19 **Abstract [228 words]**

20 Diverse forms of cultivation have evolved across the tree of life. Efficient farming requires
21 that the farmer deciphers and actively promotes conditions that increase crop yield. For plant
22 cultivation, this can include evaluating tradeoffs among light, nutrients, and protection
23 against herbivores. It is not understood if, or how, non-human farmers evaluate local
24 conditions to increase payoffs. Here, we address this question using an obligate mutualism
25 between the ant *Philidris nagasau* and epiphytic plants in the genus *Squamellaria* that are
26 farmed for their nesting sites and floral rewards. We focused on the ants' active fertilization
27 of their crop and its protection against herbivory. We found that ants benefited from
28 cultivating plants in full sun, receiving 7.5-fold more floral food rewards compared to shade-
29 cultivated plants. The higher reward levels correlated with higher levels of crop protection
30 provided by the ants. However, while high-light planting yielded the greatest immediate food
31 rewards, sun-grown crops contained less nitrogen compared to shade-grown crops. This was
32 due to lower nitrogen input from ants feeding on floral rewards instead of insect protein
33 gained from predation. Despite this tradeoff, farming ants optimize crop yield by selectively
34 planting their crops in full sun. Ancestral state reconstructions across this ant-plant clade
35 show that a full sun farming strategy has existed for millions of years, suggesting that non-
36 human farmers have evolved the means to evaluate and balance conflicting crop needs to
37 their own benefit.

38
39
40 **Significance [106 words]**

41 In human cultivation systems, farmers increasingly use technology to gather data for
42 evaluating tradeoffs between diverse - and sometimes conflicting - crop requirements to
43 maximize yield. Some social insects have also evolved agricultural practices, but it is
44 unknown how they evaluate local conditions to balance conflicting crop requirements. In the

45 obligate farming symbiosis between ants and plants in Fijian rainforests, we show how ant
46 farmers also face key tradeoffs in crop cultivation. While ants cannot simultaneously
47 maximize all services to their crops, our work demonstrates that they cultivate crops in high-
48 light conditions to maximize floral food rewards, despite the nitrogen costs of this strategy.
49 Evaluation of crop tradeoffs plays a key role in the evolution of farming strategies.
50
51

52 **Introduction**

53 Across the tree of life, organisms have evolved the ability to cultivate or ‘farm’ individuals of
54 other species (1-6). This can involve habitual planting, husbandry, and harvesting of ‘crops’,
55 such as seen in social amoebae rearing bacteria (1), marine snails propagating fungi (2), and
56 damselfish cultivating seaweed (3). True agriculture, as defined by four key steps – namely
57 habitual planting, cultivation, harvest and dependence of the farmer on the crop (7) - is
58 restricted to social insects (ants, termites, beetles) cultivating fungi (7-10) and ants cultivating
59 plants (11).
60

61 True agriculture is also practiced by humans, and generally involves the farmer deciphering
62 and actively promoting the conditions that increase yield. For plant crops, this can involve
63 evaluating tradeoffs among requirements for light, nutrients, and protection against
64 herbivores. The ability to evaluate tradeoffs is important because farmers, both human and
65 non-human, are unlikely to find conditions in which all crop needs are optimally and
66 consistently met. For example, increasing nutrient conditions may inadvertently increase
67 herbivore pressure (12), whereas increasing crop densities may negatively affect light
68 conditions for individual plants (13).
69

70 While in human farming, technology and modeling are increasingly employed to evaluate
71 complex tradeoffs (14, 15), it is not understood if, or how, non-human farmers evaluate local
72 conditions to increase payoffs. There are cases of early insect agriculture in which tradeoffs
73 are largely unresolved, and conflict can emerge between farmers selecting for edible hyphae,
74 and fungal crops allocating resources to reproductive structures, such as mushrooms (16).
75 Such conflicts, as seen between phylogenetically basal attine ants and their basidiomycete
76 fungal crops, can result in low-productivity farming (16). In contrast, there are cases of
77 agriculture involving a suite of adaptations and coevolved traits, such as practiced by leaf
78 cutter or plant-farming ants, in which ant farmers appear to actively manipulate conditions to
79 increase yield per unit input. Leafcutter ants, for example, mediate their local environment in
80 ways that increase productivity, such as by sustaining large populations of Actinomycete
81 bacteria in specific crypts that suppress parasites in fungal gardens (17). However, as farmers
82 cannot simultaneously optimize all conditions (e.g. herbivore and pathogen defense,
83 fertilization, modulating environmental variables), it is an open question as to whether, and
84 how insect farmers mediate crop tradeoffs.
85

86 To answer this question, we studied an obligate farming mutualism between the ant *Philidris*
87 *nagasau* (Dolichoderinae) and epiphytic plants in the genus *Squamellaria* (Hydnophytinae,
88 Rubiaceae), occurring in Fijian rainforests on Taveuni and Vanua Levu islands (11). *Philidris*

89 *nagasau* workers cultivate multi-plant colonies of *Squamellaria* epiphytes that can contain 50
90 or more individuals whose plant-formed cavities in modified stems (domatia) house one
91 queen and ~250,000 workers (11, 18). In this mutualism, the ants control dispersal,
92 fertilization, and defense of the epiphytes. They do this by actively collecting *Squamellaria*
93 seeds, planting them under the branch bark of their host tree, and subsequently protecting
94 both seedlings and adults from herbivory (11, 18). The ants also fertilize these nutrient-
95 limited (soilless) epiphytes by defecating on specialized and highly absorptive warts within a
96 plant's tuberous domatium, which is also the ants' obligatory nest site (11, 18). In return, the
97 ants feed on sugar and amino-acid-rich food rewards produced by the flowers' nectaries. The
98 food rewards and the domatia, which contain a complex network of interconnected cavities
99 (11, 18-21), are key to the ants' survival. Similar to the other 'true' agricultures in attine ants,
100 termites, and ambrosia beetles (7), there is an obligate dependence of the farmer on the crop
101 (11, 18). *Squamellaria* crops are likewise obligately dependent on the farmer (11, 18).

102
103 By controlling dispersal, fertilization, and defense of the crop, the farmer could potentially
104 maximize crop productivity by modulating growing conditions, but this remains poorly
105 understood. Specifically, it is unknown if farming strategies are tailored to particular
106 environmental conditions. Because of the challenges in empirically manipulating most
107 farming mutualisms, it is difficult to test how demands for light, nutrients, and protection are
108 evaluated by insect farmers. Here, we address this challenge by studying the *Philidris*
109 *nagasau*-*Squamellaria* farming mutualism under different natural light conditions. Our aim is
110 to test if ants optimize farming and defense of their crop to match local environments. Using
111 productivity metrics, behavioral assays, and stable isotope analyses, we asked: (i) whether
112 crop productivity (i.e. food rewards) is influenced by light conditions, (ii) how defense levels
113 provided by farmers to their crop differed along light gradients? and (iii) whether there are
114 tradeoffs between farming traits, such as active fertilization, and other crop services across
115 light levels? We also traced the evolutionary history of farming strategies in the
116 *Philidris*/*Squamellaria* mutualism, using a densely-sampled plant phylogeny, to ask if light
117 niche is correlated over evolutionary time to defense and fertilization of the crop by the ants.

