deshieldings with respect to its single micelle are to be expected because of three reasons. First, the chain is transferred from a medium consisting of short acyl chains (plus water in the case of monomeric solutions) to longer dodecanoate chains⁴⁴⁻⁴⁶. Secondly, the packing in the mixed micelle presumably will be tighter than in the short-chain single micelle, causing smaller interchain distances and larger *van der Waals* interactions. If only these solvent effects participate, the deshieldings should reproduce the respective site factors, thus leading to maximal differences for the methyl carbons^{30,44-46}. Thirdly, also conformational changes towards extension may contribute. Then, contrary to the effects packing induces, relative deshieldings as indicated by *opposite* values of Table II.3a should occur.

II.5 Discussion

The observed ^{13}C NMR chemical shifts of the dodecanoate single micellar solution upon dilution over the concentration range of 1.5 M to 0.15 M indicate that no changes in aggregation numbers and concomitant changes in chain

Table II.3a ^{13}C NMR shieldings (in ppm) which gauche conformers induce on the individual carbons of the C-7/C-18 fragment of an all extended dodecanoate chain^a

^bOnly decimals best resembling the experimental values (see Table II.2) are mentioned. Conformational ratios were 1.4% IV; 2.5% III and 3.2% II for the C_{11}/C_7 mixed micelle and 2.0% IV; 1.8% III; 1.8% II and 2.0% I for the C_{11}/C_6 mixed micelle.

^cMixing ratios: see footnote Table II.2.

conformations occur (*vide supra*)¹³. Therefore, the shift differences for the dodecanoate chains which occur upon formation of mixed micelles are to be ascribed exclusively to the inclusion of shorter chains or the replacement of $n\text{-C}_{11}$ chains by shorter ones. NMR-measurements would probably not distinguish between these phenomena. The latter model,

however, was postulated by *Brady*⁴⁷. Although the conditions for the latter experiments and those described in this Section differ significantly, a certain analogy between the two situations cannot be denied. The basic idea of the model presented here is not impaired by the uncertainty regarding inclusion versus replacement.

The enclosure of hexanoate molecules in dodecanoate micelles causes a clear gradient of shielding along the long chains from the ω_1 methyl towards the ω_s (i.e. C-6) methylene group. It indicates that changes in *van der Waals* interactions prevail over conformational changes. A measurable contribution of the latter effect can, however, not be ruled out. This stands in contrast with mixed micelles of dodecanoate and heptanoate or longer soaps than the latter. Consider, e.g., the dodecanoate/heptanoate mixed micelle at a mixing ratio of 1:2. The following shieldings were observed for the dodecanoate chain with respect to its single micelle (see Table II.2):

C-12	C-11	C-10	C-9	C-8	C-7	C-6
-0.07	-0.13	-0.18	-0.22	-	-0.10	-

In order to explain these changes as far as possible in terms of conformational changes, one would have to assume the following percentages of *extra gauche* conformers (see Table II.3b): 1.4% of IV, 2.5% of III and 3.2% of II. This optimal conformational rearrangement is closest to the experimental values (see Table II.2). It is still impossible to take large contributions of *gauche* conformers into account due to the discrepancy between the observed and calculated relative shift differences. Other simulated conformational rearrangements resulted in even larger discrepancies with the observed chemical shift differences. It is useful to mention, that the interchain distances between the dodecanoate chains may be only 10-30% larger than in the single micelles (sum of *van der Waals* radii) to cause sizeable shielding⁵⁰.

From these simulations, it can be observed that a definite conclusion, regarding the distinction between changes in packing or in conformation of the $n\text{-C}_{11}/n\text{-C}_6$ mixed micelles, could not be reached due to the inability to resolve the relevant C-8 resonance of the dodecanoate chain properly. However, it seems very unrealistic to explain a shielding gradient, comparable to the one observed, completely in terms of conformational changes, because there should be a large contribution of kinks around the $\omega_{1-4}-\omega_{1-3}$ bond, which seems very unlikely from a steric point of view. Furthermore, kinking around the $\omega_{1-1}-\omega_{1-2}$ linkage would result in a large shielding at the ω_1 methyl group which has not been observed. Thus, as already stated, decreasing *van der Waals* interactions (i.e. packing) are the factors mainly governing the results described here. This occurrence of chain separation between the dodecanoate chains in their mixed micelles is contrary to previously reported results on $\text{C}_{16}\text{TAB}/\text{C}_{14}\text{TAB}$ mixed micelles and solubilization of 1-decanol in octanoate micelles⁷.

The values of the $n\text{-C}_{11}/n\text{-C}_5$ mixed micelles (see Table II.2) show increased shielding for the dodecanoate chain protruding from the solubilized short soap molecules, for the 2:1 through the 1:1 mixing ratio. At smaller ratios the shieldings remain fairly constant. This implies a maximal solubilization of ca. one equiv. of hexanoate. At higher concentrations of the $n\text{-C}_5$ surfactant, mixed micelles coexist with monomers of the hexanoate anion. In the following scheme the observations are summarized:

For the $n\text{-C}_{11}/n\text{-C}_6$ mixed micelles comparable observations were made. As already mentioned (*vide supra*) comparison of calculated (Table II.3) with observed (Table II.2) *shieldings* indicated pronounced contributions of *van der Waals* solvent effects rather than conformational changes. Consequently,

it was made plausible that chain separation mainly caused the observed shieldings. Moreover, the solubilization of heptanoate increases to ca. two equiv., as can be deduced from Table II.2. *Monte Carlo* calculations⁴⁸ reveal that the conformational free energy minimum of closely packed alkyl chains is proportional to the alkyl chain length. Under the assumption that head group/solvent and head group/head group interactions in single micelles of dodecanoate are comparable to their mixed micelles, only alkyl interchain interactions are important in the process of mixed-micelle formation. This explains an enhanced solubilization when increasing the acyl chain length from six to seven carbons. Dodecanoate shielding effects increase from the 1:2 mixing ratio and reach a constant value at lower ratios. The chemical shift changes of the heptanoate component upon increasing its percentage proceed analogously to those observed for the hexanoate detergents in their mixed micelles. Thus, for lower mixing ratios, it is obvious that 1:2 mixed micelles coexist with heptanoate monomers up to the 1:8 mixing ratio. At this ratio, the remaining heptanoate detergent molecules would form a solution with a concentration exceeding their CMC-value⁴⁹. Consequently, heptanoate micelles would be formed. The heptanoate soaps would equilibrate between the mixed and the single micelles. As random mixing is preferred, a new situation for the dodecanoate soap molecules might occur, involving a statistical distribution over the available micelles. In this way, heptanoate micelles would be formed with one to two dodecanoate molecules included. We like to speculate, that for the latter chains the C-9 and C-10 carbons would presumably be located in the center of the heptanoate micelle. In this region, the average distance of both carbon atoms to other ones will be relatively large, causing smaller *van der Waals* interactions. The ω_1 methyl effects are almost independent of the *n*-alkyl chain length of the solubilized partner as can be seen from the chemical shift differences of the mixed soaps. The intermolecular distances between the ω_1 methyls apparently depend only on

the concentration of solubilized short-chain component. So at comparable mixing ratios elongation of the chain of the short amphiphile decreases the volume of the cavities between the n -C₁₁ chains, as can be deduced from the decreasing shielding effects of the n -C₁₁ methylenes from ω_5 to ω_1 (see also Figure 2.2). From the deshieldings of the short-chain soap molecules in the mixed micelles (n -C₅ up to n -C₉), it is clear that both the decanoate and the nonanoate are in good agreement with previously observed solvent effects^{30,46}. The octanoate and the heptanoate are borderline cases, while the hexanoate matches with the deshielding effects of solubilized pentanol in octanoate micelles¹⁷. These deshieldings are attributable to the extension of the hexanoate molecules as compared with their single-micellar reference solution¹⁷. This can be seen by using the *opposite* values of Table II.3a. In the next chapter of this thesis, this extension and its simulation will be discussed in more detail by means of mixed micelles of a short-chain lecithin and hydrocarbon compounds of different chain lengths. Finally, the ¹³C NMR data of the C₁₆TAB/C₁₄TAB mixed micelles, studied by Lindman *et al.*¹⁷, correspond nicely with those of the 1:1 mixed micelle of the n -C₁₁ and n -C₉ soaps of this study. In retrospect, the C₁₆TAB/C₁₄TAB mixed micelles form a special case of the more general situation as presented in detail in this chapter.

II.6 Summary/Conclusions

Observed ¹³C NMR chemical shift changes with respect to their single micelles upon mixed-micelle formation of potassium dodecanoate and short-chain potassium carboxylates (hexanoate up to and including decanoate) were ascribed in all but one case to increasing distances between the apolar ends of the long amphiphile chains as compared with its single micelle. Only at an effective chain length difference of ca. *six* carbon atoms as for the dodecanoate/hexanoate micellar systems can a different conformational equilibrium of the dodecanoate chain not be excluded.

Furthermore, recently observed solvent effects upon

mixing of *n*-alkanes of different chain lengths^{30,40} are compared with both the decanoate and nonanoate chemical shift changes upon mixing with the dodecanoate amphiphiles. This leads to the conclusion that the former detergents are mainly subject to increased intermolecular chain packing. Observed effects for the octanoate and heptanoate are not as pronounced, and these soaps should be considered as borderline cases, while the hexanoate undergoes conformational changes towards more extension.

Finally, it is observed that maximally ca. one equiv. of hexanoate or ca. two equiv. of heptanoate can be incorporated into micelles of potassium dodecanoate. At higher percentages of short-chain soaps, these maximally incorporated mixed micelles coexist with short-chain soap monomers up to the concentration where the short-chain soaps reach their CMC-value and form micelles. Then a statistical distribution of dodecanoate molecules in short-chain micelles is attained.

II.7 Experimental

Potassium alkanooates were prepared by neutralizing the corresponding carboxylic acids (Fluka AG) with potassium hydroxide (Merck AG) and purified by recrystallization from methanol. Stock solutions of 1.5 M were prepared with deionized water and stabilized with 0.1 M of potassium hydroxide. Mixed-micelle solutions were obtained from the stock solutions by adding the appropriate amounts. The resultant solutions were sonicated for 15 min. at 25°C and then allowed to stand for 5 days before measurement.

All ¹³C NMR spectra were run at 62.93 MHz on a Bruker WM 250 spectrometer under proton noise decoupling. The deuterium signal from C₆D₆ was employed as external lock signal. All chemical shifts are related to Me₄Si (C₆D₆ at 128 ppm downfield from Me₄Si). Eight transients corresponding to a spectral width of 2 KHz were accumulated in 32K data points limiting the resolution to 0.005 ppm. Pulse width was set to a 90° flip angle.

CHAPTER III

Mixed micelles of dioctanoyl-L- α -lecithin and hydrocarbon amphiphiles. Aspects of fluidization

III.1 Introduction

The importance of micelle-forming phospholipids in biomembranes has often been stated, for example, as carriers for membrane-bound enzymes^{1,2} or transmembrane transport-enhancing constituents within a bilayer membrane or particles stimulating cell division². Conformational and motional behaviour of head groups and acyl tails and perhaps also intermolecularly correlated molecular ordering³ may well be of great interest for these regulations. Efforts have been made in the elucidation of the conformational structures of micelles of short-chain lecithins by means of different spectroscopic methods. By ¹H NMR the intrinsic nonequivalence of the *sn*-1 and *sn*-2 acyl chains of dioctanoylphosphatidylcholine and dipalmitoylphosphatidylcholine is visible⁴. In total, four separate α protons were observed; the remaining proton signals either overlapped or were not assigned. The explanation was given in terms of different conformational behaviours of both chains, as suggested earlier by *Seelig et al.*⁴, who studied the gel phase and liquid crystalline phase of dipalmitoylphosphatidylcholine and dipalmitoylphosphatidylethanolamine. In this picture, the *sn*-1 and *sn*-2 chains run parallel to each other except for bending of the *sn*-2 chain near the C-2 carbon atom. This results in different effective chain lengths⁵. Recently, also ¹³C NMR spectra were published for dibutyryl-, dihexanoyl-, diheptanoyl- and dioctanoylphosphatidylcholine⁵. Again, the intrinsic nonequivalent chains resulted in partially resolved spectra. In the present study ¹³C NMR spectra with considerably better resolution will be presented. For all

but two carbons separate signals were observed and assigned to the *sn*-1 and *sn*-2 chains. It will be shown that micelles of DOPC⁷ resemble mixed micelles of *n*-alkyl detergents bearing chains of nonequivalent lengths. Increasing the effective chain length difference upon elongation of the *sn*-1 chain causes fluidization near the apolar middle region of the bilayer. *Keough et al.*⁸ described this fluidization in terms of intermolecular ordering. *Stümpel et al.*⁹ supposed intramolecular contributions like disordering conformational changes. However, *van der Waals* attractive interactions either were ignored⁹ or were presumed to be constant⁸. In our opinion, the latter have to contribute (see Chapter II). More explicitly, the extent to which (intermolecular) *van der Waals* attractions on the one hand and (intramolecular) conformational changes on the other hand cause fluidization should be a function of the effective chain length difference. Recently, a method has been developed for interpreting ¹³C NMR spectra of mixed micelles of different alkanooates¹⁰. This was performed in terms of conformational equilibria changes with respect to the single micelles on the one hand and decreasing chain packing on the other hand (see Chapter II). It was possible to distinguish these two factors to a certain extent. Also the possible influence of solvent effects on the spectra were mentioned. The model of Chapter II will now be applied to mixed micelles of DOPC and several TABs. It describes the connection between packing, conformations and the effective chain length difference (*vide supra*) with respect to the process of fluidization.

