This paper presents a complete analytical framework for obtaining the performance associated with a free-space optical (FSO) communication system with a spatial diversity and equal gain-combining technique. The system is affected by gamma–gamma scintillations with different realistic degrees of channel correlation depending only on the physical parameters of the link. We derive new analytical closed-form expressions for the average bit error rate (ABER) considering different scenarios to provide very realistic behavior of the system including different numbers of FSO receivers in several geometric configurations, with different receiving areas, different path lengths, and a variety of turbulence conditions. Furthermore, a very accurate approximate closed-form expression is also derived for the ABER of any generic coding scheme with either a very complex or, directly, no closed-form expression for its associated conditional BER that is first obtained in the ideal case of absence of turbulence. Numerical results via Monte Carlo simulation are provided to corroborate the validity of all the derived analytical expressions.  © 2022 Optica Publishing Group

## 1. INTRODUCTION

Free-space optical (FSO) communications have been studied as a competitive solution for the establishment of wireless point-to-point links. This technology has become an attractive cost-effective solution to provide highly secure and broadband transmissions in areas where fiber infrastructure is deficient or nonexistent [1–6]. In this respect, FSO communications benefit from inherent huge unregulated bandwidth availability in optical frequencies, supporting the increasing traffic demand required by today's society. However, these systems can be affected by atmospheric turbulence, characterized by a random space–time redistribution of the refractive index, and causing a variety of adverse effects on the propagating optical wave in regard to temporal irradiance fluctuations, commonly described as scintillation [7]. That scintillation produces turbulence-induced fading in the received signal intensity, leading to degradation of overall system performance.

An appropriate solution to mitigate its degrading effects is to employ a spatial diversity reception [8–12]. In this technique, by using $N$ apertures at the receiver side, the inherent redundancy of spatial diversity has the potential to significantly enhance the performance of FSO communication systems.

A way to evaluate that performance is via knowledge of the analytical expression for the probability density function (pdf) of the sum of correlated irradiances seen at the receiver side. Thus, in [11], the authors proposed an analytical approach for the correlated gamma–gamma fading channel based on an $\alpha - \mu$ distribution. However, its parameters depend on nonlinear functions requiring numerical methods to be solved. To overcome that issue, Djordjevic *et al.* [12] calculated the multivariate constant correlated gamma–gamma distribution assuming that the correlation among small-scale turbulence eddies is neglected. The result is a pdf involving an infinite summation that may complicate the evaluation of further analytical expressions associated with the performance of the FSO system. Hence, in [13], new analytical closed-form expressions were derived for the pdf of the sum of identically distributed correlated gamma–gamma random variables leading to a mathematically tractable method to characterize the statistical behavior of the received optical irradiance in a spatial diversity context. To this aim, and to achieve compact expressions, it was assumed that the signals reaching the $N$ receivers are deflected by the same eddies and, therefore, large-scale effects are common for all of them. Accordingly, the existence of a

certain degree of correlation between any pair of optical signals on the receiver side is owed only to their associated small-scale scintillations. This feature is studied in this paper, evaluating its impact on overall system performance. To include realistic scenarios, the correlation factor is written in terms of the spatial coherence radius, and so, all results depend only on the physical parameters of the link. Furthermore, various physical receiver topologies are considered, analyzing their performance in terms of error probability and for different turbulence conditions. Thus, closed expressions are proposed for the average bit error rate (ABER) as a function of the channel coding scheme, the channel conditions, and the level of correlation between detected signals. First, the on–off keying (OOK) case is analyzed for its simplicity and ease of implementation, to later compare its performance with the one obtained from the variable weight multiple pulse-position modulation (vw-MPPM) scheme, successfully proposed by the authors in indoor [14] and outdoor [15] wireless communications. The latter scheme was chosen as an illustrative example of any generic nonlinear block coding transmission technique whose conditional BER (CBER) cannot be derived in a closed-form expression. As a previous step, the hyperexponential curve fitting method presented in [16] is adopted to obtain a very accurate analytical expression for the ABER associated with the vw-MPPM technique. Finally, all analytical results derived here were numerically validated by Monte Carlo simulations.

It is worth mentioning that a terrestrial FSO link that consists of a single-mode semiconductor laser as the transmitter and $N$ photodetectors as the receiver is considered, assuming an intensity modulation with direct detection (IM/DD) scheme and an equal gain-combining (EGC) technique. Point receivers are supposed for which maximum adverse effects are observed.

## 2. SPATIAL DIVERSITY RECEPTION

Intensity fluctuations in the received signal due to channel fading induced by atmospheric turbulence can result in considerable degradation of system performance. Spatial diversity techniques provide an attractive alternative approach for fading compensation with their inherent redundancy. This technology can be used over FSO links, which implies the deployment of multiple small aperture laser transmitters and receivers. To extract the maximum benefit from the spatial diversity technique, the spacing between receivers should be greater than the fading correlation length, which may be difficult to achieve in practice due to the limited available physical space or because the receiver spacing required for uncorrelated fading may exceed the beam diameter in power-limited links with well-collimated beams. In fact, the degree of correlation among FSO receivers proved to be one of the main performance limiting factors of the system. Therefore, we consider in this work how correlation among the different atmospheric scintillation sequences captured by each photodetector affects the overall performance when they are forming several geometric configurations inside the same magnitude of total receiving area.

**Fig. 1.** SIMO model for FSO systems with a laser transmitter and $N$ optical receivers. The model is representative to evaluate the impact of spatial correlation between scintillation sequences.

### A. System Model

Figure 1 describes our single-input–multiple-output (SIMO) system model with spatial diversity reception considering $N$ identical photodetectors and the IM/DD technique. Thus, assuming EGC, the received optical irradiance, $I$, can be expressed as a sum of each individual $i$th received irradiance by every single receiver aperture, which is a random variable with gamma–gamma distribution. This variable is the result of a modulation process that can be written as $I_i = X_i Y_i$, where $X_i$ and $Y_i$ are random variables of large-scale and small-scale scintillation components, respectively, corresponding to each photodetector.

It is assumed that the same large eddies affect the signal received by the $N$ receiver apertures (see Appendix A for a complete discussion on this assumption). Hence, the large-scale scintillation component is a common contribution for all of them, i.e., $X_i = X$, $\forall I = 1, \dots, N$, with $X$ following a gamma distribution with shape parameters $\alpha_x$ and $\beta_x = 1/\alpha_x$, denoted as $\mathcal{G}(\alpha_x, 1/\alpha_x)$. Note that with this assumption, we consider the most unfavorable scenario for large-scale correlation, useful as a benchmark in optical systems design. In contrast, the diffractive small-scale turbulence effect $Y_i$ depends on each aperture, although it is assumed that each $Y_i$ is identically gamma distributed and characterized by $\alpha_{Y_i} = \alpha$ and $\beta_{Y_i} = 1/(N\alpha)$; thus $Y_i$ is denoted as $\mathcal{G}(\alpha, 1/(N\alpha))$, as detailed in [13].

Note that $\alpha_x$ and $\alpha$ are related to the effective number of large-scale and small-scale turbulent cells, respectively, and their ranges vary from values very close to one, for strong turbulence conditions, to values $\gg 1$, for weak turbulence regimes [7]. As normalized irradiance is considered, $E[I] = 1$, then

$$I = X \sum_{i=1}^{N} Y_i = XV, \tag{1}$$

where $V = \sum_{i=1}^{N} Y_i$, with $V$ being a random variable describing the small-scale atmospheric effect over the combined received optical irradiance. When taking into account the correlation factor between any pair of received small-scale sequences, i.e., the correlation between variables $Y_i$ and $Y_j$, with $i, j = 1, \dots, N$, we can build the corresponding real symmetric $N \times N$ correlation matrix, $\mathbf{C_y}$, given as

$$\mathbf{C_y} = \begin{pmatrix} 1 & p_{12} & \cdots & p_{1N} \\ p_{21} & 1 & \cdots & p_{2N} \\ \vdots & \vdots & \ddots & \vdots \\ p_{N1} & p_{N2} & \cdots & 1 \end{pmatrix}_{N \times N}, \tag{2}$$
**Fig. 2.** (a) Constant, (b) exponential, and (c) star correlation models used for the simulations carried out.

with $p_{ij}$ being the cross-correlation coefficient associated with the distance between receivers at positions $i$ and $j$, respectively. Futher details can be found in [13].

## B. Receiver Distribution Topologies

The space distribution of receivers determines a particular geometry that may affect the performance of the system. Namely, we focus on three different spatial geometries of receivers, as depicted in Fig. 2: constant, exponential, and star topologies.

The first one is the constant correlation model, described in [17], and associated with a configuration of evenly spaced receivers where $p_{ij} = p$, $\forall i, j = 1, \ldots, N$, with $p$ representing the correlation coefficient between the gamma distributed signals received at adjacent photodetectors. Its most representative example corresponds to three receivers, $N = 3$, placed in an equilateral triangle, whose associated correlation matrix is described as

$$\mathbf{C_y} = \begin{pmatrix} 1 & p & p \\ p & 1 & p \\ p & p & 1 \end{pmatrix}_{3 \times 3}. \tag{3}$$

On the other side, the second considered geometry, the exponential correlation model, corresponds to a linear equidistant photodetector array [17], with the following correlation matrix:

$$\mathbf{C_y} = \begin{pmatrix} 1 & p_1 & p_2 & p_3 & \cdots & p_N \\ p_1 & 1 & p_1 & p_2 & \cdots & p_{N-1} \\ p_2 & p_1 & 1 & p_1 & \cdots & p_{N-2} \\ \cdots & \cdots & \cdots & \cdots & \cdots & \cdots \\ p_N & p_{N-1} & p_{N-2} & p_{N-3} & \cdots & 1 \end{pmatrix}_{N \times N}. \tag{4}$$

Finally, we also consider a model of $N = 4$ receivers placed in what we call a star topology due to its physical shape, resembling a star [18,19], where there is a central photodetector surrounded by three others forming an angle of $120°$ between them with regard to the central photodetector. Its associated matrix is given by

$$\mathbf{C_y} = \begin{pmatrix} 1 & p_1 & p_2 & p_2 \\ p_1 & 1 & p_1 & p_1 \\ p_2 & p_1 & 1 & p_2 \\ p_2 & p_1 & p_2 & 1 \end{pmatrix}_{4 \times 4}, \tag{5}$$

where correlation factors $p_1$ and $p_2$ are associated with separation distances $d$ and $\sqrt{3}d$, respectively, between adjacent photodetectors, as shown in Fig. 2(c) after using the law of sines.

