In this talk we report on a study on the mixing of neutral charmed mesons and argue that, at the present stage, a CP violating weak phase of the order of some per mille can not be excluded in the Standard Model. It is shown how some, seemingly reasonable, simplifying assumptions about CKM couplings lead to the wrong conclusion that CP violation of this amount is an unambiguous indication of new physics.

The presented results rely on a recent short-distance analysis of the $\Delta C = 2$ transition, which confirms the expectation that the dominant contribution is due to effects of flavour symmetry breaking appearing in higher orders of the Heavy Quark Expansion. We investigate meson-antimeson transitions with an intermediate state coupling to the meson's sea quark background, present in dimension 10 and 12, using a factorisation approach to simplify the operator basis. On account of a lifting of GIM suppression by one power of m_s/m_c , the contribution to $y = \Delta\Gamma/2\Gamma$ is found to exceed that of the formally leading dimension six by a factor close to ten.

1. Introduction

Flavour oscillations of neutral mesons arise in presence of non-zero mass and width differences ΔM and $\Delta\Gamma$ between the long- and short-lived mass eigenstate components. First evidence for D^0 oscillations was reported in 2007 by *Belle* and BABAR, and later confirmed by CDF [1]. HFAG quotes the current world average for the D^0 mixing rates to be $x \equiv \Delta M/\Gamma = (0.59 \pm 0.20)\%$ and $y \equiv \Delta\Gamma/2\Gamma = (0.80 \pm 0.13)\%$ [2]. On the theory side, two approaches are known to predict these quantities: in the inclusive approach, the $\Delta C = 2$ transition amplitude is determined at quark-level in the full Standard Model [3, 4]. The calculation relies on the Heavy Quark Expansion (HQE), an expansion of the effective Hamiltonian into a series of local operators of increasing dimension. An alternative possibility is to obtain the width difference from an exclusive sum over hadronic intermediate states [5], requiring the knowledge of many decay amplitudes and strong phases to a high precision. At present, none of these approaches leads to completely satisfying results.

2. Dimension six and seven

Diagonalisation of the 2×2 mixing Hamiltonian $\hat{H} = \hat{M} + i\hat{\Gamma}/2$ relates mass and width difference to the off-diagonal elements M_{12} and Γ_{12} . This study reports on a calculation of Γ_{12} in an HQE framework, *i.e.* as an expansion into a series of operators \mathbf{Q}_D of mass dimension D :

$$\Gamma_{12} = \frac{1}{2M_{D^0}} \text{Im} i \int d^4x \langle \bar{D}^0 | \text{T} \mathcal{H}(x) \mathcal{H}(0) | D^0 \rangle = \sum_{D=0}^{\infty} \left(\frac{\Lambda}{m_c} \right)^D \mathbf{G}_D \langle \mathbf{Q}_D \rangle. \quad (2.1)$$

First contributions to Γ_{12} appear for $D = 6$, associated with the absorptive part of the $\Delta C = 2$ box diagram. Prior to this work, the Wilson coefficients \mathbf{G}_D have been known up to $D = 8$ and at next-to-leading order QCD. The GIM mechanism, an effect of CKM hierarchy and residual $\text{SU}(3)_F$ quark flavour symmetry, requires these contributions to be very small in the Standard Model: expanding with respect to the CKM structure and using the unitarity of the CKM matrix, Γ_{12} can be written as

$$\Gamma_{12} = -\lambda_s^2 \left(\Gamma_{12}^{ss} - 2\Gamma_{12}^{sd} + \Gamma_{12}^{dd} \right) + 2\lambda_s\lambda_b \left(\Gamma_{12}^{sd} - \Gamma_{12}^{dd} \right) - \lambda_b^2 \Gamma_{12}^{dd}, \quad (2.2)$$