III.2 Results

¹³C NMR chemical shifts of the micelles have been assigned by combining literature data and relative relaxation time values, assuming that T_1 values increase towards the apolar ends^{5,12}. Such a pattern was first suggested by *Allerhand et al.*^{12a} and subsequently by others^{12b-c}. It is primarily based on increased segmental motions or rotational diffusions near the free ends of the chains.

Such a pattern is quite general. Results are presented in Table III.1. Tables III.2-6 show the chemical shift changes of the mixed micelles with respect to the micelle solutions of the pure detergents. Assignments of the different carbon pairs to the *sn*-1 and *sn*-2 chains have been performed by assuming that the spin-lattice relaxation times of the carbons of the *sn*-1 chain are larger compared to those of the *sn*-2 chain⁵. Figure 3.3 shows the effects of TABs on the head group mobility of the DOPC in the mixed micelles. Table III.7 indicates the effects of TABs on the chemical shifts and line widths of individual lipidic head group nuclei.

III.3 Reference solutions for the mixed micellar solutions: the single micelles

The present measurements yield a better resolution for the DOPC micelles (see Table III.1) with respect to recently published data⁵. The visibility of the nonequivalent behaviour is *not* restricted to carbon atoms close to the carbonyl function⁵ but extends over almost the complete chains. The ω -methyl resonances of the lecithin show shielding compared with *micellar* solutions of the quaternary ammonium detergents. Since water penetration can be ruled out⁵, it will be shown that a decreased chain packing within the lecithin micelles may be possible. From geometrical considerations¹³, the micellar shape of the lecithin aggregates has an average area per lipid head group comparable with that of the TABs, because lipid head group repulsions should not be affected significantly by the presence of one or two alkyl chains attached to each head group. If the lecithin aggregates were spherical, the average head group area would be twice as large as the area per emerging chain with respect to spherical TAB micelles. The increase in the lipid particle size results in a decrease of the average surface area¹³, which in turn results in a tighter packing of the head groups, in order to optimize head group interactions, and consequently in a looser packing of the ω -methyls. Indeed, the lecithin micellar

shape was found to be rather rod-like¹⁴.

The ¹³C NMR chemical shifts of the DOPC micelles were insensitive to concentrating the solution from 5 mM to 50 mM. It indicates that no changes in molecular packing and conformational changes occur¹⁵. As the micellar size of the lecithin aggregates is larger than spherical, this growth of the DOPC micelles apparently does not influence the ¹³C NMR spectra significantly, since the line widths are also constant over the entire concentration range.

Furthermore, the results indicate a similarity between the behaviour of mixed *n*-alkanoates of different chain lengths¹⁰ and synthetic short-chain lecithins in an aqueous medium. Both systems represent a magnetic nonequivalence between the different alkyl chains for comparable carbon atoms.

In Table III.1 the chemical shift values of the TABs are mentioned, which will serve as the reference systems for the TABs in their mixed micellar systems with DOPC.

*III.4 Mixed micelles of DOPC and several *n*-alkyltrimethylammonium bromides*

III.4.1 Hydrophobic region: analytical considerations

Several aspects have to be considered upon interpreting ¹³C NMR chemical shifts of DOPC micelles mixed with amphiphiles of different effective chain lengths. Analogous situations in simple mixed micelles of alkanooates have been discussed in detail in the preceding Chapter (see Section II.4). It was shown that mainly two factors will influence ¹³C NMR chemical shifts of alkane moieties, *viz.* different conformational equilibria and/or different environments^{10,18}. Sometimes, these two factors are interconnected¹⁷. Different environments *per se* (solvents, packing) will cause different medium effects on the chemical shifts. The relative magnitudes at different positions in a solute are governed by site factors^{18,20}. For convenience, *relative* site factors (in ppm) within an alkane fragment are presented in Figure 3.1e. So that *van der Waals* solvent effects on the one

hand and conformational changes on the other hand could be distinguished, a schematic representation of the chemical shift changes is also offered (Figure 3.1). In terms of ^{13}C NMR chemical shift changes Figure 3.1a reproduces schematically the influence of contributions of *gauche* conformers for the alkyl fragments investigated here. Literature data from Mann, Bovey, Schneider, de Haan and coworkers^{17,21} were combined in order to arrive at the absolute values of the chemical shift changes upon the formation of a single *gauche* from an *anti* conformer. With respect to an *anti* conformer, carbons at a relative 1,4 *gauche* position are shifted upfield by about 4 ppm (except ω -methyls which are shifted upfield by about 5 ppm). Intermediate carbons change by about half this magnitude. Taking into account all possible *gauche* conformers in different ratios results in the shielding patterns presented in Figure 3.1b-c. Figure 3.1d shows the opposite effects due to generating possible *anti* conformers from *gauche* conformers. Quite obviously, no clear-cut distinction between the two aspects is possible in all cases. However, combining the literature data of Figure 3.1 and the experimental data of Tables III.2-6, it is possible to indicate approximately to what extent conformational changes on the one hand and medium effects on the other hand will contribute to the observed chemical shift changes.

III.4.2 Hydrophobic region: geometrical considerations

A few consequences of the combined influences of conformational changes and alterations in environment will now be discussed, in close analogy with mixed fatty acid soap micelles¹⁰.

First, shielding is expected for carbon atoms of those parts of the TAB chains which protrude from the DOPC acyl chains (Figure 3.2). The average distances between those alkyl chain fragments are then larger than in their single micellar solutions. This is the case for the C_{12}TAB up to the C_{18}TAB detergent. Larger interchain distances cause a diminution of *van der Waals* solvent effects. In addition,

Figure 3.1 The influence (in ppm) of single gauche conformers on the ^{13}C NMR chemical shifts of all-extended hydrocarbon chain fragments (a). (b) Possible gauche conformers of that part of the C_{16}TAB chain protruding from the DOPC molecules in their mixed micelles. Full circles at the left side of the chain fragments represent the methyls. The calculated shielding pattern which resembles closest the experimental data of the C-12/C-16 segment is given. It was obtained by weighing the gauche conformers in the ratio indicated. (c) Similar to b, for C_{18}TAB in mixed micelles with DOPC. Again only values which are closest to the experiments are mentioned. (d) Deshielding pattern of C_9TAB in DOPC micelles obtained with opposite values of a, assuming almost equal contributions of anti conformers around all bonds. (e) Relative site factors within an alkane chain fragment due to decreasing van der Waals interactions¹⁸.

increased differences in effective chain lengths possibly lead to conformational changes towards more kinking. This is consistent with the conclusions of *Petersen* and *Chan*¹⁶, and *de Haan* and *van de Ven*¹⁷, who describe intramolecular alterations as a consequence of correlated intermolecular *van der Waals* attractive interactions going from a relatively ordered (single micellar) state to a relatively disordered (mixed micellar) state, rather than the reverse. A decrease in intermolecular interactions (*i.e.* by "chain unpacking") will lead to shielding, as mentioned for neat and diluted alkanes¹⁸. Similar conclusions were reached from ¹³C NMR studies of polyethylene in different packing states¹⁹. Furthermore, it will be obvious that effects are most distinct in mixed micelles containing an excess of lecithin (*i.e.*, the 4:1 m/m mixing ratio), in which TAB undergoes the largest perturbation from the surrounding lecithin molecules.

Secondly, for the carbons in the part of the TAB chains which are situated directly in the DOPC acyl chain region of the mixed micelle, deshieldings are anticipated. These are caused by increased *van der Waals* interactions and/or by an increase in the ratio of *anti* to *gauche* isomers. These effects are expected also to increase upon raising the concentration of the zwitterionic detergent (*vide supra*). Consequently, for the lecithin acyl chains incorporated in micelles of longer *n*-alkyl chain amphiphiles, also deshieldings are expected due to increasing solvent effects along with conformational changes towards more extended forms. If only solvent effects participate, deshieldings should correspond to the respective site factors, thus leading to maximal differences for the methyl carbons²⁰. These differences increase upon lowering the lipid concentration.

Finally, for the TABs possessing effectively shorter alkyl chains as compared with DOPC, only deshieldings are anticipated (vide supra). Thus, shieldings will occur for the carbons for those parts of the lecithin acyl chains which protrude from the *n*-alkyl TAB chains. Recapitulating, combining literature data of Figure 3.1 and the experimental

data of Table III.2-6 we are now able to indicate approximately to which extent conformational changes on the one hand and solvent effects on the other hand will contribute to the observed chemical shift changes.

III.4.3 Hydrophobic region: discussion

Combination of the data of Figure 3.1 and the observed deshieldings upon intercalation of C₈TAB in DOPC micelles leads to the following conclusion. C₈TAB becomes more extended with respect to its monomeric solution^{2,3} over the entire concentration range (Table III.2, the 1:4 up to and including the 4:1 mixing ratio). This is in accordance with recently published observations of Lindman and coworkers²². Effects are most distinct in mixed micelles containing an excess of lecithin (*i.e.*, the 4:1 mixing ratio), where the C₈TAB undergoes the largest disturbing effect from the lecithin molecules.

Regarding the DOPC/C₁₂TAB mixed micelles, deshieldings are observed for the C-2/C-11 fragment indicating effects comparable with the DOPC/C₈TAB mixed micelles. However, pronounced shielding is obtained for the C-12 carbon. Since no *extra* contributions of *gauche* conformers are feasible (Figure 3.1 vs. Table III.3), only decreasing *van der Waals*

solvent effects are responsible. The reason is that the C_{12} TAB surfactant possesses a greater effective length than the DOPC molecules in the mixed micelles¹⁰, and thus protrudes from the lipid acyl chain region.

Incorporating C_{14} TAB in DOPC micelles leads to an increase of the effective chain length of the TAB amphiphile. This is reflected by the observed shieldings for the C-11/C-14 segment of the C_{14} TAB with respect to its single micelle. It is clear that conformational changes are possible in this case in principle. For folding around the C-12/C-13 bond one would expect shielding at C-11 (see Figure 3.1a). This is not observed, however (see Table III.4). A decrease in molecular packing is able to cause the experimental chemical shift differences (the chemical shift difference of the C-14 carbon is about three times larger than the corresponding value of C-13, and it is about twice as large as the chemical shift difference of C-12 for the 4:1 mixing ratio). Thus alkyl chain separation as compared with the single micelles is accomplished. Furthermore, the pattern of the observed chemical shift differences of the first eleven carbons resembles that of the C_{12} TAB molecules in their mixed micelles.

For the DOPC/ C_{16} TAB mixed micelles shieldings are observed for the C-11/C-16 part of the C_{16} TAB amphiphiles, thus showing once more an increase of the effective chain length. It is still impossible to take large contributions of *gauche* isomers into account (see Figure 3.1 and Table III.5), due to the discrepancy between the observed and calculated chemical shift differences (for all *anti/gauche* ratios). However, comparing observed with calculated chemical shift differences for the C-14/C-18 fragment of the C_{18} TAB surfactant in its mixed micellar systems with DOPC indeed indicates pronounced contributions of *gauche* conformers around the C-16/C-17 carbon bond, apart from unpacking effects (*cf.* the experimental shielding of the C-14 methylene carbon with its calculated value based on conformational changes). In retrospect, the situation described here is similar to that of the mixed micelles

of potassium dodecanoate and potassium hexanoate described in the preceding Chapter (see Section II.5). In this latter case, it was not possible to rule out conformational changes of the dodecanoate chains with respect to their single micelles. A definite conclusion could not be reached due to the inability to resolve the C-8 resonance of the dodecanoate properly.

For the phospholipid in its mixed micelles the chemical shift differences of both chains are retained almost independently of chain length and concentration of the *n*-alkyl TAB. Consequently, this implies a rather unaltered average conformational behaviour of the *sn*-1 and *sn*-2 chains in the mixed micelles. Only *van der Waals* solvent effects change upon mixed-micelle formation with the TABs. This is clearly demonstrated by maximum differences in chemical shift for the methyls¹⁸ reflecting the respective site factors²⁰. Logically, induced differences are most pronounced for mixed micelles containing less lecithin (*i.e.*, the 1:4 mixing ratio) and decrease towards the 4:1 ratio. At the lowest ratio the lecithin undergoes the largest disturbing effect from the surrounding TABs. This perturbation fades as the lipid concentration is raised to ratios where the *n*-alkyl amphiphilic TABs become the perturbed moieties in mixed micelles containing lipid molecules (*i.e.*, the 4:1 mixing ratio). So, the possibility has been demonstrated to determine, at least approximately, to what extent TABs incorporated in DOPC micelles undergo additional chain bendings as compared with the single micellar solutions.

III.4.4 *Hydrophilic region: analytical and geometrical considerations*

Prior to the following discussion (see Section III.4.5) a general principle of lecithin aggregates regarding the dynamical behaviour of the $\text{CH}_2\text{-}\ddot{\text{N}}$ linkage of the lipid head group will be discussed²⁴. In the preceding Sections, two aspects involving fluidization of the *hydrophobic* core were treated, namely packing and *anti-gauche* isomerizations. In this Section fluidization of the *hydrophilic* region will be

discussed. Recently, it became clear that the conformation of the lecithin head group is similar in the monomeric, the micellar and the bilayer state^{5,25-28}. Even additives such as fatty acid derivatives, amphiphiles and cholesterol do not affect the lecithin head group conformational equilibria²⁹⁻³². The data of Table III.7 indicate that TABs also are unable to influence either lecithin head group conformations or head group motions notably.