## C. Correlated Channels

As detailed in previous sections, the correlation matrix describes the degree of dependence among channels in reception, which is defined in a straightforward manner by the correlation coefficient. From Eq. (1), such a correlation coefficient is obtained from the small-scale scintillation component since the large-scale scintillation component is a common contribution for all of the $N$ receiver apertures.

Let us define now the correlation length $\rho_c$ of irradiance fluctuations as the width of the irradiance covariance function at $1/e^2$ of its peak value. In other words, the correlation length describes the average speckle size at the receiver. This parameter is particularly useful in determining the size of the receiver aperture needed to mitigate the effect of atmospheric turbulence, mainly in strong turbulence. Note that $\rho_c$ depends on both the weather and the link distance. For small-scale scintillations [those contributing to the correlation matrix, according to Eq. (1)], and following [20], the correlation length is determined by (1) the Fresnel zone $\sqrt{L/k}$ under weak turbulence, with $k = 2\pi/\lambda$ being the wavenumber of optical radiation, with $\lambda$ being the optical wavelength and $L$ denoting the propagation path length, and (2) by the spatial coherence radius $\rho_0$ (which is now smaller than the Fresnel zone) under strong turbulence. Note that at the onset of strong fluctuations, the coherence radius approaches the size of the Fresnel zone. In this way, when the refractive index structure parameter $C_n^2$ is treated as constant, i.e., a horizontal FSO link, the plane wave spatial coherence radius $\rho_0$ is defined, from [20], as

$$\rho_0 = (1.46 C_n^2 k^2 L)^{-3/5}, \quad l_0 \ll \sqrt{\lambda L} \ll L_0, \tag{6}$$

where $C_n^2$ represents a measure of the strength of the turbulence at each moment, and $L$ is the propagation path length. So, summarizing, in this paper, we consider

$$\rho_c = \begin{cases} \sqrt{L/k}, & \text{weak fluctuations} \\ (1.46 C_n^2 k^2 L)^{-3/5}, & \text{strong fluctuations} \end{cases}. \tag{7}$$

Interestingly, Fig. 3 shows the values of $\rho_0$ for different values of $L$ and for weak ($C_n^2 = 4 \times 10^{-15}$), moderate

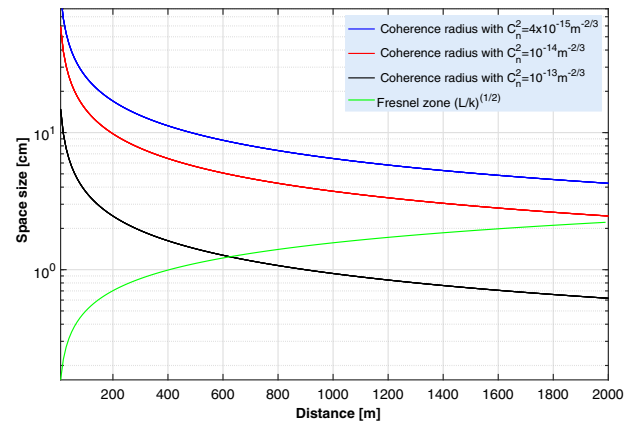

**Fig. 3.** Spatial coherence radius value, $\rho_0$, dependent on the length of the optical channel, $L$, for $C_n^2 = 4 \times 10^{-15}$ (blue line), $C_n^2 = 10^{-14}$ (red line), and $C_n^2 = 10^{-13}$ (black line), related to conditions of weak, moderate, and strong turbulence, respectively.

$(C_n^2 = 10^{-14})$, and strong $(C_n^2 = 10^{-13})$ turbulence conditions, assuming a wavelength of $\lambda = 1550$ nm. The performance of $\sqrt{L/k}$ is also provided. From Fig. 3, we can observe that the stronger the intensity of turbulence, the lower the correlation factor among channels when short link distances are considered. In this respect, separations between receivers of solely a few centimeters are sufficient enough to have totally independent channels. On the contrary, when turbulence strength decreases, either photodetectors must be placed farther apart from the others or longer propagation path links are required to obtain the maximum benefit from the spatial diversity technique.

Moreover, and from [21,22], we adopt a more restrictive value for the Fresnel zone size: $\sqrt{\lambda L}$. Hence, and with the aim of obtaining the maximum performance from a spatial diversity technique, the receivers will have to be separated by a distance greater than or equal to $\rho_c$.

Now the aforementioned spatial correlation length given in Eq. (7) can be applied to calculate the cross-correlation coefficients in the correlation matrix by using the covariance function. In [21,23], a Gaussian spatial covariance function for log-amplitude fluctuations is employed that approximates the theoretical one resulting from Rytov theory [22]. This technique is widely used in line-of-sight (LOS) propagation problems because it simplifies the procedure of obtaining both amplitude and phase fluctuations and was extended to any regime of turbulence via the modified Rytov theory [20].

On another note, a useful property in turbulent media is the well-known Taylor's hypothesis of frozen turbulence [22,24]. Under this hypothesis, the collection of atmospheric eddies will remain frozen in relation to one another, while the entire set is transported as a whole along some direction by the wind. When a narrow beam propagating over a long distance is assumed, the refractive index fluctuations along the direction of propagation are well averaged and are weaker than those along the transverse direction to propagation. Hence, based on the Taylor's frozen turbulence hypothesis, spatial statistics can be converted to temporal statistics by knowledge of the average wind speed transverse to the direction of propagation, $u_\perp$ [22,24], Thus by using both the Gaussian spatial covariance function and the space-to-time conversion of statistics provided by the frozen turbulence hypothesis, the covariance function $B_I(\rho, L)$ for the irradiance fluctuations can be written as

$$B_I(u_\perp \tau, L) = B_I(\rho, L) = B_I(d_{ij}, L) = \sigma_I^2 \exp\left(-\frac{d_{ij}^2}{\rho_c^2}\right),$$

(8)

where $d_{ij}$ is the separation distance between positions $i$ and $j$ in the plane of the receiver, perpendicular to the direction of propagation. From Eq. (8), the normalized covariance function is defined as

$$b_I(d_{ij}) = \frac{B_I(d_{ij})}{\sigma_I^2} = \rho_{I_{ij}}.$$

(9)

Thus, we can obtain a normalized correlation matrix for irradiance fluctuations for $N$ receivers in a plane transverse to the direction of propagation of the light beam. Hence,

$$\mathbf{C_I} = \begin{pmatrix} 1 & \rho_{I_{12}} & \cdots & \rho_{I_{1N}} \\ \rho_{I_{21}} & 1 & \cdots & \rho_{I_{2N}} \\ \cdots & \cdots & \cdots & \cdots \\ \rho_{I_{N1}} & \rho_{I_{N2}} & \cdots & 1 \end{pmatrix}_{N \times N}.$$

(10)

To sum up, the correlation coefficient, $\rho_I$, for the irradiance fluctuation that will be valid for any turbulent condition, and will depend on both the separation distance between the $N$ receivers, $d_{ij}$, and on the correlation length $\rho_c$ is

$$\rho_{I_{ij}} = \exp\left(-\frac{d_{ij}^2}{\rho_c^2}\right).$$

(11)

To obtain the corresponding normalized covariance function for small scales, $\mathbf{C_y}$, we must calculate its correlation coefficients, $\rho_{Y_i, Y_j} = p_{i,j}$, following the notation provided in Eqs. (3)–(5). To this aim, we derive the correlation coefficient between $I_i$ and $I_j$, both gamma–gamma random variables, in a straightforward manner due to the independence of the large- and small-scale fading coefficients, and assuming that the correlated random variables in Eq. (1) are combined with the EGC technique. Thus,

$$\rho_{I_{ij}} = \frac{B_{I_i, I_j}(d_{ij}, L)}{\sqrt{\sigma_{I_i}^2 \sigma_{I_j}^2}} = \frac{\rho_{Y_i, Y_j} \alpha_x + \rho_{X_i, X_j} \alpha + \rho_{Y_i, Y_j} \rho_{X_i, X_j}}{\alpha_x + \alpha + 1},$$

(12)

where

$$\rho_{X_{ij}} = \frac{B_{X_i, X_j}(d_{ij}, L)}{\sqrt{\sigma_{X_i}^2 \sigma_{X_j}^2}};$$

(13)

$$\rho_{Y_{ij}} = \frac{B_{Y_i, Y_j}(d_{ij}, L)}{\sqrt{\sigma_{Y_i}^2 \sigma_{Y_j}^2}}.$$

(14)

Since large-scale effects are common for $N$ receivers, i.e., we assume that $X_i = X$, $\forall i = 1, \dots, N$, then $\rho_{X_{ij}} = 1$. Accordingly, as in [11], we can obtain $\rho_{Y_i, Y_j}$ as

$$\rho_{Y_{ij}} = p_{i,j} = \frac{(\alpha_x + \alpha + 1)\rho_{I_{ij}} - \alpha}{\alpha_x + 1},$$

(15)

which now can be inserted into Eq. (2) to finally obtain $\mathbf{C_y}$.

To achieve the maximum benefit of the spatial diversity technique, the correlation coefficient must be close to zero, so the separation distance between receivers must be sufficient to consider channels as independent as possible.

