Abstract

Introduction Helminths are parasitic worms that infect millions of people worldwide and secrete a variety of excretory-secretory products (ESPs), including proteins, peptides, and small molecules. Despite this, there is currently no comprehensive review article on cataloging small molecules from helminths, particularly focusing on the different classes of metabolites (polar and lipid molecules) identified from the ESP and somatic tissue extracts of helminths that were studied in isolation from their hosts.

Objective This review aims to provide a comprehensive assessment of the metabolomics and lipidomics studies of parasitic helminths using all available analytical platforms.

Method To achieve this objective, we conducted a meta-analysis of the identification and characterization tools, metabolomics approaches, metabolomics standard initiative (MSI) levels, software, and databases commonly applied in helminth metabolomics studies published until November 2021.

Result This review analyzed 29 studies reporting the metabolomic assessment of ESPs and somatic tissue extracts of 17 helminth species grown under *ex vivo/in vitro* culture conditions. Of these 29 studies, 19 achieved the highest level of metabolite identification (MSI level-1), while the remaining studies reported MSI level-2 identification. Only 155 small molecule metabolites, including polar and lipids, were identified using MSI level-1 characterization protocols from various helminth species. Despite the significant advances made possible by the ‘omics’ technology, standardized software and helminth-specific metabolomics databases remain significant challenges in this field. Overall, this review highlights the potential for future studies to better understand the diverse range of small molecules that helminths produce and leverage their unique metabolomic features to develop novel treatment options.

Keywords Metabolomics · Lipidomics · Helminths · Parasites

1 Introduction

Helminths are classified into two major phyla: nematodes (or roundworms) and platyhelminths (or flatworms). Nematodes include intestinal worms, also known as soil-transmitted helminths, such as hookworms, roundworms, whipworms, and filarial worms. Platyhelminths include flukes or trematodes, such as schistosomes, and tapeworms, also known as cestodes (the pork tapeworm). These helminths are estimated to infect one-third of the almost three billion people in developing regions of Africa, Asia, and the Americas (Hotez et al., 2008). Intestinal nematodes alone infect approximately 24% of the world’s population, mainly affecting children in tropical and sub-tropical regions (WHO, 2020).

The intestinal nematodes, such as *Necator americanus*, *Ancylostoma duodenale*, *Ascaris lumbricoides*, and *Trichuris trichiura*, are major contributors to public health burden, causing anaemia, digestive diseases, and stunted growth (Sanchez et al., 2014). Despite their significant impact on global health burden, helminth infections are neglected tropical diseases and receive only 0.1% of global research funding (Moran, 2011). Currently, no vaccine is available for helminth infections, and the limited number of anthelmintic drugs, coupled with drug resistance in livestock animal nematodes, hinders the global fight against parasitic worms. Moreover, the gold standard for diagnosing helminth infections based on microscopy is labour-intensive and is less sensitive. PCR-based molecular diagnostic is expensive and the resource-constrained developing tropical countries cannot afford them. Therefore, there is a need for more sensitive, specific, and affordable diagnostic tools that can be used in these settings.

Helminth excretory/secretory products (ESPs) offer a promising source of biomarkers and immunomodulatory biomolecules, which are produced through unique biochemical pathways that have evolved over millennia of co-evolution between the parasites and humans (Loukas et al., 2016). The ESPs contain a variety of components, including extracellular vesicles, proteins, peptides, glycans, and small molecules, that has specific biological functions related to moulting, infection, immunopathogenesis, immunoregulation, reproduction, intra- and inter-specific competitions, and colony establishment in the gut (Eichenberger et al., 2018). Recently, the immunomodulatory and therapeutic potential of helminth-derived small molecules has been reviewed by Yeshi et al. (2022). Proteomics and glycomics techniques have been used to extensively study helminth-derived proteins, peptides, and glycans, and these studies have been reviewed elsewhere (Eichenberger et al., 2018; Wangchuk et al., 2019c).

Studies of helminth small molecules, particularly those focused on ESPs of intestinal parasites (i.e., removed from their hosts), are less advanced than transcriptomics and proteomics studies. This could be partly due to the lack of suitable culture media for gathering small molecule ESPs and complex identification protocols. The classical culture media such as RPMI-1640 contains more than 40 small molecules, hindering the identification of ESPs small molecule metabolites released in the culture media (Mai-zels et al., 2018). However, a simple single-component alternative culture media has been described recently, resolving the technical difficulties presented by RPMI culture media (McSorley et al., 2013; Wangchuk et al., 2019c). The recent development of cutting-edge analytical equipment and metabolomics bioinformatics platforms has

enabled the investigation of small molecules produced by helminths, thus gaining attention.

