15 **Abstract**
16

17 Large earthquakes occur in rocks undergoing high pressure/low temperature metamorphism
18 during subduction. Rhythmic major-element zoning in garnet is a common product of such
19 metamorphism, and one that must record a fundamental subduction process. Here we show
20 that rhythmic major-element zoning in subduction-zone garnets from the Franciscan Complex,
21 California developed in response to growth–dissolution cycles driven by pressure pulses. Using
22 electron probe microanalysis and novel techniques in Raman and synchrotron Fourier
23 transform infrared microspectroscopy, we demonstrate that at least four such pressure pulses,
24 of magnitude 100–350 MPa, occurred over less than 300,000 years. These pressure magnitude
25 and time scale constraints are most consistent with the garnet zoning having resulted from
26 periodic overpressure development–dissipation cycles, related to pore-fluid pressure
27 fluctuations linked to earthquake cycles. This study demonstrates that some metamorphic
28 reactions can track individual earthquake cycles, and thereby opens new avenues to the study
29 of seismicity.
30

31 **Introduction**
32

33 Earthquakes in subduction zones can produce devastating tsunamis (e.g. the 2004 M9.2
34 Sumatra–Andaman and 2011 M9.0 Tōhoku 'megathrust' earthquakes), and may discharge
35 subducted volatiles (Nakajima et al., 2011; Spandler et al., 2011) and trigger arc magmatism
36 (Davies, 1999; John et al., 2012). Though subduction seismicity can persist to depths > 600 km,
37 it is most frequent and energetic in the uppermost part of the subducting slab, at depths of 30–
38 70 km (Frohlich, 1989; Kirby et al., 1996; Abers et al., 2006; Green et al., 2010). The record of
39 such seismicity might be visible in high pressure/low temperature (HP/LT) metamorphic rocks
40 recovered from such depths. More so than for other tectonic environments, links between
41 metamorphism and seismicity are proposed for subduction zones. For example, seismicity at
42 anomalous (> 50–70 km) depths in the subduction setting has been related to embrittlement
43 due to metamorphic dehydration reactions and associated pore-fluid pressure development
44 and/or volume change (Green & Houston, 1995; Kirby et al., 1996; Hacker et al., 2003; Preston

45 et al., 2003; Jung et al., 2004; Nakajima et al., 2013; Schubnel et al., 2013). Geologic records
46 that contribute to our understanding of the mechanisms and magnitude–recurrence rates for
47 subduction seismicity come chiefly from Quaternary tsunami and turbidite deposits (e.g.
48 Adams, 1990; Goldfinger et al., 2003; Nanayama et al., 2003; Cisternas et al., 2005; Monecke et
49 al., 2008; Gràcia et al., 2010), subsidence/uplift histories from tidal wetlands and coral reefs
50 (e.g. Taylor et al., 1990; Nelson et al., 1996), and pseudotachylytes and breccias (e.g. Austrheim
51 & Boundy, 1994; John & Schenk, 2006; Angiboust et al., 2012). Here we show that garnet—one
52 of the more common metamorphic minerals in HP/LT metamorphic rocks—may provide new
53 insights into earthquake magnitude–recurrence rates.
54
55 The blueschist- and eclogite-facies assemblages produced in subduction metamorphism record
56 uniquely low geothermal gradients, typically < 600 °C GPa^{-1}. Subduction metamorphism can be
57 incredibly rapid, in cases involving time scales < 10^4–10^6 yr (Bjørnerud et al., 2002; Camacho et
58 al., 2005; Raimbourg et al., 2007; Dragovic et al., 2012). Rhythmic major-element zoning in
59 garnet is a common feature in HP/LT metabasic rocks (e.g. Dudley, 1969; García-Casco et al.,
60 2002; Davis & Whitney, 2006; Tsujimori et al., 2006b; Page et al., 2007; Kabir & Takasu, 2010;
61 Meyer et al., 2016), suggesting that it is a manifestation of a common process (or set of
62 processes) in the subduction setting. To explore the nature of these processes and origin of the
63 HP/LT garnet zoning, we apply several modern and novel techniques to investigate
64 metamorphism and paleoseismicity in the Jurassic Franciscan Complex, California.
65
66 **Results**
67
68 Sample CA13-01 is a garnet-bearing eclogite–blueschist from Ring Mountain, Tiburon Peninsula,
69 San Francisco Bay. Sample CA13-05A is a garnet-rich amphibolite from the same locality.
70 Detailed rock descriptions are provided in the Materials and Methods section, however, of
71 particular relevance for the P–T conditions of metamorphism is the presence of amphibole
72 (glaucophane in CA13-01; Na–Ca amphibole and glaucophane in CA13-05A) and zoisite, and the
73 absence of lawsonite in both samples. Garnets from both rocks contain rutile and quartz
74 inclusions from core to rim (quartz rare at the rim). Thermodynamic modeling of phase
75 equilibria suggests that garnet rim growth occurred at P–T of 555–585 °C, 1.4–2.0 GPa for
76 CA13-01 and 535–595 °C, 1.2–2.0 GPa for CA13-05A; these estimates are entirely consistent
77 with earlier thermobarometry of the same rocks (Tsujimori et al., 2006a). Whole-rock
78 geochemistry, methods and results for thermodynamic modeling of metamorphic phase
79 equilibria are provided in the Methods and Materials section.
80
81 Electron microprobe x-ray count maps were produced for Ca, Fe, Mg and Mn in 6–7 garnets for
82 each of CA13-01 and CA13-05A; examples of Mg and Mn maps are provided in Fig. 1 and all
83 maps are provided in the supplementary material. Complementary quantitative electron
84 microprobe traverses were measured for one garnet from CA13-01 and two garnets from CA13-
85 05A (Fig. 1). The garnets have inclusion-rich cores that are compositionally distinct from
86 inclusion poor mantles/rims (Fig. 1). Oscillatory/rhythmic zoning in both Mg and Mn is apparent
87 in the mantle/rim zone (Fig. 1), but does not correspond to obvious zoning in Ca or Fe (with the
88 exception of bands at the extreme outer edge of garnets from CA13-01). The Mg and Mn zoning