118 119 **Results and discussion**

120 121 **Crop productivity varies along a light gradient and correlates with herbivore defense** 122 **levels**

123
124 First, we asked how crop productivity, as measured by food rewards to ants, varied along a
125 natural light gradient. Mature *Squamellaria* flowers provide *P. nagasau* workers with a
126 sugary sap rich in sucrose and amino acids that is only accessible to this ant species (21). We
127 quantified food reward (number of post-anthetic nectaries, ref. 21) on $N = 133$ shoots
128 belonging to 50 *S. wilsonii* plants spanning a light gradient in Taveuni rainforest canopies
129 categorized as full shade, mid light exposed, and full sun, controlling for shoot size
130 (*Materials and Methods*).

131

132 We found that food rewards were 7.5-fold higher in plants cultivated in full sun than in plants
133 cultivated in full shade (**Fig. 1A**): higher light levels consistently led to more flowers and
134 hence food availability (**Fig. 1A**; ANOVA: $F_{2,150} = 20.19$, $P < 0.001$) (Tukey's HSD post hoc
135 test: full sun | full shade, $P = 0.0$; mid exposed | full shade, $P = 0.003$; mid exposed | full sun,
136 $P = 0.0004$). These data confirm that crop yield varies as a function of light regime and is
137 maximized when the crop is grown under high light conditions.

138
139 We then analyzed the links between crop yield and ant defense, asking how defense levels
140 provided by farmers to their crop, differed along light gradients. Specifically, we tested
141 whether higher rewards were correlated with increased crop protection, as this has the
142 potential to generate positive feedback for cultivation in sun conditions. We quantified
143 herbivory under different light levels and found that $< 25\%$ of the leaves of plants cultivated
144 in full sun showed herbivore damage. In contrast, herbivory increased to nearly 90% in plants
145 cultivated in full shade (**Fig. 1B**; ANOVA: $F_{2,150} = 70.05$, $P < 0.001$) (Tukey's HSD post hoc
146 test: full sun | full shade, $P = 0.0$; mid exposed | full shade, $P = 0.0$; mid exposed | full sun, P
147 < 0.001). The anti-herbivore defense role of *Pholidris nagasau* ants has also been shown in
148 previous ant-exclusion experiments (18).

149
150 Lower herbivory levels in full-sun could either be the result of higher ant defense or fewer
151 herbivores. We therefore measured ant patrolling behavior across light conditions,
152 systematically recording the distribution of *P. nagasau* workers on plant surfaces (*Materials*
153 *and Methods*). We found significantly more patrolling ants on full-sun plants compared to
154 fully shaded plants (**Fig. 1C**, t-test: $t = -16.17$, $df = 14.08$, $P < 0.001$), with a significant
155 negative correlation between the levels of rewards and herbivory along the light gradient
156 (**Fig. 1D**; $F_{1,151} = 105.2$, $P < 0.001$; Pearson correlation coefficient = -0.64). This suggests that
157 ants are more likely to patrol and defend *Squamellaria* under full-sun conditions when plants
158 bear more flowers, and more food rewards are available. This can also help generate partner-
159 fidelity feedbacks (18), such that there is alignment of colony size with plant size.

160
161 We further tested the alternative explanation that there are fewer herbivores in full sun by
162 running two additional experiments to determine herbivory levels across our three light
163 environments. While studies of herbivory in forest canopies generally find higher densities of
164 herbivores under sun compared to shade conditions, this can vary locally (22, 23). Therefore,
165 we quantified herbivory in three representative plant species (*Macaranga harveyana*,
166 *Miconia calvescens*, *Psychotria* sp.) with branches placed in experimental blocks across
167 different light levels (Experiment 1). After eight days, we imaged all leaves and calculated
168 herbivory levels (*Materials and Methods*). Our GLMM analysis revealed no consistent
169 association between herbivory and light level, except in *Macaranga* where we found a strong
170 positive effect of light environment ($F = 5.6$, $P = 0.01$), with a trend toward more herbivory
171 in full sun ($t = 1.96$, $P = 0.056$) (*SI Appendix, Fig. S1, Table S1*). We then repeated this
172 experiment with *Squamellaria wilsonii* (Experiment 2), and again found no significant
173 association between herbivory and light level (*SI Appendix, Fig. S2, Table S2*). Taken
174 together, these data suggest that the correlation between higher food rewards and lower

175 herbivory in full sun-grown *Squamellaria* is a result of increased patrolling by ants, not lower
176 herbivore abundance.

177

178 **The tradeoff between nitrogen fertilization and defense by ants along a light gradient**

179

180 In the variables quantified thus far – (i) food rewards to ant farmers and (ii) defense by ants
181 against herbivores – the interests of the farmer and its crop are aligned in full sun conditions:
182 ants are offered more rewards and plants benefit from better protection. However, ants
183 perform another crucial farming function, namely fertilizer input. This function is especially
184 important for nutrient-limited epiphytes that grow in soilless conditions. Targeted fertilization
185 is a key trait in this farming mutualism and involves *P. nagasau* workers defecating
186 exclusively on highly absorptive warts on the inner walls of domatia (18). This active
187 fertilization continues from the seedling to the adult stage of *Squamellaria* plants (11, 18).
188 However, it is unknown whether there are tradeoffs between active fertilization and other ant-
189 mediated crop demands across light levels.

190

191 To evaluate levels of nitrogen fertilization by *P. nagasau* under different light conditions, we
192 collected tissue from four *S. wilsonii* individuals from each of the three light environments.
193 We sampled six tissues (leaves, stem, roots, smooth cavity tissue, warty cavity tissue, and
194 tuber tissue, see *SI Appendix*, **Fig. S3A** for description) and quantified nitrogen content in
195 different tissues along the light gradient. For each tissue, we sampled triplicates, leading to a
196 total of $N = 18$ samples per plant, and a total of $N = 216$ samples.

197

198 Given the well-established positive relationship between leaf nitrogen and photosynthetic
199 capacity (24, 25), we had expected to find higher N levels in plants cultivated under sun
200 conditions. However, we found the opposite: across all tissues tested, plants growing under
201 full sun contained the least amount of N per g tissue (*SI Appendix*, **Fig. 2**, **Fig. S3B**, GLMM,
202 $t = -2.58$, $P = 0.03$), with N content increasing under mid- and fully-shaded conditions. We
203 found that the difference in N content between sun and shade was particularly pronounced in
204 the warty cavity wall (**Fig. 2**), the location in the domatia where ants defecate to fertilize their
205 crop. Here, we found that warty tissue of sun-grown plants had the lowest N per g of tissue.