Metabolomics is a technique used to characterize a complex mixture or a large number of metabolites or small molecules (< 1 kDa) that are both exogenous and endogenous and are produced by or present in an organism (Zakeri et al., 2018). In helminthology, metabolomics is a relatively new technique with great potential to identify metabolites in the cells, biofluids (including ESPs), tissues, and whole organisms (Ryan et al., 2020). Four major types of analytical equipment are widely used in metabolomics: gas chromatography-mass spectrometry (GC-MS), liquid chromatography-mass spectrometry (LC-MS), capillary electrophoresis-mass spectrometry (CE-MS), and nuclear magnetic resonance (NMR) spectroscopy (Perez de Souza et al., 2021). A review by Preidis and Hotez (Preidis & Hotez, 2015) discussed the metabolomic profiles of parasitised hosts and the potential of metabolomics techniques, including NMR, GC-MS, and LC-MS, to identify biomarkers for developing more sensitive point-of-care diagnostics for neglected tropical diseases. Kokova and Mayboroda (Kokova & Mayboroda, 2019) described the state-of-the-art NMR metabolomics of body fluids of animals or hosts infected with parasitic helminths, and Whitman et.al (Whitman et al., 2021) provided a comprehensive review of the metabolomics of parasitic helminths using mass spectrometry. To the best of our knowledge, a comprehensive review on the cataloguing of small molecules of helminths, particularly different classes of metabolites (polar and lipid molecules) identified from the ESPs and somatic tissue extracts of helminths collected *in vitro* after removal from their hosts, has not been attempted so far.

Herein, we have conducted a meta-analysis of the published information on small molecules of helminths collected from various databases, including PubMed, Embase, Scopus, Web of Science, and Google Scholar. We have collated all the available data and presented metabolites identified with the highest level of the Metabolomics Standards Initiative (MSI). We retrieved 28 metabolomics studies (involving 17 different helminth species) that used various analytical platforms and identification tools, and conducted a meta-analysis of these 28 papers. Table 1 summarises analytical equipment, databases and software used for metabolomics studies of various samples prepared from different developmental stages of helminths. We found that these 28 metabolomics studies used GC-MS, LC-MS, CE-MS, and NMR for studying the ESP and the somatic tissue extracts of various helminths. Besides these, a few helminth metabolomics studies included in this review have also applied other analytical platforms, including Raman and Fourier transform infrared (FTIR) spectroscopies, high-resolution mass spectrometry (HRM)

Table 1 Analytical techniques, databases, and software used for metabolomics studies of helminths

Phylum	Order	Helminth species	Stage	Sample	Culture media	Approaches/ design	Identification level	Number of metabolites	Analytical platform	Software(s)/databases used for metabolites identification	Reference
Nematoda	Trichocephalida	<i>Trichuris muris</i>	Embryonated eggs	SE	2% glutamax, 2% pen/strep PBS	Untargeted metabolomics	MSI-1 (polar) MSI-2 (lipids)	113 polar metabolites & 322 lipids	Q-Exactive Orbitrap MS-HPLC	KEGG, MetaCyc, LIPIDMAPS, PubChem CID, HMDB, CTs databases; open-source software IDEOM; MetaboAnalyst 3.0	(Yestri et al., 2020)
	Adult		ESPs		2% glutamax, 2% pen/strep PBS	Targeted metabolomics	MSI-1	35 polar metabolites & 16 lipids	GC-MS	Agilent's Mass Hunter Quantitative Analysis software (v.7); MAMM; MHL; KEGG; MetaboAnalyst 3.0	(Wangchuk et al., 2019b)

such as Q-Exactive Orbitrap MS/HPLC, ultrahigh performance liquid-chromatography mass spectrometry (UHPLC/MS), and atmospheric pressure (AP) matrix-assisted laser desorption/ionization mass spectrometry imaging (AP-SMALDI MSI) (Table 1). The advantages and limitations of various mass spectrometry techniques have been reviewed in-depth elsewhere (Dettmer et al., 2007).

