## ALGEMENE INLEIDING

De holle kathode boogontlading met een lage achtergronddruk en bijeengehouden door een axiaal magneetveld, is een ontledingstype waarvan de eerste uitgebreide gegevens in 1962 door Lidsky e.a. <sup>(1)</sup> zijn gepubliceerd. Gelijksortige opstellingen waren reeds geïntroduceerd door Luce <sup>(2)</sup>, en Gibbons en Mackin Jr. <sup>(3)</sup>. Doel van de opstelling van Lidsky e.a. was een hoog geïoniseerde stationaire plasmabron te creëren om daarmee een mogelijke bijdrage tot het thermonucleaire onderzoek te kunnen leveren.

De ontlading is in hoofdzaak te beschrijven door de volgende kenmerken:

De kathode wordt gevormd door een hol pijpje van hittebestendig materiaal, bij voorbeeld tantaal, wolfram of boronnitride, met een inwendige diameter van 1 tot 20 mm. Door de kathode stroomt gas, bij voorbeeld met een debiet van ongeveer  $10^{-3}$  torr  $m^3s^{-1}$  wanneer de diameter van de kathode enige mm's is. In het kathodepijpje heerst dan een druk van 0 tot 80 torr wanneer de ontlading ontstoken is. In de ruimte tussen kathode en anode is de achtergronddruk zeer laag met als uiterste waarden  $10^{-4}$  en  $10^{-2}$  torr. Het instromende gas wordt afgevoerd door één of meer hoogvakuumpompen met voldoende grote capaciteit (pompsnelheid ongeveer  $1 m^3s^{-1}$ ).

Wanneer de ontlading brandt, is de kathode tot ongeveer 2500 K verhit door een ionenbombardement, zodat een grote thermische elektronenemissie optreedt. Het gas wordt optimaal geïoniseerd in het kathodepijpje doordat de energie van straling, ionen, metastabielen en elektronen zeer goed benut wordt. Het "pendelen" van elektronen ongeveer loodrecht op de as van het pijpje geeft waarschijnlijk een grote bijdrage tot de ionisatie <sup>(4)</sup>. De stroomgeleiding vindt plaats tussen de kathode en een plaat- of cilindervormige anode die tot op afstanden van 1.5 m van de kathode verwijderd kan zijn of tussen de kathode en een ringvormige anode die meestal zeer dichtbij de kathode is geplaatst. Wanneer beide vormen aanwezig zijn, is één van beide anodes verbonden met een voedingsapparaat, de andere wordt zwevend gehouden. De stromen variëren van ongeveer 10 tot 200 A.

Een axiaal gericht magneetveld zorgt, tezamen met de holle kathode, voor de typische verschijningsvorm van deze ontlading, namelijk een lichtende plasmakolom met een diameter van 10 à 20 mm. Deze begint in de kathode en volgt de gezamenlijke symmetrieas van het kathodepijpje en het magneetveld. De ontlading heeft deze vorm, ongeacht de anodevorm, die gebruikt wordt. Bij een ringvormige anode met grote diameter is de diameter van de plasmakolom veel kleiner dan die van de ring. De beschreven vorm treedt reeds op bij velden van  $3 \times 10^{-2}$  tot  $5 \times 10^{-2}T$ . Boven deze waarden treedt soms nog zeer geleidelijk een verdergaande kontraktie op. Beneden genoemde waarden verbreedt de kolom zich zeer duidelijk. Bovendien verandert de spektrale verdeling van de door het plasma uitgezonden straling merkbaar. Bij argon bij voorbeeld wordt bij grote magneetvelden het zichtbare licht beheerst door het blauwe licht van het argon-ion (argon II) spektrum. Bij kleine magneetvelden daarentegen ziet men paarsachtig licht, voornamelijk afkomstig van het argon spektrum van neutrale deeltjes (argon I).

We geven enige waarden van temperaturen en dichtheden van het plasma der ontlading die gelden voor stromen van 10 tot 100 A, magneetvelden van  $3 \times 10^{-2}$  tot  $15 \times 10^{-2}T$  en gasdrukken van  $1 \times 10^{-3}$  tot  $1.5 \times 10^{-3}$  torr:

de elektronentemperatuur $T_e$	: $30 \times 10^3$ tot $50 \times 10^3 K$ ;
de ionentemperatuur $T_i$	: $3 \times 10^3$ tot $40 \times 10^3 K$ ;
de temperatuur van de neutrale deeltjes $T_n$	: 500 tot $15 \times 10^3 K$ ;
de elektronen- en ionendichtheid $n_e$	: $1 \times 10^{19}$ tot $3 \times 10^{19} m^{-3}$ ;
de dichtheid van de neutrale deeltjes $n_a$	: $5 \times 10^{18}$ tot $4 \times 10^{19} m^{-3}$ .

Men beschouwe deze getallen als zeer globale informatie. Voor waarden van de ontladingsstroom, het magneetveld en de gasdruk die buiten de aangegeven grenzen liggen, kunnen kleinere en grotere waarden voorkomen.

De bovengenoemde waarden van de elektronentemperatuur en in het bijzonder die van de elektronendichtheid houden in dat een plasma met grote ruimtelijke uitgebreidheid met deze parameters zich in zogenaamd "Corona evenwicht" (C.E.) bevindt<sup>(5)</sup>. We gaan hier niet verder in op de extra verliezen aan geladen deeltjes aan de grenzen van het laboratoriumplasma tengevolge van de beperktheid van het volume van het plasma.

Zonder diep op het mechanisme van het C.E. in te gaan, worden toch enkele bijzonderheden ervan genoemd. Exciterende en ioniserende verschijnselen vinden plaats door botsingen met energierijke elektronen. Deëxcitatie vindt plaats door spontane emissie van straling, recombinitie gaat samen met emissie van een stralingskwant van onbepaalde energie of gebeurt door omlading bij een botsing met een neutraal deeltje. Deze beschrijving staat in tegenstelling met die voor atmosferische bogen, die min of meer door Locaal Thermisch Evenwicht (L.T.E.) beheerst worden. Dit evenwicht wordt bijna geheel door botsingen geregeerd en de uitgezonden straling kan opgevat worden als een kleine verstoring van het evenwicht. In C.E. is de relatieve bezetting van de aangeslagen niveaus ten opzichte van het grondniveau voor gelijke elektronentemperatuur slechts een fractie van die van L.T.E.

De holle kathode boogontlading is sedert 1962 onderzocht door verscheidene groepen, waaronder die van Lidsky en Rose (1 en 6-9), die zich vooral bezig hield met de ionisatiegraad van het plasma en het temperatuurevenwicht tussen elektronen, ionen en neutrale deeltjes (1,7 en 8). Ook zijn bijdragen geleverd op het gebied van Thomson verstrooiing van laserlicht (6) en van de diffusie van het plasma in radiale richting (9).

De groep van Delcroix heeft in de eerste plaats het onderzoek naar de processen in de holle kathode opgevat (10-13), hetgeen onder andere resulteerde in een model voor het veldsterkteverloop tussen het inwendige van de kathode en de anode (11 en 12). Voorts is voor de kathode een "multichannel" ontwerp voorgesteld, bestaande uit een aantal parallel opgestelde holle kathode pijpjes (13).

Kretschmer, Boeschoten en Demeter (14 en 15) en ook Morse (16 en 17) en van der Sijde en Tielemans (18) waren vooral geïnteresseerd in de rotatieverschijnselen van het plasma, een gevolg van een loodrecht op elkaar staand radiëel elektrisch veld en drukgradiënt enerzijds en een axiaal magneetveld anderzijds.

We vermelden volledigheidshalve nog het spectroscopisch werk van Shipp en Tidwell (19 en 20), Leonard (21), van der Sijde (22) en Bleekrode en van Benthem (23).

Het onderzoek aan de boogontlading dat in de drie hierna volgende

delen beschreven wordt, omvat hoofdzakelijk een onderzoek naar het argon II en het argon I spektrum, zowel wat betreft lijnintensiteiten, waaruit de elektronentemperatuur berekend is, als lijnverbredingen, waaruit de temperaturen van de ionen en de neutrale deeltjes berekend zijn (Doppler verbreding). De elektronendichtheid is berekend uit de faseverschuiving van met het plasma in interactie gebrachte 4 mm microgolven. De drie delen zijn tevens bedoeld als publikaties. Als afsluiting volgt nog een algemene slotbeschouwing over de resultaten van het werk.

Het eerste deel houdt zich bezig met het onderzoek naar een mogelijk optreden van wat in de literatuur aangegeven wordt met thermalisatie van aangeslagen iontoestanden door zware deeltjes. We bedoelen hiermede een verschijnsel waarbij aangeslagen iontoestanden, voordat binnen ongeveer  $10^{-8}$ s spontane emissie optreedt, nog overgaan in toestanden op kleine energieafstanden van 0.05 tot 0.2 eV van de oorspronkelijke verwijderd onder invloed van botsingen met neutrale deeltjes of ionen. De temperatuur van deze deeltjes zal dan terug te vinden zijn in de bezettingsgraad van de aangeslagen toestanden. Miller e.a. <sup>(24)</sup> en Lejeune <sup>(25)</sup> nemen aan dat dit verschijnsel optreedt bij plasma's met lage gasdruk. Het probleem vertoont enige verwantschap met een door Drawin <sup>(26)</sup> berekende invloed van de neutrale deeltjes op de bezettingsgraad van toestanden met grote hoofdkwantumgetallen. De experimentele verifikatie ervan was echter door gebrek aan nauwkeurigheid niet goed mogelijk <sup>(27)</sup>.

Als grondslag van de beschouwingen in deel 1 is een nauwkeurige analyse van de in de literatuur gegeven overgangswaarschijnlijkheden van een deel van het argon II spektrum verricht (Appendix bij deel 1).

In het tweede deel worden beschreven de metingen van de intensiteit van een aantal lijnen van het argon I en II spektrum als functie van de hoogte in de plasmakolom. Door een Abel transformatie worden de stralingsprofielen als functie van de afstand  $r$  tot de as van de ontleding verkregen. Uit de verschillen die optreden wordt met behulp van formules van het Coronamodel informatie verkregen over het radiële verloop van de temperatuur en dichtheid van de elektronen ten opzichte van de waarden van de as.

In het derde deel is deze informatie gebruikt om uit de absolute

waarden van de intensiteiten van de lijnen van de argon I en II spektra en uit de faseverschuivingen van de mikrogolven de waarden van de temperatuur en dichtheid van de elektronen op de as te bepalen. Tevens wordt berekend hoeveel de afzonderlijke bijdrage is van de verschillende mogelijkheden om een 4p niveau van het argon II spektrum te bevolken.

CONFIGURATION TEMPERATURES IN A HOLLOW CATHODE ARGON ARC AND TRANSITION  
PROBABILITIES OF THE ARGON II SPECTRUM

B. van der Sijde

Department of Technical Physics, University of Technology, Eindhoven,  
Netherlands.

(Received April 8, 1971)

Summary- A comparison has been made between some kinds of configuration temperatures of the argon II spectrum and the temperatures of the atoms, ions and electrons for a hollow cathode, low-pressure, magnetically-confined, argon arc discharge in the 10 to 80 A current region. We found that thermalization by heavy particle collisions does not occur within the 4p group of the argon II spectrum (excitation energies 19.22 to 19.97 eV), and that relative line-intensity measurements over a large spectral range of 19 to 25 eV give hardly any relevant information on the electron temperature. Our conclusion is that the population densities of the excited levels are mainly determined by the excitation cross-section functions for the levels concerned. Furthermore, we have compared published transition probabilities (to 1970) for the argon II 4p group transitions. The mean values were obtained for 31 transitions with uncertainties (with two exceptions) between 1% and 20%.

I INTRODUCTION

Several authors have calculated population densities of excited levels and configuration temperatures from line-intensity measurements of the argon II spectrum. The configuration temperature is derived from the slope of the line determined by the magnetic sublevel densities (population density divided by the statistical weight of the level) plotted against the value of the excitation energy of the level in a semilogarithmic plot.

Some of the references, MILLER et al<sup>(1)</sup> and RUDKO and TANG<sup>(2)</sup> deal with argon<sup>+</sup> laser experiments with gas pressures of about 0.5 mm of Hg. Other references, of which we mention SHIPP and TIDWELL<sup>(3)</sup>, SHIPP<sup>(4)</sup>, LEONARD<sup>(5)</sup> and VAN DER SIJDE<sup>(6)</sup>, report on hollow cathode, magnetically-

confined argon arc discharges with a working pressure of  $10^{-4}$  to  $10^{-3}$  mm of Hg. Finally, LEJEUNE<sup>(7)</sup> presented measurements of the duoplasmatron experiment with a pressure of  $10^{-2}$  mm of Hg.

We are interested in the significance of configuration temperatures with respect to the temperatures of the various particles in the plasma. One of the most important problems is, whether or not the values of the configuration temperatures of spectral groups with small energy differences between the levels can be understood from a thermalization within a spectral group. Thermalization means a process of transitions between the various levels of the spectral group induced by collisions with particles by which the configuration temperature of the group is changed in that of the particles concerned. MILLER et al<sup>(1)</sup> and LEJEUNE<sup>(7)</sup> suggest such a thermalization by atoms, RUDKO and TANG<sup>(2)</sup> have arguments to deny the phenomenon.

Also the configuration temperature over a wider spectral range with excitation energies from 19 to 25 eV is of some interest. The comparison of this parameter with the electron temperature  $T_e$  can give information on the question whether or not this configuration temperature is equal to  $T_e$ . KRETSCHMER et al<sup>(8)</sup> determined  $T_e$  values from relative line-intensity measurements.

We made an investigation of a low-pressure, hollow cathode argon arc discharge, trying to solve these problems. We determined ion temperatures  $T_i$  and atom temperatures  $T_n$  by Doppler broadening measurements with the aid of a Fabry-Perot interferometer, and electron and configuration temperatures from line-intensity measurements. We compared the results with each other to find out if there are clear agreements or differences between the temperature of a certain kind of particle and a configuration temperature.

## II DEFINITION OF CONFIGURATION TEMPERATURE

The radiant flux  $\phi_{mj}$  per unit volume of a transition  $m \rightarrow j$  in the absence of absorption is given by

$$\phi_{mj} = hv A_{mj} n_m, \quad (1)$$

where  $n_m$  is the density of the population of the excited level  $m$ ;  $A_{mj}$  is the transition probability of the transition  $m \rightarrow j$ ;  $h$  is Planck's constant;  $\nu$  is the frequency of the radiation.

$n_m$  can be written as follows:

$$n_m = n_1 g_m/g_1 \exp(-E_m/kT), \quad (2)$$

where  $n_1$  is the density of the ion ground level;  $g_i$  is the statistical weight of level  $i$ ;  $E_m$  is the excitation energy of the level  $m$ ;  $k$  is Boltzmann's constant.

One can explain the parameter  $T$  as a kind of temperature, without knowing at the moment the physical sense. For L.T.E. circumstances the parameter  $T$  can only be  $T_e$ , whose value for completely established L.T.E. has to be the same as that of the heavy particle temperatures. For Corona Equilibrium (C.E.), the sense of the parameter  $T$  is less clear and may be the object of investigation.

One can try to get information on a  $T$  from relative intensity measurements of two or more lines and defined by the expression

$$T = \frac{E_m - E_p}{k \ln (\phi_{pq} A_{mj} g_m \nu_{mj} / \phi_{mj} A_{pq} g_p \nu_{pq})}, \quad (3)$$

which is equivalent to the formulation in the previous section.

If it is assumed that only inaccuracies in the quotients of the  $\phi$ -values and transition probability values ( $A$ -values) contribute to the relative error in  $T$ , we find

$$\frac{\Delta T}{T} = \frac{kT}{|E_m - E_p|} \left\{ \frac{\Delta(A_{mj}/A_{pq})}{(A_{mj}/A_{pq})} + \frac{\Delta(\phi_{mj}/\phi_{pq})}{(\phi_{mj}/\phi_{pq})} \right\}. \quad (4)$$

From relation (4) we can see that the error  $\Delta T/T$  strongly depends on the ratio of the difference between  $E_m$  and  $E_p$  and the value of  $kT$ .

In the following we shall call a temperature determined by expression (3), a configuration temperature. This expression is also used in the survey of the literature, given in the following section, even when in the reference itself the expression excitation temperature is used for

this parameter. We shall introduce an intra configuration temperature  $T_{4p}$  for the 4p group and also an inter configuration temperature  $T_{ic}$  for a spectral range between  $\sim 19$  eV and  $\sim 25$  eV.

### III LITERATURE SURVEY

In this section we shall give a review of the literature, which may be of interest to the problems, formulated in the Introduction.

MILLER et al<sup>(1)</sup> reported on measurements with an argon<sup>+</sup> laser tube. The diameter of the tube was 2 mm, the pressure of the argon gas 0.6 mm of Hg and the discharge current 5A. They found that  $T_{4p}$  is  $5.3 \times 10^3$  °K (0.46 eV) from line-intensity measurements and  $T_e$  is  $30 \times 10^3$  °K (2.5 eV). An estimation of an inter configuration temperature  $T_{ic}$ , based on Fig. 1 of (1), gives a value of  $12 \times 10^3$  °K. MILLER et al proposed a thermalization within a spectral group, based on the discrepancy between  $T_{4p}$  and  $T_e$ . For this explanation, transitions between the levels of the 4p group should take place within the radiation decay time of  $5 \times 10^{-9}$ s, leading to a rearrangement of the population densities of the levels involved. The particles, causing this rearrangement, must have a kinetic energy  $\geq 0.2$  eV, the largest energy gap in the group being 0.19 eV. Electrons are excluded from discussion, whereas the excitation from lower levels to the levels of the 4p group is caused by electrons with a mean energy of 2.5 eV. This large value in comparison with a  $T_{4p}$  of 0.46 eV just presents the problem. Ions are excluded by MILLER et al for reasons which are not perfectly clear, but based on arguments about direct excitation of the 4p levels from the ion ground level. They propose that neutral particles cause the thermalization, perhaps via short lived molecular ions.

In an extensive investigation of the argon<sup>+</sup> laser (tube diameter 2mm; pressure 0.3 mm of Hg; discharge current 5 A) RUDKO and TANG<sup>(2)</sup> found straight lines for each of the 4p, 4p', 5s, 5s', 4d and 4d' groups ( $E_m = 19$  eV to 25 eV) in a semilogarithmic plot as discussed in the Introduction. They do not derive a temperature from the slopes of the lines. Our own calculations, based on Fig. 1 of ref. (2) give for  $T_{4p}$  a value of  $7.4 \times 10^3$  °K and for  $T_{ic}$  a value of about  $12 \times 10^3$  °K. The

$T_{ic}$  includes the spectral region between 19 and 25 eV, i.e. all spectral groups mentioned above.

Moreover, RUDKO and TANG<sup>(2)</sup> performed an experiment, in which the radiation of the 4880 Å line of the argon<sup>+</sup> laser was modulated at a frequency of 800 cps. The other lines, originating from the  $4p^2D_{5/2}$  state showed a modulation of 6 to 7% with the same frequency. Lines originating from the neighbouring levels only showed a modulation of  $\leq 0.1\%$ . They concluded that these experiments do not give an indication for a thermalization process.

In a hollow cathode, low-pressure, magnetically-confined argon arc discharge experiment SHIPP and TIDWELL<sup>(3)</sup> and SHIPP<sup>(4)</sup> determined a  $T_{ic}$  based on intensity measurements of lines, originating from levels of the 4p, 4p' and 5s group. They found values between  $20 \times 10^3$  °K and  $26 \times 10^3$  °K. These high values are mainly caused by the use of an A-value for the 3588 Å line ( $^3P\ 4d\ ^4F_{9/2} \rightarrow ^3P\ 4p\ ^4D_{3/2}$  transition), which appears to be wrong by a factor of 4.5 (see reference<sup>(9)</sup> for comparison). Calculations with the improved A-value give  $T_{ic}$  values of  $14 \times 10^3$  °K to  $17 \times 10^3$  °K.

In an argon fed hollow cathode discharge, related to the device of SHIPP and TIDWELL but with another type of anode, LEONARD<sup>(5)</sup> calculated a  $T_{ic}$  in the 19 to 24 eV region with a value of  $9.3 \times 10^3$  °K (0.8 eV) from line-intensity measurements, and determined  $T_e$  to be  $30 \times 10^3$  °K (2.7 eV). The value of  $T_{ic}$  is lower than in the previous references, perhaps caused by the A-values used by LEONARD.

VAN DER SIJDE<sup>(6)</sup> determined a  $T_{ic}$  for the 4p and 4p' group for a hollow cathode argon discharge, similar to that of LEONARD. The value of  $17 \times 10^3$  °K is nearly constant over a wide range of magnetic induction values.  $T_e$  was estimated to be  $70 \times 10^3$  °K. The value of  $T_{ic}$  is rather high in comparison with the  $T_{ic}$  values of the authors, mentioned before. The reason of this fact is the selection of the levels, by which  $T_{ic}$  is determined.

LEJEUNE<sup>(7)</sup> reported on a low pressure, hot cathode, "duoplasmatron" discharge, with a  $T_{4p}$  of the order of  $6.5 \times 10^3$  °K (0.55 eV) and a  $T_{ic}$  between  $12 \times 10^3$  °K and  $20 \times 10^3$  °K (1.0 to 1.7 eV). The value of  $T_{4p}$

is in good agreement with other references. The range of  $T_{ic}$  values is rather wide; the maximum of  $20 \times 10^3$  °K is larger than in any other reference. LEJEUNE also suggests a thermalization within spectral groups of the argon II spectrum, caused by heavy particle collisions .

Reviewing this part of the survey , we can conclude that contradictory ideas have been published about the question of thermalization within a spectral group. The values of  $T_{4p}$  range from  $5.3 \times 10^3$  °K to  $7.4 \times 10^3$  °K. Apart from the differences in the physical conditions of the discharges, the variation of the value of  $T_{4p}$  can be partly caused by differences in the A-values, used in the calculations.

The range of values of  $T_{ic}$  is rather wide,  $9.3 \times 10^3$  °K to  $20 \times 10^3$  °K. The variation in the values of this parameter can be caused by the following reasons: 1) the use of various combinations of spectral groups and lines ; 2) differences in the A-values used, which may have a rather large effect, due to the great uncertainty of these values for transitions, originating from other groups than the 4p group ; 3) the influence of the physical conditions of the discharge on  $T_{ic}$ . This question will be discussed further in a following section.

We finally want to discuss the theoretical work of JOHNSON<sup>(10)</sup>, which is of interest to the subject of this paper. JOHNSON presented calculations on simultaneous charge transfer and fine structure transitions for argon neutral and argon ion excited particles. The transfer

has a collision cross-section of  $2 \times 10^{-20}$  m<sup>2</sup> for 5 eV ions and of negligibly small values for ion energies smaller than 3 eV. The reverse transition has about twice smaller values. These cross-section values are too small to be able to influence quantitatively the population density of the excited levels for the energy region of the ions in the experiments, already mentioned. This example gives arguments to assume that charge transfer processes generally have too small cross-sections to induce thermalization effects.

## IV EXPERIMENTAL

## 1. Discharge device

In<sup>(6)</sup>, a short description of the discharge device was already given. We shall extend the description now (see Fig.1a). The discharge took place in a pyrex tube (4) having a length of 1.4 m and a diameter of

Fig. 1a Simplified design of the discharge device. 1 is a hollow cathode; 2 is a ring-shaped anode; 3 is an end-anode; 4 is a pyrex tube with small side tubes; 5 are magnetic coils; 6 are diffusion pumps with baffles; 7 is a tube and window for spectral measurements; 8 is a tube and window for line profile measurements.

Fig.1b Detailed design of the water-cooled cathode. 1 is a tantalum pipe, inner diameter = 2.5 mm; 2 is a water-cooled cylinder; 3 is a fused silica cylinder; 4 is a tantalum sheet, at floating potential; 5 are tantalum fins (sometimes not present).

Fig.1c Detailed design of the end-anode. 1 is a tungsten cylinder; 2 is a tungsten rod; 3 is a tantalum conical surface, at floating potential; 4 are electrical insulators; 5 is a tantalum disc.