206

207 The low N content of full sun-cultivated plants could arise from two scenarios. First, if
208 *Squamellaria* plants grow faster in full sunlight, this could lead to lower N level by diluting
209 nitrogen inputs. However, past work argues against this possibility. Specifically, a tight linear
210 correlation has been found between the size of the worker ant colony and the size of
211 *Squamellaria* domatium (i.e. a measure of plant growth) (18). This means faster plant growth
212 is mirrored by proportional increase in ant workers, and hence nitrogen inputs, thus
213 preventing a dilution effect. We verified that this relationship between worker population and
214 domatium size holds across light levels (*SI Appendix*, **Fig. S4**). This suggests that faster
215 growth in full sun is matched by a proportional increase in fertilizing ants, preventing N
216 dilution.

217

218 A second scenario is that nitrogen input is mediated by ant diet and differs across light levels.
219 Under this scenario, an ants' feces will reflect its diet, which will differ under shade versus
220 sun conditions. This is because plants cultivated by ants in the shade produce fewer flowers
221 and hence provide less food compared to sun-grown plants (**Fig. 1A**). As a result, *P. nagasau*
222 workers may be forced to forage for supplementary sugar and protein elsewhere in the
223 canopy, including foraging as predators for insect prey. If a greater proportion of the shade
224 farmer's diet consists of insects, rather than crop-produced rewards, this will lead to a greater
225 external N input into the shade system.

226
227 To test this explanation, we traced back the nitrogen in plant tissues to either plant-derived
228 resources or insect-predation using N stable isotope ratios ($\delta^{15}\text{N}$), following previous studies
229 (22, 23). We collected *P. nagasau* from $N = 8$ colonies across the light gradient and sampled
230 the warty-walled tissue of their domatia where ant defecation takes place. We found a tight
231 positive correlation (Pearson's correlation coefficient = 0.86; $P = 0.005$; *SI Appendix, Fig.*
232 **S5**) between ant $\delta^{15}\text{N}$ and warty-walled tissue N content. This correlation implies that light-
233 dependent food availability (from flowers or insects) drives the higher nitrogen input in shade
234 conditions.

235
236 We then quantified hunting behavior. If higher N levels in low light environments comes
237 from more insect hunting, we should observe different *P. nagasau* worker behavior in shade
238 vs. light colonies. By monitoring workers outside their crops in full-sun vs. shaded colonies,
239 we found significantly higher insect hunting activities in the shade, compared to sun colonies
240 (*SI Appendix, Fig. S6A-C*). To further test the ant's hunting behavior in sun vs. shade
241 environments, we offered a cockroach placed one meter from a *Squamellaria* crop (*Materials*
242 *and Methods*). We found that both the time of discovery, and the time of arrival of the second
243 recruit was significantly shorter in the shade (*SI Appendix, Fig. S6D-F*). This suggests that in
244 sun conditions, these canopy epiphytes are forced to more tightly recycle nitrogen because of
245 a lack of external N inputs. In contrast, shade-grown plants receive more external N from ant
246 feces because ants are forced to forage for insects to supplement their food.

247
248 A second test of the hypothesis that light influences fertilization input by ants via food
249 rewards is to compare N levels of *Squamellaria* without food rewards in the sun and shade
250 conditions. To do so, we took advantage of *Squamellaria grayi*, a species that has lost the
251 ability to produce food bodies over evolutionary time (20, 21). We compared nitrogen levels
252 of both ant workers and warty tissue grown in shade vs. sun in *S. grayi*. In contrast to *S.*
253 *wilsonii* that does produce food bodies, we found there was no significant difference in N
254 levels in shade vs. sun conditions in *S. grayi* that does not produce food rewards (*SI*
255 *Appendix, Fig. S7*), further supporting our idea that plant food rewards influence ant N input
256 across a light gradient.

257
258 We tested a final alternative explanation for the lower N content of sun-exposed *S. wilsonii*,
259 namely that they might be facultative (inducible) CAM plants. CAM plants have a
260 substantially lower rubisco content, hence contain less nitrogen per g of tissue. Under this
261 scenario, *S. wilsonii* would switch on CAM metabolism under full sun, leading to lower

262 nitrogen levels. Three of the six Fijian *Squamellaria* farmed by *P. nagasau* indeed have
263 CAM capabilities (20), but when we tested *S. wilsonii* for CAM activity by measuring the δ
264 ^{13}C ratio in warty tissue, roots and leaf samples across the light gradient all samples showed
265 values near -30‰ (*SI Appendix, Fig. S8*), ruling out substantial CAM activity in this species.
266 This is also supported by leaf morphology: while the three CAM *Squamellaria* all have
267 succulent leaves, *S. wilsonii* has thin leaves (20).

268
269 Together these experiments show that tradeoffs exist between two key services offered by the
270 ant to the plant, namely defense, which is highest under full sun, and ant-mediated nutrition,
271 which is highest in the shade. By populating a probabilistic model with our empirical data,
272 we find a clear tradeoff between defense and nutrition (**Fig. 3**). Similar to tradeoffs faced by
273 human farmers, ants cannot simultaneously maximize all services to their crops (**Figs. 1-3**).
274 Given that food rewards are likely to yield the highest immediate individual benefit to the
275 ants, it is expected that ants will plant crops in full sun (**Fig. 1**), even if this results in lower
276 fertilizer inputs to their crop.

277

278 **Farming tradeoff between defense and nutrition over space and time**

279

280 The identification of a light-mediated tradeoff between defense and nutrition prompted us to
281 investigate the extent to which farming ants can manipulate their crop's light environment
282 over space and time. *Squamellaria* species are either dispersed by birds (non-farmed) or by *P.*
283 *nagasau* ants (farmed) (11). We therefore asked if there was a difference in the height at
284 which farmed vs. a non-farmed *Squamellaria* species were found when they co-occurred in
285 the same forest. We found that farmed species were significantly higher in the canopy
286 compared to non-farmed species, dispersed by birds ($N = 30$, *SI Appendix, Fig. S9*, t-test: $t =$
287 7.57 , $df = 45.44$, $P\text{-value} < 0.0001$). We then determined the mean light niche for the nine
288 Fijian *Squamellaria* species, and found that farmed species are significantly more sun-
289 exposed than non-farmed species (**Fig. 4B**; Fisher's exact test (farmed vs. non-farmed): $\chi^2 =$
290 67.79 , $df = 2$, $P < 0.001$). In farmed *Squamellaria*, seedlings were found preferentially on
291 tree trunks that received direct sunlight, suggesting that light is a potential cue for where ants
292 plant *Squamellaria* seeds.

293

294 Given the evidence that farmed *Squamellaria* is associated with sun-exposed sites, why is
295 there any diversity in the height at which ants cultivate their crops? Two hypothetical
296 strategies could be employed: (i) a *balanced cultivation* in which *Squamellaria* are planted at
297 various light levels, ensuring a balance of high crop productivity in sun-exposed plants, and
298 high nitrogen inputs in shade-exposed crops. This would be effective since ant workers move
299 among domatia (Supplementary figure S2a in ref. 11); (ii) an *immediate rewards-first*
300 *cultivation* strategy, in which *Squamellaria* are consistently planted in sun-exposed sites only.
301 If this hypothesis is true, *Squamellaria* farmed within the same ant colony will be
302 predominantly found in a single light level.

