SUMMARY

In this report the measurements are described, which have been performed on the WEU 1/3 windmill. They concern the 10 minutes mean measurements only.

All measurements are processed via a so-called bin method. This method showed to be very attractive for output measurements.

Although the windmill showed some defects (leaking pump) an overall power coefficient of the system was reached of 0.32 at a design wind speed of about 3 m/s.

ACKNOWLEDGEMENTS

The authors would like to thank A. Prijt for his technical advices and his assistance.

1 INTRODUCTION

In 1979 an apparatus was developed and built by two students of a Technical College [1] to measure, to store and to process the data measured from a (water pumping) wind mill.

This apparatus was built according to the requirements given by the Wind Energy Group, which was in need of such an apparatus to do field measurements.

In the summer and autumn of 1981 this system was used for performance measurements on the WEU I/3 wind mill.

In the beginning, the sample period of the measurements was one hour; later this was decreased to ten minutes. Only the ten minute measurements are reported here.

2 WIND MILL MEASURING EQUIPMENT AND REGISTRATION

2.1. The WEU 1/3 wind mill in Eindhoven

In the autumn of 1979 the WEU 1/2 wind mill which had been developed in the Sri Lanka project was built at the testfield of Eindhoven. In a cooperative effort between SWD and WEU this wind mill was modified in the summer of 1980. The result was the so-called WEU 1/3 wind mill [2]. The wind mill consists of a 3.05 m diameter rotor directly coupled to a pistonpump via an adjustable crank. During our measurements this crank diameter was not changed. The pistonpump used in Eindhoven is still the pistonpump as described in [2] (this was based on the WMP 1/2 pump, also developed in Sri Lanka). Differences with the pump in Sri Lanka are the airchambers which are inside the pump instead of outside and the pistondiameter, also with the revision of the windmill an iron pumprod was used instead of a PVC ons. In Eindhoven it was necessary to make a sealing at the top of the pumprod because a pressure simulation was built instead of a well. An overview is shown in Figure 1.

Figure 1: The pressure simulation for the WEU wind mill

2.2. Sensors and registration

As explained in the introduction an apparatus was developed in view of performing fieldmeasurements. The requirements for this instrument were:

1. to be used for different measuring times
 - rotor diameters
 - air densities
 - water delivery heights
2. possibility to use several anemometers
3. clear output on paper, which contains:
 - sample time
 - the different input values
 - quantities as mean power, mean windspeed etc.
4. complete automatic system
5. simple operation
6. portable.

One can meet these requirements by using two separate parts, a measuring part and a data processing part. The measuring part measures the different values, while the processing part calculates values as mean power etc. (with aid of the input values of rotor diameters, air density etc.). This last unit was never used because it was not available in time. This turned out to be advantageous as the input data -which had to be typed for processing by the micro computer- were less in number.

It was decided that four input channels were necessary: three digital channels and one analogue channel.

The three digital channels receive pulses from read-switches or opto couplers (light emitting diode and light sensor) and these pulses must be summed during the measuring period.

The analogue channel averages a signal from a potentiometer; this is done by a so-called voltage regulated oscillator, in such a way, that one degree yawing angle gives one pulse per second (two degrees yawing angle gives 2 pulses per second etc.). It should be noted, that with the existing set-up no difference was made between positive and negative yawing angles.

The four signals measured are:

1. number of revolutions of the rotoraxis (by means of a opto-coupler)
resolution: 1 pulse/revolution
2. number of litres water pumped by the wind mill (by means of a read-switch)
resolution: 1 pulse/litre
3. windrun (by means of a read-switch)
resolution: 1 pulse/100 m wind
4. yaw angle (by means of a potentiometer)
resolution: 1 pulse/(per degree yawing angle * second)

A detailed description of the different sensors can be found in Appendix A. Because the process unit was not used, only the values of the four channels were printed. An example of four measurements is listed in Figure 2.

In this figure the word "TEL" is an abbreviation of the Dutch word "teller", which is equivalent to the English word "counter".

Figure 2: An example of the output of the registration unit

The four values display the following:

counter 1: windrun

counter 2: number of revolutions

counter 3: number of litres water

counter 4: yaw angle

All measurements are averages over ten minutes periods.

3 DATA PROCESSING AND RESULTS

3.1. Data processing

The four numbers per measurements as shown in Figure 2 are stored on a cassette tape with the aid of a PET micro processor. With this same processor alle measurements are processed into values which describe the performance of a wind mill.

In total 1449 ten minutes measurements are processed.

Per measurement the following sequence of processing was done:

1. See if one of the four counters shows a zero value.

This will be the case, if for example the wind speed is zero or when the wind mill does not turn. Also a defect in one of the sensors can cause such a value.