0.3 m. The argon gas with impurity concentrations smaller than 40 p.p.m., streamed through a hollow cathode pipe (1) into the large pyrex tube and was pumped away by two mercury diffusion pumps (6) each with a baffled pumping speed of  $0.8 \text{ m}^3 \text{ s}^{-1}$ .

The cathode pipe of tantalum or tungsten containing 3%  $\text{ThO}_2$  (1), had an inner diameter of 2.5 mm and a length of 50 to 100 mm. The cathode was situated at one end of the axis of the pyrex tube (Fig.1b). Two different anodes could be used, the first being a ring-shaped one of tungsten (2), having an inner diameter of 120 mm. The axis of the ring coincided with the tube axis. The ring surrounded the discharge at a distance of 50 to 80 mm from the end of the cathode. The second anode was a cylindrical tungsten end-anode (3) with a tantalum disc (Fig.1c). The outer diameter of the disc of this anode was 50 mm. The axis of the anode also coincided with the tube axis.

When the discharge was running, one of both anodes was connected with the current supply, the other being at floating potential. The cathode was always at earth potential. The working pressure of the discharge was  $1 \times 10^{-3}$  to  $2.5 \times 10^{-3}$  mm of Hg, measured by an ionization gauge at some distance (0.5 m) from the discharge. The residual gas pressure of the system was  $1 \times 10^{-6}$  to  $3 \times 10^{-6}$  mm of Hg.

The discharge was confined around the axis of the pyrex tube by an axial magnetic field. Two magnetic coils (5) gave a bottle-shaped magnetic field (Fig.2), with continuously variable magnetic induction values between 0.01 T and 0.2 T for the two maxima in Fig. 2. In the following sections we shall use the values of the magnetic induction  $B_w$ , at a position marked w in Fig. 2.

The discharge current range for the ring-shaped anode was 10 to 100 A and for the end anode 10 to 50 A. The upper limits were imposed by the maximum heat dissipation of the anodes.

The neutral gas, streaming through the cathode pipe was highly ionized in the cathode itself. The ions formed in the cathode pipe caused a bombardment on the inner side of the cathode wall, resulting in a temperature of 2000 to 3000<sup>o</sup>K for the hottest spot of the cathode. The electrons delivered by the thermal electron emission ionized the flowing neutral gas and carry the current between anode and cathode. When the discharge was running, the voltage between cathode and anode

was of the order of 30 to 200 V. The discharge was started by a low current 1000 V supply.

Fig. 2 The value of the magnetic induction per Ampère current through the coils on the axis of the pyrex tube as a function of the distance  $z$  along the axis. The point of symmetry has been chosen as  $z = 0$ . The arrows and symbols denote the following objects: ca is the cathode; ra is the ring-shaped anode; ea is the end-anode;  $c_1$  and  $c_2$  are magnetic coils; w are windows for spectral measurements.

Near the axis of the tube, the blue radiation of the argon II spectrum could be seen. The radiating column had a diameter of 4 to 15 mm, depending on the position along the axis and on the discharge conditions. The argon I spectrum in the 4000 to 5000 Å region ( $5p \rightarrow 4s$  transitions) was very weak, partly due to the small A-values of the lines concerned. Only a few lines could be detected. The argon I spectrum in the 7000 to 8000 Å region ( $4p \rightarrow 4s$  transitions) was a factor 20 stronger, due to the greater A-values, but still a factor 10 weaker than the strongest lines of the argon II spectrum ( $4p \rightarrow 4s$  and  $4p \rightarrow 3d$  transitions). The

same qualitative light phenomena were detected with the two anodes. No radiation could be seen from the discharge region along the first 2 to 5 cm from the end of the cathode. This fact was perhaps caused by the intense radiation of the cathode itself.

## 2. Line-intensity measurements

The line-intensity measurements were performed with a 0.5 m Jarrell Ash grating monochromator (Fig.3a and 3b). The radiation of the plasma column (1) passed through a cylindrical glass tube perpendicular to the

Fig.3a Design of the device for line-intensity measurements; perpendicular to the optical axis not to scale. 1 is the plasma column; 2 is the optical axis; 3 is a fused silica window; 4 is a lens, vertically movable; 5 is a large mirror, removable for tungsten ribbon lamp measurements; 6 is a mirror, vertically movable (see Fig.3b); 7 is a mirror; 8 is a diaphragm; 9 is a lens; 10 is the monochromator entrance slit; 11 is a grating monochromator; 12 is a tungsten ribbon lamp; 13 is a  $45^\circ$  prism; 14 is a photomultiplier RCA IP 28; 15 is a Keithley electrometer; 16 is a Moseley recorder.

Fig.3b Detailed design of the position of the mirrors 6 and 7. The rotation axes make angles of  $45^\circ$  with the optical axis of the system.

pyrex tube. This small tube had a length of 150 mm and a diameter of 45 mm. After that, the radiation passed through a fused silica window (3), sealing off the glass tube. This construction enabled us to do

side-on measurements. An optical system consisting of two fused silica lenses (4,9) and three mirrors (5,6,7) made it possible to focus on the vertical entrance slit (10) of the monochromator (size  $100\mu \times 2.3 \text{ mm}$ ) a rectangular section having a length of 5 mm and a height of  $230\mu$  and situated in the vertical plane through the tube axis. As the entrance angle of the detection system was rather small (0.04 rad), the resolution of the system was not seriously decreased at the edges of the plasma column. At a radius of 10 mm the rectangular section was  $5.5 \text{ mm} \times 700\mu$ .

One lens and one mirror were vertically movable to displace the optical axis of the system, enabling us to scan the radiation profile of the plasma column. A calibrated tungsten ribbon lamp, placed at a position, which was optically equivalent to the discharge position, made it possible to perform absolute line-intensity measurements.

The breadth of the entrance slit enabled us to measure the total radiation intensity of one line. The equivalent dispersion width of the  $100\mu$  slit is 1.6 Å, in comparison with line profile widths of the order of 10 to  $100 \text{ mÅ}$ . The total radiation of one line was compared with the continuous radiation of a bandwidth of 1.6 Å.

In order to be able to compare the volume radiation of the plasma with the surface radiation of the tungsten ribbon lamp (12), the breadth of the radiation profile of the plasma was also measured in the vertical direction. By assuming cylindrical symmetry this measurement made it possible to calculate the absolute line radiation flux per unit volume. The radiation was detected by means of an RCA IP28 photomultiplier (S-5 response) (14) while a part of the information on the argon I spectrum was detected with an EMI 9698 B photomultiplier (S-20 response). The signals were measured with a Keithley 602 electrometer (15) and registered by a Mosely recorder (16).

### 3. *The Fabry-Perot interferometer*

The heavy particle temperatures were determined with the aid of a Fabry-Perot order-scanning-type interferometer (Fig.4)<sup>(11)</sup>. The interferometer provided the line profiles enabling us to derive the temperatures from calculations of the Doppler broadening of the spectral lines. A lens system (1,2) gave an image of the plasma column near the

axis of the pyrex tube on the vertical slit of a prism monochromator (Hilger and Watts) (6) giving a bandwidth of 10 to 15 Å of the spectrum. Another lens system (3,4] and the interferometer (7) itself gave an image of the ring pattern, which was scanned by a 600 $\mu$  x 50 $\mu$  movable slit (8). The ring pattern corresponded with a real image of the plasma column, so that by scanning the various rings and by moving the optical axis through the plasma column, a good impression could be obtained of the temperature distribution in a vertical direction. The radiation was detected by an EMI 6256 S photomultiplier (9), measured with a Keithley 409 picoammeter (10) and registered by a Moseley recorder (11).

*Fig.4 Device for line profile measurements. 1,2,3 and 4 are lenses; 5 is a polaroid filter; 6 is a prism monochromator; 7 is a Fabry-Perot interferometer; 8 is a movable slit; 9 is a photomultiplier EMI 6256 S; 10 is a Keithley picoammeter; 11 is a Moseley recorder.*

The magnetic field is responsible for a Zeeman splitting of the spectral lines, which for most discharge conditions could not be neglected in comparison with the Doppler broadening. In order to derive an easily interpretable signal, only the linearly polarized component ( $\Delta m = 0$ ) was measured, the two circularly polarized components ( $\Delta m = \pm 1$ ) being eliminated with a polaroid filter (5]. The apparatus broadening was known from calibration with the Cd 4800 and 5086 Å lines, giving 25 mÅ as a result. The Voigt profiles, directly measured, were deconvoluted in order to derive the pure Doppler broadening.

#### 4. Microwave interferometer

For a part of the measurements, presented in the following section, estimations of the electron densities  $n_e$  were made from phase shift measurements with a 4 mm microwave interferometer. These phase shift measurements were performed for discharge conditions, very similar to those of the presented measurements. The  $n_e$  values were of the order of  $10^{18} \text{ m}^{-3}$  for small values of the magnetic induction  $B_w$  and  $10^{19} \text{ m}^{-3}$  for large  $B_w$  values.

#### V RESULTS

Ion temperatures  $T_i$  have been calculated from the Doppler broadened

Fig.5 Example of the determination of the 4p group configuration temperature  $T_{4p}$  and the multiplet configuration temperatures  $T_{4p}$ ,  $T_{4D}$ ,  $T_{2D}$  and  $T_{2P}$ .  $\ln(\phi_{mj}/v_{mj} A_{mj}^2 g_m)$  is plotted on a scale with an arbitrary zero point against the excitation energy  $E_m$ . Discharge parameters: discharge current  $I_D = 24 \text{ A}$ ; magnetic induction  $B_w = 9 \times 10^{-2} \text{ T}$ ; pressure =  $1.5 \times 10^{-3} \text{ mm}$  of Hg; end-anode used.  $T_{4p} = 8.9 \times 10^3 \pm 250^\circ \text{ K}$ ;  $T_{4P} = 1.9 \times 10^3 \pm 200^\circ \text{ K}$ ;  $T_{4D} = 2.4 \times 10^3 \pm 200^\circ \text{ K}$ .  $T_{2D} = 1.5 \times 10^3 \pm 200^\circ \text{ K}$ ;  $T_{2P} = 2.6 \times 10^3 \pm 200^\circ \text{ K}$ .

profile of the argon II 4806 Å line, having a normal Zeeman splitting. For the calculation of the temperature of the neutral atoms  $T_n$  the profiles of the argon I 4198 Å line ( $3p_5 \rightarrow 1s_4$  transition) and 4201 Å line ( $3p_9 \rightarrow 1s_5$  transition) have been measured. For the determination of  $T_{4p}$  one transition from each upper level was chosen. These transitions have been listed in Table 6 of the Appendix. The averaging procedure to find the A-values is explained in the Appendix. The value of the parameter  $\ln(\phi_{mj}/\nu_{mj} A_{mj} g_m)$  for each line plotted against the excitation energy  $E_m$  of the upper level of the transition gives a straight line, from the slope of which  $T_{4p}$  is derived.

Figure 5 shows an example of this type of plot. The line was determined with the aid of the least-squares method. Only deviations in the ordinate have been taken into account, since the excitation energies are well-known. The uncertainty in  $T_{4p}$  is 600°K for  $T_{4p}$  between  $7 \times 10^3$  and  $8 \times 10^3$  °K. The error in  $T_{4p}$  is estimated to be about 250°K from the random deviations in the curves of Figs. 9 and 12. Systematic deviations must cause the other part ( $\sim 350$ °K) of the total uncertainty. This assumption agrees well with the fact that the deviations from the line in Fig.5 apply to all measurements, excluding only those for very low magnetic inductions. We estimate that the errors in the A-values given in Table 6 of the Appendix, contribute only about 100°K to these systematic deviations. This estimate is based on a comparison with calculations using other A-values. These values differed significantly from those presented in Table 6 of the Appendix and caused a difference of 300 °K in  $T_{4p}$ . The residual of the systematic deviations, i.e. about 250°K, are attributed to details in the excitation phenomena in the spectrum of argon II.

The large scale of Fig.5 enables us to draw lines through the points of every separate multiplet ( $^4P$  triplet,  $^4D$  quartet,  $^2D$  doublet and  $^2P$  doublet). These lines have steeper slopes than that for the 4p group. It may be remarked, that for the  $^4P$  triplet and  $^4D$  quartet these lines agree much better with the measured points than for the 4p group. In a similar way as for the 4p group we can determine multiplet configuration temperatures. For the example of Fig.5 the values of these temperatures for the four multiplets have been indicated in the legend of the Fig.. In the following figures we shall give the  $^4D$  multiplet configuration

temperature  $T_{4D}$ , being the example based on the largest number of measured points.

Fig.6 Example of the determination of  $T_{4p}$  and of the relative population densities of the  $4p$  levels for  $B_w = 9 \times 10^{-3} T$ ; the other discharge parameters are similar to those of Fig. 5.  $T_{4p} = 14.4 \times 10^3 \text{ } ^\circ K$ .

We shall give here also the results of the line-intensity measurements for very low values of  $B_w$ . For  $B_w = 2 \times 10^{-2} T$  small deviations from the picture of Fig.5 could be seen. The deviations are much larger for  $B_w = 9 \times 10^{-3} T$ , the smallest value of  $B_w$  for which measurements have been performed. The results for this value are presented in Fig.6. We see that the lines, drawn through the points of the  $4P$  triplet and  $4D$  quartet now show larger deviations from these points in comparison with the situation in Fig.5. Also the doublet and singlet points have positions, which are changed with respect to the line, drawn through the points of the  $4p$  group as a whole, in comparison with the picture of Fig. 5.

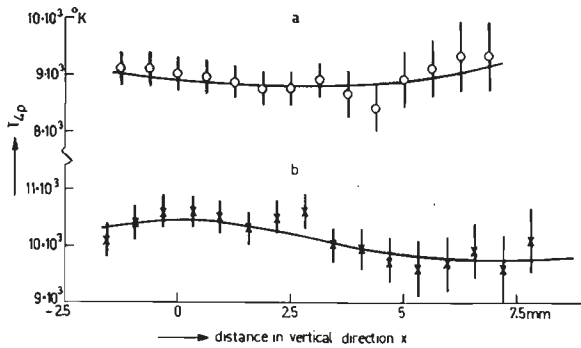

Fig.7 Configuration temperature  $T_{4p}$  for two discharge conditions as a function of the vertical scanning distance  $x$  from the axis of the discharge.  $x = 0$  denotes the position of maximum radiation intensity. *oring-shaped anode; discharge current  $I_D = 25$  A; magnetic induction  $B_w = 2.25 \times 10^{-2}$  T; pressure =  $2.0 \times 10^{-3}$  mm of Hg.  $x$  ring-shaped anode; discharge current  $I_D = 25$  A; magnetic induction  $B_w = 7.5 \times 10^{-2}$  T; pressure =  $2.0 \times 10^{-3}$  mm of Hg. The error bars give the random error of the values.*

Neither the measurements of line-intensities nor those of line profiles have been subjected to an Abel transformation. This simplification can be justified with the help of the results given in the Figs. 7 and 8. Figure 7 shows the values of  $T_{4p}$  for two different discharge conditions described in the legend of the figure and for side-on measurements scanned in a vertical direction. We conclude that the differences in  $T_{4p}$  are only 10% of the mean value, and do not depend in a systematic way on the vertical position. Other measurements show the same behaviour:

Figure 8 shows the  $T_i$ -values, derived from side-on measurements, also scanned in a vertical direction. The deviations are again not larger than about 10%. From these facts we conclude that the Abel transformation will not give a significant improvement of the presented results.

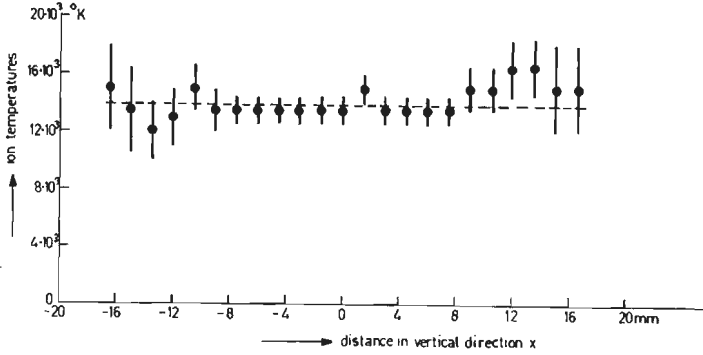

Fig.8 The ion temperature  $T_i$  as a function of the vertical scanning distance  $x$  from the axis of the discharge. Discharge conditions: ring-shaped anode; discharge current  $I_D = 50$  A; magnetic induction  $B_w = 6 \times 10^{-2}$  T; pressure =  $1.8 \times 10^{-3}$  mm of Hg. The error bars give the random error of the values.

Fig.9 Configuration and heavy particle temperatures as functions of the magnetic induction  $B_w$  for an end-anode discharge. Discharge conditions: discharge current  $I_D = 24$  A; Pressure =  $1.5 \times 10^{-3}$  mm of Hg; ● ion temperature  $T_i$ ; + neutral temperature  $T_n$ ; ○ 4p group configuration temperature  $T_{4p}$ ; ×  $^4D$  multiplet configuration temperature  $T_{4D}$ .

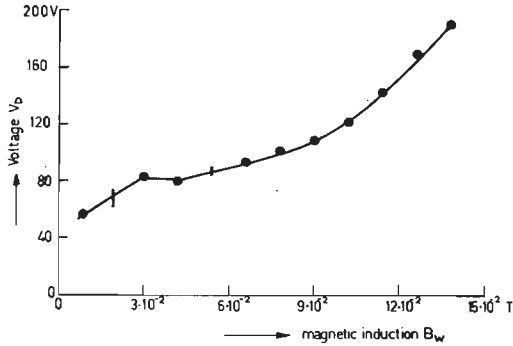

Fig.10 Voltage  $V_D$  between the cathode and the end-anode as a function of the magnetic induction  $B_w$ . See for discharge conditions Fig.9. Points or bars give the values of the voltage.

Figure 9 gives the values of the various temperatures as functions of the magnetic induction  $B_w$ . The discharge conditions are stated in the legend of the figure.  $T_{4p}$  shows a small decrement as a function of  $B_w$  in the region of small  $B_w$  values. This decreasing character of  $T_{4p}$  is affirmed by previous measurements with ten measured points in the 0 to  $5 \times 10^{-2}$ T region. A small increment seems to occur for large values of the magnetic induction.  $T_{4D}$  on the contrary is nearly constant as a function of  $B_w$ .

The curve of  $T_i$  shows a rather rapidly growing character as a function of  $B_w$ , ranging from 500 to  $16 \times 10^3$  °K. All preliminary measurements confirm the form of the presented curve, which for larger discharge currents even has larger maximum values, up to  $50 \times 10^3$  °K. The neutral particle temperature  $T_n$  only shows a small increase for small values of  $B_w$ . For greater values of  $B_w$ ,  $T_n$  is nearly constant, the total variation being between  $1.5 \times 10^3$  and  $3.5 \times 10^3$  °K.

Systematic errors in  $T_i$ , due to deconvoluting techniques and to a possible error in the apparatus broadening may range from 50% for temperatures of  $1 \times 10^3$  °K to 8% for temperatures of  $30 \times 10^3$  °K. Random errors due to the measurements themselves range from about 20% for  $1 \times 10^3$  °K to 5% for  $30 \times 10^3$  °K. The systematic errors in  $T_n$  for a value

of  $1.5 \times 10^3$  °K are estimated as about 40%, and are partly due to an uncertainty in the calibration of the apparatus broadening for the 4201 Å wavelength, which may give an error in addition. The random error in  $T_n$  is larger than that in  $T_i$  for the same value of the temperature and is estimated to be 20% for  $T_n = 3000$  °K. This fact is due to the weak

Fig. 11a. Magnetic sublevel populations  $n_m/g_m$  for the 4p group as functions of the magnetic induction  $B_w$ . See for discharge conditions Fig. 9. X  $^4P_{5/2}$  level; +  $^4P_{3/2}$ ; \*  $^4P_{1/2}$ ; ■  $^2D_{5/2}$ ; ▲  $^2D_{3/2}$ ; ▽  $^2P_{1/2}$ ; ▽  $^2P_{3/2}$ .

signals of the lines of the neutral spectrum.

The values of the voltage  $V_D$  between the end-anode and the cathode for the discharge conditions of Fig.9 are presented in Fig.10.

For the conditions of the measurements presented in Fig.9, the average population densities in the column of the magnetic sublevels of the 4p

Fig.11b. Magnetic sublevel populations  $n_m/g_m$  for the 4p group as functions of the magnetic induction  $B_W$ . See for discharge conditions Fig. 9.  $\circ$   $^4D_{7/2}$ ;  $\Delta$   $^4D_{5/2}$ ;  $\square$   $^4D_{3/2}$ ;  $\nabla$   $^4D_{1/2}$ ;  $\times$   $^4S_{3/2}$ ;  $\ast$   $^2S_{1/2}$ . The  $\nabla$  and  $\ast$  symbols coincide for many  $B_W$  values.

group have been calculated with expression (1). The results are given in Figs. 11a and 11b. We can conclude that in the lower part of the magnetic induction range, the greater part of the confinement of the plasma occurs. From  $B_w$  is  $9 \times 10^{-3}$  to  $3 \times 10^{-2}$  T the population densities grow by a factor 100 or more, from  $3 \times 10^{-2}$  to  $12 \times 10^{-2}$  T, however, by about a factor 10. Results of previous measurements with the ring-shaped anode show even more clearly a saturation effect for large magnetic fields.

Fig.12 Configuration and particle temperatures as functions of the discharge current  $I_D$ . Discharge conditions: ring-shaped anode; magnetic induction  $B_w = 9 \times 10^{-2}$  T; pressure =  $1.65$  to  $1.70 \times 10^{-3}$  mm of Hg.  $\square$  electron temperature  $T_e$ ;  $\bullet$  ion temperature  $T_i$ ;  $+$  neutral particle temperature  $T_n$ ;  $\circ$  configuration temperature  $T_{4p}$ ;  $\times$  configuration temperature  $T_{4D}$ .

Fig.13 Voltage  $V_D$  between the cathode and the ring-shaped anode as a function of the discharge current  $I_D$ . See for discharge conditions Fig.12.

In Figure 12 results are presented for the various temperatures of the plasma from measurements, which have been performed as functions of the discharge current  $I_D$ , using the ring-shaped anode. The discharge conditions are stated in the legend of the figure.  $T_i$  reaches a value of more than  $35 \times 10^3$  °K for currents of 80 A. Also  $T_n$  increases markedly as a function of the discharge current from  $3.5 \times 10^3$  to  $15 \times 10^3$  °K. On the contrary,  $T_{4p}$  and  $T_{4D}$  are constant within very narrow limits,  $7.4 \times 10^3$  to  $7.8 \times 10^3$  °K and  $2.6 \times 10^3$  to  $3.3 \times 10^3$  °K respectively, while the variation in these values has a random character.

The values of  $T_e$  for this set of measurements have been calculated from the ratio of the intensities of the argon III 3286 Å line and the argon II 4348 Å line. The values of  $T_e$  increase with the discharge current  $I_D$  from  $35 \times 10^3$  to  $45 \times 10^3$  °K. The used Corona formulae may lead to systematic errors, which are difficult to estimate. Moreover, the population density of argon<sup>++</sup> with respect to argon<sup>+</sup> will be lower than described by the Corona Equilibrium, due to diffusion losses of the charged particles. These losses will depend on the value of the magnetic induction. Therefore, the  $T_e$  will be systematically lowered by the diffusion losses and moreover the error in  $T_e$  will be a function of the magnetic induction.

Fig.13 gives the voltage characteristic for the discharge conditions of the measurements of Fig.12. We see a linear variation of  $V_D$  with the discharge current.

Fig.14 Example of the calculation of an intra group configuration temperature  $T_{ic}$  in a semilogarithmic plot as Fig.5. Discharge conditions: ring-shaped anode; discharge current  $I_D = 25$  A; magnetic induction  $B_w = 13.5 \times 10^{-2}$  T; pressure =  $2.5 \times 10^{-3}$  mm of Hg; Result:  $T_{ic} = 13.2 \times 10^3$  °K.