2 Polar metabolites identified from excretory-secretory products and tissue extracts

Before the widespread use of NMR spectroscopy, the metabolic profile of body fluids and tissues of hosts infected with parasitic helminths such as *Schistosoma japonicum* and *S. mansoni* was studied (Nishina et al., 1994). However, recent advancements in metabolomics tools and techniques have allowed identifying metabolites produced by helminths under in vitro culture conditions. Through content analysis of the available literature, it was found that a total of 100 polar metabolites (i.e., after excluding common duplicates) were identified and confirmed with available standards (MSI-level-1 identification) from six parasitic helminths (*A. caninum*, *T. canis*, *N. brasiliensis*, *T. muris*, *N. americanus*, and *D. caninum*) (Wangchuk et al., 2019a, 2019b, 2020; Yeshi et al., 2020) (Table 2). The most abundant polar metabolites in the SE were amino acids, carboxylic acids, and derivatives, while ESPs mainly contained sugars and sugar alcohols. Among these six helminths, eight polar metabolites were in common, including D-glucose-6-phosphate, L-alanine, L-methionine, L-phenylalanine, L-tyrosine, mannitol, succinic acid, and 5-oxoproline (Fig. 1; Table 2) (Wangchuk et al., 2019b, 2020; Yeshi et al., 2020). Although bacterial species also secrete succinic acid (Müller et al., 2012), it is more likely that it is a true metabolite of these six parasitic helminths, given that the six helminth studies used 5% antibiotic/antimycotic (A/A) for removing host fecal debris and washing the parasites (3–5 times washes). An additional 2% A/A was used for worm culturing media, which reduces the possibility of microbial contamination (Fig. 1). Moreover, the presence of succinic acid in the ESPs of *N. brasiliensis* was confirmed using ¹H NMR (Nadjsombati et al., 2018).

Pterin, orotate, LL-2,6-diaminoheptanedioate, and 2,5-dihydroxybenzoate have been identified as polar metabolites unique to infective L3 stage of *N. brasiliensis* in a study by Yeshi et al. (2020). Pterin, a pyrazino-pyrimidine derivative, was first discovered as a fluorescent pigments in butterfly wings by Hopkins in 1894 (Hopkins, 1894) and has since been reported in various living organisms such as

cyanobacteria, mammals, and parasites. In humans, monocytes or macrophages produce excess neopterin upon stimulation with IFN- γ (Weiss et al., 1993). Biopterin, a pterin derivative, has been reported as a ROS scavenger (Shen & Zhang, 1993) and was detected in the muscle extract of *A. lumbricoides* through paper chromatographic analysis followed by purification using a neutral pH Ecteola (Epichlorohydrin triethanolamine)-cellulose column (1.8 × 30 cm) and a Sephadex column (G-25, fine, 1.8 × 20 cm) (Fukushima, 1970). However, the specific role of biopterin has not been reported in any available literature.

Orotate, detected in the ESPs of *N. brasiliensis* L3 stage might be the end-product of de novo pyrimidine biosynthesis. Surprisingly, orotate was not detected in embryonated eggs and adult *T. muris*, despite all five enzymes involved in pyrimidine metabolism being present in helminths, including *N. brasiliensis* and *T. muris* (Yeshi et al., 2020). The role of orotate in living organisms is described as a regulator of genes involved in developing cells, tissues, and organisms as a whole (Loffler et al., 2016). In the somatic tissue extract of *A. caninum*, a non-reducing disaccharide called trehalose (also known as mycose or tremalose) was reported to be present. Trehalose was also detected (< 10% of dry weight) in *A. lumbricoides* eggs (Fairbairn & Passey, 1957) as well as matured larvae of *A. lumbricoides* and *Porrocaecum decipiens* (Kalf & Rieder, 1958). Fairbairn (Fairbairn, 1958b) detected trehalose (a source of energy and carbon) in the somatic tissues of 14 helminth species (refer Table 1 above) and suggested that parasitic nematodes possess more trehalose than trematodes and cestodes. Trehalose is commonly found in yeast and fungi (Elbein et al., 2003).

Several metabolites unique to different parasitic helminths have been identified, including amino acids and carboxylic acids, with *A. caninum* (adult) having 13, *N. brasiliensis* infective stage (L3) having three, and adult *T. canis* having one (Fig. 1, Table 1). Additionally, gluconolactone (gluconic- δ -lactone) has been reported as a unique metabolite in the ESPs of adult *T. canis* (Wangchuk et al., 2020). A representative structure of metabolites unique to different parasitic helminths is given in Fig. 2. The presence of species-specific metabolites suggests the potential for developing diagnostic biomarkers. However, the reliability of unique metabolites, both polar metabolites and lipids, may be limited as experimental conditions and analytical platforms differ across studies, and comparisons may not provide a comprehensive picture of the samples under investigation. It is also important to note that the unique or different molecules in the metabolite profiles among the helminths could be due to different experimental conditions, analytical platforms, helminth species, and their different life-cycle stages, which are known to

produce stage-specific metabolites (Barrett, 1987; Wangchuk et al., 2019b).