If one of the four numbers is zero, the measurement is ignored. This is necessary, because otherwise the processor has to divide by zero, which gives an "error" message and stops the processing.

2. If the measurement is accepted, the following quantities are calculated:

$$V = C_1 * 100 / (T * 60)$$

$$P_{\text{wind}} = 1/2 \rho V^3 \pi R^2$$

$$P_{\text{water}} = H g C_3 / (T * 60)$$

$$\eta_{\text{vol}} = C_3 / (C_2 * \text{Vol})$$

$$C_p \eta = P_{\text{water}} / P_{\text{wind}}$$

$$\lambda = 2 \pi R C_2 / (C_1 * 100)$$

$$\delta = C_4 / (T * 60)$$

$$n = C_2 / (T * 60)$$

$$Q = C_3$$

The symbols are used for:

V	: wind speed (m/s)
P_{wind}	: power in the wind (W)
P_{water}	: theoretical power to lift an amount of water Q in a period T over a head H
η_{vol}	: volumetric efficiency
$C_p \eta$: overall power coefficient
λ	: tip speed ratio
δ	: angle of yaw
n	: number of revolutions per second (1/s)
Q	: quantity of pumped water (m^3)
ρ	: density of the air (kg/m^3)
H	: delivery height (m)
R	: rotor radius (m)
T	: measuring time (minutes)
Vol	: pump volume (litres)
C_1-C_4	: numerical values of counter 1-4

It will be clear, that the calculated values are averaged over the measuring period (here: ten minutes).

3. Now a check is made, if the measured values are reliable by checking the following conditions:

1. $C_p \eta < 0.4$ (see explanation section 3.2.)
2. $C_3 < 0.6 C_2$

If a measurement does not comply with one of the conditions then the measurement was ignored.

4. Now all data are stored in bins. Each bin is characterised by a wind speed interval. This way of data handling is described in [3].

5. Per bin the mean value and the standard deviation within the bin is calculated and printed.

An example of such a calculation is shown in Appendix B. The computer programme is given in Appendix C.

The result of all measurements are given in table 1 - 9 and figure 3 - 10. Each processed quantity is stored in its appropriate bin (bin i) characterised by the corresponding wind speed interval ($\frac{i-1}{2}$ m/s and $i/2$ m/s) in which it was measured. In this way distributions are obtained for the wind speed, power in the wind, power in the water, volumetric efficiency, overall power coefficient, tipspeed ratio, yaw angle, revolutions per second and the number of litres water pumped.

In the following tables the Dutch words "KLASSE, X-GEM., ST.DEV. and AANT." mean respectively bin number, mean value within the bin, standard deviation and the number of measurements belonging to the specific bin.

3.2. First order trouble shooting

Before we will discuss the previously shown measurements we first will mention some items, which have influenced the reliability of the measurements.

1. In dismantling the pump for the winter it appeared, that the rubber disk of the foot valve was worn out. This explains why the pump was leaking when the mill was standing still. This was seen on the pressure indicator gradually dropping to zero.
2. Because the pump was leaking, the delivery height was less than the presetted delivery height of 15 m. In performing the calculations however a constant delivery height of 15 m was assumed. Especially when the wind speed is low, this effect is important and leads to an over estimate of the $C_p \eta$ values. For this reason all measured $C_p \eta > 0.4$ (see 3.1.) were objected.
3. At high wind speeds, the pressure indicator was oscillating between 12 and 17 m of water. To avoid this in future, the pressure indicator should be placed on the pressure vessel instead of close to the pump. Also a gauge-glass on the vessel will be very useful (see Figure 1).
4. The meter was full of organic compounds (leaves etc.) which causes extra resistance of the pipe line. This can be avoided by putting a filter just before the watermeter. It must be possible to clean this filter easily.
5. The wind speed indicator gave few counts resulting in a high inaccuracy at low wind speeds. Another wind speed meter (for example a "Maximum" anemometer) will solve this.
6. At low rpm of the wind mill, the water was going to and fro in the pipes. This caused extra pulses recorded by the water meter each time the small magnet passes the read-switch. This can probably be avoided by putting the water meter down-stream of the pressure vessel.
7. Too few measurements were performed, especially at high wind speeds. This will cause high inaccuracy for these high wind classes.
8. By ignoring the high C_p values as well as the low values it is doubtful wether the resulting values are correct. To ignore the high C_p values can be correct but to ignore the low values (zero values) is not always correct. The difference in number of measurements between all measured periods and the "reliable" periods is shown in Figure 11.