In section II it is stated that we can define an inter configuration temperature  $T_{ic}$  for a larger range of excitation energies than that of the 4p group, including more than one spectral group. In Fig.14 we show some results from intensity measurements of spectral lines, originating from levels of a large spectral range (19 to 25 eV), including 4p, 4p', 4d and 4d' levels. The discharge parameters are indicated in the legend of the figure. For this example  $T_{ic}$  has a value of  $13.2 \times 10^3$  °K. The values of  $T_{ic}$  of all other measurements with various discharge conditions range from  $12 \times 10^3$  to  $16 \times 10^3$  °K. The A-values have been derived from Table 1 of the Appendix for the 5062 and 4965 Å lines and from a recent publication of NERHEIM and OLSEN<sup>(9)</sup> for the other lines.  $T_e$  is estimated to be in the range of  $30 \times 10^3$  to  $60 \times 10^3$  °K for these measurements. These measurements enable us to compare our results in the next section with those of the other references.

## VI DISCUSSION AND CONCLUSIONS

The results, presented in the Figs. 5,9 and 12 are mainly intended to clear the question of thermalization by heavy particles within a spectral group with small energy differences among the subsequent levels.

In section III we saw that contradictory ideas have been published on this topic in the literature on low pressure discharges and argon<sup>+</sup> lasers.

The conclusions which can be drawn from this work, in the first place regard to the argon II 4p group with 13 levels with excitation energies between 19.22 and 19.97 eV and to the parameters of the described plasma, being:  $3 \times 10^4 \text{ } ^\circ\text{K} < T_e < 6 \times 10^4 \text{ } ^\circ\text{K}$ ;  $2 \times 10^3 \text{ } ^\circ\text{K} < T_i < 5 \times 10^4 \text{ } ^\circ\text{K}$ ;  $1.5 \times 10^3 \text{ } ^\circ\text{K} < T_n < 1.5 \times 10^4 \text{ } ^\circ\text{K}$ ;  $1 \times 10^{19} \text{ m}^{-3} < n_e = n_i < 6 \times 10^{19} \text{ m}^{-3}$ ;  $2 \times 10^{18} \text{ m}^{-3} < n_n < 4 \times 10^{19} \text{ m}^{-3}$ .  $n_i$  and  $n_n$  are the density of the ions and neutral particles respectively.

In our investigation we calculated the temperature of the various particles to compare them with the configuration temperature  $T_{4p}$  for the discharge current and magnetic induction regions available. The main idea for the comparison is, that in the case of rearrangement induced by heavy particles, having temperatures  $T_{i,n} < T_e$ , the influence of the collisions must be found in the values of  $T_{4p}$ . This influence will appear in such a way that the relation

$$T_{i,n} \leq T_{4p} < T_e \quad (5)$$

holds. The value of  $T_{4p}$  within the region between  $T_{i,n}$  and  $T_e$  must depend on the completeness of the thermalization process.

When looking at  $T_e$  and  $T_{4p}$  in Fig.12, we conclude that the difference between  $T_e$  ( $35 \times 10^3$  to  $45 \times 10^3 \text{ } ^\circ\text{K}$ ) and  $T_{4p}$  ( $7 \times 10^3$  to  $9 \times 10^3 \text{ } ^\circ\text{K}$ ) is very large, indicating that the value of  $T_{4p}$  does not give any information on the value of  $T_e$ . This conclusion can be drawn with more certainty since the  $T_e$  values most probably have to be regarded as minimum values.

A comparison of  $T_{4p}$  with  $T_i$ , based on the figures 9 and 12 leads to the conclusion that  $T_{4p}$  cannot be influenced by collisions with the ions themselves.  $T_{4p}$  is more or less constant as a function of the discharge current  $I_D$  and for  $B_w$  values larger than  $2.5 \times 10^{-2} \text{ T}$ .  $T_i$  is smaller than  $T_{4p}$  for small values of  $B_w$ , whereas  $T_i$  is larger than  $T_{4p}$  for larger values of this parameter. The results for the larger  $B_w$  values are contrary to the relation (5) which makes it impossible that

thermalization occurs by collisions with ions. Our conclusion is that no detectable quantity of transitions occurs within the 4p group as a whole, initiated by collisions with other ions.

When we compare the values of  $T_{4p}$  and  $T_n$  as functions of  $B_w$  with each others, we see from Fig.9 that the behaviour of these parameters is similar. Besides, it holds that  $T_n < T_{4p} < T_e$ , which is in agreement with relation (5). In Fig.12, however, the behaviour of  $T_{4p}$  and  $T_n$  as functions of the discharge current  $I_D$  is quite different, resulting in  $T_n > T_{4p}$  for  $I_D > 40A$ , which is in contradiction with relation (5). We conclude that no detectable interaction exists between neutral particles and the excited ions, leading to a thermalization of the whole 4p group.

It appeared from Fig.5, that lines can be drawn through the measured points of the various multiplets. For the  $4P$  triplet and the  $4D$  quartet the deviations are small, suggesting the possibility of a thermalization process within the multiplets. The  $4D$  multiplet configuration temperature  $T_{4D}$  has values between  $1.8 \times 10^3$  and  $3 \times 10^3$  °K. In Fig.9 the curves of  $T_{4D}$  and  $T_n$  has a similar form. However,  $T_{4D}$  is smaller than  $T_n$  for the greater part of the curves which is contrary to relation (5), and in Fig.12 the constant value of  $T_{4D}$  contrasts with the values of  $T_n$  which are growing as a function of  $I_D$ . Our conclusion is that from these experiments no reasons can be found to suppose a thermalization process within the multiplets, caused by collisions with neutral atoms. Collisions with ions also do not cause a thermalization.

Reviewing the results of this discussion, we conclude that comparison of the temperatures  $T_i$  and  $T_n$  of the heavy particles with the configuration temperatures  $T_{4p}$  and  $T_{4D}$  shows that thermalization processes due to heavy particles must be excluded.

These conclusions can be sustained with an estimation of the minimum value of the cross-section for collisions between excited ions and other heavy particles needed to cause a rearrangement within a spectral group or multiplet. The estimation can be made by comparing the rate of rearrangement with the spontaneous radiation decay rate of a level. One can state that rearrangement will be obvious when:

$$\langle \sigma_{n,i} \cdot v_{n,i} \rangle n_{n,i} \geq \sum_j A_{mj}, \quad (6)$$

where  $\langle \sigma \cdot v \rangle$  denotes an integration of the cross-section over the velocity distribution;  $n$  is the suffix for neutrals,  $i$  for the ions;  $\sum_j A_{mj}$  is the sum of the transition probabilities for the level  $m$ . A calculation of  $\sigma$  for the equality of expression (6) for the densities and temperatures, already mentioned gives  $\sigma_n \approx 1 \times 10^{-14} \text{ m}^2$  and  $\sigma_i \sim 10^{-15}$  to  $10^{-14} \text{ m}^2$ . These values are about a factor of  $10^3$  and  $10^4$  larger than any other cross-section value. These results support our conclusions about the absence of a rearrangement by heavy particles.

Our suggestion is that the locations of the points in Fig.5 are mainly determined by the excitation functions for the levels concerned, resulting in a more or less regular pattern within the  $4p$  and  $4d$  multiplets. Thus the physical significance of the parameters  $T_{4p}$  and  $T_{4d}$  is limited. We conclude from the deviations from other particle temperatures, including  $T_e$ , that thermal equilibrium does not exist either within the  $4p$  group or within a multiplet.

In Fig.14, we gave some results of line-intensity measurements and a  $T_{ic}$ -value for a region of 6 eV excitation energy. We now want to investigate, what information on  $T_e$  is obtainable from the slope of the line in Fig.14. It appears that  $T_{ic}$  is  $12 \times 10^3$  to  $15 \times 10^3 \text{ }^\circ\text{K}$ . These values must be compared with  $T_e$ -values larger than  $30 \times 10^3 \text{ }^\circ\text{K}$ . Our conclusion is that even for relative line-intensity measurements from levels with excitation energy differences up to 6 eV, the values of the excitation cross-sections are more important than the factor  $\exp(-E_m/kT_e)$ . Therefore, a reliable determination of  $T_e$  from these measurements is not possible.

We shall now make a comparison of the numerical results of  $T_{4p}$  and  $T_{ic}$  of this work with the values of other references in order to investigate whether reasonable agreement exists.

The values for  $T_{4p}$  are  $9 \times 10^3 \text{ }^\circ\text{K}$  for the measurements presented in Fig.9 and  $7.5 \times 10^3 \text{ }^\circ\text{K}$  for those presented in Fig.12. It appears that the first value is somewhat larger than the values of the range mentioned in section III. Differences in  $T_e$  and  $n_e$  between the discharge conditions may cause the greater value of  $T_{4p}$  in our experiment.

Our values of  $T_{ic}$ , namely  $12 \times 10^3$  to  $15 \times 10^3$  °K, are in good agreement with most other values in the literature. We suppose that the large values of LEJEUNE and TIDWELL for  $T_{ic}$  are caused by small electron densities. For these circumstances we also found an increasing value of  $T_{ic}$ .

We conclude that, apart from errors in A-values, differences in the number of spectral groups and lines and extreme circumstances as very low electron densities, the range of  $T_{4p}$  and  $T_{ic}$  values is rather small. The values of  $T_{4p}$  and  $T_{ic}$  are only weak functions of  $n_e$  and  $T_e$ . We therefore assume that the conclusions from our own investigation may be extended to the other low pressure argon discharges and the argon<sup>+</sup> lasers. We expect that thermalization effects are absent for these cases.

As pointed out above, we suppose that the locations of the points in Fig.5 are determined by numerical differences in the excitation of the various levels. This idea is supported by comparing it with the measurement at the very low  $B_w$  value of Fig.6. To our opinion, a change in the excitation mechanism takes place when  $B_w$  is increased from  $9 \times 10^{-3}$  T to larger values. This opinion is supported by the fact that preliminary measurements showed that the whole region of B-values cannot be described with one excitation process. We suppose that there is a shift from stepwise excitation for normal circumstances to direct excitation from the ion ground levels for very low electron densities. Further detailed experiments in the 0 to  $3 \times 10^{-2}$  T range may give a solution for this problem. It appears to be important in the question on the excitation mechanisms of the argon<sup>+</sup> laser and the argon low pressure, high current arc.

#### ACKNOWLEDGEMENTS

The author wishes to thank A.B.M.Hüsken and L.A.Bisschops for helpful technical assistance and J.J. de Groot and T.P.M.Hendriks for performing the measurements. He is indebted to prof. A.A.Kruithof for valuable discussions on the subject of this paper.

## APPENDIX

## A CONSIDERATION OF THE TRANSITION PROBABILITIES OF THE 4p GROUP OF THE ARGON II SPECTRUM.

Since GARSTANG<sup>(1)</sup> published the first calculations on transition probability values (abbreviation: A-value) of the argon II spectrum in 1954, a good deal of work has been done in this field, both theoretical (2-4) and experimental<sup>(5-11)</sup>. Only three of the references are practically complete for the 4p group of the argon II spectrum, having excited levels with energies between 19.22 and 19.97 eV, involving all transitions with A-values larger than  $10^5 \text{ s}^{-1}$  (3,6,8). The other references range from those giving all important transitions with large A-values to those giving only a few A-values.

Furthermore, lifetime values of the 4p group levels have been published by several authors<sup>(12-17)</sup>. The values of BENNETT et al<sup>(12)</sup> agree well with those of RUDKO and TANG<sup>(3)</sup> and SHUMAKER and POPENOE<sup>(8)</sup>. Large differences exist between the lifetime values of the  $4P$  and  $4D$  multiplets and the  $4S$  singlet, given by<sup>(13-17)</sup> and those given by<sup>(3,8)</sup>, whose values are sustained by the A-values of the other authors of<sup>(1-11)</sup>. The average difference between these two groups of references is more than 50%. The differences in the  $2D$  and  $2P$  doublet and the  $2S$  singlet values are less exceptional. In our calculations we have chosen for the values, according to the references<sup>(1-12)</sup>.

Out of need for the knowledge of the A-values in our own calculations, a systematic comparison has been set up to find one mean value for every A. This comparison involves the work of six selected authors, 1) who have a more or less complete list of the values of the strong transitions and 2) whose values are not totally or partly in great disagreement with the values of the other references. This selection has been made to avoid an arbitrary influence, exerted by one reference on only a small part of the A-values, and to safeguard the procedure against arbitrariness in the choice of rejected and accepted values of some reference. Once having obtained a final result, the work of those authors, so far held out of competition, can be compared with the calculated mean values.

Table 1 Systematic comparison of the transition probabilities  $A$  in  $10^{+7} s^{-1}$  of the  $4p$  group of argon II.

Notes:

\* The upper states have been indicated with an asterisk.

† The multiplication factor for each state denotes the ratio between the values, given in column 7 and the original values of Schnapauff himself.

‡ The multiplication factor for the original values of Chapelle et al is 1.13 for all values.

§ The deviation is the difference between the overall mean value and the theoretical or experimental mean value.

In accordance with the principle explained before, the theoretical results of STATZ et al<sup>(2)</sup>, RUDKO and TANG<sup>(3)</sup>, and KOOZEKANANI and TRUSTY<sup>(4)</sup> and the experimental results of SCHNAPAUFF<sup>(6)</sup>, CHAPELLE et al<sup>(7)</sup>, and SHUMAKER and POPENOE<sup>(8)</sup> have been chosen as the basis of our systematic comparison.

In Table 1 this comparison is presented, leading to a mean value for many transitions. In the following we shall explain the framework of Table 1. The values of some authors have been modified in a systematic way, the reason for the modification being explained below.

At first we shall pay attention to the three selected theoretical papers. GARSTANG<sup>(1)</sup> carried out calculations on absolute A-values, based on the Coulomb approximation and Intermediate Coupling (I.C.). The latter appeared to be much more adequate than the single L-S coupling. STATZ et al<sup>(2)</sup> extended the calculations of GARSTANG by introducing more parameters. This led to significantly better results for the values of the  $4p \rightarrow 4s$  transitions. Therefore, only the I.C.-values of STATZ et al have been included in our calculation.

Work done by Marantz and presented by RUDKO and TANG<sup>(3)</sup>, moreover yielded the A-values of the  $4p \rightarrow 3d$  transitions. KOOZEKANANI and TRUSTY<sup>(4)</sup> using I.C. and Hartree-Fock wave functions presented values, for the most part in good agreement with<sup>(2)</sup> and <sup>(3)</sup>.

The values of these three references are indicated in the columns 3 to 5 of Table 1. In column 6 the average of these values is given, presenting a mean theoretical value for the  $4p \rightarrow 4s$  transitions. The standard deviation is also stated. The values for the  $4p \rightarrow 3d$  transitions will be discussed later on. The degree of agreement for each multiplet or singlet is summarized in Table 2. The applied evaluation is also given.

Reviewing these results, the conclusion arises that the work of the three authors chosen, gives a very good agreement in the great majority of the values of the  $4p \rightarrow 4s$  transitions originating from the  $4P$ ,  $4D$ ,  $4S$  and  $2S$  levels, whereas the agreement for the values of the  $2D$  and  $2P$  levels can be qualified as being moderate to very poor with only four favourable exceptions. The great differences between the values for the  $2D$  and  $2P$  levels in the treatments give support to the

Table 2 Review of the degree of agreement between the theoretical A-values, based on the value of the standard deviation of the mean theoretical value.

standard deviation	degree of agreement	multiplet or singlet						totals
		$4_P$	$4_D$	$2_D$	$2_P$	$4_S$	$2_S$	
0-5%	very good	7	7	1	-	3	1	19
6-10%	good	-	-	1	2	-	-	3
11-20%	moderate	-	-	2	2	-	1	5
21-40%	poor	-	3	2	1	-	-	6
41-100%	very poor	-	1	2	1	1	-	5
	<b>totals</b>	<b>7</b>	<b>11</b>	<b>8</b>	<b>6</b>	<b>4</b>	<b>2</b>	<b>38</b>

assumption that the three sources are sufficiently independent in their calculations. This conclusion consolidates the opinion that the agreement of the A-values for the other levels is a consequence of the reliability of the obtained results.

SCHNAPAUFF<sup>(6)</sup> obtained A-values for argon II lines from intensity measurements of a cascade arc with pressures ranging from 1 to 5 atm. The A-values given by Schnapuff, were partly based on lifetime values, derived from BENNETT et al<sup>(12)</sup>, and BAKOS et al<sup>(13)</sup>, and partly on values calculated with the aid of the Coulomb approximation, using tables of BATES and DAMGAARD<sup>(18)</sup>, and of GRIEM<sup>(19)</sup>. It appears that SCHNAPAUFF'S original A-values are significantly lower than the already calculated theoretical mean values and also lower than the values of SHUMAKER and POPENOE<sup>(8)</sup>, based on experimental data. To our opinion this discrepancy is due to his choice of the lifetime values. Therefore, we have consistently used the lifetime values of BENNETT et al for those levels, for which a value is available. For the values, lacking in the work of BENNETT et al, those of SHUMAKER and POPENOE increased with 10%, have been used; the mean difference between the values, available in the two references, is given by this percentage. This choice assures

us of a set of values, independent of theoretical data. A-values, based on the lifetime values, obtained in the described way and on the relative rates of the transition probabilities for every single upper level, as given by SCHNAPAUFF, are presented in column 7. A small correction has been taken into account for transitions not considered. The multiplication factor for the original values of SCHNAPAUFF is noted in Table 1 for every upper level.

CHAPELLE et al<sup>(7)</sup> presented A-values of the argon II spectrum (of which 21 are of the 4p group), based on atmospheric pressure arc experiments. The absolute values are based on GARSTANG's value for the 4806 Å line ( $A = 7.88 \times 10^{+7} \text{ s}^{-1}$ ). Although the difference between this value and the mean theoretical value of Table 1 ( $A = 8.88 \times 10^{+7} \text{ s}^{-1}$ ) is only 13%, the latter value may be expected to be more reliable than GARSTANG's value and is more consistent with our system. The mean theoretical value is in good agreement with the value of SHUMAKER and POPENOE ( $8.72 \times 10^{+7} \text{ s}^{-1}$ ). Therefore, the original values of<sup>(7)</sup> have been multiplied by a factor 1.13. The results are shown in column 8.

SHUMAKER and POPENOE<sup>(8)</sup> used a wall stabilized atmospheric pressure arc for their A-measurements. The values were obtained in an independent way, assuming that L.T.E. circumstances were valid, and can be found in column 9.

Table 3 Review of the degree of agreement between the experimental A-values, based on the value of the standard deviation of the mean experimental value.

standard deviation	degree of agreement	..... multiplet or singlet						
		4 <sub>P</sub>	4 <sub>D</sub>	2 <sub>D</sub>	2 <sub>P</sub>	4 <sub>S</sub>	2 <sub>S</sub>	totals
0-5%	very good	8	10	5	2	1	1	27
6-10%	good	3	4	2	2	2	1	14
11-20%	moderate	3	3	1	-	-	1	8
21-40%	poor	1	-	-	1	-	-	2
41-100%	very poor	-	-	1	-	-	-	1
	totals	15	17	9	5	3	3	52

The values in the columns 7, 8 and 9 have been averaged in column 10, presenting a mean experimental value. The standard deviation is also indicated. The degree of agreement for each multiplet or singlet is summarized in Table 3.

Reviewing the results of the comparison of the experimental data, we can conclude that the agreement is better than 10% for 41 of the 52 values, while many of the other 11 values have a moderate agreement. None of the levels show deviations, which are systematically greater than others.

Finally, a comparison can be made between the mean theoretical and experimental values. The results are shown in column 11, giving an overall mean value and the difference between this value and each particular value. The degree of agreement for each multiplet or singlet is summarized in Table 4.

*Table 4 Review of the degree of agreement between the mean theoretical and the mean experimental A-values, based on the value of the deviation in column 11 of Table 1.*

standard deviation	degree of agreement	multiplet or singlet						totals
		$4P$	$4D$	$2D$	$2P$	$4S$	$2S$	
0-5%	very good	5	4	3	3	-	1	16
6-10%	good	2	3	-	1	-	-	6
11-20%	moderate	-	1	2	-	3	1	7
21-40%	poor	-	-	-	-	-	-	0
41-100%	very poor	-	-	1	1	-	-	2
	<b>totals</b>	<b>7</b>	<b>8</b>	<b>6</b>	<b>5</b>	<b>3</b>	<b>2</b>	<b>31</b>

Reviewing the final results of the  $4p \rightarrow 4s$  transitions, we can conclude that of the 31 values which could be compared, 22 are in good or very good agreement. The 9 values with larger deviations are found in the  $4D$  quartet (one value), in the  $2D$  and  $2P$  doublets due to the unreliable theoretical values, and in the  $4S_{3/2}$  and  $2S_{1/2}$  singlets,

in which the deviations are more or less unexpected and unexplained.

A similar comparison for  $4p \rightarrow 3d$  transitions was not possible as completely as has been performed for the  $4p \rightarrow 4s$  transitions being less information available than for the  $4p \rightarrow 4s$  transitions. The only theoretical data for the first mentioned transitions have been given by RUDKO and TANG<sup>(3)</sup>. Experimental values have been given by two and sometimes three references, so that a representative mean experimental value for many transitions could be given. 13 values are in good or very good agreement, 8 values are in moderate to very poor agreement with each other. It seems that the values of the  $4p \rightarrow 3d$  transitions given by RUDKO and TANG are too large in many cases by a factor 1.5 to 1.7.

When the calculations of the Appendix were performed, the survey of WIESE et al<sup>(20)</sup> was not available to us. We now conclude that the results of their calculations agree well with ours. We can see, however, a systematic difference between many of their values and those of us, due to the different way of calculation. WIESE et al do not describe exactly the method of their calculations. It seems that the lifetime values of BENNETT et al<sup>(12)</sup> have a dominant position in their calculations. Further detailed information can be found on pages 202 and 203 of<sup>(20)</sup>.

Table 5 A comparison between the results of some authors with the A-values of Table 1.

$4p \ ^2D_{3/2} \rightarrow 4s \ ^2P_{3/2}$	4727	5.6 <sup>†</sup>	0.5
$4p \ ^2P_{1/2} \rightarrow 4s \ ^2P_{3/2}$	4658	8.4	4
$4p \ ^2P_{3/2} \rightarrow 4s \ ^2P_{1/2}$	4765	6.04	2.5
$4p \ ^4S_{3/2} \rightarrow 4s \ ^4P_{5/2}^*$	3729	7.7	12
$4p \ ^2S_{1/2} \rightarrow 4s \ ^2P_{1/2}$	4579	9.3	2

\*Two alternative transitions had already been chosen and used for the calculations of this paper. This selection was based on the literature up till 1968. These transitions are:

$$4p \ ^4P_{3/2} \rightarrow 4s \ ^4P_{3/2}, \ 4933 \text{ Å}, \ A = 1.57 \times 10^{+7}s^{-1}, \ \text{dev. } 1.5\% \text{ and}$$

$$4p \ ^4S_{3/2} \rightarrow 4s \ ^4P_{3/2}, \ 3851 \text{ Å}, \ A = 6.3 \times 10^{+7}s^{-1}, \ \text{dev. } 16\%.$$

† The mean experimental value has been chosen, the mean theoretical value having a deviation of 14%.

of transitions, the number of values within an interval of two times the deviation percentage of the overall mean value ( $2\sigma$ ) and outside this interval is indicated. Moreover, the average of the absolute differences between the value of the regarding author and the overall mean value is noted. The results are presented in Table 5.

For our own calculations we wanted to know for every excited level of the 4p group the A-value of at least one transition, originating from that level. The choice is determined by the strength of the transition and the reliability of the A-values. Following this principle we made a selection, presented in Table 6.

# TEMPERATURE AND DENSITY PROFILES OF ELECTRONS IN A HOLLOW CATHODE ARGON ARC DISCHARGE

B. van der Sijde

Department of Technical Physics, University of Technology, Eindhoven, Netherlands.

