***Please check the document version of this publication:***

- A submitted manuscript is the version of the article upon submission and before peer-review. There can be important differences between the submitted version and the official published version of record. People interested in the research are advised to contact the author for the final version of the publication, or visit the DOI to the publisher's website.
- The final author version and the galley proof are versions of the publication after peer review.
- The final published version features the final layout of the paper including the volume, issue and page numbers.

# Accuracy of compression test on excised specimens.

## Numerical evaluation of cancellous bone elastic behaviour.

M.A.Terlouw, B. van Rietbergen, R.Huiskes

Eindhoven University of Technology, Department of Biomedical Engineering

### Problem

- Strain analysis in bone, is required for evaluation of bone strength and analysis of implants.
- Until recently, a porous composite material like bone could only be analysed using apparent properties.
- These are obtained through experimental testing of excised specimen. This method contains (inherent) errors [1].
  - ▷ unsupported side trabeculae
  - ▷ experimental artefacts
- Recent development of  $\mu$ CT and  $\mu$ FE methods (Fig 1.) enables numerical analysis of real-life bone architecture [2].
- Numerical analysis of excised specimen solves some experimental problems, but creates some others [2].
  - ▷ assumption of Hookean material behaviour
  - ▷ numerical errors
- When whole bone model is subjected to physiological loading, the in-situ strains and stresses can be obtained.

Figure 1 Creation of the  $\mu$ FE model

### Aims

- Numerical quantification of the inherent error in the computed strain, for
  - ▷ a numerical representation of the experimental method.
  - ▷ a numerical uni-axial strain test, in six directions

### Method

- Femur is scanned using  $\mu$ Ct, and the image of the trabecular architecture is converted to a  $\mu$ FE model.
- One healthy and one osteoporotic femur were scanned and digitized (Fig 2).
- In each femurhead, seven VOIS were defined.
- Each VOI consisted of  $100^3$  voxels.
- Three analyses were performed:

Figure 2 Position of the VOIs

### In-situ analysis

- Femur was subjected to physiological forces; local stresses and strains were computed.
- The VOIS were extracted from the deformed geometry.
- For every VOI, computed strains and stresses were averaged.
- The averaged values acted as the 'Gold standard' reference.

### Standard compression test (Uniaxial stress)

- The VOIs were extracted from the unloaded geometry.
- Every extracted VOI was subjected to free compressions in three directions.
- Side surfaces of the specimen were not prescribed.
- Stiffness matrix was computed from stresses and strains.

### Uniaxial strain

- The VOIs were extracted from the unloaded geometry.
- Every extracted VOI was subjected to confined compression in six directions.
- Side surfaces of the specimen were prescribed.
- Stiffness matrix was computed from stresses and strains.

### Quantification of the error

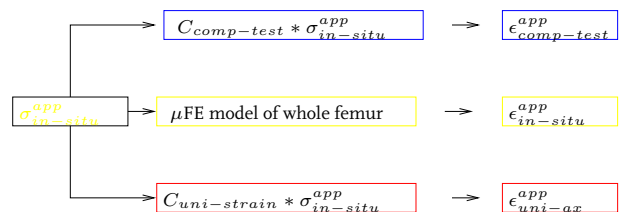

Figure 5 Computational scheme

### Results

Figure 4 Correlation plot

Correlation of in-situ strain versus comp-test strain (blue) and correlation of in-situ strain versus uni-axial (red)

### Discussion

- Both methods give a good result
- Compressive forces have absolute error of 10%
- Six compressions gives relative error of 1%