303

304 To test which strategy is more likely, we mapped the light niche of 657 *Squamellaria wilsonii*
305 individuals from $N = 100$ *Philidris nagasau* colonies in Taveuni (*Materials and Methods*).

306 We found that light level, while controlling for tree size, was a predictor of crop number per
307 colony size, with shaded colonies being significantly smaller than sun-exposed colonies (**Fig.**
308 **4A**; ANOVA, $F_{4,95} = 5.82$, $P < 0.001$). Specifically, of the 657 *S. wilsonii*, 406 were growing
309 in full sun, 208 were growing in mid-exposed conditions and 43 grew in a fully shaded
310 environment (**Fig. 4A**). We found 69% of the colonies occurred at a single light level, with
311 22 colonies farming full sun and mid-exposed crops and only 9 colonies farming mid-
312 exposed and fully shaded crops (**Fig. 4A**). In the cases where colonies spanned two light
313 niches, this was generally associated with host tree growth, namely *Squamellaria* crops
314 becoming shaded by the growth of large branches of the host tree. However, we did observe
315 rare cases of fully-shaded *Squamellaria* (including seedlings in a few instances), growing low
316 in the canopy, which reflects that farming ants have retained the ability to plant *Squamellaria*
317 outside full sun. More generally, these data reveal the absence of the *balanced cultivation*
318 strategy and are more in line with ants maximizing high-light productivity as posited by the
319 *immediate rewards-first* hypothesis. These data also suggest there are few costs associated
320 with a mostly plant-based diet for ants versus an insect-protein rich diet in shade conditions,
321 consistent with the documented herbivorous diets of arboreal ants (26, 27). This work
322 suggests more research is needed in the role of gut microorganisms in the nutrition of the ants
323 in shade vs. sun conditions.

324

325 **Evolutionary history of farming traits**

326 Given the evidence that the farmer controls the light environment in a way that maximizes
327 crop productivity, we next asked how plant traits related to farming have changed across the
328 Hydnophytinae, the ant-plant clade to which the genus *Squamellaria* belongs. We traced the
329 evolution of three farming-related traits on the Hydnophytinae phylogeny (28), which
330 contains obligately farmed species, facultatively farmed species, generalist ant-associated
331 (but non-farmed) plants, and non-ant associated plants. Specifically, we focused on the (i)
332 presence of food rewards; (ii) domatium wall differentiation, as a measure of the emergence
333 of specialized wart structures to capture ant-derived fertilizer (18); and (iii) location in the
334 canopy as a measure of the species' light niche (*Materials and Methods*).

335

336 We found evidence that farmers have influenced their crop's growing niche over
337 evolutionary time. Specifically, high light niches have evolved four times, matching
338 independent colonization by *Philidris* farming ants (**Fig. 4C**). Tests of correlated trait change
339 using Pagel's (29) approach strongly supported the correlated evolution of food rewards
340 (nectaries of the specific type found in five out of six farmed *Squamellaria*; ref. 21) and
341 domatium wall differentiation (**Fig. 4C**; $BF_{[independent-dependent]} = 72.53$; *SI Appendix, Fig. S10*).
342 Similarly, shifts to high-light environments were correlated with the evolution of the food
343 rewards and domatium wall differentiation (**Fig. 4C**; $BF_{[independent-dependent]} = 34.12$; *SI*
344 *Appendix, Fig. S11*; $BF_{[independent-dependent]} = 73.16$; *SI Appendix, Fig. S12*). This suggests that
345 traits linked to nutrition and defense evolved jointly.

346

347 We next compared the transition rates under the best-fitting correlated evolution model to ask
348 two questions. First, are food rewards more readily gained in variable light (*q12*) or in high-
349 light environments (*q43*)? And second, does domatium wall differentiation evolve more

350 readily in variable-light environments ($q12$) or in high-light environments ($q43$)? We found
351 that both food rewards and domatium wall differentiation evolved more readily in canopy
352 species, associated with high light conditions (Food rewards [mean \pm SE]: $q12 = 0.01 \pm$
353 0.0003 ; $q34 = 3.05 \pm 0.09$, Kolmogorov-Smirnov test: $D = 0.979$, $P < 0.001$; Wall
354 differentiation: $q12 = 0.01 \pm 0.0003$; $q34 = 13.95 \pm 0.0769$; Kolmogorov-Smirnov test: $D =$
355 1 , $P < 0.001$; **Figs. S11-S12**). This shows that farming traits evolved in a high light niche, and
356 suggests that despite a reduction of nitrogen to their crops, selection has favored the planting
357 of crops in high light conditions.

358

359 **Conclusion**

360 Human farmers balance diverse crop requirements across different environments to optimize
361 yield. Our data revealed that *Philidris nagasau* farmers likewise optimize crop yield by
362 controlling their crop's light environment. This farming strategy has evolved despite lower
363 nitrogen inputs associated with sun conditions because it most directly benefits farmers.
364 Further, nitrogen input from farmers cultivating crops in full sun is still roughly three times
365 higher than any by-product fertilization found in non-farmed *Squamellaria* species (18),
366 suggesting that the loss of nitrogen in full sun may be trivial in the short term.

367

368 More generally, our work highlights the role of tradeoffs in the evolution of insect
369 agriculture. While human agriculture has seen an increase in the use of technology to gather
370 data for evaluating tradeoffs, the ant-plant farming mutualism has been subject to millions of
371 years of natural selection. While ants cannot simultaneously maximize all services to their
372 epiphyte crops, our work supports the idea that they buffer environmental variation by
373 selecting the environment where their crop is most productive.

374

375 **Materials and Methods**

376

377 **Study sites**

378 In September 2014, March 2015, August 2016, August 2017, July 2018, and June 2019 the
379 first author conducted fieldwork on Viti Levu, Vanua Levu, and Taveuni, Fiji. In July-August
380 2017, G.C. and E.T.K. jointly conducted fieldwork in Taveuni. The study sites in Viti Levu
381 were Colo-i-Suva forest reserve in the south of the island (S $18^\circ 1' 46.808''$, E
382 $178^\circ 24' 0.4175''$) and forest around Navai in the center of the island (S $17^\circ 37' 49.5979''$, E
383 $177^\circ 58' 34.9315''$). In Vanua Levu, the study sites were in the Waisali forest reserve (S 16
384 $38' 19.8''$, E $179 13' 19.7''$), and along the Cross Island road before the bifurcation to
385 Nabouwalu and Labasa. In Taveuni, the study sites were along the trail to DesVoeux peak
386 and Mt. Manuca on the western side of the island (S $16^\circ 48' 25.8133''$, E $179^\circ 56' 36.6843''$),
387 and at the end of Lavena coastal walk, Bouma heritage park, on the eastern side of the island
388 (S $16^\circ 51' 45.4433''$, E $179^\circ 54' 6.5149''$).