Summary- Measurements have been performed of radial radiation profiles of argon I and II lines in a hollow cathode low-pressure magnetically-confined argon arc discharge with currents of 15 to 60 A. The working pressure of the discharge was  $\sim 10^{-3}$  mm of Hg and the electron density was  $\sim 10^{19} \text{ m}^{-3}$ . From the radiation profiles radial temperature and density profiles of the electrons have been calculated. For this calculation we made use of Corona Equilibrium formulae and we discussed how far these formulae give a good description of the excitation phenomena in the plasma. It appears that the decrease of the electron temperature in most cases is about 10% per 10 mm or smaller and that the width at half-maximum value of the electron density profile for a confined plasma is about 18 mm for an end-anode configuration situated at 1.2 m from the cathode and 27 mm for a ring-shaped anode situated near the cathode. These widths at half-maximum value are roughly independent of the magnetic induction value between  $3.75 \times 10^{-2}$  and  $12.5 \times 10^{-2} \text{ T}$ .

## I INTRODUCTION

This investigation deals with measurements of radiation profiles as functions of the distance  $r$  from the axis of argon lines and calculations of the electron temperatures and electron densities relative to the values on the axis in a hollow cathode low-pressure magnetically-confined argon arc discharge. This type of discharge, having a working pressure of about  $10^{-3}$  mm of Hg, had been introduced by LIDSKY et al <sup>(1)</sup> and was investigated by several authors <sup>(2-6)</sup>.

The discharge device and the equipment for spectral line radiation measurements were described in a previous paper <sup>(7)</sup> (see Fig.1). The radiation profiles have been determined as functions of the distance

*Fig.1 Simplified design of the cathode and anode device. 1 is a hollow-cathode; 2 is a ring-shaped anode; 3 is an end-anode; 4 are magnetic coils; 5 and 6 are tubes for spectral measurements; 7 is a pyrex tube.*

$x$  in the vertical direction which is perpendicular to the axis of the plasma column. The profiles are obtainable as functions of the radius  $r$  by application of an Abel transformation.

The electron density  $n_e$  of the plasma of the discharge when confined by the longitudinal magnetic field  $B_z$  was of the order of  $10^{19} \text{ m}^{-3}$ . This means that the plasma was in Corona Equilibrium (C.E.), resulting in the phenomenon that the collisional excitation of the levels is balanced by radiative decay only.

The method for calculation of the electron temperature  $T_e$  from spectral line-intensities for a plasma in C.E. (8) was given by McWHIRTER (9) and WILNER (10). In the next section will be discussed the fact that the Corona formulae used give a good qualitative description of the excitation phenomena in the argon II spectrum. The absolute values of  $T_e$ , calculated with this method may be greatly in error, due to numerical deviations in the cross-section data used. Therefore we only applied the method for comparing the results of the calculations of  $T_{e,0}$  for  $r = 0$  and  $T_{e,r}$  for  $r \neq 0$  with each other. It appears that reduced  $T_e$  profiles  $T_{e,r}/T_{e,0}$  can be found by comparing the profiles of two or more argon II lines with largely different excitation energies of the upper levels. By making use of this information it is also possible to calculate the reduced  $n_e$  profiles  $n_{e,r}/n_{e,0}$  from one of these argon II profiles.

The argon I profiles show a more or less complicated picture. Although the upper levels concerned are mainly populated by direct excitation from the atomic ground level, the complications in the picture may be due to an additional stepwise excitation and a small diffusion of the excited particles of the 5p group. As a consequence of the weak radiation of other groups than the 4p and 5p group, we can state that cascade radiation is not important.

## II TEMPERATURE AND DENSITY PROFILES OF THE ELECTRONS

### 1 Balance equation for argon II levels

We shall discuss the excitation and ionization phenomena that may occur in the plasma and are of interest for the explication of the radial radiation profiles. First we shall deal with the profiles of

Fig.2 Simplified diagram of the argon II excited levels or groups. Transitions are indicated with  $e^-$  (excitation by electrons),  $h\nu$  (emission of radiation) or a special line, designated with its wavelength. The thickness of the lines gives a rough qualitative impression of the importance of the processes.

the argon II lines. The radiation detected is that of spectral lines with upper levels, having excitation energies of 19.49 eV (4p group,  $4D_{7/2}$  level,  $\lambda = 4348 \text{ \AA}$ ), 22.96 eV (4d group,  $4F_{9/2}$  level,  $\lambda = 3588 \text{ \AA}$ ) and 24.85 eV (4d group,  $2F_{5/2}$  level,  $\lambda = 3351 \text{ \AA}$ ) (see Fig.2).

The levels concerned may be populated by one or more of the following processes:

- 1) simultaneous ionization and excitation directly from the atomic ground level;
- 2) simultaneous ionization and excitation from the atomic metastable levels ;
- 3) direct excitation from the two ion ground levels;
- 4) stepwise excitation from the ion ground levels through short-lived levels (e.g.  $4s \ 4P_{1/2}$  and  $4p \ 3/2$  levels for which the lifetime  $\tau = 9 \times 10^{-8}$  and  $2.7 \times 10^{-8}$ s respectively <sup>(11)</sup>);
- 5) stepwise excitation from the ion ground levels through metastable levels (e.g. some 3d levels);
- 6) cascade radiation from 4d and 5s levels to the 4p group and from 5p, 5d and 6s levels to the 4d levels concerned here;
- 7) recombination of argon doubly ionized particles to excited argon II levels.

The levels concerned may be depopulated by one or more of the processes:

- 1) spontaneous emission;
- 2) collisional deexcitation to a lower level;
- 3) excitation to a higher excited level;
- 4) ionization to doubly ionized particles.

Other conceivable processes for population as well as depopulation are neglected.

The balance equation for levels marked with suffix 3 can be written as

$$\begin{aligned}
 & n_e n_a \langle \sigma v \rangle_{sim} + n_e n_a^* \langle \sigma v \rangle_{sim}^* + n_e n_{ion} \langle \sigma v \rangle_{dir} + \\
 & + n_e^2 n_{ion} \sum_i \{ \langle \sigma v \rangle_{II}^i \cdot (\sum \langle \sigma v \rangle_{I/\Sigma A_{2i}}^i) \} + n_e \sum_j n_{2j}^* \langle \sigma v \rangle_{met}^j + \\
 & + \sum_k n_{4k} A_{4k,3} + n_e n_{ion} R_3 = \\
 & n_3 \sum_m A_{3,2m} + n_3 n_e \langle \sigma v \rangle_{deexc} + n_3 n_e \langle \sigma v \rangle_{exc} + n_3 n_e \langle \sigma v \rangle_{ion}, \quad (1)
 \end{aligned}$$

where  $n_a$  is the neutral atom density;  $n_a^*$  is the atomic metastable density;  $n_{ion}$  is the ion density;  $n_2^*$  is the ion metastable density;  $n_4$  is the density of a cascading level;  $n_{ion}^{++}$  is the doubly ionized particles density and  $n_3$  the density of the level concerned.  $\langle \sigma v_e \rangle$  denotes an integration of a cross-section over the electron velocity distribution. The suffix *sim* denotes the simultaneous ionization and excitation from the atomic ground level and *sim*<sup>\*</sup> from the atomic metastable level; the suffix *dir* denotes direct excitation from the ion ground levels; the suffices *I* and *II* the first and second step of the stepwise process; the suffix *met* excitation from an ion metastable level to a level 3; the suffices *deexc* and *exc* collisional deexcitation and excitation from a level 3 to a lower and a higher level respectively; the suffix *ion* ionization to argon<sup>++</sup> ions.

The ground levels are marked with 1, the intermediate levels with 2, the level concerned with 3 and cascading levels with 4.

$A_{21}$  denotes the transition probability for transitions from a level 2 to 1 et cetera;  $R_3$  is the radiative recombination coefficient to a level 3.

$\Sigma_i, j, k$  and  $m$ , denote sums over diverse types of levels.

In setting up the fourth term, it is supposed that absorption phenomena for the levels designated with 2 may be neglected.

We shall now try to reduce equation (1) by an examination, to find out which of the terms may be neglected.

The first term  $n_e n_a \langle \sigma v_e \rangle_{sim}$ . In section V it will be pointed out that only for a non-confined discharge with a magnetic induction  $B_w = 6.3 \times 10^{-3} T$ , the contribution of simultaneous ionization and excitation is estimated as approximately 10% for the  $4p \ ^4D_{7/2}$  level. For a confined plasma with  $n_e$  values at least 10 times higher than is found for  $B_w = 6.3 \times 10^{-3} T$  and with lower  $T_e$  values <sup>(12)</sup> the contribution will be < 1%. We shall neglect this contribution. Moreover, for the 4d levels this process can be neglected altogether.

The second term  $n_e n_a^* \langle \sigma v_e \rangle_{sim}^*$ . Cross-section data for simultaneous ionization and excitation from metastable levels of argon I to excited argon II levels are not known. Based on the probably small amount of

metastables and the probably small cross-section values due to the large energy gap of 23.5 eV for excitation to 4p levels, we suppose that this process can be neglected.

The third term  $n_e n_{ion} \langle \sigma v_e \rangle_{dir}$  and the fourth term  $n_e^2 n_{ion} \sum_i \{ \langle \sigma v_e \rangle_{II}^i \cdot (\sum \langle \sigma v_e \rangle_{I/A_{2i}}^j) \}$ . These terms of equation (1) both appear to contribute to the population of the levels denoted with 3, for example the 4p group, as will be shown in a following article (12). For  $n_e > 6 \times 10^{18} m^{-3}$  stepwise excitation through intermediate levels and for  $n_e < 6 \times 10^{18} m^{-3}$  direct excitation from the ion ground levels is the dominant process for the 4p group.

The fifth term  $n_e \sum_j n_{2j}^* \langle \sigma v_e \rangle_{met}^j$ . In (12) it also appears that no reasons could be found to suppose that metastable ions contribute to the population densities of levels designated with 3. At one point the assumption of a contribution through metastable levels is in disagreement with the results. We therefore think that the fifth term of equation (1) may be omitted.

The sixth term  $\sum_k n_{4k} A_{4k}^*$ . The contribution of cascade radiation to the population density of the 4p levels will also be discussed in (12). It appears that for the  $4D_{7/2}$  level the contribution is about 6%. It is assumed that for the 4d levels concerned this contribution is smaller. This assumption is based on the fact that the intensities of other lines than originating from the 4p, 4d and 5s groups are very weak. The influence of the cascade radiation on the form of the radiation profiles will be small. This can be seen as follows (see Fig.2). The lifetimes of the 4p and 4d levels are  $\leq 10^{-8} s$ , so that the diffusion length of hot excited ions ( $T_i = 50 \times 10^3 \text{ }^\circ K$ ) is about  $5 \times 10^{-2} mm$ . This length is 5% of the width at half-maximum value of the radial profiles, i.e. less than the inaccuracy of this width. This small diffusion length means that the radiation profiles are very nearly the same as curves, presenting the amount of created excited particles. We conclude that the profile of re-radiated cascade radiation has the same form as the profile of the upper level of the cascade radiation. This profile differs from that of the lower level as has been given by the measurements reported in this article, section IV. The 3588 Å line e.g. gives cascade radiation to the  $4p \text{ } 4D_{7/2}$  level. We remark that neglect of the contribution of the cascade radiation as regards the

the relative method used, only gives errors in the final results for  $T_e$  profiles, which are of the same order as the percentage of the cascade radiation, i.e. 4 to 8%.

The seventh term  $n_e n_{ion}^{++} R_3$ . For the conditions for which the measurements were performed, the argon III spectrum was very weak. The strongest line, with  $\lambda = 3286 \text{ \AA}$ , had an intensity of only a few per milles of that of the  $4348 \text{ \AA}$  line. The quantity of argon<sup>++</sup> ions and accordingly the recombination contribution for every separate level will be totally negligible, say < 1%.

Now, returning to deexcitation phenomena, we state that the term  $n_e \sum m A_{3\ 2m}$ , representing the spontaneous emission, fully dominates the second term  $n_3 n_e \langle \sigma v_e \rangle_{deexc}$ , representing collisional deexcitation, in agreement with C.E.. It can be calculated from our measurements that the density  $n_e$  for 4p levels is about 2% to 4% of that for L.T.E. for the same value of  $T_e$  ( $\sim 30 \times 10^3 \text{ }^\circ\text{K}$ ) for large  $B_w$  values. The estimated ratio between radiative emission and collisional deexcitation is then 250 to 500 and we conclude that the latter process may be neglected.

The third term  $n_3 n_e \langle \sigma v_e \rangle_{exc}$ . The depopulation due to excitation to higher levels will be much smaller than the population due to cascade radiation. This assertion is based on comparison with collisional deexcitation, which mainly is of the same order of magnitude as excitation to higher levels. Furthermore, when excitation from 4p  $\rightarrow$  4d should occur, a clear difference between the 4d-3588  $\text{\AA}$  and 4p-4348  $\text{\AA}$  profiles should be found due to the cumulative  $n_e$  dependency for the line profiles of the 4d levels. This point will be discussed further in section V. Based on these facts, we shall neglect the term, dealing with excitation to higher levels.

The fourth term  $n_3 n_e \langle \sigma v_e \rangle_{ion}$ . The ionization to argon<sup>++</sup> ions can be neglected for the same reasons as has been done for recombination from argon<sup>++</sup>.

We can now reduce equation (1) drastically, with  $n_{ion} = n_e$  to

$$n_e^2 \langle \sigma v_e \rangle_{dir} + n_e^3 \sum_i \{ \Sigma \langle \sigma v_e \rangle_{II}^i (\Sigma \langle \sigma v_e \rangle_{I}^i / \Sigma A_{2i\ 1}) \} + \Sigma k_{4k\ 4k\ 3} n_3 \sum m A_{3\ 2m} \quad (2)$$

We already argued that the term  $\sum_k n_{4k} A_{4k3}$  does not influence the  $T_e$  profiles more than 4 to 8%. It will be omitted in the relative comparison.

## 2. *Corona formulae for stepwise excitation*

The computation, to be developed will be applied here for the higher  $n_e$ -values, found in our experiments. Therefore we shall first describe a model based on stepwise excitation in the argon II spectrum and later on we shall improve the results for the case that the contribution of direct excitation is not negligible.

We look for a mathematical description of the stepwise excitation phenomena, which will lead to the form

$$n_3 \sum_m A_{32m} = K_{3s} \cdot f_1(n_e) \cdot f_2(T_e), \quad (3)$$

where  $K_{3s}$  is independent of  $T_e$ ,  $n_e$  and consequently of the radius  $r$ , and is characteristic for the level 3, concerned;  $f_1$  and  $f_2$  are functions depending only on  $n_e$  and  $T_e$  respectively. We shall be able to draw conclusions on  $n_e$  and  $T_e$  as functions of  $r$  by comparing the radiant flux  $P_{3,0}$  for  $r = 0$  with  $P_{3,r}$  for  $r \neq 0$ .

Considerations of McWHIRTER<sup>(9)</sup> and WILNER<sup>(10)</sup> for a C.E. plasma enable us to derive an expression conformable to equation (3). The calculations can only be considered as a general model with possibly great numerical errors in the values of the cross-sections used. We think that the special application of the calculations in this article avoids these errors (see equations (9) and (10)).

Only the most important starting points of the derivation of McWhirter and Wilner will be reviewed here. Their derivation is based on the integrated form of the excitation function of ALLEN<sup>(13)</sup>, given by SEATON<sup>(14)</sup>.

$$\langle \sigma v_e \rangle_{mn} = 5.44 \times 10^{-29} f_{mn} / (T_e^{1/2} E_{nm}) \exp(-E_{nm}/kT_e), \quad (4)$$

where  $\langle \sigma v_e \rangle_{mn}$  is the excitation function in  $m^3 s^{-1}$ ,  $f_{mn}$  is the absorption oscillator strength and  $E_{nm}$  is the excitation energy difference between the levels  $m$  and  $n$  in Joule;  $k$  is Boltzmann's

constant. The Gaunt factor, which appears in the original formulae was given here the value 0.2<sup>(13)</sup>. There is a difference of a factor 2 between the expression used by McWhirter and the one used by Wilner. We chose the form given by Wilner.

The collisional excitation by electrons is related to radiative absorption by the quantity  $f_{mn}$  and related to the spontaneous emission according to the relation

$$g_m f_{mn} = g_n f_{nm}, \quad (5)$$

where  $f_{nm}$  is the oscillator strength for emission and  $g$  is the statistical weight of a level. The introduction of one of the parameters  $f_{mn}$  or  $f_{nm}$  into expression (4) means that the description of collisional excitation phenomena is limited to those transitions which also have a spontaneous radiative decay in the reverse direction. Direct excitation starting from the ion ground levels therefore cannot be included in the derivation without some extension as a consequence of the absence of radiative transitions between most of the levels denoted with 3 (e.g. all 4p levels) and the ion ground levels<sup>(15)</sup>. We can apply the derivation of McWhirter and Wilner for the description of the stepwise excitation phenomena, as all transitions involved are optically permitted (see Fig.2).

The derivation is based on the twice repeated application of the balance equation

$$n_n \sum_i A_{n mi} = n_e \sum_i n_{mi} \langle \sigma v \rangle_{e mi n}, \quad (6)$$

where  $n_{mi}$  denotes a process from  $n \rightarrow mi$  and  $mi n$  from  $mi \rightarrow n$ . Application of the equations (4), (5), (6) and the relation between  $A_{nm}$  and  $f_{nm}$  leads to the expression

$$n_3 \sum_m A_{3 2m} = 1.035 \times 10^{-147} \cdot \frac{n_e^3 g_3}{T_e \sum g_1} \cdot \sum_m \left( \frac{A_{3 2m}}{E_{2m 1}^3 E_{3 2m}^3} \right) \cdot \exp(-E_{31}/kT_e), \quad (7)$$

where  $\sum g_1$  is the sum of the two statistical weights of the ion ground levels;  $E$  is in Joules. Note that  $\sum_i$  in expression (2) has been replaced by  $\sum_m$ , due to equation (5). The expression is conformable to

relation (3).

With the help of the expression, giving the spontaneous radiant flux  $P_{3p}$  of a level  $3p$

$$P_{3p} = h\nu_{3p, 2m} A_{3p, 2m} n_{3p}, \quad (8)$$

where  $h\nu_{3p, 2m}$  is the energy of the quantum for a transition from  $3p \rightarrow 2m$ , we can state that

$$P_{3p,r}/P_{3p,0} = (n_{e,r}/n_{e,0})^3 \cdot (T_{e,0}/T_{e,r}) \cdot \exp\{-E_{3p, 1}/k (1/T_{e,r} - 1/T_{e,0})\}. \quad (9)$$

We can also compare the radiation of the levels  $3p$  and  $3q$  with different excitation energies with each other. This comparison gives, in combination with (9)

$$\frac{(P_{3p,r}/P_{3p,0})}{(P_{3q,r}/P_{3q,0})} = \exp\left\{-\frac{(E_{3p, 1} - E_{3q, 1})}{k} \left(\frac{1}{T_{e,r}} - \frac{1}{T_{e,0}}\right)\right\}. \quad (10)$$

When the  $P$  values are measured, relation (10) provides us with the term  $(1/T_{e,r} - 1/T_{e,0})$ . When the value of  $T_{e,0}$  is known we are able to present a  $T_{e,r}$  profile as a function of  $r$ . Relation (9) then enables us to calculate the  $n_{e,r}/n_{e,0}$  profile.

### 3. *Extended Corona formulae*

We shall also mention the changes in expression (10) when direct excitation furnishes an additional contribution to the population of the levels denoted with index 3. ALLEN<sup>(13)</sup> gives an expression for the cross-section  $\sigma_f$  for forbidden transitions for electron energies  $E_e > E_{exc}$ , the excitation energy. The expression is

$$\sigma_f = 2.18 \times 10^{-20} \cdot \pi a_0^2 \cdot \Omega / (\Sigma g_1 E_e) \quad m^2, \quad (11)$$

where  $\pi a_0^2 = 8.80 \times 10^{-21} m^2$  is the cross-section of the hydrogen atom,  $\Omega$  is the collision strength in  $m^{-1}$  (13) and  $E_e$  is the electron energy in J. When integrated over a Maxwellian distribution function one finds for the direct excitation

$$\langle \sigma v \rangle_{dir} = 3.2 \times 10^{-25} \cdot \Omega / \Sigma g_1 \cdot (kT_e)^{-\frac{1}{2}} \cdot \exp(-E_{exc}/kT_e) \quad m^3 s^{-1}, \quad (12)$$

where  $E_{exc}$  is the excitation energy in J.

When introducing constant factors  $K_{3s}$  and  $K_{3d}$  for stepwise and direct excitation respectively, we can replace equation (7) by

$$n_3 \Sigma A_{3 \ 2m} = K_{3s} \cdot (n_e^3 / T_e) \cdot \exp(-E_{31}/kT_e) + K_{3d} \cdot (n_e^2 / T_e^{\frac{1}{2}}) \cdot \exp(-E_{31}/kT_e). \quad (13)$$

For the levels 3p and 3q is found an extended formulation of equation (10), given by

$$\frac{(P_{3p,r}/P_{3p,o})}{(P_{3q,r}/P_{3q,o})} = \exp \left\{ - \frac{(E_{3p \ 1} - E_{3q \ 1})}{k} \left( \frac{1}{T_{e,r}} - \frac{1}{T_{e,o}} \right) \right\} \cdot \left[ 1 + \left( \frac{K_{3p,d}}{K_{3p,s}} - \frac{K_{3q,d}}{K_{3q,s}} \right) \cdot \left( \frac{T_{e,r}^{\frac{1}{2}}}{n_{e,r}} - \frac{T_{e,o}^{\frac{1}{2}}}{n_{e,o}} \right) \right]. \quad (14)$$

This equation is valid when the factors  $(K_{3d}/K_{3s}) \cdot (T_e^{\frac{1}{2}}/n_e) \ll 1$ . It appears that for  $n_e$  values  $> 1 \times 10^{19} m^{-3}$  this condition is fulfilled (12).

We remark that the sum of the last part of the equation, apart from the original values of the terms, strongly depends on the value of  $(K_{3p,d}/K_{3p,s} - K_{3q,d}/K_{3q,s})$ . It means that only when the partition between direct and stepwise excitation for the two levels concerned is more or less equal the contribution of the second factor within braces may be omitted. If not, then the terms of the factor

$(T_{e,r}^{\frac{1}{2}}/n_{e,r} - T_{e,o}^{\frac{1}{2}}/n_{e,o})$  will still partly compensate each other.

It is clear that from this equation it cannot be decided whether the exponential term dominates enough to find a proper  $T_e$  profile. Further discussion on this subject will be referred to section V.

#### 4. Balance equation for argon I levels

The lines measured of the argon I spectrum are the 6965 Å line of the 2p<sub>2</sub> level and the 4259 Å line of the 3p<sub>1</sub> level. The former originates from the 4p group, with excitation energies of 13.0 to 13.3

Fig.3 Simplified diagram of the argon I excited levels or groups. See for further explanation Fig.2.

eV and the latter from the 5p group with energies of 14.4 to 14.7 eV (See Fig.3). Radiation from other groups is very weak.

To be able to discuss the argon I profiles we shall first survey the possible excitation phenomena in the argon I spectrum. The levels may be populated by one or more of the processes:

- 1) direct excitation from the neutral ground level;
- 2) stepwise excitation through the 4s resonance or metastable levels;
- 3) recombination of ions by a radiative process.

The levels may be depopulated by one or more of the processes:

- 1) spontaneous emission;
- 2) ionization by collisions with electrons to argon ions.

Other conceivable processes are neglected for the same reasons as given for the argon II spectrum.

The contributions of recombination and ionization are unknown, but are expected to be small. It appears that depopulation of the levels occurs by spontaneous emission, while direct or stepwise excitation must be responsible for the excitation. In <sup>(12)</sup> it appeared that in any case the dominant process will be direct excitation from the atomic ground level. The additional contribution of stepwise excitation may give some tens of percents of the population.