^cLipid backbone resonances.

^dLipid head group resonances.

No changes in chemical shift and line widths were detected. Thus, conformational and motional changes within this part of the lecithin hardly contribute to the fluidization of the hydrophilic region. However, one type of motion has not been discussed yet, *i.e.* motion of the $\text{CH}_2-\overset{\ddagger}{\text{N}}$ vector around the CH_2-CH_2 head group linkage (see Figure 3.2). This motion is monitored by the resolution of the multiplicity of the carbon resonances of the $-\overset{\ddagger}{\text{N}}\text{Me}_3$ group²⁴. As the carbon atoms involved are linked to nitrogen as well as to hydrogen, two interactions can contribute to the observed line shape, *viz.* quadrupolar and dipolar interactions.

This type of motion increases when the head group packing becomes looser (*i.e.*, a larger surface area per lipid head group). It results in smaller quadrupolar and dipolar interactions, leading to the appearance of the multiplicity of the ^{13}C resonances of the lecithin $-\overset{\ddagger}{\text{N}}\text{Me}_3$ group. In the Chapters IV and V a more detailed description of the backgrounds of this type of motion will be presented.

III.4.5 Hydrophilic region: discussion

Low aggregational densities, such as for monomeric TABs, result in triplet structures for the $-\overset{\ddagger}{\text{N}}\text{Me}_3$ resonances. On the contrary, high aggregational densities, as for micellar TABs, result in unresolved multiplicities for the $-\overset{\ddagger}{\text{N}}\text{Me}_3$ resonances³³. It will now be demonstrated that differences in intermolecular head group distances as large as those occurring between aggregated and non-aggregated states are not strictly necessary to obtain enhanced $\text{CH}_2-\overset{\ddagger}{\text{N}}$ site mobilities. In fact lateral expansion (*i.e.*, a small decrease of the aggregational density) may be sufficient.

The intermolecular head group distances of mixed micelles of DOPC and C_{18}TAB were monitored by means of the multiplicities of the lecithin $-\overset{\ddagger}{\text{N}}\text{Me}_3$ carbon resonances as a function of the TAB concentration (Figure 3.3). Intercalation of only 2% detergent at 323K already causes sufficient inter-head-group space and thus better defined splittings. At lower temperature (318K) no increase in mobility can be observed at this point (2% detergent). In this case, the

Figure 3.3 Line shapes of the lecithin $-NMe_3$ resonances of DOPC observed by means of a decoupling power of 1 Watt. Mixed-micelle ratios are indicated.

splitting only becomes visible at higher concentrations of TAB and it remains approximately the same over the entire concentration range investigated up to and including the 1:4 (m/m) lipid TAB mixing ratio. As a result, these experiments indicate, that only a slight increase in intermolecular lipid head group distance causes an increased surface area per lipid molecule and consequently considerable motional freedom for the CH_2-N vector.

III.5 Summary/Conclusions

¹³C NMR measurements of DOPC micelles detect an almost complete visibility of the intrinsic magnetic nonequivalency of the two lipid acyl chains. The chemical shift data are interpreted in terms of effectively different lengths of the *sn*-1 and *sn*-2 acyl chains due to a bending near the C-2 carbon atom of the *sn*-2 chain. Mixed micellar systems of DOPC and several TABs show a difference in effective chain lengths of the constituent types of amphiphiles. ¹³C NMR shieldings are observed for the TAB fragments which are longer than both acyl chains of the lipids. At an effective chain length difference of seven carbon atoms a sizeable contribution of *extra gauche* conformers, with respect

to their single micelles, occur for these TABs. At smaller differences a decrease of *van der Waals* interactions (*i.e.*, decreasing molecular packing) participates almost exclusively leading to chain separation. The *deshieldings* observed for the TAB segments situated directly between neighbouring lecithin chains indicate conformational changes towards more extended forms, as compared with their single micellar solutions, rather than an increase of *van der Waals* interactions. The DOPC molecules do not undergo measurable conformational changes upon mixed-micelle formation but are only subject to increased molecular packing. This may indicate that lipid conformational changes are of minor importance for solubilizing micelle bound hydrocarbon-like compounds.

Regarding the fluidity of the head group region, incorporation of TABs increases the surface area per lipid head group and consequently increases the mobility of the $\text{CH}_2\text{-}\overset{\ddagger}{\text{N}}$ site around the lipid $\text{CH}_2\text{-CH}_2$ head group linkage.

III.6 Experimental

The *n*-alkyl TABs were prepared by the reaction of trimethylamine with the *n*-alkyl bromides in alcoholic solution according to literature data¹¹. DOPC was purchased from Supelco, Inc. A lipid stock solution was prepared by removal of the organic storage solvent under a stream of nitrogen and by dissolving in CHCl_3 . This stock solution was stored at -20°C . Mixed-micelle solutions were obtained by adding the appropriate amounts of deionized water to the solid TABs and dried samples of the lipid stock solutions. The resultant solutions were sonicated for 1 min. at 25°C .

All ^{13}C NMR spectra were run at 62.93 MHz on a Bruker WM 250 spectrometer under proton noise decoupling at 45°C , unless otherwise indicated. The deuterium signal from C_6D_6 was employed as an external lock signal. All chemical shifts are related to Me_4Si (C_6D_6 at 128 ppm downfield from Me_4Si). 2000-9000 transients were accumulated of spectral width 2 KHz in 32K data points limiting the resolution to 0.005 ppm. The pulse width was set to a 90° flip angle.

CHAPTER IV

Effects of lytic compounds on the fluidity of lecithin sonicated bilayers

A measure of lipid resistance against disruption of the bilayer orientation

IV.1 Introduction

It has been recognized that single stranded *n*-alkyl amphiphiles within a biological membrane have severe implications for the stability of the cell-interface membrane. An increase in content of these surfactants forms conditions for cell-fusion and an excess of exogenously added surfactant causes lysis¹⁻⁴.

Until now, no definite descriptions regarding interactions between lytic compounds and lipids during lysis of the bilayer membrane have been presented. In order to further investigate the aspects of lysis, *n*-alkyl TABs incorporated in sonicated bilayers of dimyristoyl-L- α -phosphatidylcholine (DMPC) and dipalmitoyl-L- α -phosphatidylcholine (DPPC) have been studied in connection with recently published data concerning the fluidity (*i.e.* packing, mobility and conformational phenomena) of phosphatidylcholines and *n*-alkyl amphiphiles in different aggregational states^{5,6}. It will be shown that at concentrations of single stranded amphiphiles where no lysis occurs (*i.e.* in the bilayer state), these single stranded compounds are "squeezed" between the lipid molecules. This is due to increased aggregational densities. It results in motional restrictions within both the head group region and the alkyl chain region of the lytic compounds without affecting the lecithin mobilities. Because additives with large internal volumes, such as cholesterol, (see subsequent Chapter) are also reduced in their mobilities, an analogous picture may be obtained for integral proteins, with even larger internal volumes. It has been stated that in these cases proteins adapt the active channel conformation

only at small surface areas per molecule, *i.e.* a large aggregational density^{7,8}. From the description given in this Chapter, it can be made plausible that the surrounding lipids induce the desired protein packing.

Lysis of the bilayer occurs when the concentration of the TAB is raised to ca. one equiv. At this point the aggregational density decreases and consequently TAB mobilities increase and TAB chain extension decreases. Also the acyl chain mobilities and acyl chain kinking of the lipids increase. The toxic properties of germicidal *n*-alkyl TABs against bacteriological organisms may be explained in terms of lysis of this particular biomembrane system when such germicides are incorporated¹.

IV.2 Results and discussion

IV.2.1 Head groups

General remarks. In view of the following discussion, a few aspects regarding the dynamic behaviour of the CH₂- $\overset{\ddagger}{N}$ linkage of the head groups of the lipids and the TABs are discussed in more detail, as are the consequences for the spectral appearances in ¹³C NMR.

Quadrupolar relaxation of nitrogen-14 influences the line shapes of the resonances of the carbons directly bonded to nitrogen¹⁰. Moreover, dipolar ¹³C-¹H interactions modulate the resonances of hydrogen substituted carbons. In the case of examination of the - $\overset{\ddagger}{N}Me_3$ moiety of lecithins and TABs, a combination of these phenomena is expected. Consider the case where one aspect is eliminated, *e.g.* dipolar broadening is sufficiently suppressed¹¹. Triplet structures, due to scalar coupling to ¹⁴N (spin 1), are produced for the carbon resonances when quadrupolar relaxation is slow (*i.e.* ¹⁴N quadrupolar relaxation times exceed 0.086 sec⁶). When quadrupolar relaxation becomes faster (*i.e.* ¹⁴N quadrupolar relaxation times shorter than 0.086 sec⁶), a collapse of the triplet structure is expected. In the extreme case, a narrow singlet remains¹². Recently, London *et al.*¹¹ showed that simple methyl rotation or internal motion about the CH₂- $\overset{\ddagger}{N}$

bond will *not* influence the quadrupolar relaxation, because of the molecular symmetry around the nitrogen nucleus. Therefore, *slow and fast quadrupolar relaxation will be correlated with respectively fast and slow mobilities about the CH₂-CH₂ head group bond, affecting the orientation of the CH₂-N linkage.*

On the other hand, ¹³C-¹H dipolar interactions have to be considered. From a steric point of view, dipolar interactions within the cationic site of trimethylammonium amphiphiles will be averaged (and thus their effects will be decreased) most effectively by motions which take the -NMe₃ group over the largest number of possible directions in space, namely motions around the CH₂-CH₂ head group bond. Local motions such as internal rotation about the CH₂-N bond and methyl rotation are thus of minor importance, apart from the fact that these rotations usually are too fast to be influenced by the environment of the head groups. The rate of motion of the -NMe₃ site around the CH₂-CH₂ bond is limited by a large aggregational density. Motions around this CH₂-CH₂ bond are decreased when the aggregational density is increased (*i.e.* the "squeezing" of the head groups). This can be envisaged by a study of lipids and lytic compounds in different states (monomers and aggregates). Unfortunately, it is impossible to observe DMPC and DPPC -NMe₃ line shapes in the *monomeric* phase by ¹³C NMR without labelling (very low CMC-values^{13,14}). Still, in order to shed light on the influence of packing on -NMe₃ line shapes, the -NMe₃ resonances of the lytic TABs in non-aggregated and aggregated states were monitored (for a description see Section IV.5). It was shown that increased packing densities lead to a collapse of the triplets. Similar spectra are obtained for pure lecithin *aggregates* (Figure 4.1). Analogously to the lytic TABs, DMPC vesicles produce a broadened resonance at *e.g.* 1 Watt decoupling power. Thus one is tempted to conclude that head group mobilities are slow. However, when sufficient decoupling power (ca. 8 Watts) is applied, triplets are observed. It implies that the mobilities of the nitrogen moiety around the CH₂-CH₂ bond are much faster than one would

expect from the experiments at low level decoupling power alone.

Figure 4.1 $-\overset{13}{\text{C}}\text{NMe}_3$ line shapes of DMPC and DPPC sonicated bilayers (50 mM in water) at 323K and variable magnitudes of proton noise decoupling in 62.9 MHz ^{13}C NMR spectra (DP = decoupling power).

Incorporation of lytic compounds and lysis of the bilayer. At mixing ratios where the bilayer orientation is not (yet) subject to lysis (*i.e.* the 4:1 up to the 1:1 mixing ratio), a triplet structure for the lipid is maintained, indicating relatively large head group mobilities (Figure 4.2a-c). This is also the case for mixing ratios where mixed micelles are formed (*i.e.* the 1:2 and 1:4 mixing ratio). However, for the head group mobility of the penetrating TAB molecules some remarkable changes are perceptible. In the DMPC/C₈TAB dispersions the solubilized *n*-octyl TAB molecules are in very rapid exchange with their extraventricular monomers, because the effective concentration is far beneath the CMC-value¹³. Thus, an average state is monitored with relatively large intermolecular separations and so a triplet structure for the $-\overset{13}{\text{C}}\text{NMe}_3$ site of the C₈TAB appears. The C₁₂TAB reveals a different behaviour. Up to the 1:1 lipid/detergent mixing ratio a broad resonance is detected, due to enhanced dipolar interactions. Fast quadrupolar relaxation does not contribute to the $-\overset{13}{\text{C}}\text{NMe}_3$ line shape. This was confirmed by

the observation of $-\overset{\dagger}{N}Me_3$ triplets at elevated noise decoupling (*i.e.* 13 Watts) at various temperatures (303K-323K)¹⁵. An enhanced mobility for the TAB head group is achieved at lower mixing ratios. This is deduced from the appearance of triplets for the TAB. It substantiates literature data^{2,4} that bilayer ordering is maintained up to the mixing ratios around 1:1, and lysis of the bilayer towards micelle ordering - and concomitant smaller aggregational densities - is established at lower ratios. Thus, *in the bilayer state, the surrounding lecithin molecules force incorporated lytic compounds to reduced head group mobilities with respect to the pure lytic micelles (see Section IV.5), without decreasing notably the time scale of motion of the lipid $CH_2-\overset{\dagger}{N}$ site with respect to the pure lipid vesicle.* This packing situation may be envisaged by the difference in relative orientations of the two types of head groups (Figure 4.3). The lipid head groups are located almost perpendicular to the bilayer normal, while on the average the head groups of the lytic constituents are situated along this bilayer normal and are squeezed between neighbouring lipid molecules. In the Section IV.2.2 it will be shown that this squeezing-picture is consistent with the observations made for the hydrophobic region of the TABs.