389

390 **Defining the light gradient of farming and non-farming ant/plant symbioses in Fiji**

391 Our study system consisted of a recently described farming mutualism involving the ant
392 species *Philidris nagasau* (Dolichoderinae) which obligately and exclusively cultivates

393 *Squamellaria* ant plants (11). *Squamellaria* taxonomy follows Chomicki and Renner (20).
394 *Squamellaria wilsonii* is the most abundant species on Taveuni (11).

395

396 Initially, we aimed to provide a continuous measurement of the light level associated with
397 each plant. However, this metric proved to be unreliable due to (i) frequent cloud shading, (ii)
398 wind patterns moving branches above the *Squamellaria*, and (iii) daytime, which all
399 drastically affected light level readings. We thus opted for a discrete categorization of a light
400 environment based on canopy shading. We classified the light environment as (i) *fully*
401 *shaded*, when 90-100% of canopy cover over-shaded the ant plants – an environment typical
402 of the rainforest under story; (ii) *mid-exposed*, when 40-75% of the canopy above a
403 *Squamellaria* plant was shaded; (iii) *fully exposed*, when a maximum of 20% canopy cover
404 shaded the *Squamellaria* plants, an environment in which they were exposed to direct
405 sunlight for the majority of the day. We used this same categorization for all Fijian
406 *Squamellaria* species and counted the number of individuals in fully shade, mid-exposed, and
407 fully exposed environments.

408

409 **Quantifying herbivory along a light gradient**

410 Our aim was to compare defense and fertilization services provided by *P. nagasau* to *S.*
411 *wilsonii* plants, and the rewards provided by *S. wilsonii* to *P. nagasau* across a light gradient.
412 Except in cases where *Squamellaria* plants were accessible near the ground, we accessed the
413 plants by tree climbing, using a rope secured by a partner on the ground. This technique
414 allowed long stays in the canopy with minimal disturbance of ant colonies. To measure the
415 effectiveness of the defense function of *P. nagasau* mutualists, we quantified leaf herbivory
416 in 50 *S. wilsonii* plant individuals spanning the light gradient (10 fully shaded, 22 mid-
417 exposed and 18 fully exposed). For each individual, we used three shoots (more when
418 possible, and only two in one instance), leading to a total sample size of $N = 30$ for fully
419 shaded, $N = 71$ for mid-exposed and $N = 53$ for fully exposed plants. Leaf herbivory was
420 measured as the percentage of leaves eaten at more than 10%. We also confirmed in the field
421 that using a different threshold (i.e. 50%) did not change our results:

$$422 \quad \text{Herbivory} = \frac{\text{Number of leaves eaten at } >10\%}{\text{Total number of leaves per shoot}} * 100 \text{ (Eq. 1).}$$

423

424 **Quantifying plant-produced food rewards along the light gradient**

425 Using the same 50 *S. wilsonii* individuals ($N = 153$ shoots spanning the light gradient), we
426 quantified the food reward provided by the crop. These rewards are only accessible to the *P.*
427 *nagasau* mutualists (21). We counted the number of post-anthetic nectaries and divided this
428 number by the number of internodes of the shoot. The number of internode per shoot has
429 previously been shown to directly reflect the age of the *Squamellaria* shoot and thus allows to
430 compare the food rewards per shoots regardless of shoot age (11, 21).

431

432 **Quantifying ant patrolling activity on crops along the light gradient**

433 To test whether lower herbivory levels in full-sun were the result of higher ant defense rather
434 than fewer herbivores, we measured ant patrolling across light conditions by recording the
435 distribution of *P. nagasau* workers on the plant surface. The expectation was that if the lower

436 herbivory level of full sun *Squamellaria* reflected more ant defense, we should observe a
437 difference in patrolling activity in sun vs. shade *Squamellaria*. Patrolling activity was
438 measured as the percentage of ants present on shoot (leaves, stem, food rewards [where most
439 ants are found; cf. ref. 21]) versus the domatium surface. We selected $N = 8$ *Squamellaria*
440 *wilsonii* from distinct *Philidris nagasau* colonies growing in full shade, $N = 13$ growing in
441 mid-exposition, and $N = 20$ growing in full sun. We recorded the number of ants on the
442 shoots versus the domatium surface for 5 consecutive minutes on each plant. Observations
443 were made on sunny days at 11.00-12.00 AM and 1.00-2.00 PM, and late morning and early
444 afternoon observations were averaged.

445

446 **Testing the effect of the light level on herbivory**

447 To experimentally test the effect of light level on leaf herbivory, we designed an experiment
448 (experiment 1) wherein we placed shoots from three species in 15 blocks of cut plastic bottles
449 filled with water (*SI Appendix, Fig. S1A*). This experiment was performed in the rainforest of
450 Taveuni island, along the road leading to DesVoeux peak. We selected plants from three
451 families: *Macaranga harveyana* (Euphorbiaceae), the Neotropical invasive *Miconia*
452 *calvescens* (Melastomataceae), and *Psychotria* sp. (Rubiaceae) that likely differed in leaf
453 chemistry. *Macaranga* and *Miconia* were growing in full shade, while *Psychotria* plants were
454 sun exposed. In all cases, twigs used in the experiments came from the same plant individual
455 to control for intra-specific variation in leaf chemistry. We ensured that each twig had leaves
456 of comparable physiological age by using twigs with similar number of leaves counting from
457 the apex. We created $N = 5$ blocks per light environment (full shade, mid-exposed, and fully
458 exposed) each with three twigs per each of the three species (hence nine twigs per bottle).

459

460 We selected twigs free of herbivory or where leaf herbivory was $<10\%$ on any leaf (removing
461 some damaged leaves while selecting the twigs, prior to the experiment). The experiment
462 lasted 7 days. On the 8th day, all twigs were collected, and leaves were removed one by one
463 (total $N = 685$ leaves), and photographed. We scored all leaves eaten at $>10\%$, and calculated
464 herbivory as above (Eq. 1). In June 2019, we replicated this experiment but this time only
465 using sun-grown *S. wilsonii* twigs (experiment 2; same field site). We collected 15 twigs
466 from a single sun-exposed *S. wilsonii*, and placed each twig in a cut bottle, using $N = 5$
467 blocks in our three light levels as above. This allowed to directly test the alternative
468 hypothesis that light-dependent background herbivory rates could explain our results.

469

470 For the statistics, we used a generalized linear mixed model using the function ‘lmer’
471 implemented in the R package ‘lme4’ (30). We set herbivory as dependent variable, and light,
472 species (for experiment 1), and leaf number as fixed-effect predictors, with leaf number
473 nested within species (to represent the structure of each experimental block). We used ‘block’
474 as our random effect predictor, and again we modelled the leaf number per species nested
475 within the block. Model estimates are shown in *SI Appendix* Table S1 and Table S2.