The balance equation for the levels concerned can be written as

$$n_e n_a \langle \sigma v \rangle_{dir} + n_e^2 n_a \sum_i \langle \sigma v \rangle_{II}^i \langle \sigma v \rangle_I^i / A_{2i1} = n_3 \sum_m A_{32m} \quad (15)$$

The interpretation of argon I profiles is still complicated by the influence of the variation of  $T_e$  itself as function of  $r$  and by a diffusion of  $5p$  excited particles before radiating, due to a  $\tau = 3 \times 10^{-7}$  s for the  $3p_1$  level. The diffusion distance for the  $3p_1$  level is estimated to be  $\lambda_d = 0.15$  mm for the neutral particle temperature  $T_n = 500$  °K and  $\lambda_d = 0.5$  mm for  $T_n = 5 \times 10^3$  °K.

### III METHOD OF MEASUREMENT; ABEL TRANSFORMATION

The radiation profiles were registered with the help of an equipment, capable of measuring the line-intensities over a vertical distance  $x$  of 32.5 mm, perpendicular to the axis of the plasma column. An RCA IP28 or an EMI 9698 QB photomultiplier was used. The argon II measurements on which the radial  $T_e$ - and  $n_e$ -profiles are based, were performed with the RCA type, which is insensitive to the magnetic field of the coils. To be able to measure both argon I and II lines the EMI type was used. This type appeared to be more sensitive to the magnetic field, even when  $\mu$  metal plates were applied to screen off the cell. As a consequence, the measurements of the argon I and II lines have not been performed in one sequence. It appears, by comparison with the help of one line (4348 Å) measured with both cells, that there is a good agreement between the two sequences for the end-anode measurements and that the agreement is moderate for the ring-shaped anode measurements (see Fig.1).

The radiance profiles  $L_e(x)$  have been subjected to an Abel transformation if they could be measured down to about 10% of the maximum intensity or less. The first derivative  $L'_e(x)$  for these curves at the end of the measured part of the curve is 1% to 6% of the maximum value  $L'_e(x)_{\max}$ . At the end of the extrapolated part of the curve  $L'_e(x)/L'_e(x)_{\max}$  was always  $\leq 1\%$  while it appeared that omitting a part of the curve with  $L'_e(x)/L'_e(x)_{\max} < 2\%$  gave less than 1% error in the transformed curve. It is therefore supposed that the errors due to extrapolating the measured curve can be neglected.

The Abel transformation was performed with  $N = 65, 85$  or  $105$  equidistant points on one half of the curve. Every fifth point has been weighed by a formula given in <sup>(16)</sup>. These points with a number of  $N/5$  were used as bases of a third order "spline" function (a set of

third degree polynomials). The first derivative of the spline function was determined in the  $N/5$  points and a linear interpolation between the points gave a continuous curve for  $L'_e(x)$  <sup>(17)</sup>. The transformation itself was performed with the aid of the well-known Abel integral.

#### IV RESULTS

In the following we shall present successively the results of four series of measurements with special purposes, one run with four different values of the magnetic induction  $B_w$  for the end-anode with 50 A discharge current and one similar run for the ring-shaped anode with 60A discharge current. Important parameters as discharge current  $I_D$ , magnetic induction  $B_w$ , back ground pressure  $p_b$  and for the runs with various magnetic fields also the discharge voltage  $V_D$ , the electron temperature  $T_{e,0}$  and density  $n_{e,0}$ , the ion temperature  $T_i$ , the neutral particle temperature  $T_n$  and gasflow  $Q$  are indicated in the captions of the figures as far as these data are available.

In Fig.4 the reduced profiles  $L_e(x)/L_e(0)$  of the argon II 4348 Å line, and of the argon I 4259 Å and 6965 Å lines are given.  $B_w$  is  $6.3 \times 10^{-3}T$  and the discharge was only slightly confined. It can easily be seen that the symmetry of the curves is poor and that the three tops have been shifted with respect to each other. The zero point of the scale in the direction  $x$  is arbitrary. We assume that  $T_{e,r}$  and  $n_{e,r}$  are not symmetrical and that the tops of both profiles are situated at different positions. The curves have not been subjected to an Abel transformation. Also for this low  $B_w$ -value there is a great difference in the widths of the argon I and II line profiles. These measurements have been carried out in connection with the problem of the simultaneous ionization and excitation.

Fig.5a gives the results of three argon II lines after Abel transformation with  $\lambda = 4348 \text{ Å}$ ,  $3588 \text{ Å}$  and  $3351 \text{ Å}$ . The points indicated in this figure and in following similar figures are the  $N/5$  points given by a computer program, performing the Abel transformation. The maximum current values of the RCA IP28 photomultiplier were  $9.6 \times 10^{-7}A$ ,  $2.0 \times 10^{-8}A$  and  $4.0 \times 10^{-10}A$  respectively for the lines concerned. As a consequence of the signal to noise ratios the errors in the 3588 Å

Fig.4 The reduced radiance profiles  $L_e(x)/L_e(0)$  for some lines as functions of the distance in the vertical direction  $x$ .  $\circ$  denotes the 4348 Å-argon II line;  $+$  the 4259 Å-argon I line and  $\times$  the 6965 Å-argon I line. Conditions: end-anode; discharge current  $I_D = 50$  A; magnetic induction  $B_w = 6.25 \times 10^{-3}$  T, background pressure  $p_b = 1.25 \times 10^{-3}$  mm of Hg.

Fig. 5a The reduced radiant flux  $P(r)/P(0)$  of three argon II lines as functions of the distance  $r$  from the axis.  $\circ$  denotes the 4348 Å-line  $\bullet$  the 3588 Å-line and  $\square$  the 3351 Å-line, all of the argon II spectrum. Conditions: ring-shaped anode; discharge current  $I_D = 60$  A; magnetic induction  $B_w = 7.5 \times 10^{-2}$  T, background pressure  $p_b = 1.25 \times 10^{-3}$  mm of Hg.

profile are a little larger and in the 3351 Å profile markedly larger than in the 4348 Å profile. This could easily be seen from the measured profiles. The radial  $T_e$  profile, calculated according to expression (10), has been found from the ratio of the intensities of the 3588 Å and 4348 Å lines and that of the 3351 Å and 4348 Å lines as given in the figure. The results are presented in Fig. 5b. It appears that there is a reasonable agreement between the two sets of points. One can roughly estimate that the random error from the measurements in the expression  $\exp \{-(E/k)(1/T_{e,r} - 1/T_{e,0})\}$  is 0.020 to 0.030, which agrees fairly well with the deviations of the points from the drawn lines in Fig. 5b.

 □ calculated from the ratio of the 3351 Å and the 4348 Å-lines.  $T_{e,0} = 32 \times 10^3$  °K.

In Fig. 6 the direct results of argon I and II profiles are presented for a situation in which asymmetrical radiation profiles were found. The asymmetry of the arc could be seen visually, as well as the asymmetrical heating of the end-anode. It can be seen from the figure that there is an inverse position for the 3588 Å and 4348 Å lines in comparison with each other at one side. The radial  $T_e$  profile must be strongly asymmetrical. It appears also that at one side there is a great difference between the curves of the 4259 Å and 6965 Å.

Fig. 7 gives a comparison between the 4348 Å line, a "common" line of the 4p group, and the 4880 Å line, a laser line of that group. The

Conditions: end-anode, asymmetrical profiles; discharge current  $I_D = 40$  A; magnetic induction  $B_w = 12.5 \times 10^{-2} T$ ; background pressure  $p_b = 1.5 \times 10^{-3}$  mm of Hg.

Fig.7 The reduced radiant flux  $P(r)/P(0)$  of two argon II lines as functions of the distance  $r$  from the axis.  $\circ$  denotes the 4348 Å and  $\blacksquare$  the 4880 Å line. Conditions: discharge current  $I_D = 50$  A; magnetic induction  $B_W = 12.5 \times 10^{-2}$  T.

results have been given after application of an Abel transformation. We conclude that there is hardly any difference between the radiant fluxes  $P(r)/P(0)$  of the two lines.

From a run of four  $B_W$ -values with the end-anode, a total set of curves for one  $B_W$ -value is presented in Fig.8a. Fig.8b gives the argon II lines after Abel transformation. The calculated  $T_{e,r}$  and  $n_{e,r}$  profiles of all four  $B_W$ -values are shown in the Figs. 9 and 10 respectively. One can conclude from Fig.8a that the 4259 Å profile is broader than that of 6965 Å. This is valid for the whole run. The differences between the 3588 Å and 4348 Å profiles become smaller for larger  $B_W$  values, which can also be seen from Fig.9. The  $T_e$ -profile for  $B_W = 12.5 \times 10^{-2}$  T is estimated based on the fact that the differ-

ences between both profiles are smaller than 1% of the top value.

The  $n_e$  profiles of Fig. 10 have been calculated with the smoothed  $T_{e,r}$  curves. The results presented in Fig. 8 of (12) have the consequence that reduced  $n_e$ -profiles, based on a  $n_e^3$  dependency for the argon II profiles (equation (9)) are more or less in error. They were improved with the help of a reduced profile, based on a  $n_e^2$  dependency for the profiles. The proper reduced  $n_e$ -profile is found by linear interpolation with the help of the results of (12). It is believed that this interpolation is sufficient as a consequence of the limited differences between the two profiles and the limited accuracy of the profiles themselves. The maximum  $n_e$ -values  $n_{e,0}$  have also been calculated by linear interpolation between the two values, obtained from the two extreme approximations.

The Figs. 11a, 11b, 12 and 13 give the information on a similar

Conditions: see Fig.9. The electron densities  $n_{e,0}$  are  $0.91 \times 10^{19} \text{ m}^{-3}$ ,  $1.92 \times 10^{19} \text{ m}^{-3}$ ,  $1.70 \times 10^{19} \text{ m}^{-3}$  and  $1.57 \times 10^{19} \text{ m}^{-3}$  respectively.

of the curve of reversed sign. The temperature curves are quite similar for all  $B_W$ -values. The inaccuracy of the  $n_{e,r}$ -profiles due to errors in the  $T_{e,r}$  profiles, intensity errors and errors due to interpolation can be estimated as about 5% of the top value.

## V DISCUSSION AND CONCLUSIONS

The results of Fig.4 are intended to solve the question of simultaneous ionization and excitation of argon II-4p levels. Though the profiles of the three lines are not symmetrical, the 4348 Å line profile is the steepest at both sides, indicating that a stronger dependency on  $n_e$  may

Fig. 11a The reduced radiance  $L_e(x)/L_e(0)$  of some argon II and argon I lines. ○ denotes the 4348 Å and ● the 3588 Å argon II lines; + the 4259 Å and × the 6985 Å argon I lines. Conditions: ring-shaped anode; discharge current  $I_D = 60$  A; magnetic induction  $B_w = 12.5 \times 10^{-2}$  T; background pressure  $p_b = 1.2 \times 10^{-3}$  mm of Hg; electron temperature  $T_{e,0} = 38 \times 10^3$  °K; ion temperature  $T_i = 1.4 \times 10^3$  °K; electron density  $n_{e,0} = 1.89 \times 10^{19} \text{ m}^{-3}$ .

be supposed than for the argon I lines. The shift of the maxima of the curves can only be caused by a combination of the already mentioned shift of the top of the  $n_e$  and  $T_e$  profiles and a different dependency on  $n_e$  of argon I and argon II profiles. The argon II maximum and the  $n_e$  maximum coincide better than those of the other curves.

From the ratios of the maxima of the line-intensities we can also show that simultaneous ionization and excitation cannot be a dominant process even for  $B_w = 6.3 \times 10^{-3} T$ . The measured ratio of the 6965 Å and 4348 Å signals is 23 and is estimated to be  $\sim 15$  after Abel transformation. The ratio of the intensities of these lines, calculated on the basis of direct excitation for the 6965 Å line and simultaneous ionization and excitation for the 4348 Å line and with the help of literature data on cross-sections for both processes (18-22), appears to be 100 to 350 for  $T_e = 80 \times 10^3$  °K. Therefore the contribution of

Fig.12 The reduced electron temperature profiles  $T_{e,r}/T_{e,0}$  as functions of the distance  $r$  from the axis for four values of the magnetic induction  $B_w$ .  $\circ$   $1.88 \times 10^{-2}T$ ;  $\bullet$   $3.75 \times 10^{-2}T$ ;  $\square$   $7.5 \times 10^{-2}T$ ;  $\blacksquare$   $12.5 \times 10^{-2}T$ . Conditions: ring-shaped anode; discharge current  $I_D = 60$  A; background pressure  $p_b = 1.20 \times 10^{-3}$  mm of Hg. The electron temperatures  $T_{e,0}$  are  $30.0 \times 10^3$  °K,  $27.5 \times 10^3$  °K,  $32.0 \times 10^3$  °K and  $38.0 \times 10^3$  °K respectively; the ion temperatures  $T_i$  are  $1.4 \times 10^3$  °K,  $3.7 \times 10^3$  °K,  $11 \times 10^3$  °K and  $13.3 \times 10^3$  °K respectively; the atom temperatures  $T_n$  are  $1.3 \times 10^3$  °K,  $3.5 \times 10^3$  °K and  $5 \times 10^3$  °K respectively. For  $B_w = 12.5 \times 10^{-2}T$ ,  $T_n$  has not been measured.

the simultaneous process to the population of the  $^4D_{7/2}$  level can only be 5 to 15%. About the same contribution can be found for the 4806 Å

Fig.13 The reduced electron density profiles  $n_{e,r}/n_{e,0}$  as functions of the distance  $r$  from the axis for four values of the magnetic induction  $B_w$ , indicated in the figure. Conditions: see Fig.12. The electron densities  $n_{e,0}$  are  $1.17 \times 10^{19} \text{ m}^{-3}$ ,  $2.26 \times 10^{19} \text{ m}^{-3}$ ,  $2.35 \times 10^{19} \text{ m}^{-3}$  and  $1.89 \times 10^{19} \text{ m}^{-3}$  respectively.

line of the  $4p \ ^4P_{5/2}$  level and the  $4880 \text{ \AA}$  line of the  $4p \ ^2D_{5/2}$  level. The conclusion that for a fully confined plasma the contribution of simultaneous ionization and excitation is smaller than 1% has been based on this estimation.

By applying equation (10) for the calculation of the  $T_e$  profiles it is assumed implicitly that the contribution of the terms  $\neq 1$  of the second factor within braces in equation (14) cancels each other, although this cannot be verified by measurements. We conclude, however, that the results, shown in Fig.5b and derived from the two ratios, indicated in the caption of the figure, are in good agreement with each

other and support the use of equation (10).

From Fig.6 it can be seen that the position of the 4348 Å and 3588 Å lines can be reversed. From the fact that reversal of the position of the two lines occurs we conclude that ratios of the 3588 Å and 4348 Å lines slightly smaller than 1 can not be explained by a small additional excitation from the 4p group to the 4d group. Therefore, excitation from 4p → 4d could be neglected in equation (2).

One of the most striking features in Fig.6 is the great difference between the 4259 and 6965 Å profiles at one side indicating that partition between direct and stepwise excitation for both groups is not equal. It is evident that the difference of the ratio of direct and stepwise excitation for the 4p and 5p group of argon I, combined with the effect due to the  $T_e$ -profile makes the interpretation of the differences between the profiles of the 6965 Å and 4259 Å lines difficult. We conclude from these measurements, combined with the results of (12) that there will be some stepwise excitation to the 4p group and to a smaller amount also to the 5p group.

The results, presented in Fig.7 are to demonstrate explicitly that there is no evident difference between the profiles of laser lines and other lines of the 4p group, indicating that the excitation mechanisms for the whole 4p group are the same.

Fig.9 shows clearly that the  $T_e$ -profiles for the end-anode become flatter for increasing  $B_w$ -values. From Fig.12, it appears that the  $T_e$  differences are quite similar for all  $B_w$ -values. It seems that the decrease of  $T_e$  stops for  $r > 10$  mm. Although this effect was stated for the greater part of the measurements, it may be that inaccuracy of the measurements for these  $r$ -values was the cause thereof.

Inspection of the  $n_e$ -profiles, given in the Figs. 10 and 13 shows that the confining effect can be clearly seen by comparison of the  $1.88 \times 10^{-2}T$  measurement for the end-anode with the other measurements for this anode. The  $n_e$ -profiles for the ring-shaped anode are broader than those for the end-anode. It is possible that the rotation of the plasma column causes a decrease of confinement as can be established for the  $12.5 \times 10^{-2}T$  measurement for the ring-shaped anode. (23)

We finally conclude that by determination of the argon II and I profiles it is possible to give a contribution to the explanation of

the excitation mechanisms in the argon II and argon I spectra and to determine reduced  $T_{e,r}$  and  $n_{e,r}$  profiles with a reasonable accuracy.

#### ACKNOWLEDGEMENTS

The author is indebted to prof. A.A.Kruithof and the other members of the group of Atomic physics for discussions on the subject of this paper. He wish to thank P.A.W.Tielemans and C.H.Lemmens for carrying out some of the measurements.

EXCITATION MECHANISMS AND TEMPERATURES AND DENSITIES OF ELECTRONS IN  
A HOLLOW CATHODE ARGON ARC DISCHARGE

B. van der Sijde

Department of Technical Physics, University of Technology, Eindhoven,  
Netherlands.

Summary- For a hollow cathode low-pressure magnetically-confined argon arc discharge an investigation was made of spectral line-intensities of the argon II spectrum to ascertain the excitation mechanisms in this spectrum, especially for the 4p group (excitation energy 19.2 to 20.0 eV). It appears that for  $n_e$ -values of  $1 \times 10^{19}$  to  $2 \times 10^{19} \text{ m}^{-3}$  stepwise excitation from the ion ground levels through short-lived intermediate levels (16.3 to 16.8 eV) contributes at least 70% to the 4p- argon II group population. Direct excitation from the ion ground levels is dominant for considerably smaller  $n_e$ -values. Cascade radiation plays a minor role in populating the 4p group. The stepwise excitation may lead to laser action in this type of discharge in the same way as occurs in the common argon ion laser. The proposed mechanism is not cited in the literature as a possible mechanism for laser action.

Furthermore, the electron temperature  $T_e$  was determined from absolute line-intensity measurements of the argon I and II spectra. For argon I the method is based on cross-section data for the 4p group, for argon II on Corona Equilibrium formulae. For a well-confined plasma  $T_{e,0}$  on the axis was  $30 \times 10^3$  to  $40 \times 10^3$  °K at an axial distance of 0.6 m from the cathode.

The value of the electron density  $n_e$  was calculated from phase shift measurements with microwaves, accounting for the non-linear relation between  $n_e$  and the refractive index  $\mu$ . The calculation was performed with the help of a method described in a previous paper. The influence of the slice breadth, interacting with the microwaves and of diffraction are discussed. It appeared that  $n_{e,0}$  on the axis is  $1 \times 10^{19}$  to  $2 \times 10^{19} \text{ m}^{-3}$  for a confined plasma.

## I INTRODUCTION

For the hollow cathode low-pressure magnetically-confined argon arc discharge described in (1), the excitation mechanisms in the argon II spectrum will be discussed. The phenomena are related to those of the argon ion laser, as about the same region of electron temperatures and densities are apparent. In the discussion on the excitation mechanisms a method is developed to determine the electron temperature  $T_e$  from absolute spectral-line measurements and from the value of the electron density  $n_e$ .

The  $n_e$ -values were calculated from phase-shift measurements, performed with a 70 GHz microwave interferometer. A method is discussed to determine the  $n_{e,0}$ -values on the axis of a plasma column with a refractive index  $\mu$ , continuously changing as function of the radius  $r$ . Therefore, we applied a method as pointed out in (2), where reduced  $n_e$ -profiles were determined. A spatial mean value of  $n_e$  was determined from the phase-shifts, caused by the breadth of the plasma slice interacting with the microwaves perpendicular to the direction of wave propagation. To find a proper  $n_{e,0}$ -value, the mean value was improved by a method, described in section II. Diffraction effects did not appear apparent.

The  $T_e$ -values were determined from absolute line-intensity measurements, both of the argon I and II spectrum and with the help of the  $n_e$ -values, determined. For argon I cross-section data of direct excitation by electron collisions are available with moderate accuracy (3,4). For argon II the Corona Equilibrium (C.E.) formulae described by McWHIRTER (5) and WILNER (6) were used after a numerical improvement. The results of both methods appeared to be in disagreement with each other for small  $n_e$ -values.

Changes in the relative population densities of the 4p levels of argon II as functions of the magnetic induction  $B_w$ , the minor significance of cascade radiation and calculations of relative cross-section values for the transitions 4s group  $\rightarrow$  4p group and 3d group  $\rightarrow$  4p group give arguments to suppose a change of the excitation mechanisms as function of  $B_w$ .

It appeared possible to develop a consistent system for the

excitation in the argon II spectrum, initiated by the differences between the two methods of determining  $T_e$  and based on the different dependency on  $n_e$  for the different forms of excitation. Stepwise excitation through short-lived intermediate levels with lifetimes of  $\sim 5 \times 10^{-8}$  s and excitation energies of  $\sim 16.5$  eV mainly determines the densities of the 4p levels for  $n_e$  greater than  $6 \times 10^{18} \text{ m}^{-3}$ . Direct excitation from the ion ground levels is supposed to be dominant for  $n_e$ -values smaller than this value.

Finally, the complete results of four series of measurements with  $0 < B_w \leq 15 \times 10^{-2} T$  are presented. The results involve the  $n_e$ - and  $T_e$ -values, and the ion temperature  $T_i$  and neutral particle temperature  $T_n$ , obtained from Doppler broadening measurements. The equipment for these measurements and the method for the calculations have been described in (1). The values of the radiant flux  $P(0)$  on the axis of the column for the 7384 Å argon I and the 4806 Å argon II lines, the ionization degree  $\alpha$  and the voltage characteristics complete the data, obtained.

## II DETERMINATION OF THE ELECTRON DENSITY

### 1 Interferometer

A 70 GHz microwave interferometer with wavelength  $\lambda = 4.3$  mm was used to measure the phase shift  $\Delta\phi$  caused by the plasma column. The experimental device is presented in Fig.1. The antenna system was situated inside the vacuum tube and the wave guides were sealed-off with mica sheets. The interferometer was adjusted to zero without the plasma to measure the phase  $\phi_0$  and also with the plasma to measure  $\phi_p$ . These two values were corrected, if necessary, for temperature influences due to heating effects of the plasma on the waveguides within the vacuum system.

This type of interferometers is suitable to determine  $\Delta\phi$  with an accuracy of  $2^0$  to  $5^0$ , but with an uncertainty of  $k \times 2\pi$ , where  $k$  is an integer. The problem to find  $k$  was solved by careful determination of  $\Delta\phi$ -values for  $B_w \rightarrow 0$ , corresponding with  $\Delta\phi \rightarrow 0$  and by some check measurements with a "zebra stripe" type of interferometer, which has an oversized delay-line (7). This type yields absolute  $\Delta\phi$ -values with limited accuracy.

Fig.1 Scheme of the microwave equipment. 1 is a microwave source; 2 is an isolator; 3 is a frequency meter; 4 is a calibrated attenuator; 5 is a directional coupler; 6 is an adaptor; 7 is a vacuum-window (mica); 8 are side-tubes; 9 is an antenna; 10 is the plasma column; 11 is a phase-shifter; 12 is a hybrid tee; 13 is a crystal detector.

## 2 One dimensional slab approximation

The interferometer was used in the ordinary-wave mode, so that the electrical field vector  $\vec{E}$  was parallel to  $\vec{B}_z$ , the direction of the static magnetic field. The relation between the refractive index  $\nu$  and the plasma frequency  $\omega_p$  is then given by a simplified form of the Appleton equation (7)

$$\nu^2 = 1 - \frac{\omega_p^2/\omega_0^2}{1 - j\nu/\omega_0}, \quad (1)$$

where  $\omega_0$  is the angular frequency of the microwaves and  $\nu$  is the collision frequency of the electrons with ions for momentum transfer.

An expression for the collision frequency for electron-ion interaction is given in (8). The expression can be written in S.I. units as

$$\nu_{ei} = \frac{n_e \ln(1.24 \times 10^7 \cdot T_e^{3/2}/n_e^{1/2})}{3.8 \times 10^5 \cdot T_e^{3/2}}. \quad (2)$$

For  $n_e = 10^{19} \text{ m}^{-3}$  and  $T_e = 3 \times 10^4 \text{ }^\circ\text{K}$ ,  $\nu_{ei}$  appears to be about  $5 \times 10^7 \text{ s}^{-1}$ . Whereas  $\omega_0 = 2\pi \times 7 \times 10^{10} \text{ s}^{-1}$ , the term  $j\nu/\omega_0$  can be neglected.