For the C_{14} TAB mixed dispersions (Figure 4.2c) a similar change in the dynamic behaviour of the $CH_2-\overset{\dagger}{N}$ site is observed during the transition mixed bilayer into mixed micelle³. However, lysis of the bilayer does not provide resolved methyl resonances.

Figure 4.2a $-\overset{\dagger}{N}Me_3$ line shapes for mixed dispersions of C_8 TAB and DMPC at 323K and DP = 8 Watts. Similar patterns were observed for other mixing ratios.

Figure 4.2b $-\text{NMe}_3$ line shapes for mixed dispersions of C_{12}TAB and DMPC at 323K and DP = 8 Watts. Lipid/detergent mixing ratios are indicated. $J_{\text{C-N}}$ couplings were, when visible, 3.0 - 3.6 Hz.

Figure 4.2c $-\text{NMe}_3$ line shapes for mixed dispersions of C_{14}TAB and DMPC at 323K and DP = 8 Watts. Lipid/detergent mixing ratios are indicated. $J_{\text{C-N}}$ couplings were, when visible, 3.0 - 3.6 Hz.

Figure 4.3 Relative average orientations of the lecithin and the TAB in their mixed dispersions. The hydrophobic interior is indicated by tubes.

The increase in line width at high mixing ratios has to be ascribed to enhanced dipolar interactions, similar to the C_{12} TAB mixed bilayers. Fast quadrupolar relaxation could not be excluded, however, because at elevated noise decoupling (*i.e.* ca. 13 Watts) a "singlet" structure was still detected¹⁵ (due to thermal degeneration of the constituents of the aggregates, it was impossible to apply proton noise decoupling exceeding 13 Watts). Yet a difference exists between the single and the 1:4 mixed micellar solution of this TAB detergent (compare the data of Figure 4.7 with Figure 4.2c). Obviously, the presence of only small amounts of lecithin molecules already decreases the head group mobility of this particular TAB. Similar patterns were obtained when intercalating these lytic compounds in vesicle structures of DPPC.

IV.2.2 Hydrophobic tails

The ^{13}C NMR spectra of the pure vesicles of DMPC and DPPC - which will serve as reference samples for the mixed lipid systems - are presented in Figure 4.4. As indicated, the line widths are very much smaller than previously reported¹⁶.

Figure 4.4 ^{13}C NMR spectra of the acyl chain region of DMPC and DPPC sonicated bilayers at 323K and DP = 8 Watts. Line widths and chemical shifts are indicated. Dilution of the samples from 50 mM to 20 mM did not affect the line widths or chemical shifts.

The latter line widths were at least three times larger than those presented in Figure 4.4. It became clear that the main part of this line narrowing was a consequence of eliminated dipolar coupling. This was indicated by spectra recorded at lower levels of proton noise decoupling. A comparison of the spectra of sonicated bilayers of DMPC and DPPC shows no significant differences: line widths and chemical shifts are nearly identical. From this point of view, in combination with the results of the head groups (Figure 4.1), it is stated that on the ^{13}C NMR time scale

the vesicular dispersions of DMPC and DPPC are motionally and conformationally equivalent. This stands in contrast to earlier reports based on vibrational spectroscopy¹⁷.

Recently, a description of the phenomena involving fluidization of the hydrophobic core of mixed micellar systems of lipids and lytic TABs has been offered⁵. It was shown that those hydrophobic parts of the TAB located between the lipid molecules altered their conformational equilibria towards more extension, and were subject to increased chain packing. The lipid molecules, however, were not shown to change their conformations upon solubilization of these TABs. Furthermore, it was discussed that the hydrophobic part of the the TAB protruding from the lipid hydrophobic region was subject to conformational changes towards more kinking and/or decreased packing with respect to its single micelles. In similar terms, the lysis of the (curved) bilayer upon incorporation of TABs is now discussed. ¹³C NMR line widths and chemical shifts were investigated. Incorporation of C₁₄TAB in DMPC sonicated bilayers resulted in *undetectable* signals for the tail of the single stranded amphiphile from the 4:1 to the 3:2 lipid/detergent mixing ratio. Also, *no* line width and chemical shift changes occurred for the lecithin chains within this concentration interval. The latter indicates that no significant changes occur within the bilayer ordering and dynamics. The undetectability of the TAB resonances must be due to immobilization and subsequent dipolar broadening. Up to now, only the ¹³C-resonances of intercalated substrates with a large internal volume such as cholesterol¹⁸ and proteins¹⁸ were shown to broaden extremely. It is now demonstrated that relatively small lytics act in a similar way. (It is suggested that free axial rotation of the entire tail of the TAB is limited. Thus, TAB mobilities are diminished by the lipid, without affecting partial rotation or kink diffusion in the lecithins about their long axis. Model studies show that in the bilayer ordering intermolecular distances between the hydrophobic chains of C₁₄TAB and DMPC are on the average smaller than between the lipid *sn*-1 and *sn*-2 chain, resulting in smaller mobilities of the TAB chains and concomitant intensities

of the corresponding ^{13}C NMR resonances with respect to those of the lipid molecules in the bilayer). Obviously, when the membrane contains only small quantities of TABs, these TAB molecules are pressed between neighbouring lipid molecules, the consequence being that head group (see Section IV.2.1) as well as tail mobilities of the TABs are reduced. At higher quantities of the C_{14}TAB (i.e. at mixing ratios lower than 3:2), the resonances of the C_{14}TAB become visible, because the bilayer undergoes lysis and mixed micelles, with lower aggregational densities and concomitant enhanced mobilities are formed^{2-4, 19}. In addition, the decrease of the DMPC acyl chain line widths is another indication for this disruption of the bilayer: line widths are typically 2 - 3 Hz for mixed micelles (Figure 4.6). Then one is able to notice (Figure 4.5a) that the C_{14}TAB shows deshieldings compared with its single micelle solution.

Figure 4.5 Deshieldings (ppm) of C_{14}TAB and C_{12}TAB upon incorporation in DMPC sonicated dispersions at 323K and $DP = 8$ Watts (a). Deshieldings (ppm) of C_{12}TAB upon incorporation in DPPC sonicated dispersions at 323K and $DP = 8$ Watts (b). Molar lipid/detergent mixing ratios are indicated. Total amphiphile concentration equals 50 mM (see the experimental Section IV.4).

The pattern of deshieldings indicates that the lipid molecules force the C_{14} TAB towards more extension upon incorporation, analogously to the detailed description regarding mixed aggregates of short-chain lecithins and several TABs⁵. Also the lipid resonances change position when lysis of the bilayer takes place. The observed shieldings for the C-12/C-14 lipid fragment (see Table IV.1) suggest that increased chain folding and/or decreased chain packing⁵ are the result of the bilayer disruption. Moreover, the line widths of the ^{13}C NMR resonances of the acyl tails (Figure 4.6) decrease.

Figure 4.6 Line widths (Hz) of the acyl region of DMPC vs. the concentration of incorporated C_{14} TAB at 323K and DP = 8 Watts (the decrease in line width is not due to a decrease of the magnetic non-equivalence between similar carbons of the sn-1 and sn-2 acyl chains. The magnetic non-equivalence remains ca. 0.1 ppm for the micellar as well as for the bilayer state).

Compared with the DMPC/ C_{14} TAB mixed bilayers, an enhanced detectability for the single stranded TAB occurs in the DMPC/ C_{12} TAB and especially in the DMPC/ C_8 TAB mixed bilayer systems. This is a result of the relatively enhanced exchangeability between intravesicular aggregated and

Table IV.1 Chemical shift changes of the acyl region of DMPC and DPPC upon mixing with C_{14} TAB in different ratios at 323K and DF = 8 Watte. Resolved resonances, obtained by means of resolution enhancement, are mentioned separately

extravesicular monomeric C_8 TAB and C_{12} TAB compared with the C_{14} TAB. As a consequence, chemical shift changes of the former surfactants are less pronounced than for the C_{14} TAB, but point out a comparable behaviour (a typical example is given in Figure 4.5a). Mixed bilayer systems of DPPC and TABs revealed quite the same pattern: for example, C_{12} TAB is forced by the surrounding lecithin molecules towards more extended forms as compared with its single micelle (Figure 4.5b), as can be observed from the deshielding pattern. When disrupting the bilayer structure, also the lipid molecules are subject to increased kinking and/or decreased chain packing (Table IV.1), analogous to the DMPC mixed systems.

IV.3 Summary/conclusions

Intercalation of low percentages (<50% m/m) of several n -alkyl TABs in lecithin vesicles preserves the lipid bilayer orientation. In these mixed vesicles, the TAB molecules are

forced towards *restricted motions* of the $-\overset{\dagger}{N}Me_3$ site and the alkyl chains due to an increased density for the TABs. Moreover, the TABs are compelled towards *more chain extension* as compared to their single micelles. However, neither a decrease of the lecithin $-\overset{\dagger}{N}Me_3$ site mobility around the CH_2-CH_2 head group linkage, nor a decrease in acyl chain mobility, nor a change in acyl chain kinking is detected. In other words, the lecithin bilayer reacts upon disruption by squeezing "intruding" compounds towards less mobility.

The disruption of the bilayer is achieved when the TAB concentration is raised to ca. one equiv.: lysis of the bilayer occurs and mixed micelles are formed. It results in a decrease of the aggregational density. Consequently, the TAB mobilities increase and their chain extension decreases. At this point, also an increase of the lecithin acyl chain mobility and acyl chain kinking are detected. Thus, the driving force for lysis of the bilayer has to be ascribed solely to the potency of the TABs to form micellar structures.

IV.4 Experimental

The *n*-alkyl TABs were prepared by the reaction of trimethylamine and the *n*-alkyl bromides in alcoholic solution according to literature data⁹. DMPC and DPPC were purchased from Supelco, Inc. and Sigma. To obtain mixed micelle and/or bilayer solutions of DMPC and DPPC, dry samples of the lecithin and the TABs were added to the appropriate amount of deionized water. Solutions were sonicated in NMR-tubes within a Branson Model 50-D ultrasonic water bath between 0°C and 20°C. Typically, solutions were clear after a period of ten minutes. During this interval no thermal degeneration or hydrolysis occurred, as monitored by thin layer chromatography with $CHCl_3$: MeOH: H_2O = 65: 25: 4 (w/w) as eluents. Multibilayer suspensions of DMPC and DPPC were prepared by adding the appropriate amounts of deionized water to dry lecithin and vortexing vigorously above the main phase transition temperature. Pure DMPC and DPPC vesicles were prepared by means of sonication in the above mentioned water bath between 0°C and 20°C; operation time : typically one hour. Solutions

were blueish transparent and no hydrolysis or thermal degeneration occurred according to thin layer chromatography. Laser light scattering showed that these samples were not monodispers: particle sizes varied between 250 Å and 1000 Å. The distribution function showed a large fraction of small particles (around 250 Å) and a small fraction of large particles (exceeding 1000 Å). The total amphiphile concentration was 50 mM for all pure and mixed lipid samples.

All ^{13}C NMR spectra were run at 62.93 MHz on a Bruker WM 250 spectrometer under proton noise decoupling at 323K, unless indicated otherwise. The deuterium signal from C_6D_6 was employed as an external lock signal. All chemical shifts are related to Me_4Si (C_6D_6 at 128 ppm downfield from Me_4Si). 10,000-100,000 transients were accumulated in 4K data points zero-filled to 32K points before Fourier Transformation. Spectral width was 2 KHz. No relaxation delay was employed. Pulse width was set to a 90° flip angle. The decoupling circuit was carefully tuned prior to the various experiments in order to operate at levels exceeding 2 Watts.

IV.6 Appendix

To demonstrate the influence of molecular packing on the line shape of $-\overset{\text{N}}{\text{Me}}_3$ resonances, several TABs were studied in the monomeric and micellar state. The results are also useful for the study of the line shapes of lecithin $-\overset{\text{N}}{\text{Me}}_3$ resonances. It should, however, be stressed that, whereas in lecithin vesicles the $\text{CH}_2-\overset{\text{N}}$ vector will be approximately parallel to the bilayer plane, corresponding vectors in the TABs will be perpendicular to the aggregate surface (Figure 4.3).

The *n*-octyl TAB is not capable of forming aggregates at the concentration investigated¹³, and shows well resolved triplets for the $-\overset{\text{N}}{\text{Me}}_3$ moiety (Figure 4.7). The large C_{18} TAB micelles show "singlet" structures under these conditions. It is consistent with the picture of a highly mobile $\text{CH}_2-\overset{\text{N}}$ vector when the aggregational density is low, as for monomeric C_8 TAB; at high aggregational densities a "singlet" resonance is observed, as for micellar C_{18} TAB. Thus, when the molecular

Figure 4.7 $^{-1}\text{NMe}_3$ line shapes of several TABs at different temperatures and decoupling power.

packing increases, head group mobilities around the $\text{CH}_2\text{-CH}_2$ bond decrease. However, for the TABs possessing intermediate chain lengths, interesting developments occur. For these detergents, the appearance of triplet structures is strongly related to the applied decoupling power and operating

temperature. At 323K and 8 Watts decoupling one can clearly recognize a pattern of head group mobility around the $\text{CH}_2\text{-CH}_2$ head group bond. Two reasons may be offered to explain this pattern in terms of aggregational densities. First, the CMC is lowered from C_8TAB to C_{18}TAB . Consequently, monomeric concentrations are decreased to almost zero in this series, due to a shift of the equilibrium monomer=aggregate to the right. On the NMR time scale essentially *this* shift is monitored, and it is expressed in the increased contributions of molecular aggregation to the $-\text{NMe}_3$ line shapes from C_8TAB to C_{18}TAB . Secondly, from geometrical considerations⁷, also increasing aggregate sizes from C_8TAB up to C_{18}TAB lead to the observed change in mobility due to stronger head group interactions (larger radii of curvature) and consequently larger aggregational densities.