### D. Statistical Distribution of the Received Irradiance *I*

The channel model assumed here is based on the modified Rytov theory, defining the normalized irradiance as a product of two gamma random processes related to large- and small-scale turbulent eddies. Therefore, and from Eq. (1), the irradiance gamma–gamma pdf, $f_I(I)$, assumes that small-scale irradiance fluctuations are modulated by large-scale irradiance fluctuations of the propagating wave. Then, the $V$ pdf can be calculated in the way proposed in [25]. Next, the statistical distribution of the total received irradiance, $I$, can be directly

obtained by averaging the pdf of $V$ over the gamma distribution characterizing the variable $X$, obtaining, as shown in [13], the pdf of the combined received irradiance as

$$f_I(I) = \frac{2}{[\det(\mathbf{A})]^\alpha \Gamma(\alpha_x)} \sum_{i=1}^{N'} \sum_{m=1}^{\alpha_i} \frac{c_{mi}}{\Gamma(m)} \lambda_i^{\frac{m-\alpha_x}{2}} \alpha_x^{\frac{m+\alpha_x}{2}}$$

$$\times I^{N\alpha-1-\frac{m-\alpha_x}{2}} K_{m-\alpha_x}\left(2\sqrt{\frac{\alpha_x I}{\lambda_i}}\right), \qquad (16)$$

where $\{\lambda_i\}_{i=1}^N$ are the eigenvalues of the matrix $\mathbf{A} = DC$, with $\mathbf{D}$ being a $N \times N$ diagonal matrix with entries $\beta$ for $i = 1, \ldots, N$, whereas $\mathbf{C} = \sqrt{\mathbf{C_y}}$ is an $N \times N$ positive definite correlation matrix whose elements are the correlation coefficients of the underlying Gaussian processes that lead to gamma distributed fading, and $\det(\mathbf{A}) = \prod_{i=1}^N \lambda_i$. Furthermore, $\Gamma(\cdot)$ corresponds to the gamma function, $N'$ is the number of the different eigenvalues of matrix $\mathbf{A}$, and $K_\nu(\cdot)$ is the modified Bessel function of the second kind and order $\nu$. On the other hand, parameter $\alpha_i$ is the product of the algebraic multiplicity of the eigenvalue, denoted as $\mu_A(\lambda_i)$, with parameter $\alpha$, i.e., $\alpha_i = \mu_A(\lambda_i) \cdot \alpha$. It is obtained using the partial fraction expansion method described in [26] for performing the conversion from product to summation of fractions that is applied in Eq. (22) in [13] to obtain Eq. (23) in [13]. Finally, $c_{mi}$ is a coefficient depending on $I$ and arising from the partial fraction expansion procedure written as

$$c_{mi} = \frac{1}{(\alpha_i - m)!} \frac{d^{\alpha_i-m}}{dw^{\alpha_i-m}} \left[ \prod_{\substack{j=1 \\ j \neq i}}^{N'} \frac{1}{(w - d_j)^{\alpha_j}} \right]_{w=d_i}$$

$$= \frac{1}{(\alpha_i - m)!} \sum_{\substack{k_1 + \cdots + k_{N'} = \alpha_i - m \\ \hat{i}}} \binom{\alpha_i - m}{k_1 \underset{\hat{i}}{\cdots} k_{N'}}$$

$$\times \prod_{\substack{j=i \\ j \neq i}}^{N'} \left[ (-1)^{k_j} (\alpha_j)_{k_j} (d_i - d_j)^{-\alpha_j - k_j} \right], \qquad (17)$$

where $\hat{i}$ means that $k_i$ is omitted in the previous corresponding sequences. Then $(\alpha_j)_{k_j}$ represents the Pochhammer symbol with $d_i = -I/\lambda_i$; $\alpha_i$ is the product of the algebraic multiplicity of the eigenvalue, denoted as $\mu_A(\lambda_i)$; and the set of $k_i$ coefficients arises from the multinomial theorem.

Two particular scenarios can be considered from Eq. (16). The first one arises when the small-scale scintillation sequences, $Y_i$, are completely uncorrelated, whereas the second one is obtained when those received sequences are totally correlated. For the first scenario, small-scale effects are considered completely independent, and the correlation matrix, $\mathbf{C_y}$, is reduced to a diagonal matrix. For this case, large- and small-scale effects are modeled as $X \sim \mathcal{G}(\alpha_x, \beta_x)$ and $V = \sum_{i=1}^N Y_i \sim \mathcal{G}(N\alpha, 1/(N\alpha))$, respectively. The second scenario consists of receiving $N$ totally correlated small-scale irradiance fluctuations. Hence, $V = \sum_{i=1}^N Y_i \sim \mathcal{G}(\alpha, 1/(\alpha))$. Then, the irradiance pdf follows a classic gamma–gamma distribution [27]. In the next section, some analytical BER

expressions will be derived to characterize system performance under any turbulence regime, any number of photodetectors, any degree of correlation among their received sequences, and any coding technique for the three topologies shown in this section, and representing any possible realistic scenario. Note that in this paper, weather-induced attenuation has not been considered for the sake of clarity. Although that effect also degrades the performance of FSO systems in the way shown in [28], due to its deterministic nature, such atmospheric attenuation acts merely as a scaling factor as indicated in [29].

## 3. AVERAGE BER FOR UNCODING OOK TRANSMISSION SCHEME

BER is one of the most useful figures of merit to assess the performance of any communication link. In this section, we derive the BER expression assuming an IM/DD link using OOK affected by additive white Gaussian noise (AWGN) with zero mean and variance $\sigma_n^2$, owing to the high intensity shot noise produced by ambient light. In the next section, we will generalize this expression to any coded transmission scheme.

As a previous step, the associated CBER is first calculated for a given electrical signal-to-noise ratio (SNR) when analyzing an AWGN channel in the ideal case of absence of turbulence (namely, denoted by $\gamma_0$), assuming each transmitted symbol equally likely to be sent. Furthermore, the instantaneous electrical SNR can be defined as $\text{SNR} = i_S/\sigma_n = \sqrt{\gamma}$, with $i_S = RP_r I$ being the detector signal current, and where $\sigma_n$ designates the root-mean-square (rms) noise current. Accordingly, the electrical SNR in absence of atmospheric fluctuations is henceforth $\text{SNR}_0 = \sqrt{\gamma_0}$, and it is obtained as $i_{S_0}/\sigma_n$, with $i_{S_0} = RP_r$ representing the signal current in the ideal case of absence of turbulence, with $\gamma_0 = \frac{(P_r R)^2}{\sigma_n}$, and consequently, $\gamma = I^2 \gamma_0$. Hence, and from [30], the CBER associated with an IM/DD AWGN channel using OOK is expressed as

$$\text{CBER}(I, \gamma_0) = P_b(e|I) = \frac{1}{2}\text{erfc}\left(\frac{P_r R I}{\sigma_n \sqrt{2}}\right) = \frac{1}{2}\text{erfc}\left(I\sqrt{\frac{\gamma_0}{2}}\right), \qquad (18)$$

where $P_r$ is the average of total received optical power, with $R$ being the responsivity and $\sigma_n^2$ denoting the AWGN variance, whereas $\text{erfc}(\cdot)$ is the complementary error function.

Now, as shown in [30], the ABER, $P_b(e)$, can be obtained by averaging $P_b(e|I)$ given in Eq. (18) over $f_I(I)$ given in Eq. (16):

$$P_b(e) = \int_0^\infty P_b(e|I) f_I(I) \, dI. \qquad (19)$$

To solve Eq. (19), we express both the Bessel function included in Eq. (16), $K_{a-b}(\cdot)$, and the complementary error function from Eq. (18), $\text{erfc}(\cdot)$, as Meijer-G functions using Eqs. (07.34.03.0605.01) and (07.34.03.0619.01) in [31], respectively. Thus,

$$G_{0,2}^{2,0}(z|a, b) = 2z^{\frac{a+b}{2}} K_{a-b}\left(2\sqrt{z}\right); \qquad (20)$$

$$G_{1,2}^{2,0}\left(z \,\middle|\, \begin{matrix} a \\ a - 1, \, a - 1/2 \end{matrix}\right) = \sqrt{\pi} z^{a-1} \text{erfc}(\sqrt{z}). \qquad (21)$$

Now we can solve Eq. (19) by applying Eq. (07.34.21.0013.01) in [31]. Hence,

$$
\begin{aligned}
P_b(e) = &\frac{1}{4\pi^{3/2}[\det(\mathbf{A})]^\alpha \Gamma(\alpha_x)} \sum_{i=1}^{N'} \sum_{m=1}^{\alpha_i} \frac{1}{\Gamma(m)} \frac{\lambda_i^{\frac{m-\alpha_x}{2}} \alpha_x^{\frac{m+\alpha_x}{2}}}{(\alpha_i-m)!} \\
&\times \sum_{\substack{k_1+\cdots+k_{N'}=\alpha_i-m \\ i}} \binom{\alpha_i-m}{k_1 \cdots_i \ k_{N'}} 2^{2N\alpha-m+\alpha_x} \\
&\times 2^{\sum_{\substack{j=1 \\ j\neq i}}^{N'}[-2\alpha_j-2k_j]} \\
&\times \prod_{\substack{j=1 \\ j\neq i}}^{N'} \left[ (-1)^{k_j} (\alpha_j)_{k_j} \left( \frac{-1}{\lambda_i} + \frac{1}{\lambda_j} \right)^{-\alpha_j-k_j} \right] \\
&\times \left( \frac{\alpha_x}{\lambda_i} \right)^{-\left( N\alpha - \frac{m-\alpha_x}{2} + \sum_{\substack{j=i \\ j\neq i}}^{N'} [-\alpha_j-k_j] \right)} \\
&\times G_{5,2}^{2,4} \left( \frac{8\gamma_0 \lambda_i^2}{\alpha_x^2} \middle| \begin{matrix} A, B, C, D, 1 \\ 0, \frac{1}{2} \end{matrix} \right),
\end{aligned}
\tag{22}
$$

where

$$
A = \frac{1 + \sum_{\substack{j=1 \\ j\neq i}}^{N'} [\alpha_j + k_j] - N\alpha}{2},
$$

$$
C = \frac{1 + \sum_{\substack{j=1 \\ j\neq i}}^{N'} [\alpha_j + k_j] - N\alpha + m - \alpha_x}{2},
$$

$$
B = \frac{2 + \sum_{\substack{j=1 \\ j\neq i}}^{N'} [\alpha_j + k_j] - N\alpha}{2},
$$

$$
D = \frac{2 + \sum_{\substack{j=1 \\ j\neq i}}^{N'} [\alpha_j + k_j] - N\alpha + m - \alpha_x}{2}.
$$