Equation (1) can be reduced to

$$\mu^2 = 1 - \omega_p^2/\omega_0^2 = 1 - n_e/n_{ec} \quad (3)$$

where  $n_{ec}$  is the critical electron density for the frequency applied.

The basic equations for the relationship between the phase shift  $\Delta\phi$  caused by a plasma slab, which is non-homogeneous in the direction of wave propagation  $x$  and homogeneous in planes perpendicular to that direction at one hand and  $n_e(x)$  at the other hand, are given by relation (3) and

$$\Delta\phi = \phi_0 - \phi_p = k_0 D' (1 - \bar{\mu}), \quad (4)$$

where  $k_0$  is the wave vector in vacuo;  $D'$  is the thickness of the slab defined by relation (5) and  $\bar{\mu}$  is the average refractive index, given by relation (6) (see Fig.2). It is supposed that the plane wave approximation is satisfactory. The boundary of the slab has been more or less arbitrarily chosen by the statement that the thickness  $D'$  is determined by

$$n_e(x) = 0.05 n_{e,0} \quad (5)$$

where  $n_{e,0}$  is the maximum  $n_e$ -value.  $\bar{\mu}$  is determined by

$$\bar{\mu} = (1/D') \int_{-1/2 D'}^{1/2 D'} \mu(x) dx. \quad (6)$$

With the relations (3) and (4) we can state

$$\Delta\phi = k_0 D' \left\{ 1 - \frac{1}{D'} \int_{-1/2 D'}^{1/2 D'} \sqrt{1 - \frac{n_e(x)}{n_{ec}}} dx \right\}. \quad (7)$$

When the reduced values  $n_e(x)/n_{e,0}$  are known the value of  $n_{e,0}/n_{ec}$  and thus of  $n_{e,0}$  can be calculated with relation (7).

The plasma column considered can be assumed to be homogeneous in the axial direction and to have radial symmetry with a certain  $n_{e,0}$  value on the axis and some  $n_e(r)$  profile in the  $x$ - $y$  plane,

Fig.2 Simplified design of the plasma column, interacting with microwaves.

corresponding with a variable  $\mu < 1$ . In (2) a method was pointed out to calculate  $n_e(r)/n_{e,0}$  from spectroscopic measurements. One can use the plasma slab approximation, replacing  $n_e(r)/n_{e,0}$  by  $n_e(x)/n_{e,0}$  to calculate a first approximate value  $n_{e,01}$ , neglecting at the moment the dependency of  $n_e$  in the  $y$  direction.

### 3. Slice breadth approximation

For a real plasma column, the relation between  $\Delta\phi$  and the  $n_e$ -profile is more complicated as given in relation (7). To be able to improve the slab approximation, we consider the refraction phenomena in a cylinder more in detail. Extending the derivation of HEALD and WHARTON<sup>(7)</sup>, we can calculate the breadth  $Q$  of a slice interacting with the microwaves for a cylindrical rod with a dielectricum, having a constant  $\mu < 1$  (see Fig.3). This model is supposed to be an equivalent of the real plasma column in interaction with the microwaves. The relations between the various angles in Fig.3 are based on the geometrical optical approximation and on the small angle approximation. They are

$$\begin{aligned} \theta_1 &= \mu \theta_2 & ; & \theta_1 - \theta_i = P/D & ; \\ \theta_e &= \theta_i + 2(\theta_2 - \theta_1) & ; & \theta_i + 2\theta_2 - \theta_1 = P'/D. & \end{aligned} \quad (8)$$

Fig.3 Refraction of microwaves by a cylindrical rod. The parameters are indicated in the figure and explained in the text.

These relations are valid for the ray just received by the antenna. The first three expressions of (8) result in

$$\theta_e = 2(1/\mu - 1) P/D + \{2(1/\mu - 1) + 1\} \theta_{i1}. \quad (9)$$

With (8),(9) and the relations

$$\theta_{i1} = \frac{P}{2(L+R_1)-D} \quad \text{and} \quad \theta_e = \frac{A-P'}{2R_2-D}, \quad (10)$$

one can derive an expression for  $P/D$ , only based on geometrical quantities and  $\mu$ :

$$P/D = \frac{A(L+R_1 - D/2)}{4(1/\mu-1)R_2(L+R_1) + D(L+R_1+R_2)}. \quad (11)$$

A similar expression for  $P'/D$ , being the largest breadth, interacting with the microwaves, can be derived. One finds

$$P'/D = \left\{ \frac{2(L+R_1)}{\mu(L+R_1-D/2)} - 1 \right\} P/D. \quad (12)$$

We shall approximate the breadth  $Q$  of the slice in interaction in the  $y$  direction with  $Q = (P+P')/2$ , giving

$$Q/D = \frac{(L+R_1)A}{4(1-\mu)R_2(L+R_1) + \mu D(L+R_1+R_2)} \quad (13)$$

Now we shall try to correct the  $n_{e,01}$ -value already found for the influence of the slice breadth  $Q$ . We chose two extreme approximations for the plasma column, to be able to estimate the parameter  $Q/D$ .

The first approximation is a rod having a diameter  $D'$  as defined by relation (5) and a  $\bar{\mu}$  value as defined by the relations (4),(5) and (6). Due to the large value of  $D'$  and consequently the small value of  $1-\bar{\mu}$  in this approximation, it appears that the value  $Q'$  in relation (13) is a major estimate for the slice breadth. As  $0.8 < \mu < 1$  in most cases, the value of  $\mu$  itself is less influenced by the approximation.

The second approximation is a rod with a diameter  $D''$  as defined by the width at half-maximum value of the reduced  $n_e$ -profile and a  $\mu''$ -value corresponding with  $n_{e,01}$ . The  $D''$ -value may be considered as a more or less small estimate of  $D$ . It is obvious that the value  $1-\mu''$  is too large. Consequently, the value  $Q''$  will be a minor estimation for the slice breadth. As it is impossible from these elementary estimates to decide which of the two approximations is the better, we shall adopt for the parameter  $Q$  the value given by  $(Q'+Q'')/2$ . We are now able to replace the slab approximation  $n_{e,01}$  by a second approximation  $n_{e,02}$ , based on the estimation of the slice breadth. We suppose that the approximation of the top of the  $n_e$ -distribution by a triangular shape is good enough for the estimates, so that

$$n_{e,02} = 2 n_{e,01} - n_{eQ} \quad \text{or} \quad (14)$$

$$n_{e,02} = \frac{2 n_{e,01}}{1 + n_{e \text{ red } Q}},$$

where  $n_{eQ}$  and  $n_{e \text{ red } Q}$  are the  $n_e$ -value and reduced  $n_e$ -value, respectively at a distance  $r = Q/2$  from the axis.

The differences found for both approximations are the largest for a well-confined plasma column and negligible for non-confined plasmas. The maximum error in relation (14) is estimated to be 5% from the differences between the two approximations. The total amount of the correction is  $\leq 15\%$  so that a second iterative step with improved  $n_{e,0}$ -values appears to be superfluous.

#### 4. Miscellaneous questions

Another question to be considered is, whether "rays" cross each other due to the  $r$ -dependent  $\mu$ -value, in such a way that information of an inner layer does not reach the antenna, in contradiction with an outer layer of the plasma slice. One can approach this problem by replacing  $Q$  by  $y$  and  $A$  by  $y'$  in equation (13) and differentiating the variables  $y$  and  $y'$  with respect to each other. One can formulate the demand that for  $\Delta y > 0$  the shift in the antenna plane  $\Delta y'$  must be  $\geq 0$ . With the differentiated form and equation (13) itself the expression

$$\left| \frac{\partial n_e}{\partial y} \right| \leq \frac{2\mu n_{ec}}{y} \left\{ \frac{4(1-\mu)R_2(L+R_1) + D(L+R_1+R_2)}{4R_2(L+R_1) - D(L+R_1+R_2)} \right\} \quad (15)$$

is obtainable and when  $(L+R_1) \approx R_2 \approx R$  is introduced, one finds

$$\left| \frac{\partial n_e}{\partial y} \right| \leq \frac{2\mu n_{ec}}{y} \left\{ \frac{\mu(D-2R) + 2R}{2R-D} \right\}. \quad (16)$$

It appears that for the nearly triangular  $n_e$ -profiles found, equation (16) is fulfilled, so that no complications on this point need be expected.

We shall now pay attention to eventual diffraction problems of the system of microwaves and plasma column. We can state for the plasma that  $3 \approx D''/\lambda \approx 10$ , where  $\lambda = 2\pi/k_0$ . ROSEN <sup>(8)</sup>, and HEALD and WHARTON <sup>(7)</sup> treat the refraction for a system of a "plasma rod" with a value of  $n_e/n_{ec} = 0.56$ . The diffraction losses can be estimated from the difference between the experimental values of Fig.4.16 and the theoretical values of Fig.4.18 of <sup>(7)</sup> (see Fig.4). It appears

*Fig.4 Diffraction loss caused by a cylindrical rod as function of  $D/\lambda$  i.e. the diameter of the rod divided by the wavelength of the microwave .*

that errors due to diffraction are largest for  $D/\lambda = 1.5$  and are totally negligible for  $D/\lambda \gg 3$ .

When for plasma columns with continuously varying refractive index  $\mu$  the expression

$$\lambda (\nabla^2 \mu / \mu) \ll 1 \quad (17)$$

holds, it is assumed that diffraction phenomena may be neglected. For the profiles measured, the values of expression (17) appeared to be  $< 0.1$ , so that errors due to diffraction are expected to be small.

Based on these facts, we suppose that the errors due to diffraction phenomena are in any case less than 10% and are probably negligible and we abandon to improve the calculated  $n_e$ -values.

The estimation of the total error in the  $n_e$ -values is somewhat complicated by the fact that the  $\Delta\phi$  measurements were performed in a plane shifted about 15 cm from that of the spectroscopic measurements from which the reduced  $n_e$ -profiles were calculated. Though there are differences between the spatial radiation profiles as a function of  $z$  and hence of the  $n_e$ -profiles, we suppose that the number of electrons per unit length in axial direction is more or less constant. Due to the non-linear relation between  $\mu$  and  $n_e$  expressed in (3), it may be expected that the  $\Delta\phi$ -values slightly change when the  $n_e$ -profile varies

as a function of  $z$ . We assume that the total error, due to the different location of the measurements is about 10%.

Finally, we estimate the error, caused by errors in the reduced  $n_e$ -profiles to be about 10%, so that we can state with the errors in the slice breadth and in the  $\Delta\phi$  measurement, that  $\Delta n_{e,0}/n_{e,0}$  is about 30%. The error in the ratio of two  $n_{e,0}$ -values of various conditions is estimated as about 10%.

### III DETERMINATION OF THE ELECTRON TEMPERATURE

The calculation of the electron temperature  $T_e$  will be performed starting from absolute line-intensity measurements both of the argon I and the argon II spectrum.

For the first method, the radiant flux  $P(0)$  of the 7384 Å line of argon I, originating from the  $2p_3$  level was obtained after an Abel transformation. For this level the transition-probability values (A-values) and the cross-section value  $\sigma$  found in the literature were the most reliable. For  $\Sigma A$  of the  $2p_3$  level  $3.6 \times 10^7 s^{-1}$  was adopted and for A of the 7384 Å line  $0.92 \times 10^7 s^{-1}$ , which are mean values of (10-14). For the maximum value of  $\sigma$  of the  $2p_3$  level  $3.5 \times 10^{-22} m^2$  was adopted, a mean value of (3,4), accounting for deviations due to cascade radiation.

When direct excitation is the dominant populating process for the  $2p_3$  level and according to C.E. circumstances, spontaneous radiation decay is the dominant depopulating process, we may write

$$n_{2p_3} \Sigma A = n_e n_a \langle \sigma v_e \rangle, \quad (18)$$

where  $n_{2p_3}$  is the population density of the  $2p_3$  level;  $n_{2p_3}$  can be calculated with the A- and  $P(0)$ -values for the 7384 Å line.  $n_a$  is the neutral particle density and was calculated with the relation  $p = n_a k T_n$  for  $T_n = 500^\circ K$ , whose value is valid for discharge currents, smaller than 50A. The pressure  $p$  was measured with an ionization gauge at some distance from the discharge.  $v_p$  in the discharge volume due to neutral particles is small, so that the pressure measurement is a good representation of the pressure near the axis.  $\langle \sigma v_e \rangle$  denotes the

integration of the excitation cross-section function  $\sigma$  over the electron velocity distribution. For the mathematical description of  $\sigma$  we used the approximation given by Fabrikant <sup>(15)</sup> from threshold to top-value and a straight-line approximation for the remaining part. A curve giving  $T_e$  as a function of the  $\langle\sigma v_e\rangle$ -values is presented in Fig.5. From the curve  $T_e$  can be read when  $\langle\sigma v_e\rangle$  is calculated from relation (18).

Fig.5 The electron temperature  $T_e$  as a function of the value of  $\langle\sigma v_e\rangle$  of the  $2p_3$  level (7384 Å line).

The errors in  $\langle\sigma v_e\rangle$  are estimated to be 10% due to  $n_{2p_3}$ , 10% to  $\Sigma A$ , 30% to  $n_e$ , 30% to  $n_a$ , 30% to  $\sigma$  and 20% to the approximation for  $\langle\sigma v_e\rangle$ , used. These errors are for an important part uncorrelated systematic errors. We estimate the total error due to the parameters in relation (18) to be 25 to 50%. These errors cause 5 to 10% uncertainty in the determination of  $T_e$  for  $T_e = 35 \times 10^3 \text{ K}$ . Also systematic errors, due to other population mechanisms up to about 50% do not harm the method severely. The random error in  $T_e$  between the various points is 3% or

Fig. 6 The electron temperature  $T_e$  as function of the magnetic induction  $B_w$ . + symbols from the radiant flux of the argon I 7384 Å line. • o and □ symbols from the radiant fluxes of argon II lines for  $f = 50$ ,  $f = 100$  and  $f = 200$ , respectively. Conditions: end-anode; discharge current  $I_D = 40A$ ; pressure  $p_p = 1.5 \times 10^{-3}$  mm of Hg.

less.

The second method is based on measurements of the argon II-4p group line-intensities and on a Corona Equilibrium (C.E.) formula, described in (2), equation (7). The level populations are calculated from the radiant fluxes  $P\{0\}$  of four lines (4765 Å, 4806 Å, 4848 Å and 4880 Å) and A-values of (1). The  $n_e$ -values were calculated as described in section II.

As pointed out in (2), the method to determine  $T_e$ , is based on stepwise-excitation through short-lived intermediate levels. Assuming at the moment that stepwise-excitation is the proper mechanism, still great errors may occur. The  $\sigma$ -values used in the C.E. model can only be considered as very rough approximations of the absolute values. To obviate this problem, we introduced a factor  $f$  in the expression, given in equation (7) of (2). The factor  $f$  has to be regarded as the multiplication  $f = f_1 \times f_2$  of the two errors in the values of  $\sigma$  for the first and the second step of the excitation. We calculated  $T_e$ -values for several  $f$ -values and compared the results with those of the above described method.

In fact, the factor  $f$  varies from one to the other 4p level with about a factor 4 between the smallest and largest value. The variation of  $f$  for the various transitions accounts for differences in the  $P(0)$  values as far as not caused by differences of the excitation energy of the 4p levels. The parameter  $f$  introduced in Fig.6, is the factor belonging to the 4p  $^4P_{5/2}$  level and the 4806 Å line.

This figure shows a series of results for  $T_e$  as functions of the magnetic induction  $B_w$ . The  $f$ -values range from 50 to 200. Irrespective of the  $f$ -values used, we may conclude from the figure that between the two methods of determining  $T_e$  there are large deviations for small  $B_w$ -values. For  $f = 100$  there is a good agreement for large  $B_w$ -values. Further discussion on these deviations are delayed to section V.

#### IV MISCELLANEOUS REMARKS ON EXCITATION

##### 1 Population densities

In <sup>(1)</sup> it has been remarked that the ratios of the population densities of the 4p levels of argon II seem to change when the magnetic induction  $B_w$  is lowered to small values. For this paper, we measured the line-intensity of one line of every level of the 4p group to calculate the population density of that level for a set of  $B_w$ -values. A part of the results is presented in Fig.7. The changes in the population densities as functions of  $B_w$  can be seen in the subsequent figures of Fig.7. This example is in agreement with the other measurements. The measurements presented in Fig.7 are not subjected to an Abel transformation.

We note from large to small  $B_w$ -values a shift of the points, representing the  $^4P_{3/2}$  and  $^4P_{1/2}$  levels, with respect to each other, the lift of the  $^4D_{5/2}$  point with respect to the neighbouring points, the lift of the  $^2D_{5/2}$  point, the  $^2P$  doublet and the  $^2S_{1/2}$  point with respect to the other multiplets and the lower position of the  $^4S_{3/2}$  point. 0.1 of the vertical scale corresponds with about 10% change in the population density. We conclude that changes of about 40 to 60% in the density ratios occur when changing from large to small  $B_w$ -values.

It has already been suggested <sup>(1)</sup> that a possible reason for the changes in the ratios of the population densities occur by changes in the excitation mechanisms when the  $B_w$ -value is varied widely. This

Fig.7 Magnetic sublevel populations on an arbitrary scale as functions of the excitation energy  $E_m$ . a: Magnetic induction  $B_w = 15 \times 10^{-2} T$ ; b:  $B_w = 7.5 \times 10^{-2} T$ ; c:  $B_w = 3 \times 10^{-2} T$ ; d:  $B_w = 1.8 \times 10^{-2} T$ ; e:  $B_w = 1.5 \times 10^{-2} T$ ; f:  $B_w = 1.2 \times 10^{-2} T$ . Significance of the symbols from left to right:  $\bullet$   $^4P_{5/2}$ ,  $^4P_{3/2}$  and  $^4P_{1/2}$  level;  $\circ$   $^4D_{7/2}$ ,  $^4D_{5/2}$ ,  $^4D_{3/2}$  and  $^4D_{1/2}$  level;  $\square$   $^2D_{5/2}$  and  $^2D_{3/2}$  level;  $\triangle$   $^2P_{1/2}$  and  $^2P_{3/2}$  level;  $\blacktriangledown$   $^4S_{3/2}$  level and  $\nabla$   $^2S_{1/2}$  level. Conditions: ring-shaped anode; discharge current  $I_D = 25A$ ; pressure  $p_b = 1.0 \times 10^{-3}$  mm of Hg.

variation corresponds with large differences in  $n_e$ -values. A possible explanation of the phenomena is that direct excitation from the ion ground levels to the 4p levels is dominant for small  $n_e$ -values and that stepwise excitation through short-lived intermediate levels ( $\tau \approx 5 \times 10^{-8}$ s) occurs for large  $n_e$ -values. However, it may be that metastable levels act as intermediate levels, either for small  $n_e$ -values or for large  $n_e$ -values. Also the contribution of cascade-radiation has to be taken into account. From Fig.7 alone, we cannot decide which mechanism occurs for large and small  $n_e$ -values respectively.

## 2 Cascade radiation

The contribution of the cascade radiation from 4d and 5s levels to the population density of the 4p levels was determined as part of the investigation of the excitation mechanisms for the 4p levels. The calculation of the percentage of cascade-radiation for a particular level is based on the measurement of all line-intensities involved; this means the intensities of lines having the level concerned either as lower, or as upper level. When cascading levels are designated with 4k, the 4p level with 3 and lower intermediate levels with 2m, the contribution is defined as

$$\frac{\sum_k P_{4k} \nu_{4k}^3 / h\nu_{4k}^3}{\sum_m P_{3\ 2m} \nu_{3\ 2m}^3 / h\nu_{3\ 2m}^3}, \quad (19)$$

where P is the radiant flux of a line. It is assumed that spontaneous emission is completely dominant as deexcitation mechanism <sup>(2)</sup>.

The results are presented in Table 1. The first column gives the various 4p levels, the second column is the average value of two conditions, namely the discharge current  $I_D = 75$  A with the ring-shaped anode and  $I_D = 40$  A with the end-anode, both for  $B_W = 2.4 \times 10^{-2}$ T. The electron temperature  $T_e$  is more or less equal for these two circumstances. The third column is a mean value for  $I_D = 75$  A with the ring-shaped anode and  $I_D = 35$  A with the end-anode, both for  $B_W = 7.5 \times 10^{-2}$ T.

We conclude that there is an increment of the amount of cascade radiation of about 20% for  $B_W = 2.4 \times 10^{-2}$ T in comparison with that

Table 1 Percentages of the population densities of the argon II 4p levels due to cascade radiation from the 4d and 5s groups for two values of  $B_w$ .

excitation levels of the 4p group of argon II	percentage of cascade radiation $B_w = 2.4 \times 10^{-2}T$	percentage of cascade radiation $B_w = 7.5 \times 10^{-2}T$
$4p_{5/2}$	4.8	3.6
$4p_{3/2}$	6.9	3.7
$4p_{1/2}$	6.0	3.7
$4d_{7/2}$	6.4	6.3
$4d_{5/2}$	5.7	8.0
$4d_{3/2}$	8.1	5.8
$4d_{1/2}$	8.5	5.6
$2d_{5/2}$	11.2	9.4
$2d_{3/2}$	4.8	8.0
$2p_{1/2}$	5.7	4.0
$2p_{3/2}$	2.3	1.9
$4s_{3/2}$	16.9	15.0
$2s_{1/2}$	0.2	0.3
mean value	6.7	5.6

for  $B_w = 7.5 \times 10^{-2}T$  for the mean value. The part of the population due to cascade radiation is small in any case. We expect that the contribution of cascade radiation to the densities of the 4p levels is also limited for  $B_w < 2.4 \times 10^{-2}T$ . There is no connection at all between the changes of Fig.7 and those of Table 1. We conclude that it is not apparent that the contribution of cascade radiation is an explanation for the changes in Fig.7.

### 3 Excitation cross-sections

Information on excitation cross-sections can be found from calculations based on a method introduced by RACAH (16) and extended by EDMONDS (17). With this method, relative values of the cross-sections for transitions from one to another multiplet were calculated, using the dipole-dipole interaction approximation. The method is restricted to optically permitted transitions, as it is based on the L-S coupling approximation. We give for example the results for  $4s^4P \rightarrow 4p^4P$  transitions and for  $3d^4D \rightarrow 4p^4P$  transitions in Table 2. Multiplication of a number in the table with

Table 2 Relative cross-section values for excitation by electrons for  $4s^4P \rightarrow 4p^4P$  and  $3d^4D \rightarrow 4p^4P$  transitions in the argon II spectrum.

	$4p^4P_{5/2}$	$4p^4P_{3/2}$	$4p^4P_{1/2}$
$4s^4P_{5/2}$	1.4	1.8	0
$4s^4P_{3/2}$	1.8	.18	.18
$4s^4P_{1/2}$	0	.18	.11
$3d^4D_{7/2}$	1.6	2.88	0
$3d^4D_{5/2}$	.36	.84	0
$3d^4D_{3/2}$	.04	.14	.33
$3d^4D_{1/2}$	0	.07	1.0

the population density of a 4s or 3d level is proportional to the excitation rate to the level, concerned. As these densities are unknown, the numbers in the columns can not be added up.

The most important conclusion, to be drawn from Table 2, is that the population of the  $4p^4P$  multiplet cannot be dominated by excitation from the  $3d^4D$  multiplet. The reason is that every separate  $3d^4D$  level yields more transitions to  $4p^4P_{3/2}$  than to  $4p^4P_{5/2}$ , which is in disagreement with the results of Fig.7. This implies that the suggestion that possibly metastable levels as the  $3d^4D_{7/2}$  level and perhaps the  $3d^4D_{1/2}$  level are dominant for either small  $B_w$ -values or large  $B_w$ -

values is not right for the  $4p\ ^4P$  multiplet and very doubtful for other multiplets.