CHAPTER V

Effects of cholesterol on the fluidity of lecithin sonicated bilayers

V.1 Introduction

Various analytical methods have been applied to shed light on the complex behaviour of cholesterol solubilized in a membrane. These studies showed for instance that cholesterol broadens, lowers or disrupts the phospholipid phase transitions; alters membrane permeability; influences phospholipid chain conformations and/or chain packing; condenses the bilayer fluidity at temperatures above the main phase transition and liquefies the bilayer at temperatures below the main phase transition¹⁻¹⁶. In this Chapter it will be described that, upon rigidification of the bilayer by the solubilization of cholesterol, one type of motion which has not been discussed earlier is affected, namely the motion of the phospholipid $\text{CH}_2-\overset{\dagger}{\text{N}}$ head group site around the CH_2-CH_2 head group bond.

V.2 Results and discussion

Membrane fluidity is strongly related to inter- and intramolecular mobilities, conformational changes and alterations in packing of the phospholipids and membrane bound substrates, the constituents of the bilayer¹⁸. Several details regarding the dynamic behaviour of the $\text{CH}_2-\overset{\dagger}{\text{N}}$ site of the phospholipid head group have been offered in the preceding Chapter. Also, for the lipid acyl chain region data have been presented to differentiate between conformational changes and chain packing¹⁹. Contrary to lytic TABs¹⁷, cholesterol broadens the resonances of the $-\overset{\dagger}{\text{N}}\text{Me}_3$ site of DMPC sonicated bilayers (Figure 5.1) and, besides observed deshieldings (Figure 5.2), also increases

the phospholipid acyl chain line widths (Figure 5.3).

Hydrophilic region. The conformation of the lecithin polar head group is similar in the monomeric, micellar and bilayer state and is independent of the fatty acyl chain length^{7,20}. Bulky metabolic regulating additives such as cholesterol are unable to change the polar head group conformation^{7,14,18,20-26}. Furthermore, ¹³C NMR studies indicate that the presence of cholesterol in phospholipid bilayers has little or no influence on the internal motion of the choline methyls^{14,16}, nor does it effect the motion of the phosphate segment¹⁴. In other words, the factor governing our results will be a change of intermolecular head group distances of the lecithins (Figure 5.1).

Figure 5.1 Cholesterol induced changes of the line shape of the $-\dot{N}Me_3$ resonances of DMPC sonicated bilayers at 323K and DP = 8 Watts.

A change towards larger head group distances - and from our point of view subsequent enhanced mobilities for the $CH_2-\dot{N}$ site - is frequently referred to^{10,14}. This change is ascribed to the so-called "spacer"-effect cholesterol is supposed to induce for the head group region of the lecithin bilayer. However, from Figure 5.1 it is now clear that the $CH_2-\dot{N}$ vector mobility of the lecithin around the CH_2-CH_2 head group axis actually decreases upon addition of the sterol.

Hydrophobic region. The resonances of cholesterol could

not be observed due to significant broadening. In agreement with recently published data^{8,16,27}, we attribute this broadening to strong dipolar interactions. The observed line broadening of the resolved carbon resonances of the lecithin acyl region of DMPC (Figure 5.3) is certainly - although partially - caused by strong dipolar interactions too (lower decoupling power enlarged the line widths of these carbon resonances). However, non-motional aspects such as chemical shift non-equivalences between the lecithin *sn*-1 and *sn*-2 chains and/or between the inside and outside monolayered lecithins may be altered. The residual part of the line broadening may depend on several motional restrictions^{16,28-30}.

Figure 5.2 Cholesterol induced deshieldings of the lecithin acyl chain region in DMPC sonicated bilayers at 323K and DP = 8 Watts, versus the sterol concentration.

The main factor which has to be taken into account is the intramolecular process of chain reorientation. For the very reason that its correlation time is typically 10^{-9} - 10^{-10} sec for small, non-sterol containing vesicles and 10^{-7} sec for large or sterol-rich particles^{29,30}, a change in the rate of chain reorientation induces the largest line broadening as compared to other processes^{16,28-30}. For the DMPC/cholesterol mixed bilayer systems, stability was maintained for samples containing ca. 30 mole % sterol or less. Up to this limit, it was possible, to estimate chemical shift differences for the lecithin acyl chain region (Figure 5.2). For the carbon resonances investigated, deshieldings increase with the effective sterol concentration. For the hydrophobic interior it is possible to draw a plot of these deshieldings versus the carbon atom position (Figure 5.4). In agreement with recently published data¹⁹, the pattern of Figure 5.4 reveals a tendency towards more extension and/or increased intermolecular packing. In connection with the relatively small deshieldings of the ω -Me group, no large conformational changes within the C-12/C-14 region as compared with the pure lecithin vesicle are indicated.

Figure 5.3 Cholesterol induced line widths of the lipid acyl region upon incorporation in DMPC sonicated bilayers at 323K and DP = 8 Watts, versus the concentration of the sterol.

Figure 5.4 Deshielding pattern for the hydrophobic acyl chain end of DMPC upon solubilization of 30 mole % cholesterol at 323K and DP = 8 Watts, versus the carbon atom position of DMPC.

Interpretations. From a strong increase in turbidity it is concluded that addition of cholesterol increases the vesicle size significantly. This is in agreement with the observations of *de Kruijff et al.*²¹. It is well-known that the sterols are located beyond the lecithin head group region of the vesicle^{7,8} and thus no *direct* sterol-lipid interactions exist in the head group region. Thus the embedded sterol nuclei push the lecithin acyl chains aside and increase the average radius of curvature of the vesicle. The increase in particle size leads to higher aggregational densities between the lecithin head groups¹⁸. However, too close an approach of the repulsing lecithin head groups is avoided¹⁹. In order to minimize the free energy of the vesicle, a compensation occurs through an increase of the aggregational density of the hydrophobic interior. The implications for the ¹³C NMR spectra are twofold. First, higher aggregational densities within the lecithin head group region decrease the lecithin head group mobility (see Chapter IV). Secondly, higher aggregational densities within the hydrophobic interior induce chain extension and/or reduced chain mobility (see Chapter IV). Indeed, cholesterol decreases the mobility of the lecithin -NMe₃

site around the $\text{CH}_2\text{-CH}_2$ head group bond (Figure 5.1). Due to the increase in the hydrophobic packing the resonances of cholesterol itself could not be observed, while also a decrease of the lecithin acyl chain motions was induced (Figure 5.3).

Besides this rather macroscopic view, a more detailed semi-quantitative interpretation of the data is possible, by means of a model of *Chan et al.*³¹. It suggests that incorporated cholesterol is complexed to one lecithin molecule and this complex in turn is associated with a second lecithin molecule via a *van der Waals*-type interaction. At low sterol concentrations (ca. 10 mole %), the remainder of the bilayer is built up by free lecithin and interfacial boundary lecithin. However, controversions exist about the binding sites within the complex³¹. At ca. 20 mole % sterol, free lecithin domains disappear, and only interfacial boundary lecithins remain between the 2:1 lecithin/cholesterol complexes³². Upon increasing the sterol concentration, the interfacial boundary lecithin disappears completely at 33.3 mole %, and only lecithin/cholesterol complexes remain.

From the observations presented in this Chapter, it is possible to add some additional quantitative data to the model of *Chan et al.*³¹: low concentrations of sterol (10 mole %) only influence the lecithin acyl region (Figure 5.3), while the lecithin head group mobilities remain unaltered (Figure 5.1). Broadening of the head group $-\overset{\oplus}{\text{N}}\text{Me}_3$ resonance starts only at ca. 20 mole % of cholesterol. This indicates that the lecithin head group mobility around the $\text{CH}_2\text{-CH}_2$ head group linkage is only reduced, when free lecithin domains vanish. In other words, interfacial boundary lecithins are more rigid and more tightly packed than free lecithins. Enhancing the sterol concentration to levels where also interfacial boundary lecithins disappear - and thus lecithin/cholesterol complexes remain - reduces the lecithin acyl and head group mobility even further. At this point, also stretching and/or packing of the acyl chains is very pronounced (Figure 5.2). Recapitulating, the fluidity increases along the series: sterol-complexed lecithin - boundary lecithin - free lecithin.

V.3 Summary/conclusions

^{13}C NMR spectroscopy is applied to monitor the fluidity of DMPC sonicated bilayers upon incorporation of cholesterol. Cholesterol is pressed between lipid molecules, resulting in extremely broadened resonances which indicate low sterol mobilities. This is in line with observations by others¹⁶. Also, the results are similar to those of incorporated lytic compounds such as several TABs¹⁷. However, contrary to mixed bilayers of lecithins and TABs, the surrounding lecithins adjust to the bulk of the intercalated sterol nucleus. Cholesterol pushes the lecithin acyl chains aside and thus increases the average radius of curvature of the mixed vesicle. This in turn results in a decrease of the mobility of the $-\text{NMe}_3$ site of the lecithin around the CH_2-CH_2 head group bond. Furthermore, cholesterol broadens the ^{13}C NMR resonances of the lecithin acyl chains due to stronger dipolar interactions caused by retarded chain reorientation. Also, the sterol forces the lecithin chains towards more chain extension and/or larger chain packing.

At low sterol concentrations, it was observed that only the hydrophobic region of the membrane is rigidified while at higher (20 - 30 mole %) sterol contents, also the head group region is affected and rigidification of the entire membrane occurs. The results were interpreted semi-quantitatively in terms of a model concerning sterol-complexed lecithins, boundary lecithins and free lecithins.

V.4 Experimental

DMPC was purchased from Supelco, Inc. and Sigma. Cholesterol was obtained in 98% purity from Supelco, Inc. Pure DMPC vesicles were prepared as previously described¹⁷. Mixed sonicated bilayers of DMPC and cholesterol were prepared as follows. A chloroform solution of both constituents was evaporated to dryness under a stream of argon. Residual traces of organic storage solvent were removed overnight at 60°C and 0.005 mm Hg. Deionized water was added and the sample was sonicated during one hour between 0°C and 15°C within a Branson Model 50-D ultrasonic water bath in NMR-tubes.

No degeneration or hydrolysis took place, as monitored with thin layer chromatography with CHCl_3 : MeOH: H_2O = 65: 25: 4 (w/w) as eluents. Cholesterol-rich samples were always more turbid than the pure lecithin samples, indicating larger particle sizes. All samples maintained their stability during the experiments. Total concentration of lecithin and cholesterol was 50 mM for the pure and mixed samples.

The ^{13}C NMR spectra were run at 62.92 MHz on a Bruker WM 250 spectrometer under proton noise decoupling at 50°C . The deuterium signal from C_6D_6 was employed as an external lock signal. Chemical shifts are related to Me_4Si (C_6D_6 at 128 ppm downfield from Me_4Si). 10,000 - 100,000 transients were accumulated in 4K data points zerofilled to 32K before Fourier Transformation. Spectral width was 2 kHz. No relaxation delay was employed. Pulse width was set to a 90° flip angle. The decoupling circuit was carefully tuned prior to the experiments in order to operate at levels exceeding 2 Watts.

CHAPTER VI

Chiral model membranes. A CD and ^{13}C NMR study

VI.1 Introduction

Recently, a mechanism for the stereospecific hydride uptake of the redox coenzyme NAD(P)^+ has been proposed^{1,2}. It showed that this hydride uptake was mediated by the out of plane orientation of the carboxamide group³. Experimental evidence for this hydride transfer mechanism was offered by the stereoselective reduction of (9*R*)-*N*- α -methylbenzyl-1-propyl-2,4-dimethyl-3-carbamoylpyridinium cation by means of sodium dithionite^{2,4}, resulting in one diastereoisomeric pair (4*S*,9*R*)-(+)-*N*- α -methylbenzyl-1-propyl-2,4-dimethyl-1,4-dihydronicotinamide and the corresponding (4*R*,9*R*)-(-)-isomer, in which the carboxamide group is forced out of plane by two adjacent methyl groups as was established by X-ray molecular structure determinations and ^1H NMR lanthanide induced shift experiments. The outcome of the reduction is a *syn* orientation of the hydrogen at C-4 and the carbamoyl moiety. Since it was demonstrated that the corresponding 2,4-dimethyl-3-carbamoylpyridinium cations can also be optically active⁵, the suggestion was put forward that the absolute configuration of the carbamoylpyridinium moiety controls the stereochemistry of the hydride uptake. This behaviour is related to the well-known A or B specificity of the coenzyme NAD(P)^+ under enzymatic conditions⁶. These chiral nicotinamide compounds were used as detergents via alkylation of the pyridine nitrogen with *n*-dodecyl bromide and explored as chiral model compounds for the formation of single micelles and as model substrates in vesicles of chiral lecithins. Since previous studies suggest chiral discrimination for several chiral surfactants⁷, experiments

were carried out to search for enantiomeric differences using highly purified enantiomerically pure nicotinamide detergents under various conditions with CD and ^{13}C NMR.