From the latter equation, we can distinguish two particular scenarios associated with the two extreme cases of $p=0$ and $p=1$, corresponding to non-correlated (nc) and totally correlated (tc) small-scale scintillations. After some algebraic manipulations, Eq. (22) can be written, respectively, as

$$
\begin{aligned}
P_b^{nc}(e) = &\frac{2^{N\alpha+\alpha_x-1}}{4\pi\sqrt{\pi}\,\Gamma(N\alpha)\Gamma(\alpha_x)} \\
&\times G_{5,2}^{2,4} \left( \frac{8\gamma_0}{(\alpha_x N\alpha)^2} \middle| \begin{matrix} \frac{1-N\alpha}{2}, \frac{2-N\alpha}{2}, \frac{1-\alpha_x}{2}, \frac{2-\alpha_x}{2}, 1 \\ 0, \frac{1}{2} \end{matrix} \right),
\end{aligned}
\tag{23}
$$

$$
\begin{aligned}
P_b^{tc}(e) = &\frac{2^{\alpha+\alpha_x-1}}{4\pi\sqrt{\pi}\,\Gamma(\alpha)\Gamma(\alpha_x)} \\
&\times G_{5,2}^{2,4} \left( \frac{8\gamma_0}{(\alpha_x\alpha)^2} \middle| \begin{matrix} \frac{1-\alpha}{2}, \frac{2-\alpha}{2}, \frac{1-\alpha_x}{2}, \frac{2-\alpha_x}{2}, 1 \\ 0, \frac{1}{2} \end{matrix} \right).
\end{aligned}
\tag{24}
$$

## 4. AVERAGE BER FOR A GENERIC CODING TRANSMISSION SCHEME

In this section, we want to show how to derive analytical closed-from expressions for the exact ABER of FSO systems with spatial diversity and correlated channels employing any generic coding scheme. As a representative example of the latter, we analyze the use of vw-MPPM, successfully proposed by the authors in indoor [14] and outdoor [15] wireless communications due to its high efficiency.

The vw-MPPM scheme is seen as a type of modulation whose purpose is to increase the peak-to-average optical power ratio (PAOPR) parameter to provide better performance in the optical link. This is a desired feature for any FSO system affected by turbulence, overcoming the imposed distortion when a system bandwidth constraint is required. The basic design criterion is to keep the average optical power transmitted at a constant level.

On another note, rate-adaptive transmission schemes are usually preferred for keeping the quality of service against adverse channel conditions. In this respect, and depending on the available SNR, the bit rate will be adapted (the stronger the intensity of turbulence, the slower the data rate) until a sufficiently low error probability is attained. Thus, the rate-adaptive transmission scheme using block coding of variable Hamming weight is a very good alternative to maximize link performance, achieving a high rate adaptability by simply changing the coding translation matrix. This coding technique is based on MPPM where codewords with different Hamming weights are allowed. This fact minimizes the presence of pulses at the optical signal leading to an increment in the PAOPR so vw-MPPM can be seen as an improved version of both the conventional classical scheme based on PPM and MPPM in terms of link performance.

For the sake of completeness, we briefly describe the vw-MPPM technique. Thus, the coding process consists of a translation procedure between the input data alphabet, $C_K$, with $k$-bit codewords, and the coded alphabet, $\tilde{C}_N$, a subset of $C_N$, comprising $2^n$ possible $n$-bit codewords. For the proper choice of $\tilde{C}_N$, codewords with different Hamming weights are proposed, leading to a block coding with a variable amount of pulses. Hence, if $C_{n,w}$ is the block code consisting of all possible codewords of length $n$ with a Hamming weight of $w$, the code $\tilde{C}_N$ is defined using the following codes $C_{n,w}$:

$$
\tilde{C}_N = \left( \bigcup_{i=0}^{x-1} C_{n,i} \right) \cup \tilde{C}_{n,x},
\tag{25}
$$

with $\tilde{C}_{n,x}$ representing the codewords subset of $C_{n,x}$ used in $\tilde{C}_N$. Thus, the coding table associated with $\tilde{C}_N$ consists of all the possible codewords with Hamming weight $i$, $0 \leq i \leq (x-1)$, together with a subset of $x$-weighted codewords given by the expression $2^k - \sum_{i=0}^{x-1} \binom{n}{i}$, where $\binom{n}{i}$ is the number of codewords of $C_{n,i}$. In this sense, the rate associated with the block code is given by $k/n$.

Since vw-MPPM is a nonlinear block coding scheme, the standard methods based on the characteristic functions of linear block codes are not suitable to obtain closed-form expressions of CBER. This is another reason that we have selected this modulation as a representative example of any generic coding technique. The authors successfully proposed in [16] a novel alternative based on a hyperexponential fitting technique to achieve a very accurate CBER expression,

**Table 1.    Hyperexponential Fitting Parameters *a*, *b*, and *c* in the Absence of Turbulence**

| Code Rate | *a* | *b* | *c* |
|---|---|---|---|
| 2/3 | 0.3870 | 2.7150 | 0.8890 |
| 6/12 | 0.6364 | 6.8958 | 0.8871 |
| 9/36 | 0.7246 | 42.4424 | 0.8600 |

given by

$$\text{CBER}(I, \gamma_0) = P_b(e|I) \approx a \exp\left[-b\left(\gamma_0 I^2\right)^c\right], \qquad \textbf{(26)}$$

with $\gamma_0$ being, again, the electrical SNR in the absence of turbulence, and where the hyperexponential fitting parameters are $a$, $b$, $c \in \Re^+$. In Table 1, we show the hyperexponential fitting parameters for most relevant vw-MPPM code rates [14].

Thus, the ABER, $P_b(e)$, is again obtained by averaging $P_b(e|I)$ given in Eq. (26) over $f_I(I)$ presented in Eq. (16), in the form

$$P_b = \int_0^\infty a \exp\left[-b\left(\gamma_0 I^2\right)^c\right] f_I(I)\mathrm{d}I. \qquad \textbf{(27)}$$

Following a procedure similar to the one detailed in [16], the Fox-H [32] function is identified after employing the Mellin transform along with some of its properties. In a more straightforward way, we can invoke Eq. (07.34.21.0012.01) in [31] if, previously, we write not only the modified Bessel function included in Eq. (16), $K_{a-b}(\cdot)$, as a Meijer-G function, as shown in Eq. (20), but also the hyperexponential function from Eq. (26) in the way indicated by Eq. (07.34.03.0228.01) in [31]:

$$G_{0,1}^{1,0}\left(b\gamma_0^c I^{2c}\,\middle|\,\begin{matrix} - \\ 0 \end{matrix}\right) = \exp[-b(\gamma_0 I^2)^c]. \qquad \textbf{(28)}$$

Now it is possible to use Eq. (07.34.21.0012.01) in [31] to solve Eq. (27) as

$$
\begin{aligned}
P_b(e) = {} & \frac{a}{[\det(\mathbf{A})]^\alpha \Gamma(\alpha_x)} \sum_{i=1}^{N'} \sum_{m=1}^{\alpha_i} \frac{1}{\Gamma(m)} \frac{\lambda_i^{\frac{m-\alpha_x}{2}} \alpha_x^{\frac{m+\alpha_x}{2}}}{(\alpha_i-m)!} \\
& \times \sum_{k_1+\cdots_i+k_{N'}=\alpha_i-m} \binom{\alpha_i-m}{k_1\ldots_i k_{N'}} \prod_{\substack{j=1 \\ j\neq i}}^{N'} \\
& \times \left[(-1)^{k_j}(\alpha_j)_{k_j}\left(\frac{-1}{\lambda_i}+\frac{1}{\lambda_j}\right)^{-\alpha_j-k_j}\right] \\
& \times \left(\frac{\alpha_x}{\lambda_i}\right)^{-\left(N\alpha - \frac{m-\alpha_x}{2} + \sum_{\substack{j=1 \\ j\neq i}}^{N'}[-\alpha_j-k_j]\right)} H_{2,1}^{1,2}\left(\frac{b\gamma_0^c\lambda_i^{2c}}{\alpha_x^{2c}}\,\middle|\,\begin{matrix}\hat{A},\ \hat{B} \\ (0,1)\end{matrix}\right),
\end{aligned}
$$
$$\textbf{(29)}$$

where

$$\hat{A} = \left(1 + \sum_{\substack{j=1 \\ j\neq i}}^{N'}[\alpha_j + k_j] - N\alpha, 2c\right),$$

$$\hat{B} = \left(1 + \sum_{\substack{j=1 \\ j\neq i}}^{N'}[\alpha_j + k_j] - N\alpha + m - \alpha_x, 2c\right).$$

In Eq. (29), $H_{ij}^{kl}(\cdot)$ represents the Fox-H function, a generalization of the Meijer-G function introduced in [33] and defined from the Mellin–Barnes integral. We must remark that the expression obtained in Eq. (29) is completely generic, valid for any turbulent regime, any degree of correlation among channels, any number of receivers and geometric topology, and

whatever coding and modulation technique will be used, as long as it can be adjusted with this numerical method.