3 Lipids of the excretory-secretory products and tissue extracts of helminths

Out of the 28 helminth metabolomics studies we reviewed, 17 solely focused on lipidomics analysis (as shown in Table 2), using untargeted (8 studies) and targeted (9 studies) approaches. However, only seven of these studies achieved MSI level-1 identification (i.e., confirmed the identity of lipids with authentic standards) (refer to Table 3 and Fig. 3), while 10 studies reported MSI level-2 (putatively identified) lipids. Due to the large number of putative lipids identified, it is not feasible to include them all in this review, and they can be accessed from the references in Table 2. For example, in the infective stages of *N. brasiliensis* and *T. muris*, 350 putative lipids were identified, with glycerophospholipids and glycerolipids being the predominant lipid groups (Yeshi et al., 2020). In *S. mansoni*, Ferreira et al. (2014a) reported the presence of phospholipids and triacylglycerols, with phosphatidylcholines (PCs) being the major lipids (Ferreira et al., 2015). Similarly, Wang et al. (2020) putatively identified 587 lipids from the somatic tissue extract of *Ascaris suum*.

The identities of 55 lipids produced by 10 different helminth species at various life cycle stages were confirmed through MSI level-1 identification protocols after excluding duplicates (Table 3). Many unique MSI level-1 identified lipids were reported, such as seven unique lipids

(elaidic acid, erucic acid, heneicosylic acid, lignoceric acid, nonadecylic acid, pelargonic acid, and stearic acid) from *A. caninum*, five (linoleic acid, linolenic acid, 2,5-dimethyl-2E-tridecenoic acid, 7-methyl-6E-hexadecenoic acid, and 7,7-dimethyl-5Z,8Z-eicosadienoic acid) from *D. viviparus*, three (caproic acid, valeric acid, and tiglic acid) from *A. lumbricoides*, and one in *T. canis* (α -glycerophosphorylcholine) (Table 3). Only three lipids were isolated and identified using ^1H NMR spectroscopy (i.e., from somatic tissues of *T. canis*) (see Table 2). There were 41 lipids common to all 17 helminths included in Table 3, such as palmitic acid, oleic acid, and stearic acid, which were present in eight helminth species (*A. caninum*, *T. canis*, *D. caninum*, *N. brasiliensis*, *T. muris*, *D. viviparus*, and *S. ratti*).

The presence of fatty acids such as cis-octadecenoic acid, branched-chain, and monoenoic acids like oleic and vaccenic acid can modify the physical properties of host cell membranes and result in cell rupture (Ward, 1982). However, caution should be exercised when considering common and unique lipids among these helminths, as each study's experimental conditions and analytical platforms vary. Stearic acid (C18) was found to be one of the major fatty acids in the ESPs of adult *A. caninum* (Wangchuk et al., 2019c), *T. muris*, and *N. brasiliensis* (Wangchuk et al., 2019b), *T. canis* (Wangchuk et al., 2020), *D. caninum* (Wangchuk et al., 2019a), and *Ascaridia galli* (Ghosh et al., 2010). Additionally, stearic, palmitic, palmitoleic, and oleic acids were the most prevalent fatty acids identified in the free-living (L1 – L3) and parasitic stages of *D. viviparus* (Becker et al., 2017).

Fig. 1 Venn diagram showing both common and uncommon MSI-1 identified polar metabolites among different helminth species