476

477 **Quantifying nitrogen fertilization along the light gradient**

478 Fertilization by defecation is a key function in this farming mutualisms and involves *P.*
479 *nagasau* workers defecating exclusively on highly absorptive warts on the inner domatium

480 walls (11, 18). To evaluate the nitrogen fertilization by *P. nagasau* in the different light
481 conditions, we collected four *S. wilsonii* individuals for each light environment. We next
482 sampled six plant parts (leaves, stem, roots, smooth cavity tissue, warty cavity tissue, and
483 tuber tissue, see *SI Appendix, Fig. S3A* for description). For each tissue, we sampled
484 triplicates, leading to a total of $N = 18$ samples per plant, and a total of $N = 216$ samples.
485 Samples consisted of tissue aliquots that were silica-dried in the field and analyzed via
486 isotope ratio mass spectrometry.

487

488 **Quantifying nitrogen content in ants and *Squamellaria* when food rewards for the ants** 489 **are absent**

490 To confirm that light influences fertilization input by ants, we compared the nitrogen content
491 of *Squamellaria* that do not offer food rewards to ant farmers in the sun vs. shade. We took
492 advantage of *Squamellaria grayi*, a farmed species that has lost the ability to produce food
493 bodies over evolutionary time (20, 21). The expectation was that if the light-dependent
494 nitrogen input derives from the abundance of food rewards, absence of food rewards should
495 lead to similar nitrogen levels in both ant workers and plant tissues. We thus sampled
496 *Philidris nagasau* workers and *Squamellaria grayi* plant tissues from $N = 5$ colonies from
497 full sun vs. $N = 5$ colonies in full shade environments. Ant workers and plant tissues (leaves,
498 stem, roots, smooth cavity tissue, warty cavity tissue, and tuber tissue) were sampled and
499 dried as above, and submitted to isotope ratio mass spectrometry.

500

501 **Isotope Ratio Mass Spectrometry**

502 For measurements of nitrogen content, $\delta^{15}\text{N} \text{‰}$ and $\delta^{13}\text{C} \text{‰}$ measurements, plant tissues
503 were harvested and dried with silica gel. Samples were ground to fine powder with a mixer
504 mill MM301 (Retsch). Stable N and C isotope values relative to air N_2 and to the Pee Dee
505 belemnite standard, respectively, were determined from approximately 10 mg (± 0.5 mg) of
506 sample in case of N isotopes and from 200 μg of sample in case of C isotopes with the stable
507 isotope ratio mass spectrometer MAT253 (Thermo Scientific, Wilmington, USA), the organic
508 elemental analyzer Flash 2000 Elemental Analyzer (Thermo Scientific), and a Conflo IV
509 (Thermo Scientific) at the Institut für Geowissenschaften (Institute for Geological Sciences)
510 at the University of Mainz, Germany.

511

512 **Monitoring ant hunting behavior in full sun vs. in the shade**

513 Our hypothesis that farming ants provide more nitrogen in the shade implies more hunting
514 activity in the shade as opposed to the sun. To quantify this, we monitored hunting behavior
515 in $N = 5$ *Philidris nagasau* colonies living in *S. wilsonii* growing in full sun and $N = 5$ plants
516 growing in the shade, both along the DesVoeux peak track, Taveuni. We monitored hunting
517 behavior in a radius of 2 meters from each *Squamellaria* individual, and in each case, we
518 selected *Squamellaria* of similar sizes in shade versus sun. To ensure replicability in our
519 measure of hunting behavior across colonies, we recorded hunting behavior for 10 minutes
520 between 12.00 AM – 1.00 PM on sunny days (*SI Appendix, Fig. S6A*). Next, we performed
521 an experiment to determine the times to discovery and to arrival of the first recruit (second
522 ant) to an immobilized cockroach placed in the full shade or full sun at 1 m of a *S. wilsonii*.
523 The experiment was replicated 5 times in each light environment (*SI Appendix, Fig. S6D-F*).

524

525 **Determining the light niches of farmed vs. non-farmed *Squamellaria***

526 We quantified distribution patterns of $N = 30$ *Squamellaria imberbis* (farmed) and the same
527 number of *S. wilkinsonii* (bird dispersed) in a region where both coexist in a rainforest on the
528 island of Vanua Levu around the Waisali forest reserve (S 16 38'19.8", E 179 13'19.7"). We
529 determined the height at which *Squamellaria* were growing using the standard tangent
530 method (31). Knowing the distance angles between the horizon and the *Squamellaria* at two
531 adjacent distances next to the tree, one obtains:

532
$$H = \frac{D \cdot \tan(\alpha) \cdot \tan(\beta)}{\tan(\alpha) - \tan(\beta)}$$

533 Where H is the height of the *Squamellaria* in the tree, D , the distance on the ground from
534 which the two angles were measured, α , the angle between the horizon and the *Squamellaria*
535 from the point closer to the tree, and β the angle from the more distant point on the ground.
536 For each of the two species, we measured $N = 15$ specimens along the same transect.

537

538 Next, we determined the light niche of all nine *Squamellaria* species, which grow in forests
539 with different height. We quantified the proportion of plants per species growing in full sun,
540 mid-exposed or full shade along transects across Viti Levu, Vanua Levu and Taveuni islands
541 in Fiji (see *Field Sites*). Sample sizes were as follow: *S. thekii* ($N = 20$), *S. grayi* ($N = 40$), *S.*
542 *huxleyana* ($N = 20$), *S. major* ($N = 20$), *S. imberbis* ($N = 100$), *S. wilsonii* ($N = 100$), *S.*
543 *tenuiflora* ($N = 60$), *S. wilkinsonii* ($N = 60$), *S. jebbiana* ($N = 20$).

544

545 **Quantifying the light niche of *Squamellaria wilsonii***

546 To quantify the light niche of *Squamellaria wilsonii* and to address whether *Philidris*
547 *nagasau* ants plant across light levels, ensuring a balance of high crop productivity in sun-
548 exposed plants, and high nitrogen inputs in shade-exposed crops ('balanced cultivation'), or
549 whether a single colony would consistently plant *Squamellaria* in sun-exposed sites
550 ('immediate-rewards-first cultivation strategy'), we mapped the light niche of 657
551 *Squamellaria wilsonii* individuals from $N = 100$ *Philidris nagasau* colonies in Taveuni, along
552 the DesVoeux peak track as well as near the hydroelectric Somosomo dam. For each of the
553 100 *Philidris nagasau* colonies, the *Squamellaria* individuals occupied by the respective ant
554 colonies (excluding seedlings that could not be accurately quantified) were counted, and the
555 light level (full shade, mid-exposed, full sun) of each was determined, following our
556 classification scheme described above. We then plotted the percentage of plants in each of the
557 light levels for the 100 colonies.