## 5. RESULTS AND DISCUSSION

In this section, we present some Monte Carlo numerical results for different turbulence conditions used to corroborate the validity of the ABER expressions proposed in this paper. It is worth mentioning that we have used the code given in Appendix E in [34] to numerically evaluate the special functions (Meijer-G and Fox-H functions) included in the equations derived in this work. In addition, we must recall that we have always considered point detectors in this paper for which turbulence-induced signal fluctuations can be quite deleterious to system performance. Accordingly, we implement a method based on the Cholesky decomposition on covariance matrix $\mathbf{C_y}$, for generating correlated gamma random variables. That method is performed by matching their first and second moments, as detailed in [35]. Finally, we must mention the way we use Eq. (7). Thus, following Fig. 3, we obtain the definition of the correlation factor from Eq. (7) by taking into account that small-scale contributions to scintillation are associated with turbulent cells smaller than the first Fresnel zone or the transverse spatial coherence radius, $\rho_0$, given in Eq. (6), whichever is smallest [30]. Hence, the smallest value from both magnitudes will determine the definition of Eq. (7) employed in the results presented in this paper. As detailed in previous sections, we suppose that large-scale fluctuations are common for all receivers, an approximation completely consistent with the receiving areas considered in this paper (30 and 60 cm$^2$) where the point photodetectors will be distributed, as detailed below. Last, the figures of results shown in this section and involving BER performance represent the OOK transmission scheme unless noted otherwise. In all those figures, the numerical results are represented by circles to demonstrate the validity of the analytical expressions developed in the previous section.

Figure 4 shows the analytical results corresponding to the two extreme cases represented in Eqs. (23) and (24). The forward error correction (FEC) technique limit is displayed as a reference, indicating an ABER $\leq 3.8 \times 10^{-3}$. The FEC (with only 7% of overhead) with an ABER limit of ABER $\leq 3.8 \times 10^{-3}$ for hard decision [36] is widely adopted in many communication systems including those operating at optical frequencies on atmospheric [37–41] or even underwater turbulence [42]. This ABER limit represents the error-free transmission regime when FEC is employed. Moreover, for terrestrial systems, the International Telecommunication Union (ITU) has also standardized a 7% coding overhead (to guarantee interoperability of systems) [43]. In this case, the standard FEC scheme uses the ITU standard Reed Solomon code RS(255,239). Other options are, for example, to employ enhanced FEC where several codes are serially concatenated with a certain interleaving depth, and some iterations of decoding are used to improve the error correction capability, which adds a 7% data rate overhead and provides more than 8 dB of gain [38].

Coming back to the aforementioned ABER limit of $3.8 \times 10^{-3}$, for such a reference, a difference of 2.2 and 9 dB
**Fig. 4.** BER versus average electrical SNR for extreme small-scale correlation cases $p=0$ and $p=1$. $N=3$ receivers for $C_n^2 = 4 \times 10^{-15}$, $C_n^2 = 10^{-14}$, and $C_n^2 = 10^{-13}$ m$^{-2/3}$, related to conditions of weak, moderate, and strong turbulence, respectively.

**Fig. 5.** Configuration of receivers and obtained separation among them considering a fixed circle area of 30 cm$^2$ in reception for three different correlation models called (a) constant, (b) exponential, and (c) star models.

in SNR$_0$ is obtained when considering weak and strong turbulence, respectively. As expected, better performance is obtained when employing non-correlated small-scale scintillations and weak atmospheric turbulence.

However, in many situations, it is not realistic to consider totally uncorrelated channels. On the contrary, the separation between receivers determines the degree of correlation associated with the sequences of power received by them. Therefore, the adoption of a particular physical configuration (topology) of photoreceivers may impact the overall performance of the link. In this paper, we have analyzed the three different topologies depicted in Fig. 2 with the purpose of both offering a realistic scenario and weighting the impact of the separation distance among receivers. Moreover, the receivers are included in the same fixed area of 30 cm$^2$, with two different shapes: a circular surface and a square one. Thus, Figs. 5 and 6 show the obtained maximum separation distances for both scenarios. For instance, Fig. 7 shows how to obtain the maximum separation distance among photodetectors in a square surface of 30 cm$^2$.

In this respect, Fig. 8 shows an analytical simulation for the BER associated with the constant correlation model, as indicated in Eq. (3), with the receivers distributed in a fixed square area, whereas the values obtained from the small-scale correlation, $p$, and total correlation, $\rho_I$, are shown in Table 2 according to Eqs. (11) and (15). In addition, as in the rest of the simulations, conditions of weak, moderate, and strong

**Fig. 6.** Configuration of receivers and obtained separation among them considering a fixed square area of 30 cm$^2$ in reception for three different correlation models called (a) constant, (b) exponential, and (c) star models.

**Fig. 7.** Constant correlation model inside a square area of 30 cm$^2$. Photodetectors are placed on nodes B, D, and F.

turbulence have been considered, with $C_n^2 = 4 \times 10^{-15}$ m$^{-2/3}$, $C_n^2 = 10^{-14}$ m$^{-2/3}$, and $C_n^2 = 10^{-13}$ m$^{-2/3}$, respectively, as well as three different path lengths of $L = 700$ m, $L = 1500$ m, and $L = 1800$ m. For the sake of clarity, the performance of an ideal AWGN channel is added as a reference. We can observe how the longer the propagation path length, the worse the performance we obtain. For example, for a strong turbulence regime, and considering a separation between receivers of $d = 5.35$ cm [Fig. 5(a)], the results get worse as the length of the link increases. Such performance can be improved when the different channels become more uncorrelated.

Since the difference in separation distance between correlative photodetectors when using a circular surface is barely 0.32 cm with respect to the case of employing a square area (both fixed to 30 cm$^2$), their associated behaviors do not show a significant difference, and, therefore, Fig. 8 can represent both cases. Accordingly, and related to that small difference in separation distance between receivers, the correlation coefficients present values for a circular area (see Table 3) similar to those for a square surface.

On the other hand, Fig. 9 depicts the obtained behavior for the exponential correlation model and a square area of 30 cm$^2$. If Fig. 9 is now compared to Fig. 8, we can appreciate a slight improvement of this latter topology with
**Fig. 8.** BER versus average electrical SNR for the constant model of correlation with a receiving square area of 30 cm² and $N = 3$ receivers. Results are shown for weak, moderate, and strong turbulence, $C_n^2 = 4 \times 10^{-15}$, $C_n^2 = 10^{-14}$, and $C_n^2 = 10^{-13}$ m$^{-2/3}$, respectively, and link lengths of 700, 1500, and 1800 m, respectively.

**Fig. 9.** BER versus average electrical SNR for the exponential model of correlation with a square area of 30 cm² and $N = 3$ receivers. Results are shown for weak, moderate, and strong turbulence, $C_n^2 = 4 \times 10^{-15}$, $C_n^2 = 10^{-14}$, and $C_n^2 = 10^{-13}$ m$^{-2/3}$, respectively, and link lengths of 700, 1500, and 1800 m, respectively.

| Link Length | 700 m $p\|\rho_I$ | 1500 m $p\|\rho_I$ | 1800 m $p\|\rho_I$ |
|---|---|---|---|
| $C_n^2 = 4 \times 10^{-15}$ | 0.072\|0.517 | 0.292\|0.632 | 0.359\|0.666 |
| $C_n^2 = 10^{-14}$ | 0.072\|0.502 | 0.292\|0.620 | 0.359\|0.656 |
| $C_n^2 = 10^{-13}$ | → 0\|0.375 | → 0\|0.375 | → 0\|0.375 |

respect to the exponential one, from 0.75 dB for the case of $C_n^2 = 4 \times 10^{-15}$ m$^{-2/3}$ and $L = 700$ m for an error probability of $10^{-5}$, to around 3 dB for $C_n^2 = 10^{-14}$ m$^{-2/3}$ and $L = 1800$ m for the same value of error probability. The curves representing $C_n^2 = 10^{-13}$ m$^{-2/3}$ remain the same since the correlation factor affecting them in both topologies tends to zero for a small-scale fluctuation (totally uncorrelated small-scale scintillations). As in the constant correlation model, the use of either a circular surface or a square one hardly induces a slight change in performance (better when a circular area is employed since the distance between correlative receivers is larger).

Last, the results obtained from the star receiver topology are shown in Fig. 10, with $N = 4$ receivers spread in a square area

**Fig. 10.** BER versus average electrical SNR for the star model of correlation with a square area of 30 cm² and $N = 4$ receivers. Results are shown for conditions of weak, moderate, and strong turbulence, $C_n^2 = 4 \times 10^{-15}$, $C_n^2 = 10^{-14}$, and $C_n^2 = 10^{-13}$ m$^{-2/3}$, respectively, and link lengths of 700, 1500, and 1800 m, respectively.

of 30 cm². For this case, we also offer the results of the same scenario but distributing the photodetectors in a circular area (Fig. 11) instead of a square one. A slight improvement in performance is observed again when considering a square surface (corresponding to an increase of barely 0.18 cm in *d*; see Figs. 5 and 6), except for the case of $C_n^2 = 10^{-13}$ m$^{-2/3}$ since, as we explained above, the channels are totally uncorrelated for that value of structure parameter.