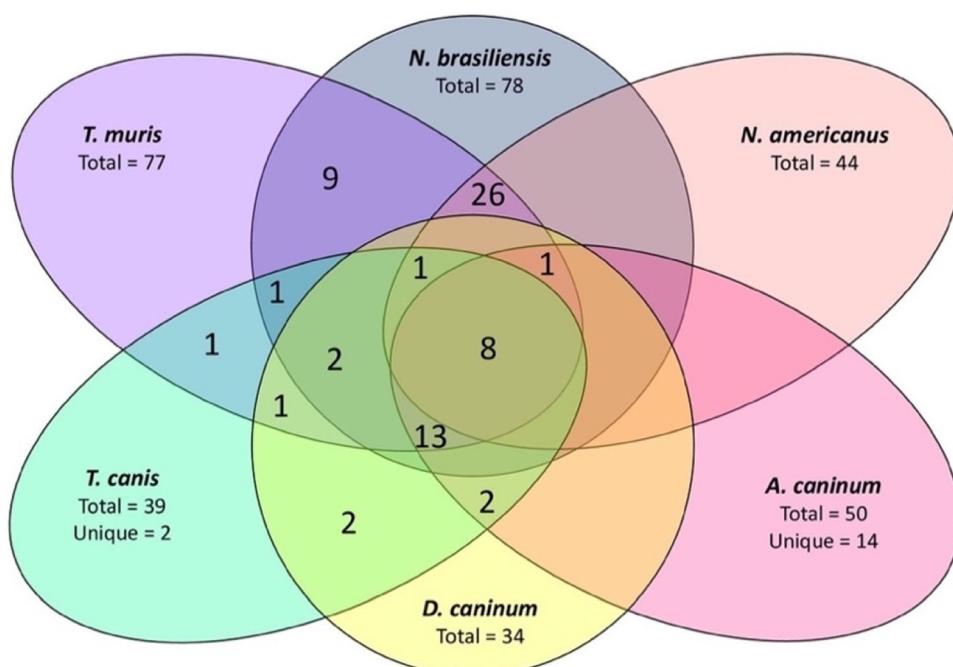

Table 2 Polar metabolites identified (MSI-1 confirmed) from the excretory-secretory products and tissue extracts of helminths (Fairbairn, 1958a; Nadjsombati et al., 2018; Wangchuk et al., 2019a, 2019b, 2019c, 2020; Yesi et al., 2020)

Polar metabolites	Helmint and life-cycle stage	Sample types	Formula	Chemical sub class*
Adenine	<i>Nippostrongylus brasiliensis</i> (L3); <i>Trichuris muris</i> (embryonated eggs, adult); <i>Necator americanus</i> (L3)	SE, ESPs	C ₅ H ₅ N ₅	Purines and purine derivatives

MSI-1 Metabolomics Standards Initiative Level-1; SE somatic extract; ESPs excretory/secretory products; L3 third-stage larvae

*Chemical sub class as described in HMDB and PubChem

Fig. 2 Chemical structures of commonly reported compounds (polar) unique to specific helminth species. Compounds 1–13: unique to adult *A. caninum*; compound 14: unique to adult *T. canis*; compounds 15–17: unique to infective larval third stage (L3) of *N. brasiliensis*

Barrett (1981) reported that helminths have a higher percentage of unsaturated C18 fatty acids than other lipid compositions. However, as they transition from free-living to the parasitic stage, considerable changes occur, including alterations in energy metabolism (Harder, 2016) and membrane fatty acid composition (Proudfoot et al., 1990). For instance, free-living stages require more unsaturated fatty acids in their membrane to protect themselves from low environmental temperatures, but these fatty acids are not required as they develop into the parasitic stage (Hazel & Williams, 1990). The majority of the fatty acids identified in adult stages of *A. caninum* (Wangchuk et al., 2019c), *T. muris* and *N. brasiliensis* (Wangchuk et al., 2019b), *D. caninum* (Wangchuk et al., 2019a), and *D. viviparus* (Becker et al., 2017) were saturated fatty acids, which supports the phospholipid membrane hypothesis (Proudfoot et al., 1990), as membrane phospholipids have a polar head and two nonpolar tails (composed of fatty acids), whereby one of the tails has saturated fatty acids (Lombard, 2014). However, in *Haemonchus contortus*, fatty acid saturation levels decreased as they matured into the parasitic stage (Wang et al., 2018). There was a reduced synthesis of triradylglycerols and increased glycerophospholipids (predominantly glycerophosphocholines)

and glycerophosphocholines) as *H. contortus* transitioned from free-living to the parasitic stage. In *Trichinella papuae* L1 stage, glycerophospholipids were dominant, with the most abundant glycerolipid diglycerides (Mangmee et al., 2020). The tegumental membranes of *S. mansoni* are also enriched with unsaturated fatty acids such as eicosenoic acid (20:1) and 5-octadecenoic acid, which were absent in their host (Retra et al., 2015). Phosphatidylethanolamines (PE) were abundant in *O. ochengi* worms and bovine nodule fluid, suggesting that these phospholipids might be released from *O. ochengi* into the host and could serve as potential biomarkers (Wewer et al., 2017).