where $\lambda_q = V_{cq}^* V_{uq}$. The CKM couplings $\lambda_s = \mathcal{O}(\lambda)$ and $\lambda_b = \mathcal{O}(\lambda^5)$ induce a hierarchy in powers of the Wolfenstein parameter $\lambda \simeq 0.2255$. In the limit of exact $\text{SU}(3)_F$ symmetry the linear combinations in brackets cancel to zero. $\text{SU}(3)_F$ breaking effects enter as terms proportional to powers of $\bar{z} = \bar{m}_s^2(\bar{m}_c)/\bar{m}_c^2(\bar{m}_c)$. Residual flavour symmetry gives rise to cancellations down to terms of order \bar{z}^2 in the CKM-leading, and of order \bar{z} , respectively, in the CKM-subleading contribution, *i.e.*

$$\Gamma_{12} = -(1.15 \bar{z}^2 - 59.7 \bar{z}^3) \lambda_s^2 - 5.5 \lambda_s \lambda_b \bar{z} - 1.96 \lambda_b^2 \simeq \lambda^{9.0} + \lambda^{8.0} + \lambda^{9.5}. \quad (2.3)$$

Numerically, we find $\Gamma_{12} = -(0.20 - 0.16i) \cdot 10^{-5}$, and accordingly $y \leq |\Gamma_{12}| \cdot \tau_D \simeq 10^{-6}$ [6], in agreement with previous studies. If the experimental average for y remains at its current central value, this is orders of magnitude too small. We remark that commonly the small imaginary parts of λ_d and λ_s are neglected, which is equivalent to setting $\lambda_b/\lambda_s \simeq 0$ in (2.2). Γ_{12} then is found to be real with high accuracy. Yet actually $\text{SU}(3)_F$ symmetry is efficient enough to make the second term in (2.2) even exceed the first one, such that the approximation $\lambda_b \ll \lambda_s$ certainly is

Figure 1: Contributions to the $\Delta C = 2$ transition formally appearing in dimension 6, 9 and 12 in the HQE. Crosses indicate intermediate states coupling to the diquark condensate.

not justified. Keeping all CKM factors exactly, $\arg \lambda_b = 1.17$ introduces an order one phase to Γ_{12} . We therefore think that strong claims, CP violation of the order of 1‰ was an unambiguous sign of new physics, should be met with some caution. As to an understanding of the remarkable deviation of the $D = 6, 7$ quark-level result from experiment, four main lines of argumentation are common: ⁽¹⁾ One could suspect the malfunction of heavy quark methods at the charm threshold, where QCD may become unmanageable and the inverse quark mass may no longer be a suitable expansion parameter. To investigate the behaviour of the perturbative expansion in QCD and $1/m_c$, we calculated the $\mathcal{O}(\alpha_s)$ and $D = 7$ corrections to the Γ_{12}^{ab} and found them to be below $\sim 25\%$. Although we certainly must not expect a precision prediction of D^0 mixing rates, this does not seem to us as an indication for a breakdown of the expansion. ⁽²⁾ Valence quark dynamics may cease to offer a reliable description for the hadron-level transition and non-perturbative long-distance dynamics, violating quark hadron duality, may become important. The dominant contributions to the $\Delta C = 2$ transition in this case would not be captured by the HQE approach. ⁽³⁾ There are reasons to expect $SU(3)_F$ -breaking effects in higher orders of the HQE, which could drastically enhance $\Gamma_{12}^{ss} - 2\Gamma_{12}^{sd} + \Gamma_{12}^{dd}$ and $\Gamma_{12}^{sd} - \Gamma_{12}^{dd}$. ⁽⁴⁾ And finally: also new physics could be responsible, *e.g.* by violating the 3×3 unitarity of the CKM matrix [7] or by introducing right-handed charged currents.

A more definite statement about the reliability of heavy quark methods could be provided by a future calculation of charmed meson decay widths; they receive the leading contribution from the spectator model charm decay $\Gamma_0(c)$ in $D = 3$, where GIM suppression is absent. For the time being, a first estimate can be obtained from a comparison of lifetime ratios $\tau(D^+)/\tau(D^0) \simeq 2.5$ and $\tau(D_s^+)/\tau(D^0) \simeq 1.2$ to experiment: writing $\Gamma = \Gamma_0(c)(1 + \delta)$ and neglecting the small difference in phase space between the decays of D^+ and D_s^+ , we extract that the leading order HQE is off by $\delta(D^0) = +17\%$, $\delta(D^+) = -53\%$ and $\delta(D_s^+) = -3\%$, respectively. Albeit in no way compulsive, this supports the expectation that the HQE should at least reproduce the correct order-of-magnitude. Note that this estimation is largely free of hadronic uncertainties, which cancel with $\Gamma_0(c)$.