To better understand the behavior of these systems, Fig. 12 shows a comparison in performance when employing $N = 3$ receivers with regard to $N = 4$, when those receivers have been distributed in a circular area and following an exponential correlation model. Here we can appreciate an important feature. Figures 12(a) and 12(b) do not show a difference in performance when increasing the number of photodetectors from $N = 3$ to $N = 4$, except for the case of considering all small-scale effects totally uncorrelated (dotted lines). This fact means that it is not justified to enlarge the complexity of the system when the available space is reduced (30 cm²
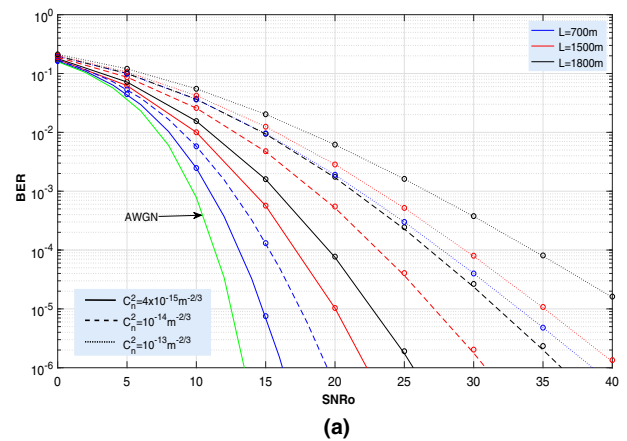

**Fig. 11.** BER versus average electrical SNR for the star model of correlation with a circular area of 30 cm$^2$ and $N = 4$ receivers. Results are shown for conditions of weak, moderate, and strong turbulence, $C_n^2 = 4 \times 10^{-15}$, $C_n^2 = 10^{-14}$, and $C_n^2 = 10^{-13}$ m$^{-2/3}$, respectively, and link lengths of 700, 1500, and 1800 m, respectively.

in the scenario taken as an illustrative example). As seen in Fig. 5, the separation distance between receivers is reduced from 3.09 cm ($N = 3$) to 2.06 cm ($N = 4$). The reduction in separation distance implies an increase in the magnitude of the correlation factor between photodetectors that compensates for the benefit of increasing the number of photoreceivers. Nevertheless, when this limitation is overcome and it is feasible to add a new photodetector while maintaining the separation distance between correlative receivers, then an improvement in performance is appreciated as shown in Fig. 12(c), more remarkable when such separation distance is longer.

On the other hand, the ABER of vw-MPPM coding transmission is discussed from the results obtained from Eq. (29), numerically validated via Monte Carlo simulation. Thus, Fig. 13(b) shows the results obtained when using Eq. (29) with a 2/3 code rate. They are compared to the ones depicted in Fig. 13(a) and extracted from Eq. (22) for classic OOK modulation. A constant correlation model considering a circular area of 30 cm$^2$ was employed, where the photodetectors are separated $d = 5.35$ cm according to Fig. 5(a). Succinctly, an improvement of around 7 dB on average can be measured between the performance associated with the vw-MPPM case [Fig. 13(b)] compared to the OOK one [Fig. 13(a)] for an ABER of 10$^{-5}$. Evidently, the improvement in performance associated with the vw-MPPM technique is at the expense of a reduction in data rate by a factor of 1/3. Last, the numerical simulation corroborates the validity of Eq. (29) for any condition (correlation factor, topology, turbulence regime, etc.) and coding and modulation techniques.

A similar comparison is shown in Fig. 14, including an exponential correlation model with a 60 cm$^2$ circular area, with $N = 2$ and $N = 4$ receivers, and assuming a strong turbulence regime. An improvement of around 6 dB on average was registered in favor of the vw-MPPM scheme in relation to OOK modulation at the reference BER of $3.8 \times 10^{-3}$.

As a remarkable comment, the areas considered in this work are aligned to current commercial solutions: for instance, a 30 cm$^2$ aperture is similar to the one implemented by the SONAbeam $Z$ series (50 mm diameter), whereas a 60 cm$^2$

**(a)**

**(b)**

**(c)**

**Fig. 12.** Comparison of BER versus average electrical SNR for the exponential model of correlation with a receiving circular area of 30 cm$^2$, using (a) $N = 3$ receivers and (b) $N = 4$ receivers. In addition, the case of $N = 4$ receivers with each pair of consecutive receivers separated 3.09 cm is shown in (c).

area is a magnitude closer to the SONAbeam $E$ series (10 cm diameter) [44].

Finally, we want to recall that our paper is intended to consider point receivers, where turbulence-induced signal fluctuations affect system performance with the maximum adverse effect. Certainly, this would be true if the receiving aperture in an optical communication system is smaller than
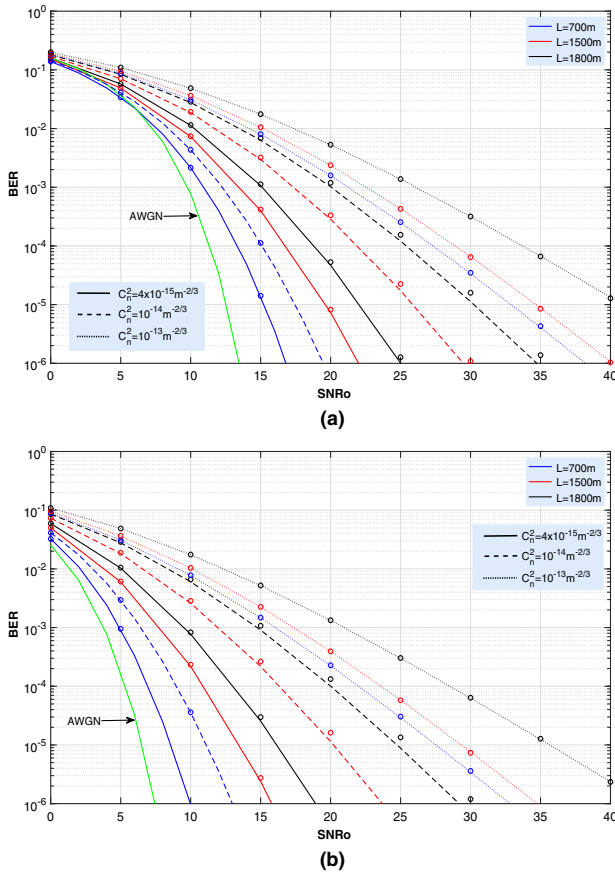

**Fig. 13.** BER versus average electrical SNR for the constant model of correlation with a 30 cm$^2$ circular area and $N = 3$ receivers, using (a) OOK and (b) vw-MPPM with a 2/3 code rate.

**Fig. 14.** BER versus average electrical SNR for the exponential correlation model with a receiving circular area of 60 cm$^2$, for $N = 2$ and 4 receivers. Results are shown for $C_n^2 = 10^{-13}$ m$^{-2/3}$ (strong turbulence) and link lengths of 700, 1500, and 1800 m.

the correlation width of irradiance fluctuations, $\rho_c$. If a receiving aperture of diameter $D$ is larger than the latter scale size, the receiver will average the fluctuations over the aperture, and the scintillation will be less compared to scintillation measured with a point receiver [45]. Aperture sizes larger than $\rho_c$ will experience some form of "aperture averaging," which in effect reduces the scintillation experienced by the

receiver photodetector. Hence, from Eq. (7), it is possible to distinguish two different situations: first, for the case of weak conditions, the correlation scale of irradiance fluctuations is defined by the size of the Fresnel zone ($\sqrt{\lambda L}$ in this paper); thus, significant aperture averaging takes place only when $D > 2\sqrt{\lambda L}$. Second, for strong turbulence conditions, the correlation scale is determined first by the spatial coherence scale $\rho_0$, as we discussed in Section 2.C. The same conclusions are derived in [46]. In this respect, and for the magnitudes considered in our paper, the detectors could be considered as point detectors if (1) for the case of a weak turbulence regime, the separation between two correlative receivers is $D < 2\sqrt{\lambda L}$, i.e., $D < 6.5$ cm ($L = 700$ m), 9.6 cm ($L = 1500$ m), and 10.56 cm ($L = 1800$ m), and (2) for the case of a strong turbulence regime, the separation between two correlative receivers must be $D < \rho_0$, i.e., $D < 2.32$ cm ($L = 700$ m), 1.48 cm ($L = 1500$ m), and 1.32 cm ($L = 1800$ m).

Thus, from the configuration of receivers employed in our paper (Figs. 5 and 6), the maximum distance between receivers is 5.67 cm [corresponding to the constant configuration with three receivers shown in Fig. 6(a) in our paper]. For that scale size, we are in the limit of considering point receivers for all cases of weak ($C_n^2 = 4 \times 10^{-15}$ m$^{-2/3}$) and moderate ($C_n^2 = 10^{-14}$ m$^{-2/3}$) turbulence and including the three different propagation path lengths considered in the paper for these two values of structure parameters in addition to any of the spatial configurations of receivers analyzed in our paper for a receiving area of 30 cm$^2$.

However, for the case of strong turbulence ($C_n^2 = 10^{-13}$ m$^{-2/3}$), the supposition of point detectors does not hold. In this case, the assumption of having point receivers is intended only for showing the maximum adverse effects from a turbulent atmosphere. This assumption is also taken into account in many other papers [21,24], especially when studying systems based on an IM/DD scheme (as in this paper) for which irradiance fluctuations are primarily concerned.

## 6. CONCLUSION

In this work, a complete analysis of the performance associated with a SIMO configuration with spatial diversity has been performed in realistic scenarios. The derived analytical expressions for the ABER are obtained in terms of the correlation length of the received irradiance fluctuations, and depending on the propagation path length, the refractive index structure parameter or the impact of the correlation matrix of small-scale scintillations on overall performance, assuming that the large-scale turbulence-induced fading is a common contribution for all receivers. Precisely such a correlation matrix also depends on the separation distance between photodetectors, i.e., the correlation factors are not fixed to certain values for academic purposes, but calculated in a realistic way from the configuration of the FSO link, the number of photodetectors, or the physical available space in reception. Moreover, the correlation length, in addition, is determined by comparing the magnitudes of the spatial correlation value and the first Fresnel zone, according to Fig. 3.