Giera et al. (2018) found that the lipid composition of different life cycle stages of *S. mansoni* varied. Prostaglandins were enriched in eggs, while the cercaria stage contains mainly resolvins. Mature eggs of *S. mansoni* had higher levels of phospholipids, while immature eggs contained more neutral lipids (Bexkens et al., 2019). *S. mansoni* does not oxidise fatty acids because they lack the genes encoding enzymes required for β -oxidation. Instead, they (mostly females) uptake and use fatty acids, including stored fatty acids such as triacylglycerols, which are used for membrane phospholipid biosynthesis in developing

Table 3 Lipids identified (MSI-1) from the excretory-secretory products, and tissue extracts of helminths (Grechus & Grechus, 1966; Learmonth et al., 1987; Minematsu et al., 1990; Nadjsombati et al., 2018; Wangchuk et al., 2019a, 2019b, 2019c, 2020; Yeshi et al., 2020)

MSI-1 Metabolomics Standards Initiative level-1; SE somatic extract; ESPs excretory-secretory products; L3 third stage larva; L4 fourth stage larva

*Chemical sub class as described in HMDB, LipidMaps, and PubChem

Fig. 3 Venn diagrams showing the MSI-1 identified lipids among different helminth species

miracidia (Bexkens et al., 2019). Prostaglandins are not only enriched in *S. mansoni* eggs, but they are also major lipids in *T. suis* ESPs (Laan et al., 2017).

4 Metabolic pathways and biosynthesis

This review found that 155 metabolites, including 100 polar compounds and 55 lipids were identified using MSI level-1 identification protocols. Therefore, our discussion of biosynthetic pathways is focussed on these metabolites. We observed that helminths primarily rely on amino acids, carbohydrates, and lipids metabolism in both adults and infective stages, depending on the culture media used for ESPs collection. Amino acids were the most commonly reported metabolites from helminths, and pathway analysis revealed that aminoacyl-tRNA biosynthesis, arginine biosynthesis, lysine degradation, aspartate, alanine, and glutamate metabolism were the most common amino acid pathways (Yesi et al., 2020). Yesi et al. (2020) also suggested that isocitrate, a unique metabolite in the ESPs of *N. brasiliensis* infective stage, could be the product of glyoxylate metabolism, a common pathway in free-living nematodes. Adult helminth parasites typically use two forms of energy metabolism: anaerobic glycolysis, which is predominant in schistosomes and filarial nematodes, and degradation of carbohydrates to phosphoenolpyruvate (PEP) through the same glycolytic pathway without oxygen (Tielens, 1994). The presence of PEP in adult *T. muris* and most of the helminths included in this review suggests that anaerobic degradation of carbohydrates to PEP could be one of the primary energy pathways.

Parasites typically have a functionally incomplete TCA cycle (Prichard, 1989), as observed in the parasitic helminths discussed in this review. Glucose is obtained from the host and subsequently utilised in anaerobic glycolysis (Müller et al., 2012). Parasitic helminths, in particular, prefer lipids and amino acids over carbohydrates as a source of energy (Clark, 1969). Amino acid metabolism is a major pathway for these parasites, and they use the TCA cycle and fatty acid degradation for this purpose rather than for ATP production (Tielens and van den Bergh, 1993). Studies have shown that C¹⁴-labelled glucose in dog hookworm is not converted to glycogen (Araujo et al., 2013) but is instead diverted into amino acid production (Perez Gimenez et al., 1967) in a metabolism dominated by fermentative processes (Müller et al., 2012; Warren & Poole, 1970). Exposure to dog sera increases feeding rates in dog hookworm (L3 stage) (Warren & Guevara, 1962), and large diffusible solutes (such as the protein fraction) stimulate glucose consumption (Komiyama et al., 1956). Adult dog hookworms are capable of aerobic metabolism, and cyanide inhibition studies indicate that they have a

TCA cycle that can oxidize pyruvic and succinic acids (Warren & Karlsson, 1965). However, NADH respiration is not strongly coupled to oxidative phosphorylation, and hookworms lack respiratory control (Warren, 1970). The activity of succinoxidase in adult *A. caninum* is not tightly coupled to the synthesis of ATP, and external NADH oxidation that is not coupled to phosphorylation can occur. The low phosphorylation or oxidation ratios may reflect loosely coupled respiratory pathways or the existence of two respiration pathways—one coupled to the esterification of inorganic phosphate and another to the NADH pathway (Warren, 1970).

Recent studies have shown significant interest in immunometabolism, which investigates the metabolic profiles of activated immune cells and their role in immune homeostasis (O'Neill et al., 2016). In particular, six pathways have been linked to immune function: glycolysis (which is pro-inflammatory), the TCA cycle, the pentose phosphate pathway, fatty acid oxidation, fatty acid synthesis, and amino acid metabolism. Interestingly, high levels of fatty acids and amino acids have been found to inhibit cell activation of the mTOR pathway, which can have anti-inflammatory effects (O'Neill et al., 2016). It would be intriguing to investigate the levels of mTOR expression at the site of gastrointestinal helminth attachment in the gut to determine whether this is one of the mechanisms by which the worms induce immune tolerance. Furthermore, M1 and M2 macrophages have distinct differences in their TCA cycles, with M2 macrophages having a complete TCA cycle, while M1 macrophages have a TCA cycle that is broken in two places (after citrate and succinate) (O'Neill et al., 2016). Notably, M2 macrophages are associated with helminth expulsion, yet we observe that *A. caninum* exhibits the broken TCA cycle pattern associated with M1 macrophages, suggesting that other factors may influence macrophage polarisation in helminth infections.