VI.2 Synthesis of the optically active model substrates

The synthetic steps involved in the preparation of **8** are outlined in Figure 6.1. Refluxing crotonaldehyde **1** and ethyl- β -aminocrotonate **2** in the presence of piperidine according to Hantzsch⁶ gave the dihydropyridine **3**. Oxidation by means of *p*-chloranil yielded ethyl-2,4-dimethyl nicotinate **4**. The 2,4-dimethylpyridinium carboxylic acid **5** was obtained after hydrolysis and acidification of **4**. Deprotonation by triethyl amine and chlorination resulted in 2,4-dimethylpyridinyl carbochloride **6**, which was converted to *N,N*-dimethyl-2,4-dimethyl-3-carbamoyl pyridine **7**. Alkylation with *n*-dodecyl bromide afforded the racemic C_{12}CPB β^1 . The asymmetry of compound **8** results from the steric interactions between both ring methyls and the carbamoyl site, leading to an out of plane orientation of the carbamoyl group^{1,2,4}. The separation of both enantiomers of **8** was accomplished by complexation with optically pure silver- α -bromocamphor- Π -sulfonate monohydrate and repeated crystallization of the diastereoisomeric mixture. Full details are presented in the Experimental Section VI.5.

Figure 6.1 The preparation of the racemic detergent **8**.

VI.3 Results and discussion

VI.3.1. Single micelles of C_{12} CPB as reference solutions for the mixed aggregates. Determination of the CMC by means of CD spectroscopy

When varying the concentration of 1-dodecylpyridinium iodide and the chloride, an abrupt change in the UV absorption around 280 nm was detected⁹. A similar procedure was applied to 1-dodecylnicotinamide chloride micelles¹⁰. The concentration at which this breakpoint occurred was interpreted as the CMC of the surfactant, since its value is in good agreement with the CMC obtained by other physico-chemical procedures¹¹. The closely related compound *8*, however, showed no change in the UV spectral data for the same transition. Non micelle-forming compounds, such as the 1-methyl derivative *9*, act similar to *8*.

Characteristic differences between compounds *8* on the one hand and micellar *8* on the other hand are observed by means of CD (Figure 6.2a-b). The CD spectra of *8* and *9* show each two transitions at 240 nm and 270 nm. The extinction coefficients ($\Delta\epsilon$) for compound *9* are constant upon dilution. This is valid for both wave lengths (Figure 6.2b). The $\Delta\epsilon$ curve *versus* the concentration of *8* shows a remarkable discrepancy from *Lambert-Beer* around the CMC for the CD absorption at 240 nm (Figure 6.2a). One is able to notice (Figure 6.2a and Figure 6.3a) that an increase of the aggregational density - which is the result of an increase of the amphiphile concentration - alters the intensity of both CD bands. The change of the 240 nm band at concentrations above the CMC may be due to an increase of the very strong dichroic absorption at the short wave length side. However, the absolute intensity and position of this strong multiple band could not be detected properly

Figure 6.2a $\Delta\epsilon$ plot versus the concentration of $(-)-C_{12}CPB$. A similar plot, although with negative $\Delta\epsilon$ values, was obtained for $(+)-C_{12}CPB$.

Figure 6.2b $\Delta\epsilon$ plot versus the concentration of $(-)-9$.

Figure 6.3 $\Delta\epsilon$ plot versus the wave length of (-)- $C_{12}GPB$ for different concentrations (a). $\Delta\epsilon$ plot versus the wave length of (+)- $C_{12}GPB$ for different concentrations (b).

due to an overload of the detection system. Explanation of the concentration effects on the absorption band at 240 nm in terms of other aspects, such as increasing particle sizes and microscopic changes in solvent effects, are unlikely because these would modulate all absorptions in a corresponding manner^{12,13}. Spectra similar to the 50 mM spectrum of Figure 6.3a and 6.3b are obtained for the 1-methyl analogue *s* in acetonitrile⁵. This may indicate that (partial) dehydration occurs upon aggregation which results in a less polar

environment for the carboxamide group of compound *8*. This effectuates deviations from planarity within the carboxamide group and/or deviations of the out of plane orientation of the carboxamide group with respect to the pyridinium moiety¹⁴.

VI.3.2 The influence of chiral L-DMPC on the CD absorption spectra of (-)- and (+)-C₁₂CPB

Spontaneous formation of mixed micelles occurs when DMPC molecules are mixed with a large excess of the chiral C₁₂CPB amphiphile. The CD spectrum obtained for this mixed-micellar dispersion is identical with the single-micelle solution of *8* (compare Figure 6.3a (50 mM) with Figure 6.4a (mixing ratio 1:4), and compare Figure 6.3b (50 mM) with Figure 6.4b (mixing ratio 1:4)). Low concentrations of L-DMPC do not influence the rotational strengths of the absorptions of (-)-*8* and (+)-*8* respectively. Changes in the chirality of (-)-*8* and (+)-*8* respectively are seen upon a further increase of the aggregational density (Figure 6.4a (mixing ratio 4:1) and Figure 6.4b (mixing ratio 4:1) respectively). Incorporation of low contents of (-)-*8* and (+)-*8* respectively in L-DMPC vesicles shows unambiguously that a strong increase of the aggregational density induces a complete disappearance of the absorption band at 240 nm. However, one should keep in mind that the λ -axis in Figure 6.3 and 6.4 is not identical with the experimental base line. It is indicated by the decay of the maximal value of the 240 nm absorption along the series:

monomeric *8* → micellar *8* → *8* in vesicles of DMPC
 (Figure 6.3) (Figure 6.3) (Figure 6.4)

Furthermore, one should consider the effect of the particle dimensions on the CD spectral data¹². The probability of absorption is proportional to the beam intensity. Since the interior of a particle absorbs intensively, the effect of a large particle is one of casting a shadow obscuring chromophores behind it. This results in a decrease of the CD band intensities¹², which is demonstrated by the decrease of the $\Delta\epsilon$ value of the absorption band at 280 nm by ca. 20%

going from the mixed-micellar state to the vesicular state (Figure 6.4a and 6.4b). Of course, this effect is proportional to the absolute band intensity. Since the CD band at 240 nm disappears *completely* going from the mixed-micellar to the vesicular state, the effect of increasing particle sizes is of minor importance for this particular absorption.

Figure 6.4 $\Delta\epsilon$ plot versus the wave length of (-)- C_{12} CPB incorporated in aggregates of L-DMPC (a). $\Delta\epsilon$ plot versus the wave length of (+)- C_{12} CPB incorporated in aggregates of L-DMPC L-DMPC (b). Molar lecithin/ C_{12} CPB mixing ratios are indicated. The 1:4 mixing ratio represents a mixed-micellar solution and the 4:1 mixing ratio represents a mixed-vesicular solution.

VI.3.3 ¹³C NMR results of the mixed L-DMPC/C₁₂CPB dispersions

The results of Table VI.1 indicate that, comparable with the DMPC/TAB mixed aggregates of Chapter IV, squeezing occurs for the C₁₂CPB amphiphiles. Deshieldings are observed along the hydrophobic chain of the C₁₂CPB revealing chain extension, similar to the incorporated TABs¹⁵. When incorporated in the chiral L-DMPC vesicles, both C₁₂CPB enantiomers act similarly. No differences in the spectral parameters are observed when comparing the L-DMPC/(-)-C₁₂CPB mixed aggregates with the L-DMPC/(+)-C₁₂CPB mixed aggregates. In other words, there is no evidence that one of the C₁₂CPB enantiomers accommodates preferentially in the chiral-lecithin vesicle.

Table VI.1 Chemical shifts and deshieldings (in parentheses) of the C₁₂CPB amphiphiles upon mixing with L-DMPC^a

(-)-C ₁₂ CPB carbons	mixing ratios	
	4:1	1:4
C-1	58.76 (+0.00)	58.76 (+0.00)
C-2	-	30.30 (+0.05)
C-3	26.47 (+0.15)	26.40 (+0.08)
C-10	32.58 (+0.47)	32.24 (+0.13)
C-11	23.17 (+0.33)	22.95 (+0.14)
C-12	14.25 (+0.06)	14.26 (+0.07)
(+) -C ₁₂ CPB carbons	mixing ratios	
	4:1	1:4
C-1	58.76 (+0.00)	58.76 (+0.00)
C-2	-	30.29 (+0.05)
C-3	26.42 (+0.12)	26.37 (+0.07)
C-10	32.58 (+0.48)	32.22 (+0.12)
C-11	23.17 (+0.33)	22.93 (+0.14)
C-12	14.26 (+0.07)	14.24 (+0.05)

^aThe total amphiphile concentration was 50 mM.

Table VI.2 offers the chemical shift of the carbonyl carbon of the C₁₂CPB as a function of the aggregational density. In order to eliminate solvent effects, corresponding chemical shifts of the non micelle-forming 1-methyl analogue **9** are also presented (Table VI.3).

Table VI.2 ¹³C NMR chemical shift of the carbonyl carbon of the chiral C₁₂CPB amphiphiles versus the aggregational density

	monomer (5 mM)	micelle (50 mM)	mixed micelle ^a	mixed vesicle ^b
				
	aggregational density			
δ _{C=O} (ppm) ^c	167.0±0.05	166.6±0.05	166.6±0.05	166.2±0.05

^aThe mixed micelle represents the L-DMPC/C₁₂CPB 1:4 mixed system.

^bThe mixed vesicle represents the L-DMPC/C₁₂CPB 4:1 mixed system.

^cBoth C₁₂CPB enantiomers possess identical chemical shift values.

It is well recognized that a large deshielding occurs for the carbonyl carbon conjugated with an aromatic ring when the carbonyl group has an out of plane orientation due to the presence of an α-substituted *t*-Bu group. For instance, a chemical shift difference of +8.6 ppm is observed between the carbonyls of *t*-butyl-2,6-dimethylphenyl ketone and its *t*-butyl analogue with no methyl substituents on the aromatic ring: *t*-butylphenyl ketone¹⁶. The chemical shift changes which were observed going from the mixed vesicular to the monomeric solution (Table VI.2) may indicate a change of the average carbonyl position with respect to the pyridinium ring. However, one should realize that the effects are small, and that a partial dehydration of the C₁₂CPB carbonyl upon incorporation in

DMPC aggregates may already bring about such chemical shift changes as well¹⁶.

Table VI.3 ¹³C NMR chemical shift of the carbonyl carbon of the chiral C₁₂CPB amphiphiles versus the concentration

	5 mM	50 mM	with 10 mM DMPC ^a	with 40 mM DMPC ^b
$\delta_{C=O}$ (ppm) ^c	167.0±0.05	166.8±0.05	166.8±0.05	167.0±0.05

^aRepresentation of the L-DMPC/C₁₂CPB 1:4 mixed systems.

^bRepresentation of the L-DMPC/C₁₂CPB 4:1 mixed systems.

^cBoth C₁₂CPB enantiomers possess identical chemical shift values.

VI.4 Summary/conclusions

The CD spectral data of chiral C₁₂CPB are readily influenced by the aggregational density of the C₁₂CPB. A decay of the absorption band at 240 nm occurs when the intermolecular packing increases. The largest effect occurs for very dense DMPC vesicles in which the C₁₂CPB is incorporated. In order to interpret these observations in terms of a deviation of the planarity within the carboxamide group and/or deviations of the out of plane orientation of the carboxamide group with respect to the pyridinium moiety, ¹³C NMR chemical shifts of the carbonyl carbon of the C₁₂CPB were measured. However, no definite conclusions could be reached. The hydrophobic alkyl chains of the C₁₂CPB were found to change their conformational equilibria towards more extension. As the (-)-C₁₂CPB and the (+)-C₁₂CPB enantiomer behave similarly, no intermolecular stereoselective interactions could be detected between the individual C₁₂CPB enantiomers in the L-DMPC vesicles.

In other words, although squeezing occurs for the C₁₂CPB amphiphiles in L-DMPC vesicles, the difference in the effective surface areas of the two diastereoisomeric C₁₂CPB/DMPC mixed-amphiphile aggregates is not large enough

to induce stereoselective interactions between both C_{12} CPB enantiomers in the L-DMPC vesicles.

Recently, Tsai *et al.*⁷ showed spectral differences between several chiral phospholipids, which were ascribed to chiral recognition. These spectral differences are absent in the aggregates of L-DMPC with (-)- β and (+)- β respectively. Obviously, chiral recognition can easily be observed intramolecularly between diastereoisomers (*i.e.* diastereoisomeric recognition).

VI.5 Experimental

➤ General remarks

The ^1H NMR spectra were recorded with a Varian EM-360 A NMR spectrometer using Me_4Si as internal standard ($\delta = 0.00$). The ^{13}C NMR spectra were run at 75.476 MHz on a Bruker CXP 300 spectrometer under proton noise decoupling at 50°C. The deuterium signal from C_6D_6 was employed as an external lock signal. All chemical shifts are related to Me_4Si (C_6D_6 at 128 ppm downfield from Me_4Si). 10,000-100,000 transients were accumulated in 4K data points zerofilled to 32K points before Fourier Transformation. Spectral width was 17 KHz. No relaxation delay was employed. Pulse width was set to a 90° flip angle. The decoupling circuit was tuned prior to the various experiments in order to operate at levels of 8 Watts. The optical rotations were measured on an Optical Activity AA-10 polarimeter. The CD-spectra were recorded on a Jobin Yvon Dichrograph Mark III-S. The UV spectra were obtained from a Perkin-Elmer Double Beam Grating Spectrophotometer model 124. DMPC was purchased from Supelco, Inc. and Sigma. The preparation of (mixed) vesicles and (mixed) micelles was outlined already in Chapter IV. Ethyl- β -aminocrotonate **2** and crotonaldehyde **1** were purchased from Aldrich. Ethyl-2,4-dimethyl-1,4-dihyronicotinate **3**⁸, ethyl-2,4-dimethyl-nicotinate **4**⁸, 2,4-dimethyl-3-carboxylpyridine hydrochloride^{2,5}, *N,N*-dimethyl-2,4-dimethyl-3-carbamoylpyridine^{5,17} and silver-(+)- α -bromocamphor- β -sulfonate monohydrate¹⁸ were prepared using modified literature procedures. For all

measurements, the total amphiphile concentrations were 50 mM, unless indicated otherwise.