Furthermore, three illustrative spatial geometries of receivers were considered [17,19], giving rise to three small-scale

correlation matrices that characterize the correlation between fading signals in each of the diversity branches: constant, exponential, and star correlation models. Indeed, a topology will present better performance if the separation distances among its photodetectors are larger, as corroborated in this paper. For instance, the configuration with a constant correlation model presents better performance than that obtained from an exponential correlation model with $N = 3$ photodetectors since their separation distances are shorter than the ones achieved for the constant model, assuming the same fixed surface (identical magnitude and identical geometric shape) to distribute the photodetectors. The same conclusions can be obtained when comparing the star topology in relation to the exponential one. Since the received area considered in this work is not very large (typically 30 cm$^2$, or even 60 cm$^2$), the differences in behavior among topologies are not remarkable (around 2–3 dBs for an ABER of 10$^{-5}$). It is expected to obtain a more remarkable difference when that area becomes larger.

On another note, and regarding the limited physical available space on the receiver side for distributing photodetectors, there may exist situations as the ones shown in Figs. 12(a) and 12(b) where the whole FSO system does not experience any improvement in performance when adding new photodetectors. The underlying reason resides in the short separation distances among photodetectors, and, consequently, the correlation factor becomes larger, countering the benefit of having different diversity branches in the considered EGC spatial diversity technique. Of course, if totally uncorrelated channels are supposed, then the addition of new photoreceivers always improves the performance of the system.

Finally, we have incorporated the study of the vw-MPPM as an illustrative example of a generic nonlinear block coding technique whose CBER cannot be derived in a closed-form expression. Its analysis was carried out by employing a hyperexponential fitting procedure. Here, the improvement in performance with respect to the OOK scheme is more remarkable, as vw-MPPM includes a rate-adaptive transmission scheme using block coding, thus increasing its resulting PAOPR. These results, and the others included in this paper, corroborate the validity of the derived analytical expressions.

## APPENDIX A

In this appendix, the assumption of common large-scale effects affecting all receivers is discussed in detail. From the early works published by Taylor [47], based on some measurements of intensity and scale inside wind tunnels [48], or by Kolmogorov [49], with a turbulent flow composed of "eddies" of different sizes, we know some features that can justify this approach. Thus, for example, near the ground, the value of the outer scale of turbulence is thought to be comparable with the height above ground (around 20 or 30 m if we consider a typical scenario with the transceivers over two different buildings), much larger than either the beam waist propagating through the atmosphere or the radius of the receiver. In this respect, it seems that when the turbulent process begins, the approach of considering a common large-scale effect for all receivers becomes real.

Then, the energy is input at small wavenumbers and dissipated at much larger wavenumbers. In this wavenumber range called the inertial subrange, the Reynolds number is so high for the large eddies that they are unstable and break apart. Thus, they transfer energy to smaller scales (higher wavenumbers) down to the inner scale of turbulence $l_0$, a scale of only a few millimeters where the Reynolds number approaches unity and the energy is dissipated into heat. This heat is seen as the starting point to begin a new turbulent process. All these features in combination with Taylor's hypothesis (eddies staying in the same place for a long time compared to the typical data rates, and moving as a whole) allow us to think of having a varying number of large-scale eddies in the link affecting all receivers at the same time, as we will show below.

In addition, Tatarskii [22,50] predicted that the correlation length of irradiance fluctuations is of the order of the first Fresnel zone. On the other hand, measurements [51,52] of the irradiance covariance function under strong-fluctuation conditions revealed that the correlation length decreases when increasing the Rytov variance and that a large residual correlation tail emerges at large separation distances. That is, in the strong-fluctuation regime, the correlation length of irradiance fluctuations is determined by the spatial coherence radius $\rho_0$ [see Eq. (6)] of the optical wave, whereas the width of the residual tail is characterized by the scattering disk calculated as $L/(k\rho_0)$, with $L$ denoting the propagation path length and $k$ being the wavenumber of optical radiation. All these parameters (size of the Fresnel zone, spatial coherence radius, scattering disk, and a comparison with the received beam waist) will be discussed in more detail later.

Furthermore, the sets of observations made about irradiance measurements in [53,54] contributed to understand and develop expressions for the large-scale and small-scale irradiance covariance functions. The two-scale process associated with scintillation is described in detail in [55] and discussed in [56]. Moreover, all these findings help Andrews *et al.* [20] to develop a heuristic model of irradiance fluctuations for a propagating optical wave in a weakly inhomogeneous medium under the assumption that small-scale irradiance fluctuations are modulated by large-scale irradiance fluctuations of the wave. There, the upper bound for small turbulent cells was defined by the smallest cell size between the Fresnel zone and the transverse spatial coherence radius, $\rho_0$, of the optical wave, whereas the lower bound for large turbulent cells was defined by the largest cell size between the Fresnel zone and the scattering disk.

To conclude this review of theory of optical scintillation based on experimental observations, we recently proposed and developed in [57] a new statistical model for turbulence, the Málaga model (seen as a generalization of the gamma–gamma one) whose physical model was presented in [58] after a deeper interpretation of the Málaga model. In this respect, its propagation model and the turbulence-induced scintillation effects can be physically interpreted as the superposition of several generalized-K sub-channels corresponding each one to a different physical optical path. It was demonstrated (and validated with Monte Carlo simulations) that the large-scale fading characteristic associated with each sub-channel is established by $\alpha_x$ defined in Section 2 (the same parameter as in a

gamma–gamma model, and related to the effective number of large-scale cells of the scattering process, as discussed in [27]), and, as expected, it is common for every generalized-K term. In contrast, small-scale fluctuations depend on the specific subchannel, where the more severe conditions, the lower the probability of the optical power to be coupled to the LOS component. Even more, different optical sub-channels may be associated with a different turbulence condition. An additional feature comes from the probability that a certain portion of the optical signal travels through the $k$th optical path. This probability was demonstrated to follow a binomial distribution [58] depending on the parameters of the Málaga distribution (many of them coincident to their corresponding ones in gamma–gamma distribution) that configures the probability for optical power to be coupled to the LOS component. It means that large-scale fluctuations associated with large-scale cells of the scattering process will have a higher or lower weight in the final received fluctuating intensity, depending on either the probability for the optical signal traveling through a concrete subchannel or on the optical power distribution among the contributing sub-channels.

All the arguments related above support our initial assumption, and now it is possible to evaluate its accuracy. The idea is not new since Fig. 6 in [59] shows the propagation geometry of an optical wave through a turbulent atmosphere, where common eddies inducing correlated deflection into all receivers are included. In that paper, the authors give a physical recalling that channel correlation arises mainly from the deflection effects of large-scale eddies whose sizes are larger than the scattering disk, consistent with what we have detailed above. Those common eddies simultaneously deflect light in both channels considered in [59] and thus generate channel correlation; in contrast, the independent eddies modify light in only one channel and thus degrade the correlation. With increasing turbulence strength, the spatial coherent radius decreases [30], and hence, the scattering disk increases. Therefore, the average size of the large-scale eddies is increased. Accordingly, the probability of interacting with common eddies increases, although for this case, we must compare that average size of the large-scale eddies with the beam waist of the optical transmitted signal, wider as a consequence of the stronger turbulence regime.

A similar model is applied in [60]. There, it is concluded that if the propagation path length is much larger than the laser beam divergence, and if the receivers are sufficiently close, then the signals received by the photodetectors are likely to be deflected by the same eddies, implying that large-scale effects can be assumed to be the same for all receivers. In addition, the width of the light beam issued by a transmitter laser expands as the propagation path length increases. This effect is depicted in Fig. 2(a) in [61], which we include here in Fig. 15 for the sake of completeness.

If now a horizontal FSO transmission with a Gaussian profile for the beam intensity is considered [62], the radius of that beam, at a distance $z$ from the laser source, is given by [30]

$$W_e(z) = W(z)\sqrt{1 + 1.625\sigma_R^{12/5}\Lambda}, \qquad \textbf{(A1)}$$

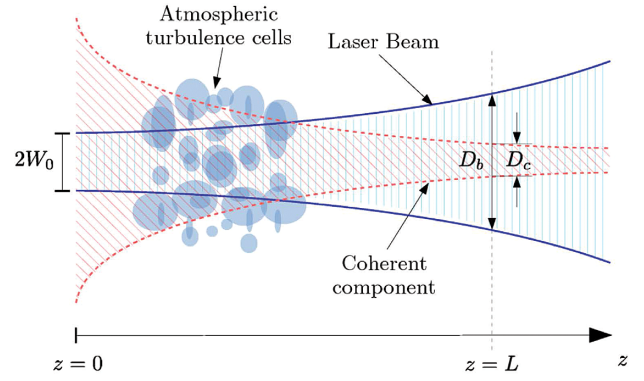

**Fig. 15.** Propagation model of a partially coherent Gaussian laser beam: $W_0$ is the initial beam radius, $D_b = 2W_e$ is the beam diameter, and $D_c = 2\rho_0$ is the transverse coherence diameter, both at $z = L$. Figure taken from [61].

where $\sigma_R^2 = 1.23C_n^2 k^{7/6}L^{11/6}$ is the Rytov variance, with $C_n^2$ being the refraction index structure parameter, which is directly related to turbulence strength, with $k$ being the wavenumber and $L$ representing the propagation path length. Moreover, $\Lambda = 2z/(kW^2)$, with $z$ being the propagation distance and $W$ being the beam radius at $z = L$, whereas the generic expression for $W(z)$, the beam radius in the absence of turbulence, is defined by

$$W(z) = W_0\sqrt{\left(1 - \frac{z}{F_0}\right)^2 + \left(\frac{2z}{kW_0^2}\right)^2}. \qquad \textbf{(A2)}$$

In Eq. (A2), $W_0$ is the beam radius at the $1/e$ point of the field ($1/e^2$ of the irradiance) at the transmitter, $F_0$ is the phase front radius of curvature at the transmitter output (we can consider a collimated beam, i.e., $F_0 \to \infty$), $k = 2\pi/\lambda$ is the wavenumber, and $\lambda$ is the wavelength. In this paper, we have considered $\lambda = 1550$ nm, three different magnitudes for the structure parameter, $C_n^2 = 4 \times 10^{-15}$, $10^{-14}$, and $10^{-13}$ m$^{-2/3}$, and three different propagation lengths, $L = 700$, 1500, and 1800 m. Moreover, we can assume $W_0 = 2.5$ cm, as in [30]. Then, operating, we obtain the representative values included in Table 4.