The interactions of the end products of helminth metabolism within the host have not been extensively studied. Additionally, there needs to be more investigation into the role of secondary metabolites produced by helminths and their roles in the host-parasite relationship. Parasites often utilize fermentation as a metabolism, producing end products such as short-chain fatty acids (SCFAs). However, we can easily distinguish cellular intermediates of biochemical pathways in the case of *A. caninum*. While these molecules may be released from dying cells or the worm itself, we believe that the hookworm actively secretes these molecules to create an environment of tolerance and immune homeostasis around its attachment sites, despite the relative impermeability of its outer cuticle. It has been observed that successful parasites, including *A. caninum*, use anaerobic metabolism during active

parasitism to produce fatty acids, such as SCFAs, which may play essential roles in modulating host immune responses.

Helminths in their parasitic stages contain more diverse range of fatty acids than their non-parasitic stages (Becker et al., 2017), as lipids are essential for establishing their niches inside their hosts (Sato et al., 2008). Glucose is metabolized to produce SCFAs, such as acetate and propionate, while L-valine and L-leucine are the precursors of isobutyric acid and isovaleric acid, respectively, as demonstrated by labelling studies (Warren, 1970). *A. lumbricoides* was the first to have a few SCFAs, such as acetic acid, propionic acid, *n*-valeric acid, methylbutyric acid, and methylvaleric acid, reported in 1965 (Beames, 1965). Our studies involving *A. caninum*, *D. caninum*, *T. canis*, and *T. muris* (Wangchuk et al., 2019b, 2019c) showed that fatty acids, including SCFAs, were the major lipids metabolised when cultured outside their host using a single-component culture media (Glutamax). Another group reported the presence of saturated fatty acids (not SCFAs) from the ova of *A. caninum* (Gyawali et al., 2016). The origin of the excreted SCFAs of *A. caninum* was demonstrated through D-glucose-¹⁴C isotope labelling, which suggested intermediary glucose metabolism in both aerobes and anaerobes (Warren & Poole, 1970). The formation and excretion of acetate as a metabolic end-product of energy metabolism have also been reported in many other helminth parasites, such as *F. hepatica*, *A. suum*, and *H. contortus* (Tielens et al., 2010).

However, another body of scholarly literature suggests that helminths cannot synthesize most essential lipids, including SCFAs, and instead rely on obtaining them exogenously from their host (Smyth, 1994). For instance, it is reported that schistosomes obtain lipids from their host and convert them to triglyceride (TG) (Brouwers et al., 1997), as they cannot synthesize fatty acids (Berriman et al., 2009). Analyses of the available literature have revealed that two enzymes are involved in propanoate synthesis in *A. caninum*. However, enzymes involved in SCFAs biosynthesis, such as cytosolic acetyl-CoA synthetase or an organellar acetate: succinate CoA-transferase, are poorly represented when mapped against the known metabolic KEGG pathways of 81 worm genomes (Wangchuk et al., 2019c). This suggests that helminths are unable to synthesize SCFAs. It has been suggested that gut microbiota could be another source of SCFAs in helminth ESPs. Studies have shown that experimental human hookworm infection enriches bacterial species in the gut interface and elevates the production of SCFAs (Giacomin et al., 2015). The SCFAs such as acetate, butyrate, and propionate are produced and utilized by bacteria and benefit host epithelial cells by producing molecules such as vitamin B₁₂ (Belzer et al., 2017). However, due to

contradictory biosynthetic information described in the literature, further studies will be needed to define the contribution of the commensal microbiome to fatty acid production, especially SCFAs synthesis in helminths.

Helminth-derived lipids also participate in biochemical interactions between the host and the parasite. However, most lipids reported from various helminth metabolomics studies, including those listed in Table 2, are putative, and only about 55 lipids have been identified at MSI level-1 (confirmed with reference standards), primarily fatty acyls (as shown in Table 3). Fatty acids are crucial in various biological processes, and some, such as the *cis*-form of octadecanoic acid (stearic acid), monoenoic acids (oleic acid and vaccenic acid), and other branched-chain acids, aid in penetrating the host cell membrane (Ward, 1982). The presence of octadecanoic acid (stearic acid) and oleic acid in the ESPs or somatic tissues of at least seven helminths (as listed in Table 1) suggests that these compounds may play a role in host invasion and establishing infection (Yeshi et al., 2020).