➤ (-)-*N,N*-dimethyl-1-dodecyl-2,4-dimethyl-3-carbamoylpyridinium bromide **8**

A stirred solution of dodecyl bromide (25 g; 100 mmol) and amide **7** were heated to 90^o-100^oC during two days. The excess dodecyl bromide was decanted. The precipitate was washed with Et₂O and dried, which resulted in 6.6 g (69%) of bromide **8**: oil; ¹H NMR (CDCl₃) δ 0.90 (t, 3, CH₂CH₃), 1.25 (m, 20, 10 CH₂), 2.50 (s, 3, CH₃), 2.77 (s, 3, CH₃), 3.00 (s, 3, CH₃), 3.17 (s, 3, CH₃), 4.73 (t, 2, NCH₂), 7.80 (d, 1, PyrH), 9.06 (d, 1, PyrH).

A diastereomeric pair of **8** was obtained after complexation with silver-(-)-α-bromocamphor-Π-sulfonate monohydrate. Repeated crystallization from acetone/hexane resulted in the pure (--) diastereoisomer. Treatment of the (--) complex with Amberlite IRA-400 (Br⁻-form) resulted in (-)-**8**: CD (H₂O) Δε +0.6 (278 nm), +0.65 (240 nm). [α]_D²⁰ = -12.4 (H₂O, c = 0.005 M).

➤ (+)-*N,N*-dimethyl-1-dodecyl-2,4-dimethyl-3-carbamoylpyridinium bromide **8**

Prepared analogously to (-)-**8** using silver-(+)-α-bromocamphor-Π-sulfonate monohydrate: CD (H₂O) Δε -0.6 (278 nm), -0.65 (240 nm). [α]_D²⁰ = +12.3 (H₂O, c = 0.005 M).

CHAPTER VII

CPMAS NMR in non-hydrated and hydrated phospholipid aggregates and model substrates

VII.1 Introduction

Nuclear magnetic resonance has been used extensively to gain insight into the structure and dynamics of model and biomembranes, in combination with many other techniques¹. The often complex internal structures of many biomembranes, however, are not always accessible to spectroscopic methods. For example, rigid (parts of) membranes, having large internal viscosities, induce substantial line broadening of ^{13}C resonances monitored by common ^{13}C HR NMR. This type of NMR spectroscopy is mainly applicable to isotropic solutions. A way to overcome the detection of broad resonances is to eliminate the dipolar ^{13}C - ^1H interactions contributing to the line width, through elevated power decoupling². HR NMR in anisotropic systems became a routine method with the development of cross polarization magic angle spinning (CPMAS), which was first experimentally recognized by *Schaefer* and *Stejskal*³. It combines pulsed NMR excitation with high-speed sample rotation and high power decoupling. Rapid sample rotation around an angle of 54.7° with respect to the external magnetic field diminishes the chemical shift anisotropy contributions caused by non-averaged molecular orientations. In combination with strong dipolar decoupling "liquid-like" narrow lines are observed. The ^{13}C relaxation times in the solid state, however, are very long and large delay times are necessary to obtain reasonable signal to noise ratios. One way to prevent this is offered by cross polarization between the ^{13}C (rare spin) and ^1H nuclei⁴, which is initiated by spin locking the protons⁵. In this manner, the magnetization of the ^{13}C and ^1H nuclei directed along the main axis of the external magnetic field,

possess the same time dependence, and thus energy transfer is possible *via* the spin-flip mechanism. As a result, the delay time is now controlled by the relaxation mechanism of the ^1H nuclei only, instead of the ^{13}C nuclei. Accordingly, the acquisition time becomes much shorter and relatively large signal to noise ratios are obtained readily.

Until now, ^{13}C -CPMAS has not been used extensively in the field of phospholipid research. However, the interest in applying this technique is increasing rapidly. ^{13}C -CPMAS spectra of phospholipids in the anisotropic bilayer state have been presented⁶, revealing highly resolved resonances for unsaturated phospholipids in excess of water. In this Chapter, the ^{13}C -CPMAS experiment is used to gain insight into the molecular organization within phospholipid aggregates and model substrates at low water contents.

VII.2 The rotational speed dependence of the ^{13}C -CPMAS spectra

It should be stressed that, contrary to the HR measurements presented in the preceding Chapters, CPMAS experiments are in principle no longer non-destructive, due to the presence of strong ultracentrifugal forces in the sample at fast rotational sample speeds and a substantial heat transfer to the sample, especially when it absorbs radiofrequencies readily. Figure 7.1 indicates that sample rotation faster than ca. 2.6 KHz introduces additional resonances after a certain time interval (typically 30 hrs.). The clearest example is the *extra* low field resonance in the $-\overset{\text{+}}{\text{N}}\text{Me}_3$ region of the phospholipid at about 53 ppm. Not so very distinct, but also observable are the additional resonances in the acyl region between 24 and 29 ppm. These spectral changes are *not* observed when rotating the sample at 2.6 KHz. This indicates that the occurrence of the additional resonances is caused by an increase of the centrifugal force when increasing the rotor speed to 4 KHz. The latter frequency corresponds to a pressure at the rim of the rotor of ca. 20 atm. Obviously, at least one phase transfer is achieved at such large internal pressures.

Figure 7.1 The rotational speed dependence of the ^{13}C -CPMAS spectrum of DPPC. The upper spectrum shows DPPC at 2.6 KHz sample spinning. The "53 ppm"-region (left) and the "24-29 ppm"-region (right) at 4 KHz spinning are shown below. The number of transients (N) is also indicated.

VII.3 Hydrated and non-hydrated DPPC

Amorphous samples of DPPC were prepared by dilution with a solvent and subsequent evaporation. Spectra like the one presented in Figure 7.1 were readily obtained. Upon hydration, the only change observed was the broadening of the carbonyl

Table VII.1 Chemical shifts of hydrated and non-hydrated DPPC, at 2.6 KHz sample spinning^a

^dThe resolved resonances correspond to the *sn*-1 and *sn*-2 acyl chains of the DPPC. The reproducibility of the measurements was 0.5 ppm.

resonances of the *sn*-1 and the *sn*-2 chain: the two resonances were no longer detected separately (Table VII.1). It indicates that hydration occurs for this group in particular and not for carbons located further inside the hydrophobic region. It was impossible, unfortunately, to operate at higher water contents due to a large heat uptake by the internal water amount, which ultimately resulted in phase transitions and subsequent spinning instability.

VII.4 Mixing TABs with DPPC in the hydrated phase

At the water contents investigated, DPPC possesses the bilayer orientation⁷. Incorporation of C₁₄TAB gave the following implications (Table VII.2 and Figure 7.2). First, the reproducibility of the chemical shifts (Table VII.2) was estimated at 0.5 ppm. Thus, when chemical shift changes are induced by interactions between C₁₄TAB and DPPC, these do not exceed 0.5 ppm. Such chemical shift changes are comparable with the values obtained for lecithin dispersions with higher water amounts⁸. In other words, when changes in conformation or packing occur, these are not larger than those for the micellar and vesicular phase⁸. Secondly, changes in DPPC and C₁₄TAB mobilities were studied. This was done by means of the T_{1ρ}^H-values of the protons of both compounds (Figure 7.2, only the readily detectable resonances of the methyl carbons of the hydrophobic and hydrophilic region were observed). The T_{1ρ}^H relaxation time represents the time constant with which the spin-locked magnetization in the rotating frame decays^{4,9}. T_{1ρ}^H-values are usually much longer than the spin-spin relaxation time T₂^H and shorter than the spin-lattice relaxation time T₁^H. Typical values are T₂^H ~ 10⁻⁵ s and T_{1ρ}^H ~ 10⁻⁴ - 10⁻² s. Although T_{1ρ}^H processes are influenced by inter- and intramolecular spin diffusion^{10,11} - and thus their T_{1ρ}^H-values represent an *average* over all protons in the amphiphiles - and, moreover in the case presented here, internal methyl rotation¹¹ also contributes, some conclusions can be reached from the plots of Figure 7.2. The T_{1ρ}^H of DPPC increases with raising concentrations of C₁₄TAB (a fast decay of the ¹³C NMR signal intensity implies a short T_{1ρ}^H-value

Figure 7.2 (continued)

and a slow decay corresponds with a long $T_{1\rho}^H$ -value). These observations indicate that the lecithin mobility on the former mentioned time scale *increases*. The $T_{1\rho}^H$ -value of C_{14} TAB decreases when raising the concentration of DPPC. This indicates that C_{14} TAB mobilities *decrease* when the DPPC concentration is raised.

VII.5 Summary/conclusions

The central questions in many studies of phospholipid bilayers are, as far as the hydrophobic parts are concerned, concentrated around the problem of occurrence of chain kinking and/or unpacking and the reasons for this. A number of studies have been performed using vibrational spectroscopy and NMR. A useful reference of the differences in vibrational spectroscopy was given by *Bush et al.*¹². The measurements described in this Chapter concern only variations in water contents over a rather limited concentration range. The discussion is thus confined to this point. *Gaber et al.*¹³ indicated that solid *n*-hexadecane and DPPC would have the same *anti/gauche* ratios. The chemical shifts of the pure DPPC phases indicate that DPPC, even in the absence of water, is less rigid and/or tightly packed than solid *n*-alkanes¹⁴. This is concluded from the fact that for DPPC shielding of about 1 ppm are found with respect to solid alkanes.

Hydration of the DPPC was found to influence the carbonyl carbons only. In the past, two moles of water per lipid molecule were claimed to induce conformational changes within head group and acyl tails, as detected by Raman spectroscopy^{12,13}. In particular, *Bush et al.* came to the conclusion that addition of two moles of water effectuated a decrease of the crystallinity due to increased molecular motions in the head group region and the interfacial region. However, the conformational changes in the acyl chains are in the order of only 5%. These fall within the reproducibility of the CPMAS experiments presented here. Recently, the working procedure of *Gaber et al.*¹³ was critically reviewed by *Snyder et al.*¹⁵. The latter indicated that care should be taken with the interpretations of *Gaber et al.*¹³, using certain IR- or Raman absorption bands as

so-called *anti* or *gauche* markers. This, in *Snyder's* opinion, could lead to erroneous results. This might also be the case for the experiments of *Bush et al.*¹². On the other hand, however, the present CPMAS NMR results might verify the outcome of *Bush et al.*¹² independently. It can be noted in passing, that *Snyder's* suggestion that in the gel phase of DPPC only interactions between all-*anti* chains occur, fits in the present description of the NMR results¹⁶.

$T_{1\rho}^H$ measurements indicate that squeezing of the C_{14} TAB substrate by lecithins takes place in the flat bilayer state, analogously to the vesicular dispersions outlined in Chapter IV. Obviously, small radii of curvature are not necessary to obtain squeezing of the substrate. No evidence for large conformational changes were found to occur simultaneously with the squeezing of the C_{14} TAB by DPPC. This is concluded from the fact that the chemical shift changes to be expected based on studies of more mobile systems, are of the same order of magnitude as the reproducibility of the measurements (see Chapters II and III).

VII.6 Experimental

Multibilayer dispersions of DPPC were prepared as follows. A chloroform solution of the lecithin was evaporated to dryness under a stream of argon. Residual traces of organic solvent were removed overnight at 60°C and at 0.005 mm Hg. The lecithin was transferred to an Andrew-rotor and the appropriate amount of deionized water was added (2 moles water on 1 mole lecithin). Mixed multibilayer dispersions of DPPC and C_{14} TAB were prepared similarly, by drying a chloroform solution of both constituents and subsequent adding the appropriate amounts of water (2 moles water on 1 mole amphiphile, *i.e.* lecithin plus TAB).

The ^{13}C -CPMAS NMR spectra were run at 75.476 MHz on a Bruker CXP 300 spectrometer. The chemical shifts are related to Me_4Si . 4,000-60,000 transients of 1K data points were accumulated and zero-filled to 32K points prior to Fourier Transformation. Spectral width was 17 KHz. The pulse delay employed varied from 4 s for the non-hydrated samples to

15 s for the hydrated samples. The ^1H -pulse duration was 3 μs , corresponding to a ^1B -field of ca. 20 Gauss. The contact time employed was 2.5 ms and varied during the $T_{1\rho}^{\text{H}}$ experiments. The acquisition time was 29 ms and the rotor speed was 2.6 kHz, unless indicated otherwise.