Figure 11: The difference between the number of all measurements and the selected measurements

4 DISCUSSION

4.1. Theoretical model and comparison with the measurements

Before we will discuss the results of the measurements we first will derive a theoretical curve, with which we can compare the measured values.

In fact there are two ways of predicting the power versus wind speed curve (which is the most important curve).

1. Based on the theory as described in [4] and [5]. In this model the $C_p-\lambda$ curve is described by a quadratic curve and the pump as a constant torque load.
2. Combining a -in the wind tunnel- measured $C_p-\lambda$ curve of a rotor with the rps-wind speed curve and assuming a constant η -value equal to 0.75 (generally accepted value for pump efficiency).

Starting with the first possibility we find in [5] that we need the following quantities: design wind speed (V_D), the ratio lambda maximal, lambda optimal (L), the maximal total energy efficiency ($(C_p \eta)_{\max}$) and the sweptarea of the rotor (A). The value of the design wind speed V_D can be found as described in [6]. This gives for this design wind speed 4 m/s (for detailed values see Appendix D). The value of L is 1.8 and for $(C_p \eta)_{\max} = 0.24$ (see Figure 13). These two values can be found in [7]. Although [7] refers to the THE I/2 rotor, it is assumed that the WEU I/3 rotor has the same characteristics. For the pump efficiency a value of 0.75 is taken, which is a generally accepted value. The following formula, which describes the output curve, can be derived.

$$P = \left\{ L \frac{V_D^2}{V} - (L-1) \left(\frac{V_D}{V} \right)^4 \right\} 1/2 \rho V_D^3 A (C_p \eta)_{\max}$$

Writing this as a dimensionless formula and complete it with the specific values give

$$C_p = 0.24 \left\{ 1.8 \left(\frac{4}{V} \right)^2 - 0.8 \left(\frac{4}{V} \right)^4 \right\}$$

This formula is drawn in Figure 12 (curve I). Also the curve is drawn with a design speed of 3 m/s and a $(C_p \eta)_{\max}$ of 0.30, which corresponds more to the measured results (curve II).

Another possibility to derive a C_p - V curve is with aid of the C_p - λ curve (from [7]) and figure 9. We suppose here that the pump has a constant efficiency of 75%. In figure 13 the C_p - λ curve is shown as presented in [7].

Curve III plotted in Figure 12 is the result of the derivation. The deflection of the line for wind speeds higher than 5 m/s is the result of the safety system. When the wind speed is higher than 5 to 6 m/s the rotor is turned out of the wind.

For a rotor in yaw the C_p value will be less than the value for which the rotor is perpendicular to the wind. The theoretical curve III in Figure 12 is based on the C_p - λ curve without yaw, so the C_p values are too high. In Figure 12 we can also draw the measured C_p - V curve; this gives curve IV.

We see now that the measured curve fits fairly well with curve II and curve III, and curve III fits fairly well with curve II, at least at low wind speeds.

An important question is now, how it is possible, that curve I, the curve based on a design speed of 4 m/s does not fit at all to the measured curve.

First of all we must have a look at Figure 5. There we see, that the volumetric efficiency is 60% - 55%. This is quite low, compared to values of 80% - 90% which are usually accepted. One of the explanations can be the leaking piston and foot valve. If we also accept then that the energetic efficiency will be 60% - 55%, then we find for the design wind speed 3 instead of 4 m/s. We can explain this as follows.

The low volumetric efficiency can be regarded as a 60% smaller stroke. The formula for the design speed contains the stroke to the power of one half

$$V_D \sim (s)^{1/2}$$

Because the root of 0.60 is about 0.8 this gives for V_D 3 instead of 4 m/s. It is very remarkable that from Figure 13 and Figure 9 also follows a design speed of about 3 m/s.

Figure 12: The theoretical and measured curves for the output of the wind mill

Figure 13: The c_p - λ curve for the THE 1/2 wind mill. It is supposed, that the WEU 1/3 rotor has the same characteristics

4.2. Final remarks

As conclusion for the measurements as presented in this report we remark the following:

- The measuring method gives a good idea of the output of the wind mill. Typing the output ($C_1 - C_4$) for processing is however time consuming.
- In future one should consider the remarks of section 3.2. Especially the points 2, 3, 5 and 6 need attention.
- From Figure 12 it can be seen, that the measured curve can be predicted reasonably.
- One has to check in advance, whether the whole wind mill is in good condition (see point 1, section 3.2.).
- The whole wind mill system has a good efficiency when the wind speed is equal to the design wind speed ($C_p \eta = 0.32!$).
- It is desirable that attention is paid to the fact, that measuring devices must be fastened to a prototype before the windmill is erected on the field.