The population of the  $4p\ ^4P$  multiplet may be in agreement with the data of Table 2, when it is assumed that the majority of the excitations occurs through the  $4s\ ^4P$  multiplet, perhaps with some additional excitations through the  $3d\ ^4D$  multiplet.

Similar calculations for  $4s\ ^4P \rightarrow 4p\ ^4D$  and  $3d\ ^4D \rightarrow 4p\ ^4D$  transitions show that it is not possible to decide whether the majority of the excitation phenomena occurs through the  $3d\ ^4D$  or through the  $4s\ ^4P$  multiplet.

We finally conclude that stepwise excitation through short-lived levels is in agreement with the data of these calculations and that excitation through metastable levels is at least at one point in disagreement with these data.

## V EXCITATION MECHANISMS

In Fig.6 we found large differences between the values of  $T_e$ , based on direct excitation in the argon I spectrum and those, based on stepwise excitation in the argon II spectrum. An interpretation of these differences will be given now.

The curve of  $T_e$  calculated from the argon I line-intensity is the flattest curve which can be found for argon I, for direct excitation is proportional to  $n_e$ . Assumption of partly or almost totally stepwise excitation should give a much steeper curve, as this phenomenon is proportional to  $n_e^2$ . The largest deviations with respect to the curve drawn in Fig.6, should occur for large  $B_w$ - and  $n_e$ -values.

On the contrary the  $T_e$  curve determined from argon II line-intensities is the steepest curve which can be found for argon II, as stepwise excitation is proportional to  $n_e^2 \times n_i = n_e^3$ . Contribution of direct excitation from the ion ground levels should give a flatter curve with the largest deviations with respect to the curves drawn for small  $B_w$ - and  $n_e$ -values. It can be seen from Fig.6 that factors 2 and 4 in the factor  $f$  used, give variations of  $T_e$  from  $T_e > 200 \times 10^3\ ^\circ K$  to  $T_e = 99 \times 10^3\ ^\circ K$  and to  $67 \times 10^3\ ^\circ K$  respectively for  $B_w = 1 \times 10^{-2}T$ . It appears from this example that large contributions of direct excitation in the argon II spectrum for small  $B_w$ -values may give large

errors in the calculation of  $T_e$ .

The contributions of direct excitation and stepwise excitation in the argon II spectrum can be calculated if we assume that the  $T_e$ -curves from the argon I line-intensity are correct. We then are able to set up a balance equation for the population density  $n_3'$  for a 4p level, accounting for contributions of direct and stepwise excitation<sup>(2)</sup>

$$n_3' \sum_m A_{3, 2m} = K_d (n_e'^2 / T_e'^{\frac{1}{2}}) \exp(-E_3 / kT_e') + K_s (n_e'^3 / T_e') \exp(-E_3 / kT_e'), \quad (20)$$

where ' denotes a particular discharge condition.  $K_d$  and  $K_s$  are constants for a particular level 3.  $m$  is a summation over all intermediate levels, involved.  $E_3$  is the excitation energy of the level 3. A similar equation holds for  $n_3''$ ,  $T_e''$  and  $n_e''$  for a second discharge condition, denoted with ''.

We call  $n_3' \sum_m A_{3, 2m} = z$ ,  $K_d (n_e'^2 / T_e'^{\frac{1}{2}}) \exp(-E_3 / kT_e') = x$  and  $K_s (n_e'^3 / T_e') \exp(-E_3 / kT_e') = y$ . The equation (20) can be written as

$$x + y = z \quad (20a)$$

and the equation for the condition with '' as

$$\begin{aligned} & (n_e'' / n_e')^2 \cdot (T_e' / T_e'')^{\frac{1}{2}} \cdot \exp\{-E_3 / k(1/T_e'' - 1/T_e')\} x + \\ & (n_e'' / n_e')^3 \cdot (T_e' / T_e'') \cdot \exp\{-E_3 / k(1/T_e'' - 1/T_e')\} y = (n_3'' / n_3') z. \end{aligned} \quad (20b)$$

As the  $n_e$ ,  $T_e$  and  $n_3$  values are known,  $x/z$  and  $y/z$  can be solved. Their ratios give the contribution of the two kinds of excitation mechanisms for the condition, denoted with '. The equations can also be solved to find the ratios for the condition, denoted with ''. By comparing every possible pair of two conditions ( $B_w$ -values) with each other for one series of measurements, one can derive a set of values for  $x/z$  and  $y/z$  for every condition. This set can be averaged to find the most proper result for the condition concerned. The deviations due to errors in  $n_e$ ,  $T_e$  and  $n_3$  of the other conditions are thus averaged by this procedure.

Fig.8 Percentage of the stepwise excitation mechanism for the populating of the argon II 4p levels as function of the electron density  $n_e$ . Conditions:  $\circ$  end-anode, discharge current  $I_D = 20$  A;  $\bullet$  end-anode,  $I_D = 40$  A.

The results of the calculations for two series of measurements are presented in Fig.8 as functions of  $n_e$ . They appear to lead to the same curve. The contribution of the stepwise excitation ranges from about 1% for  $n_e = 10^{17} \text{ m}^{-3}$  to about 80% for  $n_e = 2 \times 10^{19} \text{ m}^{-3}$ .

In (2), it has already been discussed that proper  $n_e$ -values can be derived by interpolation between values, based on reduced  $n_e$ -profiles, related to stepwise excitation and those, related to direct excitation. These corrections have already been performed for the results of Fig.8. Also the  $T_e$ -values have been adjusted to the proper  $n_e$ -values. The improvements for  $n_e$  were 10 to 35% from large to small  $n_e$ -values, and correspondingly for  $T_e$ ,  $1 \times 10^3$  to  $5 \times 10^3$  °K. It appeared that only one step of the iteration process to find the partition between stepwise and direct excitation was sufficient, as the values of  $y/z$  became only 10% larger by the changes mentioned.

It appears from the results of Fig.8 that stepwise excitation is the dominant process for  $n_e > 6 \times 10^{18} \text{ m}^{-3}$  and that direct excitation is dominant for  $n_e < 6 \times 10^{18} \text{ m}^{-3}$ . The random error in  $y/z$  for most points

is about 5 to 10%. The results can be considered as the explanation of the large deviations for the two methods of  $T_e$ -determination, illustrated in Fig.6.

These calculations are based on the  $T_e$ -values, derived from the argon I line-intensities, i.e. on direct excitation in the argon I spectrum. When this assumption is not fully correct, and  $T_e$ -values for large  $B_w$ -values should be somewhat lower, then the contribution of stepwise-excitation should be slightly higher. It can be calculated that stepwise excitation in the argon II spectrum becomes  $\approx 90\%$  instead of 75% when direct excitation in the argon I spectrum contributes only 50% of the population of the  $2p_3$  level. The values of Fig.8 have to be regarded as minimum values. It is not possible with the method used to distinguish whether the percentages given in Fig.8 are correct, or somewhat too low.

We may conclude now that the calculation of  $T_e$  from argon I spectral line-intensities is satisfactory for  $n_e$ -values  $\approx 1 \times 10^{19} \text{ m}^{-3}$  with an accuracy of approximately 10% and that for larger  $n_e$ -values there may be an error in addition up to about 10%. The definite calculations with argon II line-intensities show that the  $T_e$ -values for  $f = 100$  and  $n_e \approx 7 \times 10^{18} \text{ m}^{-3}$  are in agreement with those from the argon I line-intensities.

## VI RESULTS

The results of four series of measurements as functions of the magnetic induction  $B_w$  are presented in the Figs. 9 to 16. The conditions are stated in the caption of Fig.9. The radiant flux  $P(0)$  of the 4806 Å argon II line and the 7384 Å argon I line are shown in the Figs. 9 and 10 respectively. By comparing both figures we state that the  $P(0)$  value of the 4806 Å line changes more than a factor  $10^3$  and that the  $P(0)$  value of the 7384 Å changes about a factor 10. This difference in variation is mainly due to the difference in the dependency on  $n_e$ . The curves for the ring-shaped anode are somewhat steeper than those for the end-anode.

The results of the calculations of the electron density  $n_e$  can be found in Fig.11. The confining effect of the magnetic field can clearly

Fig.9 The radiant flux  $P(0)$  of the argon II 4806 Å line as function of the magnetic induction  $B_W$ . Conditions: ○ end-anode, discharge current  $I_D = 20$  A, background pressure  $p_b = 1.0 \times 10^{-3}$  mm of Hg ; ● end-anode,  $I_D = 40$  A,  $p_b = 1.5 \times 10^{-3}$  mm of Hg; □ ring-shaped anode,  $I_D = 25$  A,  $p_b = 1.0 \times 10^{-3}$  mm of Hg; ■ ring-shaped anode,  $I_D = 75$  A,  $p_b = 1.25 \times 10^{-3}$  mm of Hg.

be seen from the changes of  $n_e$  by a factor 40 or more.

The results for the electron temperature  $T_e$  are presented in Fig.12. We can see from the figure that for  $B_W > 3 \times 10^{-2}$  T, the  $T_e$ -values are  $28 \times 10^3$  to  $38 \times 10^3$  °K, with a small increment for large  $B_W$ -values. For small  $B_W$ -values a marked increase can be stated. We remark that for  $0.75 \times 10^{-2}$  T  $< B_W < 1.05 \times 10^{-2}$  T the discharge was unstable for the end-anode configuration. For  $B_W$ -values of about  $0.5 \times 10^{-2}$  T,  $T_e$ -values

larger than  $10^5$  °K were found. These last values have large errors.

For the 75 A ring-shaped anode series the  $T_e$ -values were calculated

Fig.13 The ion temperature  $T_i$  as function of  $B_w$ . See for explanation of the symbols Fig.9.

based on argon II line-intensities with the factor  $f = 100$ . It appeared that due to the large  $T_n$ -values of this series (see Fig.14),  $n_a$  could not be calculated accurately. The relations  $p = n_a k T_n$  and  $n_a = \text{constant}$  does not satisfy and give too large and too small values, respectively in comparison with the method used.

In the Figs. 13 and 14 the results of the ion temperature  $T_i$  and neutral atom temperature  $T_n$  are presented. Both temperatures were found with the aid of a Fabry-Perot interferometer.

Fig.14 The atom temperature  $T_n$  as function of  $B_W$ . See for explanation of the symbols Fig.9.

The  $B_W$ -values of the measured points do not always coincide with those of the other figures. We can state a rapid growing of  $T_i$  with the discharge current and with  $B_W$ .  $T_n$  is approximately 400 to 500  $^{\circ}K$  for three series. Only for the discharge current  $I_D = 75 A$ , a larger  $T_n$  value was found. We do not discuss here the problem whether the large  $T_n$ -values are corresponding with a Maxwellian distribution or not.

The ionization degree  $\alpha = n_e / (n_e + n_a)$  was calculated and the results are stated in Fig.15. Also here a marked dependency on  $I_D$  and  $B_W$  can be seen. The  $\alpha$ -values for the ring-shaped series are larger than for the series with the end-anode.

Finally, the voltage characteristics of the four series can be found in Fig.16. The most striking phenomenon is a difference between the values for the ring-shaped anode and the end-anode. The difference

Fig.15 The ionization degree  $\alpha$  of the plasma as function of  $B_w$ . See for explanation of the symbols Fig.9.

Fig.16 The voltage characteristics of the discharge as function of  $B_w$ . See for explanation of the symbols Fig.9.

of about 25 V may be explained as due to the electrical field  $E_z$  along the axis. From this difference  $E_z$  is found to be 15 to 20  $V\ m^{-1}$ , in agreement with (18). The increase of the voltage  $V_D$  for large  $B_w$  - values for the ring-shaped anode is probably due to increasing  $E_r$  - fields in the surrounding of this anode.

Measurements of the gas flow gave the following results: approximately:  $1.55 \times 10^{-3}$ ,  $2.30 \times 10^{-3}$ ,  $1.65 \times 10^{-3}$  and  $2.90 \times 10^{-3}$  mm of Hg. $m^3s^{-1}$  for discharge currents  $I_D$  of 20, 40, 25 and 75 A respectively .

## VII DISCUSSION AND CONCLUSIONS

One of the most important results of this work is the ascertainment that stepwise excitation through short-lived intermediate levels contributes to the population of argon II-4p levels. The percentage of the population due to this excitation mechanism as function of  $n_e$  is given in Fig.8. In fact, a small amount of the percentages is due to cascade radiation from that part of the population of the cascading levels, also created by stepwise excitation. When the partition of direct and stepwise excitation for the cascading levels is similar to that of the 4p levels, the percentages presented should be corrected with approximately 5% for large  $n_e$ -values. For small  $n_e$ -values the correction is not exactly known, but it is supposed that it has about the same ratio to the stepwise excitation as for large  $n_e$ -values.

It may be assumed that the 4p  $^4P$  multiplet is mainly populated through the 4s  $^4P$  multiplet and that the 4p  $^4D$  multiplet is probably populated both through the 4s  $^4P$  and 3d  $^4D$  multiplets. It is not possible to make a decision for the doublets and singlets. Perhaps there is an additional population by stepwise excitation through the 4s  $^2P$  doublet (17.2 eV) but the lasering effects of transitions between some of the 4p levels and this doublet must be caused by population through other multiplets.

We have seen that direct excitation from the ion ground levels is the main excitation mechanism for small  $n_e$ -values. In Fig.7 it can be seen that the doublet levels show a larger density for small  $n_e$  - values relative to the density of the multiplets, probably caused by

a preferential direct excitation from the  $3p^2P$  ground level doublet to the  $4p$  group doublets. The so-called configuration temperature  $T_{4p}^{(1)}$  increases from about  $6.5 \times 10^3$  to  $10.5 \times 10^3$  °K from large to small  $B_w$ -values. This effect is mainly caused by the lift of the doublet points.

An affirmation of the excitation mechanisms proposed can be found in the following consideration. We calculate for the levels with excitation energies 19.22 eV and 19.97 eV the ratio of the population densities, a) when it depends on the expression  $(1/E_{13})\exp(-E_{13}/kT_e)/\Sigma A$ , corresponding with direct excitation and

b) also on  $(1/E_{23})^3\exp(-E_{13}/kT_e)/\Sigma A$ , corresponding with stepwise excitation<sup>(2)</sup>.

$E_{13}$  is the total excitation energy with values 19.22 and 19.97 eV respectively, and  $E_{23}$  is the excitation energy of the second step from  $\sim 16.5$  eV for both levels. For  $T_e = 30 \times 10^3$  °K, the configuration temperatures  $T_{4p}$ , corresponding with the ratios found were  $> 30 \times 10^3$  °K for direct excitation and approximately  $10 \times 10^3$  °K for stepwise excitation. The results can be compared with a  $T_{4p}$  for the Figs. 7a and 7b, being  $7 \times 10^3$  °K. We see that the slopes, found in Fig.7 may be explained by stepwise excitation formulae with reasonable satisfaction. The deviations of the population densities from the straight lines are to be considered as differences between the excitation cross-sections of neighbouring levels.

Finally, we show a combined argon I and II excitation energy diagram in Fig.17, in which the contributions of the various excitation mechanisms are inserted for  $T_e = 30 \times 10^3$  °K and  $n_e = 2 \times 10^{19} m^{-3}$ . The results are also based on discussions in (2).

The excitation mechanism proposed for the  $4p$  argon II group is contrary to the arguments of BENNETT et al<sup>(19)</sup>, who assumed that direct excitation from the neutral ground level causes the laser action of the argon ion laser and also of KITAEVA et al<sup>(20)</sup>, who argue that direct excitation from the ion ground levels is the dominant process. The contribution of cascade radiation is smaller than found by RUDKO and TANG<sup>(21)</sup>.

Comparison of our results with the calculations of KITAEVA et al<sup>(20)</sup>, also discussed in (22) and (23), shows a complete disagreement.

Fig.17 Simplified diagram of the argon I and II spectrum with the excitation and deexcitation balance for the argon II 4p group for  $T_e = 30 \times 10^3 \text{ }^\circ\text{K}$  and  $n_e = 2 \times 10^{19} \text{ m}^{-3}$ .

The first reason can be found by comparing the  $\langle \sigma v_e \rangle$  values. An estimation for the  $4p \text{ }^4\text{P}_{5/2}$  level from our results gives  $\langle \sigma v_e \rangle \approx 3 \times 10^{-18} \text{ m}^3 \text{ s}^{-1}$  for  $T = 30 \times 10^3$  to  $35 \times 10^3 \text{ }^\circ\text{K}$  against  $\langle \sigma v_e \rangle \approx 3 \times 10^{-17} \text{ m}^3 \text{ s}^{-1}$  in (20), both for direct excitation. On the contrary, the values for  $\langle \sigma v_e \rangle_I \times \langle \sigma v_e \rangle_{II}$  for the stepwise process through 4s levels are  $5 \times 10^{-30} \text{ m}^6 \text{ s}^{-2}$  and  $1.5 \times 10^{-29} \text{ m}^6 \text{ s}^{-2}$ , respectively. The second reason is the very large A-value of  $2.5 \times 10^9 \text{ s}^{-1}$ , supposed by KITAEVA for the 4s levels, against the A-value of  $2 \times 10^7 \text{ s}^{-1}$ , adopted by us (24). These two differences, and mainly the second, cause the large differences between the results.

In (2) we found that the reduced radiant flux profile of the 4880 Å laser line and the 4348 Å line are similar within very narrow limits, indicating that no differences exist between the excitation mechanisms of laser lines and normal spectral lines.

It may be remarked that HUCHITAL and RIGDEN (25) and also JENNINGS et al (26) found laser action for a hollow cathode argon arc discharge, similar to our type of discharge. We therefore conclude that stepwise excitation may lead to laser action in this type of discharge in the

same way as occurs in the common argon ion laser.

The determination of the  $T_e$ -values is in rough agreement with values of LEONARD (27) and of LIDSKY et al (28), who for certain circumstances also found values of about  $30 \times 10^3$  °K. The range of values for  $T_e$ , found in the literature is  $30 \times 10^3$  to  $100 \times 10^3$  °K. The  $n_e$ -values are in reasonable agreement with values of GERRY and ROSE (29) and of LEONARD (27). The range of  $n_e$ -values, found in the literature is for confined plasmas  $1 \times 10^{19} \text{m}^{-3}$  to approximately  $10 \times 10^{19} \text{m}^{-3}$ .

In conclusion, we may state that for the argon plasma an alternative method for the determination of the electron temperature  $T_e$  is presented. It is valuable to compare the results of this method with those of other methods as probe measurements and Thomson scattering.

#### ACKNOWLEDGEMENTS

The author wishes to thank prof. A.A.Kruihof and the members of the group of Atomic Physics for helpful discussions on the subject of this paper. He is indebted to W.M.J. Berden, E.J.J.M. Verstraelen, G.J. de Vlieger and P.A.W.Tielemans for carrying out a part of the measurements and to A.B.M.Hüsken for his help in the calculations presented in this paper.

## ALGEMENE SLOTBESCHOUWING

We zullen in dit gedeelte een overzicht geven van de resultaten die verkregen zijn uit de metingen van de intensiteiten van lijnen uit de spektra van argon I en II, de stralingsprofielen als functie van de afstand tot de as van de ontlading en de faseverschuivingen van 4 mm microgolven. De informatie omtrent de uit Dopplerverbreiding verkregen ionentemperaturen  $T_i$  en temperaturen van neutrale deeltjes  $T_n$  is alleen in de discussie betrokken, voor zover nodig voor de interpretatie van het waargenomen spektrum <sup>(2)</sup>.

Zoals in <sup>(1)</sup> is opgemerkt, worden ionisatie en aanslag bepaald door botsingen van atomen en ionen met voldoende energierijke elektronen. We moeten verwachten dat de numerieke waarden van werkzame doorsneden voor exciterende botsingen van groot belang zijn voor de grootte van de bezetting van de aangeslagen niveaus en dat deze van niveau tot niveau verschillen in de bezetting kunnen veroorzaken. Een gevolg daarvan is dat de bezetting van deze niveaus zowel in absolute maat <sup>(1)</sup> als relatief ten opzichte van elkaar <sup>(2)</sup> niet aan een Boltzmann-verdeling zal voldoen. Verandert het mechanisme van de aanslag als functie van de elektronendichtheid van bij voorbeeld directe aanslag vanaf het grondniveau naar stapsgewijze aanslag via tussengelegen niveaus dan kan men verwachten ook veranderingen in de verhoudingen van de bezettingen van de aangeslagen niveaus te zullen waarnemen. Voorbeelden hiervan zijn de veranderingen in de bezettingen van de 4p groep van argon II, zoals weergegeven in de figuren 5 en 6 van <sup>(2)</sup> en Fig.7 van <sup>(4)</sup>. In deze figuren is een relatieve maat voor de bezetting van de aangeslagen niveaus uitgezet als functie van de aanslagenergie.

Een nauwkeurig beeld van de bezettingen van aangeslagen niveaus kan afgeleid worden uit de resultaten van lijnintensiteitsmetingen met behulp van de betrekking

$$P_{32} = h\nu_{32} A_{32} n_3 \quad (1)$$

waarin  $P_{32}$  de stralingsstroom voor een overgang tussen een niveau 3 (bij voorbeeld de 4p groep bij  $\sim 19.5$  eV) en een niveau 2 (bij voorbeeld de 3d of 4s groep bij  $\sim 16.5$  eV) is,  $h\nu_{32}$  de energie van het betreffende kwant,

$A_{32}$  de bijbehorende overgangswaarschijnlijkheid en  $n_3$  de bezetting van het niveau 3. Voor een goede bepaling van de bezetting is het vereist dat voor minstens één overgang uitgaande van niveau 3 de waarde  $A_{32}$  binnen 5 tot 10% nauwkeurig bekend is. Door een zorgvuldige en kritische beschouwing van de beschikbare literatuur zijn we er voor de 4p groep van argon II in geslaagd, deze waarden zo nauwkeurig te verkrijgen. De resultaten zijn vastgelegd in de tabellen 1 en 6 van de Appendix van <sup>(2)</sup>.

In <sup>(2)</sup> is verder de reeds in <sup>(1)</sup> genoemde veronderstelling uit de literatuur betreffende de thermalisatie van de bezetting van niveaus binnen een spektrale groep getoetst voor de 4p groep van argon II. Aangezien een rechte met een bepaalde helling in de reeds genoemde figuren van <sup>(2)</sup> en <sup>(4)</sup> overeenkomt met een bepaalde waarde van een zo genoemde configuratietemperatuur  $T_{4p}$  voor de 4p groep, is het duidelijk dat een mogelijke thermalisatie zich moet uiten in een rangschikking van de gemeten punten langs een bepaalde helling met niet te grote afwijkingen daarvan. Op grond hiervan kan men uit de genoemde figuren al opmaken dat de 4p groep als geheel waarschijnlijk geen thermalisatie vertoont. Deze veronderstelling is in overeenstemming met het feit dat niet steeds voldaan wordt aan het in <sup>(2)</sup> aangelegde criterium voor thermalisatie

$$T_{i,n} \leq T_{4p} < T_e \quad , \quad (2)$$

waarin  $T_e$  de elektronentemperatuur is.

Uit de genoemde figuren blijkt dat voor waarden van de magnetische inductie  $B_w \approx 3 \times 10^{-2} T$  de punten van het  $4P$  multiplet redelijk en voor het  $4D$  multiplet goed op een rechte liggen. We merken op dat de waarden van de configuratietemperatuur voor de diverse multiplets verschillen te zien geven. Ze variëren van 1500 tot 2600 K volgens Fig.5 van <sup>(2)</sup>. De vergelijking van de waarden van de configuratietemperatuur  $T_{4D}$  voor het  $4D$  multiplet met  $T_i$  en  $T_n$  in Fig.12 van <sup>(2)</sup> leidt tot de konklusie dat niet altijd aan uitdrukking (2), waarin  $T_{4p}$  is vervangen door  $T_{4D}$ , is voldaan.

In <sup>(4)</sup> is besproken dat de hellingen voor de 4p groep als geheel voor magneetvelden groter dan  $3 \times 10^{-2} T$  in redelijke overeenstemming zijn met hellingen die berekend kunnen worden uit de Coronaformules voor

stapsgewijze aanslag, zoals weergegeven in uitdrukking (7) van (3). Berekningen met de theorie van Racah en Edmonds<sup>(4)</sup> laten zien dat de relatief grote hellingen van de multiplets te begrijpen zijn, indien de bezettingen van de tussenniveaus bij 16 à 17 eV geen al te grote onderlinge verschillen vertonen.