89 in some garnets incorporate features of zone incursion (embayments), and circumferential
90 pinching and swelling (Fig. 1). All garnets analyzed display systematic asymmetry in the location
91 of relatively steep compositional gradients (Fig. 1). These features are consistent with the
92 major-element zoning being a result of cycles of garnet growth separated by gaps during which
93 there was no growth or there was dissolution, such that the embayments and steep
94 compositional gradients mark garnet growth 'unconformities'. Quantitative Mn traverses (Fig.
95 1) confirm the asymmetry in the compositional gradients that flank the Mn highs; relatively
96 steep gradients occur on the rim side of Mn highs for sample CA13-01 and on the core side for
97 sample CA13-05A. Rim-side asymmetry (as observed in CA13-01) must involve overgrowth of
98 thin (high-Mn) resorption bands by lower-Mn garnet, whereas core-side asymmetry (as
99 observed in CA13-05A) must involve overgrowth of the 'unconformity' surface by higher-Mn
100 garnet. The two modes presumably reflect different supply/demand scenarios for Mn following
101 garnet dissolution; reactions associated with the rim-side scenario cannot provide a sanctuary
102 for all Mn liberated by garnet dissolution, leading to back-diffusion of Mn into the garnet. Fig. 2
103 outlines models for the development of the two types of asymmetric zoning as a result of
104 garnet growth–dissolution cycles.
105
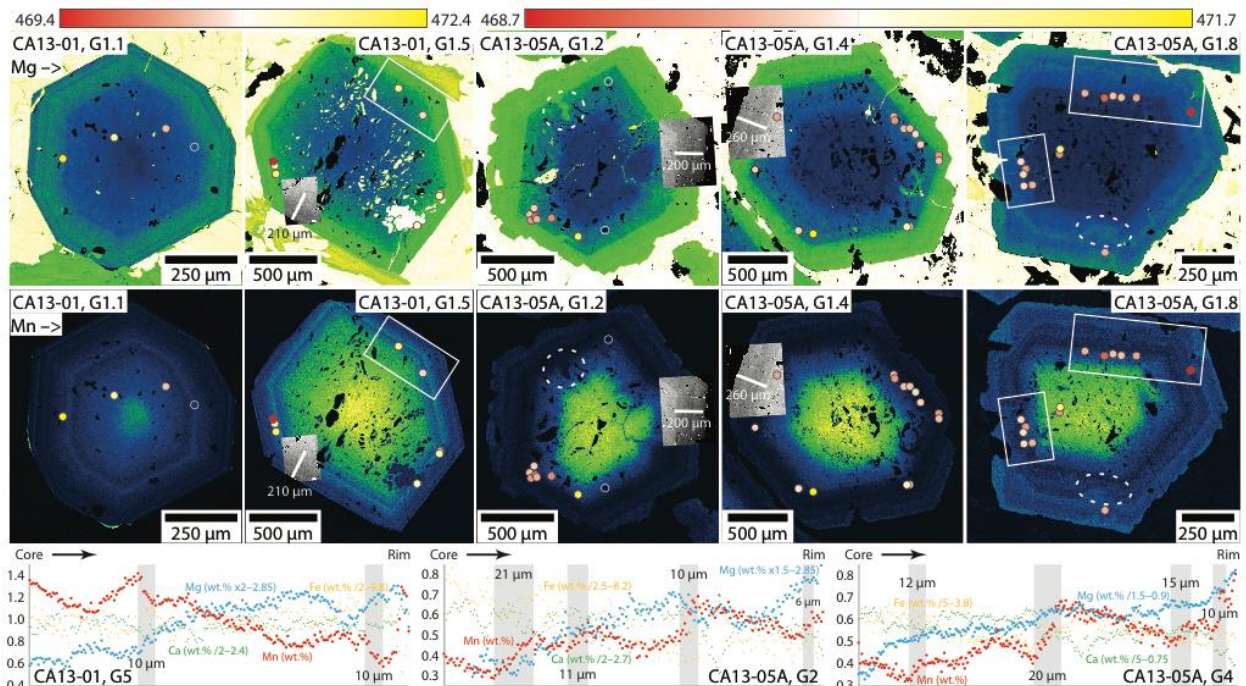