558

559 **Statistical analysis**

560 We compared (i) plant defense by ants in the different light environments, (ii) ant-mediated
561 nitrogen fertilization in the different light environments, (iii) food reward abundance in
562 function of the light level, and (iv) the correlation between food reward abundance and
563 herbivory. For (i, ii, and iii), we used first one-way ANOVA followed by post-hoc tests when
564 the data were normally distributed (as verified by a Shapiro-Wilk test) and when there were
565 no random effect to take into account. When data were non-normal and/or random effects
566 were present, we used a generalized linear mixed model (GLMM). Specifically, we used a

567 GLMM to test the effect of light environment on nitrogen level. We used a GLMM approach
568 modelled under penalized quasi-likelihood (PQL), using a Gaussian probability with the
569 function ‘glmmPQL’ implemented in the R package MASS (32). In this model, light level
570 and tissues are the fixed effects while specimens (from which several samples are drawn) are
571 the random effect.

572

573 We further used multinomial logistic regressions to obtain a probabilistic framework of
574 plant defense by ants, ant-mediated nitrogen fertilization, and food reward abundance in
575 function of the light environment categories (**Fig. 3**). For all logistic regressions, we first used
576 the actual overall sample size ($N = 153$ for food rewards and plant defense and $N = 205$
577 nitrogen fertilization), and we subsequently used a simulated sample size of 1,000. In all
578 cases, results between real and simulated sample sizes were comparable. For the multinomial
579 logistic regressions, we used the R package ‘MASS’ (32), and dependencies, relying on the
580 function ‘polr’. To test the correlation between food reward abundance and herbivory, we
581 used Pearson’s correlation coefficients implemented in function ‘corr’ of the ‘stats’ package
582 in the R base. We used the ‘stats’ package in the R base and ‘anova’ from the car package to
583 generate P -values, and the package ‘ggplot2’ (33) for plotting graphs, all in R version 3.4.3.

584

585 **Testing the evolutionary correlation of defense, nutrition, and niche evolution**

586 We inferred the evolutionary history of defense and nutrition traits on the Hydnophytinae
587 phylogeny (28) and then tested for their correlated evolution. We coded all 76 ingroup
588 species for the absence (coded ‘0’) or presence (coded ‘1’) of concealed post-anthetic flower
589 rewards (21, 28) as defense trait (*this study*). The majority of Hydnophytinae form nutritional
590 symbioses with ants, either involving specialized Dolichoderinae species (from the genera
591 *Philidris* and *Anonychomyrma*) or involving generalist species (11, 18-21, 28). A key
592 nutrition trait is the structure of the inner domatium walls. Specialized species have domatia
593 with differentiated warty tissue where ants defecate and non-absorptive smooth tissue where
594 they raise their brood. By contrast, species forming generalist symbioses have poorly
595 differentiated domatium walls with ‘wart-like’ and ‘smooth-like’ areas that are variable over
596 space and time. Species that have lost symbioses with ants have lost the absorptive warts
597 (18). In order to perform a test of correlated evolution, we coded domatium internal wall type
598 as a binary variable with either poorly differentiated walls or wart absence as ‘0’ and
599 differentiated walls as ‘1’.

600

601 We next studied the evolutionary history of light niche in the Hydnophytinae. Hydnophytinae
602 that form facultative symbiosis with many generalist ant species are predominantly found in
603 the lowlands, non-mutualists occur typically at high altitude, and specialized species are
604 found across different altitudes (28). We coded the light niche as a binary trait (light-variable
605 coded ‘0’ or high-light coded ‘1’) based on literature (28, 34-37). Light-variable
606 environments correspond to species that can be found at widely varying height in the canopy,
607 and which typically are species dispersed by birds and forming generalist symbioses with
608 various ant species (11). We included in this category species that are the few *Myrmecodia*
609 species inhabited by lowland rainforest *Anonychomyrma* ants, which grow in shaded light
610 environments. We categorized species of high light environments by their reported ability to

611 live high up in the rainforest canopy, in open, semi-dry forests, or even as terrestrial, soil-
612 rooted plants in open highlands in New Guinea. In all three traits, 0 → 1 transitions
613 correspond to the evolution of defense, nutrition traits or high light niche.

614

615 To infer the evolutionary history of defense and nutrition traits, we used two approaches.
616 First, a stochastic mapping method, relying on the function ‘make.simmap’ in the phytools
617 package (v. 04-60) (38), which implements the stochastic character mapping approach
618 developed by Bollback (39). We estimated ancestral states under the best-fitting model as
619 determined by AIC and then simulated 1,000 character histories on the MCC tree. We
620 summarized the 1,000 simulated character histories with probability density plotted on the
621 phylogeny using the function ‘densityMap’.

622

623 Second, we used the Bayesian reversible jump MCMC approach implemented in BayesTraits
624 v. 2 (40), using a sample of 1,000 trees from the BEAST analysis to account for phylogenetic
625 uncertainty, a chain of 50 million generations with rate coefficients and ancestral states
626 sampled every 1,000th generation. We ensured that the acceptance rate was between 20 and
627 40%, as recommended in the manual, and reconstructed the nodes of interest using the
628 command ‘addnode’. We reconstructed all key nodes and reported the probabilities above
629 nodes in Fig. 4.

630

631 To test for possible evolutionary contingencies or correlations between defense and nutrition
632 traits and the niche type, we used a method for discrete traits (29, 40) as implemented in
633 BayesTraits v. 2 (40). We again used the maximum clade credibility (MCC) tree from
634 BEAST but pruned the outgroups and first ran a model of independent trait evolution and
635 estimated the four-transition rate parameters α_1 , α_2 , β_1 , β_2 , wherein double transitions from
636 state 0,0 to 1,1 or from 0,1 to 1,0 are set to zero. We then ran a model of dependent trait
637 evolution with eight parameters (q_{12} , q_{13} , q_{21} , q_{24} , q_{31} , q_{34} , q_{42} , q_{43}). To compare these
638 non-nested models, we calculated their Bayes factor scores.

639

640 **Data availability.** All data generated in this article is available in the online Supporting
641 Information.

642

643 **Acknowledgements**

644 We thank Jeremy Aroles for help with fieldwork, Benoît Chomicki for help with fieldwork
645 and video, drone and photographic support, Alivereti Naikatini and Marika Tuiwawa for
646 fieldwork assistance and permissions, Michael Maus for conducting the isotope
647 measurements, Pepijn Kooij for discussion and Stuart West, Bill Wcislo and an anonymous
648 reviewer for comments that helped improve the manuscript. This work was supported by
649 grants from the Ammodo Foundation to E.T.K., as well as from the German Research
650 Foundation (DFG) grants RE 603/20-1 and -2. GC was supported by a Glasstone research
651 fellowship and a Junior Research Fellowship at the Queen’s college, both at the University of
652 Oxford, UK as well as a National Geographic grant (WW-133R-17) and currently by a
653 NERC independent research fellowship (NE/S014470/1).