Summary

Membrane mediated processes appear through the presence of incorporated substrates (proteins, cholesterol, single stranded amphiphiles). In general, the central part of the membrane is formed by a phospholipid bilayer. This bilayer is built up by a hydrophilic outside region (the phospholipid head groups) and a hydrophobic inside region (the phospholipid acyl chains), which shows fluid-like characteristics. A most convenient method in the study of the fluidity of the bilayer is ^{13}C NMR, capable of monitoring each individual carbon. However, this method has been hardly applied to (model systems for) biomembranes, because of the difficulties in interpreting the ^{13}C NMR spectral parameters.

This thesis describes a method which translates ^{13}C NMR spectral data into a number of aspects of the membrane fluidity. This method has been made suitable for measuring colloidal particles (micelles, vesicles and flat bilayers). The interpretations of the ^{13}C spectra were carried out in terms of membrane fluidity (*i.e.* changes in conformational equilibria, intermolecular hydrophobic interactions and intermolecularly correlated mobilities of the constituents of the colloidal particles). This procedure was first tested experimentally on well-defined single- and mixed-*micellar* structures of fatty acid salts with different *n*-acyl chain lengths. Then, the procedure was extended towards mixed micelles consisting of biological components and model compounds for biomembrane substrates, *i.e.* a short-chain lecithin and several single stranded trimethylammonium bromides (TABs). It was shown, that the lecithin possesses the intrinsic property of making the incorporated TAB substrates rigid. A further extension towards large

anisotropic systems was made by the investigation of *vesicular* colloidal solutions of long-chain lecithins. It was shown, that at low concentrations of the TAB substrate also rigidity of the TABs was induced by the surrounding long-chain lecithins, without affecting the lecithins. Furthermore, it was demonstrated that upon disruption of the mixed-vesicular structure towards mixed-micellar structures through raised concentrations of substrate (ca. 1 equiv.), the rigidity of the TABs was reduced. Non-amphiphilic substrates such as cholesterol were reduced in their dynamics analogous to the amphiphilic TABs. In the case of intercalation of cholesterol, however, it was demonstrated that the sterol-surrounding lecithins were also made rigid. It was found to be related to the large dimension of the sterol.

Many of the metabolites traversing the biomembrane are optically active. The chiral single-stranded model substrate *N,N*-dimethyl-1-dodecyl-2,4-dimethyl-3-carbamoylpyridinium bromide (C_{12} CPB) was made rigid by the lecithins (analogous to the former mentioned substrates), which resulted in changes of the chirality of the substrate. In this case rigidification of the chiral C_{12} CPB was shown to affect CD spectral absorptions. The possibility of a conformational change within the chiral polar head group of the C_{12} CPB was discussed.

Finally, the ^{13}C NMR operating procedure was applied to colloidal particles best resembling the biomembrane backbone, *i.e.* *bilayer* particles. Similar to micellar lecithins and vesicular lecithins, the lecithin molecules in the bilayer orientation were found to resist against disruption of the bilayer by substrates.

Biomembranes are much more complicated than the model systems described in this thesis. Nevertheless, a general membrane property was detected, *viz.* that membrane substrates are squeezed within the membrane, as induced by the surrounding lecithin molecules.

Samenvatting

Processen waarbij het membraan betrokken is, verlopen door de aanwezigheid van geïncorporeerde substraten (proteïnen, cholesterol, *n*-alkylamfifielen). In het algemeen wordt het centrale deel van het membraan gevormd door een dubbellaag van fosfolipiden. Deze dubbellaag wordt opgebouwd door een hydrofiele buitenzijde (de kopgroepen van de fosfolipiden) en een hydrofobe binnenkant (de acyl ketens van de fosfolipiden), welke vloeistofeigenschappen vertoont. Een uiterst geschikte methode om de vloeibaarheid van de dubbellaag te bestuderen is ^{13}C NMR, welke in staat is om ieder koolstofatoom individueel te observeren. Echter, vanwege de moeilijkheden om de ^{13}C spektrale gegevens te interpreteren is deze techniek zelden toegepast op (modellen voor) biomembranen.

In dit proefschrift wordt een manier beschreven om de ^{13}C spektrale gegevens te interpreteren naar een aantal aspecten van het vloeistofkarakter van het membraan. Deze methode is toepasbaar gemaakt voor de studie van kolloïdale deeltjes (micellen, vesicles en vlakke dubbellaagen). De interpretaties van de ^{13}C spektra werden uitgevoerd in termen van de vloeibaarheid van het membraan (d.w.z. veranderingen van konformatie-evenwichten, intermoleculaire hydrofobe interacties en intermoleculair gekorreleerde mobiliteiten van de bestanddelen van de kolloïdale deeltjes). In eerste instantie werd deze methodiek getest op goed gedefinieerde enkelvoudige en gemengde *micellen* van zouten van vetzuren met verschillende ketenlengtes. Vervolgens werd de interpretatiemethode uitgebreid naar gemengde micellen bestaande uit biologische verbindingen en modelsubstraten, d.w.z. een lecithine met een korte *n*-acylketenlengte en enkele *n*-alkyltrimethylammoniumbromides (TABs). Aangetoond

werd, dat de lecithinemolekulen de intrinsieke eigenschap bezitten om de geinkorporeerde TAB substraten te verstarren. Een verdere uitbreiding naar grote anisotrope systemen werd gemaakt door de bestudering van kolloidale oplossingen van *vesicles* van lecithines met een lange *n*-acylketenlengte. Het bleek, dat bij lage concentraties van de TAB substraten eveneens verstarung optrad van de TAB molekulen. Dit werd veroorzaakt door de omringende lecithinemolekulen, zonder dat deze zelf werden beinvloed. Eveneens werd duidelijk dat, bij uiteenvallen van de vesiclestructuur in micellaire structuren onder invloed van ca. 1 equivalent substraat, de starheid van de TAB substraten afnam. Niet-amfifiele substraten zoals cholesterol verstarren eveneens, analoog aan de TABs. Echter bleek het dat, wat betreft het geinkorporeerde cholesterol, de omringende lecithinemolekulen ook verstarren. De oorzaak hiervan was de grote afmeting van het cholesterolmolekuul.

Een groot aantal metabolielen welke door het membraan getransporteerd worden, zijn optisch aktief. Het chirale modelsubstraat, *N,N*-dimethyl-1-dodecyl-2,4-dimethyl-3-carbamoyl-pyridiniumbromide (C_{12} CPB) verstarde onder invloed van de omringende lecithinemolekulen, analoog aan de TABs, hetgeen resulteerde in veranderingen in de chiraliteit van het substraat. In dit geval bleek, dat bij verstarung van het chirale C_{12} CPB CD-absorpties werden beinvloed. Een mogelijke konformatieverandering in de chirale kopgroep van het C_{12} CPB werd besproken.

Tenslotte werd de ^{13}C NMR interpretatiemethode toegepast op kolloidale deeltjes welke de beste gelijkenis vertonen met de biologische lecithineaggregaten, namelijk de deeltjes met de *vlakke dubbellaag*orientatie. Analoog aan micellaire en vesiculaire lecithines werd gedemonstreerd dat ook in dit geval de lecithinemolekulen zich verzetten tegen het uiteenvallen van de dubbellaag o.i.v. *n*-alkylsubstraten.

Biomembranen zijn meer gekompliceerde systemen dan de in dit proefschrift beschreven modelsystemen. Niettemin werd een intrinsieke eigenschap van het membraan ontdekt, namelijk dat de membraansubstraten in het membraan worden samengedrukt door de omringende lecithinemolekulen.

Curriculum vitae

De auteur van dit proefschrift werd geboren op 18 mei 1955 te Tilburg. Na het behalen van het HBS-B diploma aan het Jacob Roelands College te Boxtel werd in september 1972 begonnen met de studie Scheikundige Technologie aan de Technische Hogeschool te Eindhoven. Het afstudeerwerk werd verricht bij de vakgroep Organische Chemie onder leiding van prof. dr. H.M. Buck en dr. ir. A.A. Macco. Het doctoraalexamen werd op 28 februari 1979 afgelegd. Tot 1 december 1979 was hij in dienst van de Technische Hogeschool te Eindhoven. Op 1 december 1979 trad hij in dienst van de Nederlandse Stichting voor Zuiver-Wetenschappelijk Onderzoek als wetenschappelijk assistent bij de vakgroep Organische Chemie. Het in dit proefschrift beschreven onderzoek stond onder leiding van prof. dr. H.M. Buck en dr. ir. J.W. de Haan. Thans is hij in dienst van International Flavors & Fragrances B.V. te Tilburg.

Dankwoord

Aan het totstandkomen van dit proefschrift hebben velen een bijdrage geleverd, waarvoor ik ze zeer erkentelijk ben. Enkelen wil ik met name noemen. Tegenover ing. M. Achten en H.M.P.J. van Hal zou ik mijn hartelijke dank willen uitspreken voor hun bijdragen op het experimentele gebied. Voor de fysische metingen ben ik veel dank verschuldigd aan: drs. L.A.M. Bastiaansen, G.J. Bezemer, P.L.M. van den Bosch, H. Eding, dr. ir. J.W. de Haan en ing. L.J.M. van de Ven. Dr. ir. J.W. de Haan en ing. L.J.M. van de Ven dank ik in het bijzonder voor de vele opbouwende discussies die we hebben gevoerd.

Mevrouw P. Meyer-Timan en H. Eding ben ik zeer erkentelijk voor hun medewerking aan de uiteindelijke vormgeving van dit proefschrift.

The work described in this thesis was supported by the Netherlands Foundation for Chemical Research (S.O.N.) with financial aid from the Netherlands Organization for the Advancement of Pure Research (Z.W.O.).

Stellingen

1. De konstatering dat fosfolipiden bij lage watergehaltes zijn georiënteerd in de dubbellaagstructuur, dient in overeenstemming te zijn met de binaire fasediagramgegevens.

V. Luzatti, "Biological Membranes, Physical Fact and Function" (D. Chapman, Ed.), Acad. Press, London, 1968, 71;

V. Luzatti, T. Gulik en A. Tardieu, Nature, 1968, 218, 1031.

2. Het is opmerkelijk dat *Ebright* en *Wong* ervan uitgaan dat de adeninebase van cyclisch 3',5'-adenosinemonofosfaat (cAMP) direkt deelneemt aan de interactie tussen DNA en het complex van cAMP en het cAMP receptor proteïne, terwijl uit röntgen-onderzoek door *McKay* en *Steitz* is gebleken dat het cAMP molecuul diep in het cAMP receptor proteïne opgesloten ligt.

R.H. Ebright en J.R. Wong, Proc. Natl. Acad. Sci. USA, 1981, 78, 4011;

D.B. McKay en T.A. Seitz, Nature, 1981, 210, 745.

3. Uit de resultaten van *van Haastert et al.* moet gekonkludeerd worden dat de vorming van een kovalente binding tussen het enzym en cyclisch 3',5'-adenosinemonofosfaat plaatsvindt door een aanval van een enzymligand op de *endo* positie van het fosfor atoom en niet, zoals door hen wordt verondersteld, op de *exo* positie.

P.J.M. van Haastert, P.A.M. Dijkgraaf, T.M. Konijn,

E.G. Abbad, G. Petridis en B. Jastorff, Eur.
J. Biochem., 1983, 131,659.

4. Bij de bepaling van de stereochemie van de methylmalonyl coenzym A isomerisatie wordt geen rekening gehouden met het gegeven dat het gepostuleerde radikaalmechanisme voor de intramoleculaire koolstofmigraties kan leiden tot racemisatie van de chirale centra.

J. Retey, Recent. Adv. Phytochem., 1979, 13,1.

5. Het verdient aanbeveling om bij de bereiding van oestrogenen *via* asymmetrisch geïnduceerde cyclisatiereacties, enantiomeer zuivere precursors te gebruiken.

C.G.M. Janssen, proefschrift, T.H. Eindhoven, 1982;
A.A. Macco en H.M. Buck, J. Org. Chem., 1981, 13,
2655.

6. De berekeningen van *Howell et al.*, welke aangeven dat er geen energiebarrière bestaat voor fragmentatie van PH_4 naar $\text{PH}_3 + \text{H}\cdot$, dienen kritisch te worden herbezien.

J.H. Howell en J.F. Olsen, J. Amer. Chem. Soc.,
1976, 98,7119.

7. Het verdient aanbeveling om de rol van vijfgekoördineerde fosforintermediairen in fosfolipiden te onderzoeken.

8. De veronderstelling van *Roberts et al.* dat de koolstofatomen van de *sn*-1 ketens van lecithines met korte acylketenlengte langere ^{13}C spin-rooster relaxatietijden bezitten dan die van de *sn*-2 ketens, is aanvechtbaar.

R.A. Burns en M.F. Roberts, Biochemistry, 1980,
19, 3100.

9. Voor het juist interpreteren van spektrale gegevens van fosfolipide dubbellagen en vesicles met behulp van elektronen-spin-resonantie, moet men zich de versturende effecten van de geïncorporeerde spinlabel duidelijk realiseren.

K. Madden, L. Kevan, P.D. Morse II en
R.N. Schwartz, J. Amer. Chem. Soc., 1982, 104,10.

10. Analooq aan de preventieve werking van de bijsluitertekst van een medicinaal preparaat, zou een vergelijkbaar effect verwacht kunnen worden indien op het etiket van alcoholika eveneens werd vermeld: "... kan de rijvaardigheid beïnvloeden".

R.J.E.M. de Weerd

Eindhoven, 4 oktober 1983.

Erratum

page 30, *Table II.3b*: C_{11}/C_7° should read C_{11}/C_6° , and C_{11}/C_6° should read C_{11}/C_5° . This is also valid for these abbreviations in the footnote of this Table.