From Table 4, the beam waist at the receiver will vary from 2.5 cm ($W_e = W_0$ since the optical beam is affected by a very weak turbulence regime) to 31.7 cm (strong turbulence and the longest path, $L = 1800$). From Eq. (7), the correlation lengths (which describe the average speckle size at the receiver) take the values of 3.3, 4.8, and 5.3 cm (when approaching its value to $\sqrt{\lambda L}$) for weak turbulence and $L = 700$, 1500, and 1800 m, respectively; for strong turbulence and the same values of $L$, respectively, their values are 1.16, 0.74, and 0.66 cm. From Fig. 3, we can see how the cases of $C_n^2 = 4 \times 10^{-15}$ and $C_n^2 = 10^{-14}$ m$^{-2/3}$ for all propagation path lengths considered (700, 1500, and 1800 m) can be considered as weak fluctuations since the value of the Fresnel zone is below the curves representing the coherence radius for $C_n^2 = 4 \times 10^{-15}$ and $C_n^2 = 10^{-14}$ m$^{-2/3}$. Additionally, it is reasonable to think that since the average speckle size at the receiver is larger than the received beam waist, and, moreover, from Figs. 5 and 6, the

**Table 4.     Atmospheric Link Parameters**

| $C_n^2$ | $L$ | $W_e$ | Correlation Length ($\sqrt{\lambda L}$) (Average Speckle Size) | First Fresnel Zone ($\sqrt{L/k}$) | Scattering Disk ($L/(k\rho_0)$) | Spatial Coherence Radius ($\rho_0$) |
|---|---|---|---|---|---|---|
| $4 \times 10^{-15}$ m$^{-2/3}$ | 700 m | 2.5 cm | 3.3 cm (3.3 cm) | 1.31 cm | 0.22 cm | 8.01 cm |
| $4 \times 10^{-15}$ m$^{-2/3}$ | 1500 m | 2.53 cm | 4.8 cm (4.8 cm) | 1.92 cm | 0.73 cm | 5.07 cm |
| $4 \times 10^{-15}$ m$^{-2/3}$ | 1800 m | 2.59 cm | 5.3 cm (5.3 cm) | 2.11 cm | 0.98 cm | 4.55 cm |
| $10^{-14}$ m$^{-2/3}$ | 700 m | 2.51 cm | 3.3 cm (3.3 cm) | 1.31 cm | 0.37 cm | 4.62 cm |
| $10^{-14}$ m$^{-2/3}$ | 1500 m | 2.78 cm | 4.8 cm (4.8 cm) | 1.92 cm | 1.26 cm | 2.93 cm |
| $10^{-14}$ m$^{-2/3}$ | 1800 m | 3.20 cm | 5.3 cm (5.3 cm) | 2.11 cm | 1.69 cm | 2.62 cm |
| $10^{-13}$ m$^{-2/3}$ | 700 m | 3.51 cm | 3.3 cm (1.16 cm) | 1.31 cm | 1.49 cm | 1.16 cm |
| $10^{-13}$ m$^{-2/3}$ | 1500 m | 19.5 cm | 4.8 cm (0.74 cm) | 1.92 cm | 5.03 cm | 0.74 cm |
| $10^{-13}$ m$^{-2/3}$ | 1800 m | 31.7 cm | 5.3 cm (0.66 cm) | 2.11 cm | 6.74 cm | 0.66 cm |

radius of the receiver is, approximately, 3 cm for each topology when considering a 30 cm$^2$ receiving area, then most of the large-scale fluctuations must be common for all receivers. However, the probability that signals received in each photodetector pass through the same eddies (common eddies) decreases for strong turbulence since the channel correlation decreases as both $L$ and $C_n^2$ increase. In this case, the average speckle size (i.e., correlation length) is smaller than the beam waist and small-scale fluctuations (diffractive effects) are most noticeable. In this respect, our assumption (common large-scale fluctuations for all receivers) turns into a worst case of performance, showing an upper error bound obtained for a particular FSO link under design.

Following [30], large-scale fluctuations in irradiance are generated by turbulent cells larger than that of the first Fresnel zone or the scattering disk $L/(k\rho_0)$, whichever is largest. From the values included in Table 4, we can see how the sizes of cells inducing large-scale fluctuations are larger than 3.3 cm ($L = 700$ m), 4.8 cm ($L = 1500$ m), and 5.3 cm ($L = 1800$ m) for $C_n^2 = 4 \times 10^{-15}$ m$^{-2/3}$ and $C_n^2 = 10^{-14}$ m$^{-2/3}$; for the case of $C_n^2 = 10^{-13}$ m$^{-2/3}$, large-scale fluctuations are caused by cells with sizes larger than 3.3 cm (still $\sqrt{\lambda L}$ dominating for $L = 700$ m), 5.03 cm ($L = 1500$ m), and 6.74 cm ($L = 1800$ m), the latter two path lengths dominated by the scattering disk. Again, we recall that we have adopted in this paper a more restrictive value for the Fresnel zone size, $\sqrt{\lambda L}$. This means that if we compare these eddy sizes (for $C_n^2 = 4 \times 10^{-15}$ m$^{-2/3}$ and $C_n^2 = 10^{-14}$ m$^{-2/3}$) to those scale sizes characterizing $W_e(L)$ for the same two structure parameter values, and considering that the correlation length also indicates the average size of turbulent cells, then we can extract the following conclusions:

1. Following [56], if $\rho_0 > \sqrt{L/k}$, then the coherence length is greater than the first Fresnel zone, and the magnitude $\sqrt{\lambda L}$ is the size of the dominant inhomogeneities producing scintillations. Cell sizes involved in large-scale fluctuations of intensity for $C_n^2 = 4 \times 10^{-15}$ m$^{-2/3}$ and $C_n^2 = 10^{-14}$ m$^{-2/3}$ are larger than the received beam waist for all lengths considered in this paper. Their average sizes imply that the probability of having a cell of that average size (and even larger) is high. For example, for the case of $C_n^2 = 10^{-14}$ m$^{-2/3}$ and $L = 1500$ m, the average eddy size is 4.8 cm, almost twice larger than the size of the beam waist at the receiver, i.e., $W_e = 2.78$ cm, being very

likely that the transmitted optical beam can pass through turbulent cells larger than its beam waist, which is 2.78 cm at $L = 1500$ m, but less for any other position between the transmitter ($W_0 = 2.5$ cm was the supposed transmitted beam waist) and the receiver. So the approach of having a common contribution of a large-scale scintillation component for all receivers is very accurate.

2. However, and again, from [56], if $\rho_0 < \sqrt{L/k}$, then eddies whose scale sizes are of the order of $\sqrt{\lambda L}$ no longer cause scintillations, and the dominant scale size is $\rho_0$. For the case of strong turbulence considered in this paper ($C_n^2 = 10^{-13}$ m$^{-2/3}$), it is straightforward to check from Table 4 that cells contributing to large-scale scintillations are of sizes larger than 1.49 cm ($L = 700$ m), 5.03 cm ($L = 1500$ m), and 6.74 cm ($L = 1800$ m). If we compare those values with the ones for $W_e$ (3.51, 19.5, and 31.7 cm, respectively, for the same distances), we see how the received beam width is larger than the cell sizes from which a turbulent eddy is considered as a large-scale eddy (causing large-scale fluctuations). For this case of strong turbulence, the approach can be seen only as a mathematically tractable closed-form approximation to obtain an upper error bound in performance of any FSO system. Notwithstanding, the average dominant inhomogeneity scale size for this scenario ($\rho_0$, as indicated in [56], i.e., 1.16, 0.74, and 0.66 cm for $L = 700$, 1500, and 1800 m, respectively) informs that the probability of meeting an eddy with a size larger than the ones given by the scattering disk (the minimum size to consider an eddy as a large-scale one in this scenario) is really low since the difference in size between both magnitudes is large. In this respect, the effect for this strong turbulence scenario is mostly associated with small-scale fluctuations (the Fresnel zone defines the dominant scale size for scintillation, in this case, associated with diffractive effects) and not with large-scale fluctuations. For this reason, our initial assumption (common eddies affecting all receivers), although being here an upper bound limit, nevertheless, should not offer a remarkable difference in respect to the real performance associated with any FSO system under study. In addition, the presence of large aerosols (rain, drizzle, fog, etc.) in the atmosphere reduces the effective size of the largest turbulence scales, making our assumption even more realistic.

3. Saying that, from the discussion provided in [11,20,30], large-scale fluctuations in irradiance are generated by turbulent cells larger than that of the first Fresnel zone or the scattering disk $L/(k\rho_0)$, whichever is largest, and can be described by the method of geometrical optics. In our case, large-scale fluctuations are caused by cells with sizes larger than 1.49 cm ($L = 700$ m), 5.03 cm ($L = 1500$ m), and 6.74 cm ($L = 1800$ m) for the case of $C_n^2 = 10^{-13}$ m$^{-2/3}$, as indicated in the previous item.

4. To support the previous item, in [63], it is also stated that channel correlation mainly depends on large-scale turbulence eddies rather than small-scale turbulence eddies. For the strong turbulence regime where scintillations are dominated by eddies whose scale sizes are given by $\rho_0$, shorter than the width of the first Fresnel zone, those scintillations become independent of the turbulence intensity and the path length, which, in essence, explains the saturation effect, as related in [56].

5. Finally, we have similar conditions as in [59] to ensure that channel correlation arises mainly from the deflection effects of large-scale eddies.