APPENDIX A

1. rpm measurements

On the axis of the WEU I/3 wind mill a disk was fastened with one slit on the circumference. This slit is situated in such a manner, that when the crank is in the highest position, the slit passes the opto-coupler*. Each time the slit passes this sensor the light falls on the cell and a pulse signal is generated. These pulses are counted in an electronic circuit which is situated in the central apparatus.

2. water quantity measurements

These measurements are done with a commercial waterflow meter. In this flow meter a read-switch is mounted on a dial, so with every litre of pumped water one contact is made. A bounce-free circuit was made and fed from the central apparatus.

The make of the water meter was: Pollux SPX.

The type number was M-N 20 (x) ZK-1.

3. wind run measurements

For these measurements a Casella cup anemometer is used. The internal gearing is such, that per 100 meter wind which passes the anemometer one pulse is given by a read-switch. The signals are counted in the central apparatus in the same way as the pulses of the water meter.

The make and type of the anemometer were: Casella; W 1254/2.

4. Measurement of the yaw angle

These measurements are done with a wind vane that was mounted on the head of the wind mill. A potentiometer which was fed from the central apparatus gave a signal varying from zero to twelve volts. When the rotor was perpendicular to the wind, the potentiometer gave six volts.

* This position is chosen to avoid double counting when the wind mill oscillates around the bottom dead point.

A voltage controlled oscillator changed this signal into a number of counts. This was done in the following way:

each second a sample was taken from the potentiometer. This sample was translated into a number of pulses and summed in the according memory. The number of pulses generated when the wind mill was yawed 10 degrees to the wind is 10 pulses each second. The conformity of yaw angle and number of pulses generated is shown in Figure 14.

Figure 14: The conformity of voltage (as yaw angle) and the number of generated pulses

APPENDIX B

Example of calculations belonging to measurements of ten minutes.

$$T_1 = 13 \quad \rho = 1.25 \text{ kg/m}^3 \quad g = 9.81$$

$$T_2 = 145 \quad \text{Vol} = 0.59229 \text{ l}$$

$$T_3 = 62 \quad H = 15 \text{ m}$$

$$T_4 = 8976 \quad R = 1.525 \text{ m}$$

$$V = 13 * 100 / (10 * 60) = 2.17 \text{ m/s}$$

$$P_{\text{wind}} = 1/2 * 1.25 * (2.17)^3 * \pi * (1.525)^2 = 46.45 \text{ W}$$

$$P_{\text{water}} = 15 * 62 * 9.81 / (10 * 60) = 15.21 \text{ W}$$

$$\eta_{\text{vol}} = 62 / (145 * .59229) = .72$$

$$C_p \eta = 15.21 / 46.45 = .33$$

$$\lambda = 2 * \pi * 145 * 1.525 / (100 * 12) = 1.07$$

$$\delta = 8976 / (10 * 60) = 14.96^\circ$$

$$n = 145 / (10 * 60) = 0.24 \text{ s}^{-1}$$

$$Q = 62 \text{ l}$$

Further for each value the squared value was calculated.

This was done to calculate the standard deviation with the formula

$$\sigma = \frac{\overline{X^2} - \frac{\sum_{i=1}^N X_i^2}{N}}{N}$$

Before summing a measurement into the corresponding bin, one can check if the values are acceptable. For our measurements all measurements with a overall power coefficient above 40% were omitted as well as measurements with a volumetric efficiency higher than 100%. Now the bin number was chosen according to the wind speed. In this case is the fifth bin C, 0-0.99 m/s-, 1st bin; 0.5-0.999-, 2nd bin, etc.). Now each value was summed in its according bin and also the total numbers which are summed are put in a bin.

If all measurements are processed on this way the mean values of each bin, and the standard deviation, is calculated and printed.

The programme, used for analysing the data.

APPENDIX D

The design wind speed.

From [5] we know that the design wind speed can be determined with the following formula:

$$V_D = \frac{sD^2 \rho_w g H \lambda_o}{4 (C_p \eta)_{\max} \rho \pi R^3}$$

The symbols and their value are:

s	= stroke of the pump	0.57 m
D	= diameter of the pump	0.115 m
ρ_w	= water density	1000 kg/m ³
g	= gravitational acceleration	9.81 m/s ²
H	= delivery height	15 m
λ_o	= optimal lambda value	2
$(C_p \eta)_{\max}$	= maximal energy efficiency	0.24
ρ	= density of the air	1.25 kg/m ³
R	= radius of the rotor	1.525 m

This gives for V_D the value 4 m/s.