752 **Figure captions**

753

754 **Figure 1.** Crop productivity varies across a light gradient and correlates with anti-herbivore
755 defense efficiency. (A) Normalized number of food bodies per shoot along a light gradient.
756 Inset shows food rewards (post-anthetic nectaries), with a *Philidris nagasau* worker foraging
757 on one such food reward. (B) Herbivore damage on crops along a light gradient. (C) Ant
758 patrolling activity on the domatium vs. shoot across the light gradient. Patrolling activity was
759 measured as the percentage of ants present on the shoot (leaves, stem, food rewards [where
760 most ants are found; c.f. ref. 16]) versus the domatium surface. (D) Linear relationship
761 between the number of food bodies ($y = -0.012x + 1.182$; $R^2 = 0.40$, $P < 0.001$).

762

763 **Figure 2.** Ant nitrogen fertilization of crops along a light gradient. The boxplot shows the
764 percentage of nitrogen in warty domatium walls where the ants defecate (see ref. 14) along a
765 light gradient.

766

767 **Figure 3.** Models linking nutrition and defense via plant crop productivity (food rewards) to
768 the light environment in *Squamellaria wilsonii* reveals tradeoffs. (A-B) Multinomial logistic
769 models showing the probability of herbivory (A) and nitrogen content in warts (B) as a
770 function of the light level.

771

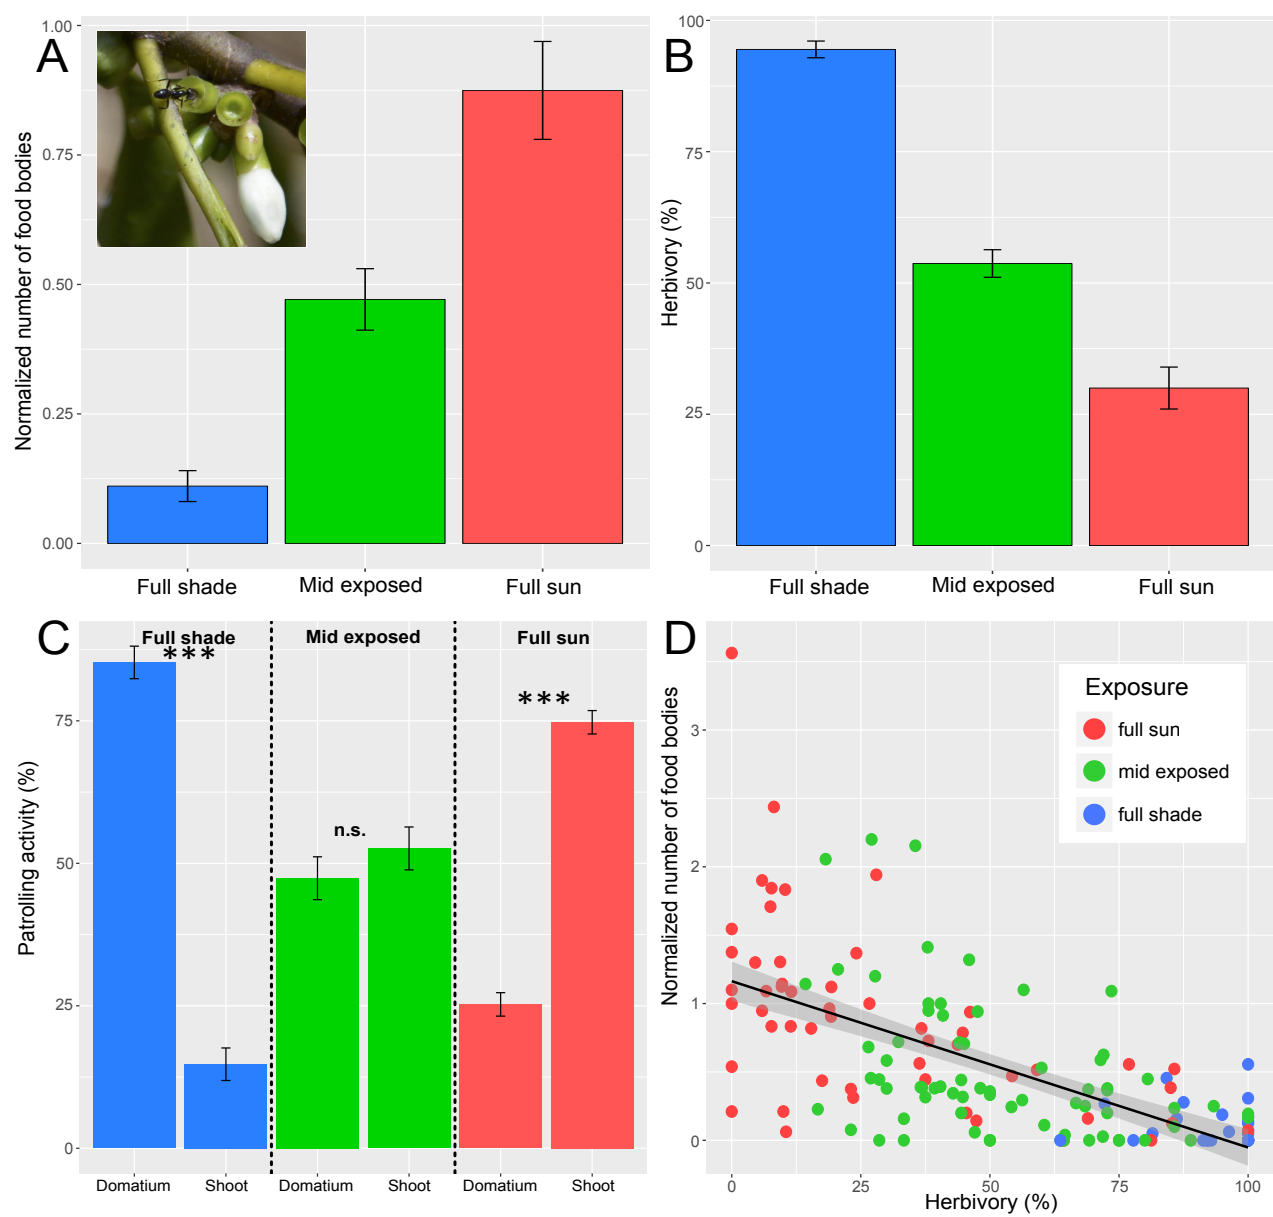

772 **Figure 4.** Farming ants control plant light niche over ecological and evolutionary time. (A)
773 Light niches of 657 *Squamellaria wilsonii* plants occupied by 100 *Philidris nagasau* colonies
774 in Taveuni. (B) Current (ecological) light niche of farmed vs. non-farmed Fijian
775 *Squamellaria*. (C) Ancestral state reconstruction of light niche over a phylogeny of the
776 Hydnophytinae (30), estimated from a maximum likelihood approach (35) with 1,000
777 simulations of character states, and a reverse-jump MCMC approach using 1,000 trees from
778 the dating analysis (36), taking into account phylogenetic uncertainty (shown as probabilities
779 above branches).