The utilization of lipids by helminths varies across different stages of their life-cycle. During the parasitic adult stage, helminths mainly rely on their host for energy and nutrients, utilizing only specific fatty acids and fat-soluble vitamins for energy (Tielens, 1997). Many lipids are stored and excreted, later becoming food for gametes in adults, without other essential functions (Barrett, 1968; Cheng, 1986). It is hypothesized that SCFAs, such as propionate and acetate, identified in the ESPs of adult *A. caninum*, *N. brasiliensis*, and *T. muris*, may be stored as food reserves for gametes (Andoh et al., 1999; Kovarik et al., 2011; Tedelind et al., 2007). Other lipids, such as phosphatidylcholines (PCs), have been identified as major lipids in *S. mansoni* (Ferreira et al., 2015), while pterin was detected in the ESPs of the infective L3 stage of *N. brasiliensis* (Yeshi et al., 2020). Succinate (succinic acid) is among the metabolites reported to be secreted or excreted by a few helminth species, including *N. brasiliensis*, *N. americanus*, *T. muris*, *A. caninum*, *D. caninum*, and *T. canis* (Table 1).

Over 500 putative metabolites, including lipids, have been reported from a single helminth species (Wang et al., 2018, 2020; Wangchuk et al., 2019b; Yeshi et al., 2020), yet their bioactivity remains largely unexplored. Currently, only 20–30% of the total metabolites are known, with 70–80% remaining unidentified due to limitations in identification protocols and helminth-specific compound libraries. There is a pressing need for extensive and comprehensive metabolomics studies. In 2020, a new pulsed MS ion generation technique called triboelectric nanogenerator inductive nanoelectrospray ionization (TENGi nanoESI) MS was introduced. This technique enables the analysis of volume-limited samples, even at nanolitre scale, via LC–MS (Li et al., 2020). Such technological

advancement are likely to popularise metabolomics studies of helminths. Isolating compounds from helminths could result in discovering many novel molecules new to science, thereby improving the understanding of helminth biology and their molecular interactions with hosts.

5 Conclusion

While there is a significant amount of literature on genomic and proteomic analyses of parasitic helminths, metabolomics is a relatively new ‘omics’ technology that has recently been applied to study helminth metabolomics. The metabolome is the final downstream product of the genome and proteome and has proven to be complementary approach to genomics and proteomics techniques in understanding helminth biology at a more comprehensive level. Metabolomics techniques are increasingly being used to study helminths in various ways, including in vitro parasite culture, in vivo animal models, and clinical studies in humans. Initially, many metabolomics studies focused on detecting changes in the metabolome profile of infected hosts (mostly in vivo animal and human biofluids) compared to ESPs derived from in vitro parasite culture.

We analyzed 28 studies that reported the metabolomic assessment of ESPs and somatic tissue extracts of 17 helminth species grown under in vitro culture conditions. Of these 28 reported studies, included in this review, 19 achieved the highest level of metabolite identification (MSI level-1), while the remaining studies reported MSI level-2 identification. Only 155 small molecule metabolites, including polar and lipids, were identified using MSI level-1 characterization protocols from various helminth species. Although MSI level-1 is the best and the highest identification level, its use is limited by the number of known standards, which are often expensive and may not be readily available to researchers or metabolomics institutes. As a result, targeted and MSI level-1 platforms are only sometimes feasible options for researchers.

The advances in analytical technologies and identification tools offer immense potential for providing a comprehensive metabolic snapshot of helminths throughout their lifecycle and greater opportunities for higher identification rates. However, several challenges must be addressed when using this latest ‘omics’ platform. These challenges include:

- The need for expensive analytical instrumentation such as MS and NMR to obtain raw data makes it challenging for resourced-constrained countries with high helminth endemicity to conduct metabolomics studies. Moreover, none of these analytical platforms

can provide a complete picture of complex helminth-derived samples.

- The requirement of sophisticated bioinformatics tools and statistical software for data management, integration, mining, and interpretation. Although many free software programs are available, no standardized software programs can be used across all the analytical platforms.
- Existing helminth databases, such as WormBook, WormBase, and Wormatlas focus on the biology, breeding, genome, proteome, and biochemistry of the free-living model nematode *Caenorhabditis elegans*, rather than parasitic helminths. As the metabolic pathways and metabolome compositions of the free-living *C. elegans* and parasitic helminths are expected to be different, a database specializing in parasitic helminth-specific small molecules is needed.