3. Flavour symmetry breaking in higher dimensions

Formally, the smallness of the $\Delta C = 2$ box diagrams is due to the fact that one mass insertion per internal fermion line is required to break the $SU(3)_F$ flavour interference in (2.2), and a second one to compensate the chirality flip—leading to the double GIM suppression present in (2.3). It should, in accordance, be possible to lift one order of GIM suppression by cutting one of the internal fermion lines, allowing the loose ends to couple to the meson’s sea quark and gluon background. Diagrams of this kind appear in dimension $D \geq 9$ and $D \geq 12$, respectively, and commonly have been expected to be the dominant contributions within the HQE [3].

This work considers diagram topologies with one intermediate state coupling to the low-energy background (*cf.* Fig. 1), contributing at $D \geq 9$. We propose a factorisation approach to estimate the

meson state matrix elements of the appearing six-quark operators: we assume vacuum saturation for the coupling of the quark fields from the intermediate state, *viz.* we model the meson's non-valence substructure with the vacuum condensate, neglecting the effect of higher excitations. Doing so reduces the operator basis to $Q = \bar{u}_L \gamma^\mu c_L \otimes \bar{u}_L \gamma_\mu c_L$ and $Q_S = \bar{u}_R c_R \otimes \bar{u}_R c_R$. To overcome $SU(3)_F$ interference, the effect of the diquark condensate has to be included up to next-to-leading order in the spatial separation between the quark fields,

$$\begin{array}{c} \longrightarrow \times \quad \times \longrightarrow \\ \langle \bar{q}q \rangle \end{array} = \langle 0 | : q(x) \otimes \bar{q}(0) : | 0 \rangle = -\frac{\langle \bar{q}q \rangle}{4N_c} \times \mathbb{1}_c \left(\mathbb{1}_D - \frac{im}{4} \not{x} \right). \quad (3.1)$$

Within this setup, non-vanishing contributions appear in $D = 10$ and $D = 12$. As expected, we find small $\mathcal{O}(1\%)$ corrections to the Γ_{12}^{ab} , which reveal a pronounced breaking of $SU(3)_F$ symmetry and survive as large effects after the flavour cancellations in (2.2). Numerically,

$$\delta\Gamma_{12} = -(1.8 + 0.1i) \cdot 10^{-5} = -0.43 \lambda_s^2 \bar{z}^{\frac{3}{2}} + 0.38 \lambda_s \lambda_b \bar{z}^{\frac{1}{2}} \simeq \lambda^{7.3} + \lambda^{8.2}. \quad (3.2)$$

Note that the contribution to the CKM leading part $\Gamma_{12}^{ss} - 2\Gamma_{12}^{sd} + \Gamma_{12}^{dd}$ exceeds its $D = 6$ value by a factor of 13. The prediction for the mixing rate y likewise is enhanced by a factor $\mathcal{O}(10)$ to $y \lesssim 0.9 \cdot 10^{-5}$. The weak phase $\arg\Gamma_{12}$ still remains at the level of $\sim 3\%$. In the light of these results, CP violation at the per cent level does not seem unnatural in the $\langle \bar{q}q \rangle$ contribution.

4. Future perspectives

Our results are valid in the limit of factorisation and vacuum saturation of the sea-quark contribution. Non-factorisable contributions still need to be quantified. A similar calculation for M_{12} is subject of ongoing work. A result for M_{12} will allow definite predictions of y and the physical weak phase $\phi = \arg(-M_{12}/\Gamma_{12})$. Further efforts could also be directed towards diagram topologies with an intermediate coupling to the four-quark condensate ($D \geq 12$), from which a second order of flavour violation can be expected, possibly associated with an even larger enhancement of y .