Op grond van bovenstaande beschouwingen kunnen we de veronderstelling van thermalisatie door neutrale deeltjes of ionen binnen een bepaalde groep of multiplet van het spektrum verwerpen en aannemen dat de ligging der punten in de betreffende figuren bepaald wordt door het evenwicht tussen de vorming van aangeslagen deeltjes door een aantal botsingsprocessen en de verdwijning ervan door spontane emissie. Voor grote magneetvelden kan dit evenwicht met enige verwaarlozing weergegeven worden door de vergelijking

$$n_e \sum A_{32m} = n_e^3 \{ \sum_i \langle \sigma v_e \rangle_{II}^i (\sum \langle \sigma v_e \rangle_{I}^i / \sum A_{2i1}) \}, \quad (3)$$

waarin de indices 1, 2 en 3 respectievelijk één van beide grondniveaus, een tussenniveau en een 4 p niveau aanduiden.  $\langle \sigma v_e \rangle$  in een integratie over het produkt van elektronenenergieverdeling en werkzame doorsnede,  $I$  voor de eerste en  $II$  voor de tweede stap.

Eén van de doeleinden van dit onderzoek is geweest te komen tot een bepaling van de elektronentemperatuur  $T_e$  uit spektroskopische metingen. De bepaling van  $T_e$  in ontladingen die afwijkingen van L.T.E. vertonen of daar in het geheel niet aan voldoen, is bij aanwezigheid van een magneetveld in het algemeen moeilijk.

De resultaten van sondemetingen kunnen worden verstoord door elektronenemissie van de sonde zelf bij nadering van de plasmapotential als gevolg van verhitting van de sonde door het elektronenbombardement. Bovendien is de theorie betreffende sondemetingen in magneetvelden niet genoeg ontwikkeld om geheel zeker te zijn van een goede interpretatie van de meetresultaten.

Bepalingen uit de elektrische geleidbaarheid  $\sigma$  volgens

$$\sigma = \frac{1.5 \times 10^{-2} \cdot T_e^{3/2}}{\ln(8.25 \times 10^6 \cdot T_e^{3/2} / n_e^{1/2})} \quad (4)$$

vraagt een goede kennis van de stroomdichtheid  $J$ , de longitudinale

elektrische velsterkte  $E_z$  en van de elektronendichtheid  $n_e$ . Bovendien blijkt dat voor onze ontlading de waarden van  $T_e$ , berekend met uitdrukking (4) grote absolute verschillen laten zien ten opzichte van de resultaten van Fig.12 van (4). Bovendien wordt het verloop van  $T_e$  als functie van de magnetische inductie  $B_w$  ook niet goed weergegeven.  $E_z$  is daarbij geschat uit de spanningskarakteristieken van Fig.16 van (4).

Bepaling van  $T_e$  uit de Thomson verstrooiing kan beschouwd worden als de meest universele methode, geldig voor alle gassen onder alle omstandigheden mits de elektronendichtheid groot genoeg is ( $\lambda \cdot 10^{19} \text{m}^{-3}$ ) en de Rayleigh verstrooiing van atomen niet teveel invloed heeft. Het is experimenteel echter een lastige methode, die een lange voorbereidings-tijd vereist. Deze methode kon niet worden toegepast.

Er is daarom gezocht naar een alternatieve methode, die gebruik maakt van absolute lijnintensiteiten, vooral van argon I lijnen. De elektronendichtheid  $n_e$ , de dichtheid van de neutrale deeltjes  $n_a$ , de werkzame doorsnede  $\sigma$  voor aanslag door elektronen en de betreffende overgangswaarschijnlijkheden moeten voor deze methode bekend zijn. Zie uitdrukking (18) van (4). Voor de bepaling van  $T_e$  is de lijn bij  $\lambda = 7384 \text{ \AA}$  uit de 4p groep gekozen, omdat hiervoor de combinatie van overgangswaarschijnlijkheden en werkzame doorsnede het best bekend is. Andere lijnen van de 4p groep geven overeenstemmende informatie. De methode kan fysisch relevante informatie geven als een redelijk deel (meer dan 30%) van de bevolking van het aangeslagen niveau door het betreffende mechanisme, directe aanslag, wordt geleverd. Naarmate de directe aanslag meer domineert neemt de systematische fout af. Een groot voordeel van deze methode is dat elektronentemperaturen reeds bepaald kunnen worden bij een elektronendichtheid van  $\lambda \cdot 5 \times 10^{17} \text{m}^{-3}$ , hetgeen bij Thomson verstrooiing waarschijnlijk met grote onnauwkeurigheden zou samengaan.

De elektronendichtheid  $n_{e,0}$ , bepaald uit de faseverschuiving van microgolven, moet bekend zijn voor de berekening van  $T_e$ . De dichtheidsbepaling is alleen dan redelijk nauwkeurig wanneer de effectieve breedte van de plasmakolom voldoende nauwkeurig bekend is. In uitdrukking (7) van (4) is weergegeven hoe  $n_{e,0}$  op de as berekend kan worden, wanneer een gereduceerd-profiel  $n_{e,r}/n_{e,0}$  bekend is. Deze gereduceerde

profielen zijn berekend uit de intensiteitsprofielen van argon II lijnen <sup>(3)</sup>.

Met het model van stapsgewijze aanslag zijn zowel  $T_{e,r}$  als  $n_{e,r}$  ten opzichte van  $T_{e,o}$  en  $n_{e,o}$  bepaald (uitdrukkingen 9 en 10 van <sup>(3)</sup>). In <sup>(4)</sup> is gevonden dat de stapsgewijze aanslag minder dan 100% van de bevolking van de 4p niveaus levert. Enige korrektheid is daarom nodig. De nauwkeurigheid in de bepaling van de profielen kan hierdoor minder goed worden, inzonderheid die van  $T_e$ . Vergelijking van de resultaten van de drie lijnen met elkaar laat echter zien dat de onnauwkeurigheid minder groot is, dan vermoed zou kunnen worden.

De onnauwkeurigheden in de  $T_e$ - en  $n_e$ -profielen werken slechts in geringe mate door in de absolute waarden van deze grootheden zodat de uiteindelijke resultaten van <sup>(4)</sup> niet worden aangetast door deze systematische fouten in de profielen.

De resultaten voor de  $T_e$ -profielen laten een geleidelijke afname van  $\sim 10\%$  zien in het gebied waar deze profielen redelijk betrouwbaar zijn (zie de figuren 9 en 12 van <sup>(3)</sup>). De  $n_e$ -profielen hebben een halfwaardebreedte van ongeveer 18 en 27 mm voor respectievelijk eindanode en ringanode voor de meeste waarden van de magnetische inductie (zie de figuren 10 en 13 van <sup>(3)</sup>).

Met behulp van de kennis van de gereduceerde dichtheidsprofielen van <sup>(3)</sup>, is de methode om absolute waarden van  $n_e$  te bepalen verder ontwikkeld <sup>(4)</sup>. Om te kunnen corrigeren voor systematische fouten, die ontstaan omdat de mikrogolven in interactie treden met een plakje van het plasma dat inhomogeen is in één richting loodrecht op de voortplantingsrichting van de mikrogolven, zijn twee uiterste benaderingen van "staaf" modellen ingevoerd om de dikte van het plakje te kunnen afschatten en een korrektheid voor  $n_e$  te kunnen aanbrengen. Verder is aandacht geschonken aan eventuele buigingsverschijnselen en aan de eenduidige informatieoverdracht uit één plakje naar de antenne van de mikrogolfopstelling.

Uit de vergelijking van de resultaten voor de elektronentemperaturen bepaald uit de intensiteit van de 7384 Å lijn van argon I en die uit de intensiteiten van een aantal argon II lijnen met behulp van Corona formules (uitdrukking 7 van <sup>(3)</sup>) als functie van het magneetveld kon binnen vrij nauwe grenzen worden vastgelegd dat direkte aanslag voor het argon I

spektrum en stapsgewijze aanslag voor het argon II spektrum dominerend moeten zijn. Bij de vergelijking blijkt dat het produkt  $\langle \sigma v_e \rangle_{II} \langle \sigma v_e \rangle_I$  voor het stapsgewijze proces, afhankelijk van het niveau, ongeveer een faktor 50 tot 120 groter moet zijn dan volgens de Coronaformules wordt gegeven. De zo gevonden waarde blijkt binnen een faktor 3 overeen te stemmen met waarden die Kitaeva e.a. (zie ref. 20 van (4)) hebben berekend.

De percentuele bijdrage van stapsgewijze aanslag als functie van de elektronendichtheid is te vinden in Fig.8 van (4) en een totale balans van bevolking en ontvolking van een 4p niveau voor  $n_e = 2 \times 10^{19} \text{ m}^{-3}$  in Fig.17 van (4). Berekeningen en schattingen, vermeld in (3), zijn hierin verwerkt.

De gevonden resultaten houden in dat de opvattingen over de mechanismen van de laserwerking van de argon ion laser vrij zeker moeten worden herzien. De tot nu toe meest gangbare opvatting dat de direkte aanslag van de grondniveaus van het ion naar de 4p groep het dominerende proces zou zijn, dient vervangen te worden door dat van stapsgewijze aanslag via kortlevende tussengelegen niveaus. Dat deze opvatting ook geldig is voor niveaus met laserwerking, bewijst Fig.7 van (3), waar een vrijwel volledige overeenkomst betreffende het uitgezonden lichtprofiel tussen de 4348 Å lijn (normale lijn) en de 4880 Å lijn (laser lijn) te zien is. De konklusie hieruit is dat de aanslag mechanismen voor beide lijnen dezelfde zijn.

Het feit dat laserwerking geconstateerd is voor gelijksoortige ont-ladingen met gasdrukken  $\geq 10^{-2}$  torr (ref. 25 en 26 uit (4)), welke hoger zijn dan in onze ontlading, kan erop wijzen dat een vorm nodig is, waarin relatief grote elektronendichtheden voorkomen. De aanwezigheid van doorboorde ronde schijven met gaten van 3 tot 6 mm diameter wijst ook in die richting. Dit zou in overeenstemming zijn met onze bevindingen.

Als algemene konklusie mag nog genoemd worden dat het ook in gas-ontladingen en plasma's mogelijk is om dominerende processen te vinden in het te onderzoeken systeem door een optimale variatie van parameters (hier vooral het magneetveld) zonder dat een complete kennis van basisgegevens als overgangswaarschijnlijkheden en werkzame doorsneden voorhanden is en dat het zelfs mogelijk is redelijke schattingen voor een deel van deze gegevens te vinden.

## SAMENVATTING

Voor een holle kathode boogontlading in argon met een lage achtergronddruk en die bijeen gehouden werd door een magneetveld, is een onderzoek verricht naar intensiteiten van lijnen van de argon I en II spektra en naar de stralingsprofielen ervan als functies van de afstand tot de as van de ontlading. De ontladingsstromen varieerden van 10 tot 80 A, de axiale magnetische velden van  $\sim 5 \times 10^{-3}$  tot  $15 \times 10^{-2} T$  en de achtergronddruk was ongeveer  $10^{-3}$  torr.

Het aanslagmechanisme van de 4p groep van het argon II spectrum kon worden vastgesteld; stapsgewijze aanslag van de grondniveaus der ionen via kortlevende tussenliggende niveaus draagt tenminste voor 70% bij in de bezetting van de 4p groep, wanneer de elektronendichtheid  $n_e$  ongeveer  $10^{19} m^{-3}$  bedraagt. Voor aanzienlijke kleinere waarden van  $n_e$  overheerst direkte aanslag vanuit de grondniveaus der ionen. Het is vrijwel zeker dat de laserwerking van de argon ion laser het gevolg is van deze stapsgewijze aanslag.

Het bleek dat "thermalisatie" door ionen of neutrale deeltjes, dit is een herrangschikking van aangeslagen deeltjes tussen de verschillende aanslagniveaus tengevolge van botsingen met zware deeltjes, in de 4p groep niet voorkomt. Voor dit deel van het onderzoek werd een vergelijkende studie van de overgangswaarschijnlijkheden van de 4p groep gemaakt.

De elektronentemperatuur  $T_e$  is bepaald uit absolute lijnintensiteitsmetingen. De waarde van  $T_e$  op een afstand van 0.6 m van de kathode was ongeveer  $35 \times 10^3 K$  voor een plasma met een magnetische inductie  $B_w > 5 \times 10^{-2} T$ . Uit de stralingsprofielen werd  $T_e$  als functie van de afstand tot de as der ontlading bepaald.  $T_e$  daalde ongeveer 10% per 10 mm.

De elektronendichtheden  $n_e$  zijn bepaald uit faseverschuivingsmetingen met mikrogolven. Er werd rekening gehouden met de vorm van het  $n_e$ -profiel en met het niet homogeen zijn van het plakje plasma dat in interactie is met de mikrogolven. De  $n_e$ -waarden op de as waren  $1 \times 10^{19}$  tot  $2 \times 10^{19} m^{-3}$  voor een magnetische inductie  $B_w > 5 \times 10^{-2} T$ . Elektronendichtheidsprofielen werden ook bepaald uit de stralingsprofielen. De halfwaardebreedte van de profielen was ongeveer 18 mm bij gebruik van een anode op 1.2 m afstand van de kathode en ongeveer 27 mm voor een ringvormige anode vlakbij de kathode voor  $B_w > 5 \times 10^{-2} T$ .

## SUMMARY

An investigation was made of intensities of lines of the argon I and II spectra and of the radiation profiles thereof, as functions of the distance to the discharge axis for a hollow cathode low-pressure magnetically-confined argon arc discharge. The discharge currents varied from 10 to 80 A, the axial magnetic fields from  $\sim 5 \times 10^{-3}$  to  $15 \times 10^{-2}$ T, and the background pressure was about  $10^{-3}$  mm of Hg.

The excitation mechanism of the 4p group of the argon II spectrum could be ascertained; stepwise excitation from the ion ground levels through short-lived intermediate levels contributes at least 70% to the 4p group population density for electron densities  $n_e$  of approximately  $10^{19} \text{ m}^{-3}$ . Direct excitation from the ion ground levels is dominant for considerably smaller  $n_e$ -values. It is almost certain that the laser action of the argon ion laser results from this stepwise excitation mechanism.

It was found that thermalization by ions or neutral particles, i.e. a rearrangement of excited particles between the various excitation levels caused by collisions with heavy particles does not occur within the 4p group. For this part of the investigation, a comparative study of the transition probabilities of the 4p group was made.

The electron temperature  $T_e$  was determined from absolute line-intensity measurements. The value of  $T_e$  at a distance of 0.6 m from the cathode was about  $35 \times 10^3 \text{ K}$  for a well-confined plasma with magnetic induction values  $B_w > 5 \times 10^{-2}$ T. From the radiation profiles  $T_e$  as a function of the distance to the axis could be determined. The decrease of  $T_e$  was approximately 10% per 10 mm.

The electron densities  $n_e$  were determined from phase-shift measurements with microwaves. The form of the  $n_e$ -profiles and the non-homogeneity of the slice, interacting with the microwaves were accounted for. The  $n_e$ -values on the axis were  $1 \times 10^{19}$  to  $2 \times 10^{19} \text{ m}^{-3}$  for a magnetic induction  $B_w > 5 \times 10^{-2}$ T. Electron density profiles were also determined from the radiation profiles. The width at half-maximum value of the profiles was about 18 mm when using an anode at 1.2 m from the cathode, and approximately 27 mm for a ring-shaped anode near the cathode, both for  $B_w > 5 \times 10^{-2}$ T.

## CURRICULUM VITAE

geboortedatum en - plaats:

15 mei 1938 te Soest.

middelbare schoolopleiding:

Chr.Lyceum te Dordrecht, 1950-1956.

Gymnasium- $\beta$  diploma in juni 1956.

universitaire opleiding:

Technische Hogeschool te Delft,  
afdeling der Technische Natuurkunde, 1956-1962.

Assistent aan de Hogeschool, 1960-1962.

Diploma natuurkundig ingenieur in oktober 1962.

Het afstudeerwerk werd verricht o.l.v. Prof. dr. M.J.Druyvesteyn  
en betrof een onderzoek naar de ordeningsverschijnselen  
in een goud-zilver legering.

militaire dienst:

Detachering bij de Technisch Fysische Dienst TNO-TH  
en werkzaam voor een departementale  
"Adviescommissie geluidhinder door vliegtuigen", 1962-1964.

dienstverband Technische Hogeschool Eindhoven:

vanaf november 1964 werkzaam als wetenschappelijk medewerker in de  
afdeling der Technische Natuurkunde, groep Atoomfysica.

## DANKBETUIGING

Het schrijven van een dankbetuiging bij de afsluiting van de werkzaamheden voor een promotie is als een ogenblik van reflectie.

Mijn ouders ben ik ervoor erkentelijk dat zij indertijd de keuze van een academische studie hebben gesteund. Dat mijn vader door zijn overlijden deze gebeurtenis niet meer kan meemaken, werpt daarop een schaduw.

Een promotiearbeid, verricht aan een vrij omvangrijke opstelling, is zeker niet een éénmanszaak. Een welgemeend dankwoord aan allen, die op het technische vlak hebben meegewerkt aan de opbouw van de opstelling of aan de uitvoering van de experimenten, is op zijn plaats. Aan W.P. van den Akker en J.J. Bleize, die in de eerste jaren bij de opbouw betrokken waren; aan N. de Jong, in latere jaren werkzaam en aan de huidige "bemanning", A.B.M.Hüsken en L.A.Bisschops.

Vele studenten hebben hun werk verricht aan de opstelling. De laatste generaties hebben direkt tot de resultaten van dit proefschrift kunnen bijdragen. Ik dank ook allen voor hun aandeel, groot of klein.

Een woord van dank aan prof.dr. A.A.Kruithof en de leden van de staf van de groep Atoomfysika. Op verscheidene gebieden is een goede samenwerking geweest. Het onderwerp van dit proefschrift zou een produkt genoemd kunnen worden van de interesse van een gasontladingsgroep die zich met een hooggeïoniseerd plasma bezighoudt.

Mej.M.A. van Basten wilde ik hartelijk danken voor het vele werk dat zij verricht heeft voor het typen van het manuskript en mej. M.C.K. Gruyters voor de goede verzorging van de figuren ervan.

De opofferingen die mijn gezin en in het bijzonder mijn vrouw zich hebben getroost tijdens de voorbereidingen van dit proefschrift, wil ik met dankbaarheid noemen.

Stellingen, behorende bij het proefschrift van B. van der Sijde.  
Eindhoven, 14 december 1971.

1

In een argon plasma met zeer lage gasdruk worden, in tegenstelling met de suggestie van MILLER e.a., de bezettingen van dicht bij elkaar gelegen aangeslagen niveaus in het spektrum van geïoniseerd argon niet beïnvloed door botsingen tussen aangeslagen ionen en neutrale deeltjes of ionen.

R.C. Miller e.a., Bell System. Techn. J. 46, 281 (1967).  
Dit proefschrift, p.33-36.

2

De door McWHIRTER en WILNER beschreven methode om voor een plasma in Corona evenwicht de elektronentemperatuur te bepalen uit een vereenvoudigde balansvergelijking voor een aangeslagen niveau, levert bij toepassing in het argon ion spektrum zeer onnauwkeurige resultaten op.

R.W.P. McWhirter in Plasma Diagnostic Techniques, p. 208-214, Ac. Press, New York (1965)  
B. Wilner, Acta Polytechn. Scand., Physics and Nucleonics 41, 1 (1966).  
Dit proefschrift, p. 93-96 en p.101-104.

3

Het blijkt mogelijk om voor een argon plasma in Corona evenwicht de elektronentemperatuur te bepalen uit een vereenvoudigde balansvergelijking van een aangeslagen niveau van atomair argon, wanneer gebruik gemaakt wordt van de uit de literatuur bekende gegevens omtrent de optredende elementaire processen.

Dit proefschrift, p. 93-96 en p. 101-104.

4

Het is voor een argon boogontlading met holle kathode onmogelijk om uit de relatieve bepaling van twee of meer lijnintensiteiten van het argon ion spektrum een indruk te verkrijgen van de elektronentemperatuur.

C.B. Kretschmer e.a., Phys. Fluids 11, 1050 (1968).  
Dit proefschrift, p. 33 en 36.

5

De door KITAEVA e.a. voorgestelde direkte aanslag vanuit de ion grond-niveaus naar de bovenniveaus van de laserlijnen in het argon ion spektrum ter verklaring van de inversie in het spektrum, dient vervangen te worden door het beeld van stapsgewijze aanslag via kortlevende tussengelegen niveaus.

V.F. Kitaeva e.a., I.E.E.E.J. Quant. Electr. QE-5, 72 (1969).  
Dit proefschrift, p. 96-104 en p. 110-113.

6

"Partial Local Thermal Equilibrium" en het "Collisional-Radiative Model" zijn twee verschillende benamingen voor één en dezelfde plasmakonditie.

7

Het verdient overweging een onderzoek in te stellen naar de mogelijkheden om luchtverontreinigende moleculen als CO, NO, SO<sub>2</sub> en dergelijke af te breken met een holle kathode ontlading.

8

Het is mogelijk om bij experimenten ter bepaling van de absolute waarde van de totale werkzame doorsnede voor aanslag door elektronen, die uitgevoerd worden met een cilindervormige configuratie, gebruik te maken van een R.P.D. (retarding potential difference) methode.

L. Kerwin e.a., in Case Studies in Atomic Collision Physics I, p. 529-530,  
N.Holland Publ. Cy, Amsterdam (1969).

9

De bewering van DAVIES e.a. dat in een niet-zelfstandige Townsend-ontlading een monochromatische ultra violet bron bij kleine veranderingen van de uittree-energie zorg zou kunnen dragen voor een konstante initiële foto-elektronenstroom, is onjuist.

D.E. Davies e.a., Proc. 4<sup>th</sup> Int. Conf. Ionization Phenomena in Gases, p. 161, Uppsala (1959).

10

De meting van de totale doorsnede van meeratomige molekulen bij botsingen met atomen levert geen uitsluitsel over de anisotropie van de wisselwerkingspotentiaal van deze molekulen.

11

Het verdient aanbeveling om ter bescherming van jonge kinderen in het verkeer de voorrangssituatie tussen overstekende voetgangers en rijdend verkeer te wijzigen in die straten van de bebouwde kom, die voor het doorgaande verkeer van weinig of geen belang zijn.

12

De bestaande direkte en indirecte subsidiëringen als premiereregelingen en aftrekbaarheid van de renten van hypotheekleningen bij de inkomstenbelasting, welke bestaan voor huur- en koophuizen, staan een evenwichtig subsidiebeleid gebaseerd op de inkomensverdeling in de weg.

13

Ieder programma in het kader van ontwikkelingshulp dient vergezeld te gaan van een programma ter stimulering van de geboortebeperving.

14

De op de T.H.E. gevolgde verkiezingsprocedure voor Hogeschoolraad en afdelingsraden dient aangemerkt te worden als nodeloos ingewikkeld; een systeem waarbij elke kiezer evenveel stemmen uitbrengt als voor zijn geleding zetels ter beschikking zijn en degenen met de meeste stemmen verkozen worden verklaard, verdient de voorkeur.

15

Een goede discussie over de toelaatbaarheid van de aanleg van de start- en landingsbaan 04-22 op het vliegveld Welschap bij Eindhoven uit het oogpunt van lawaai-overlast, wordt niet bevorderd door aanvechtbare prognoses omtrent het aantal en de soort vliegtuigbewegingen van de "Stichting Vliegveld Welschap" enerzijds, en een aantal diskutabele beweringen in de rapporten van de "Werkgroep tegen Geluidshinder door Vliegtuigen" anderzijds.

Rapport Technisch Fysische Dienst TNO-TH nr. 018-213.

Enige rapporten van de "Werkgroep geluidshinder door Vliegtuigen", januari-juli 1971.