106
107 **Fig. 1.** Color-enhanced wavelength-dispersive spectrometer (WDS) x-ray count maps for Mg
108 (top row of images) and Mn (middle row of images) in garnets from Ring Mountain. Decreasing
109 Mg and Mn content are indicated by yellow–green–blue–black color progression. Spots give
110 location of Raman quartz analyses and are colored according to peak position (±1.5 cm^{-1} about
111 470.9 cm^{-1} for CA13-01; ±1.5 cm^{-1} about 470.2 cm^{-1} for CA13-05A; see data in Fig. 3d).
112 Transparent spots correspond to partially transparent analyses in Fig. 3d. Spot size indicated is
113 larger than actual ~1 μm spot. White rectangles show notable zones with varying Raman
114 response associated with compositional zoning boundaries (blow-ups provided in the
115 supplementary material). Dashed white ellipses highlight examples of zoning

116 embayments/incursions. Gray back-scattered electron images indicate locations of quantitative
117 (WDS) electron microprobe traverses at bottom of figure. Regions with steep compositional
118 gradients in the traverses are indicated by vertical gray bands (with length scale indicated).
119
120 ***Franciscan garnet growth–dissolution cycles due to pressure(–temperature) fluctuations***
121
122 The modal garnet contours for both rocks (see phase assemblage diagrams in Materials and
123 Methods section) suggest that modest changes in T or, more so, P might have triggered
124 significant garnet production/loss and therefore caused the garnet zoning (i.e. 5–15 vol.%
125 growth/dissolution, relative to starting garnet content, for ΔT of 40 °C or ΔP of 100 MPa). The
126 gentle slopes in P–T space for both Mg- and Mn-in-garnet isopleths (see phase assemblage
127 diagrams in Materials and Methods section) are also consistent with rhythmic zoning in Mg and
128 Mn having developed primarily in response to changes in P. Garnet zoning is complemented by
129 irregular major-element zoning in glaucophane, omphacite and zoisite in CA13-01, and
130 glaucophane, hornblende and zoisite in CA13-05A. Up-pressure dehydration reactions likely
131 involved breakdown of glaucophane and zoisite to form garnet, jadeite, quartz and H_2O in
132 CA13-01, and breakdown of hornblende and zoisite to form garnet, glaucophane and H_2O in
133 CA13-05A (see Materials and Methods section). In order to test the role of pressure fluctuations
134 in driving garnet growth–dissolution cycles, we performed high-resolution barometry by Raman
135 microspectroscopy on quartz inclusions in garnet, and novel synchrotron Fourier transform
136 infrared (FTIR) microspectroscopy on garnet.
137
138
139 **Fig. 2.** Conceptual models for development of rim-side (top row of garnets with Mn back-
140 diffusion during resorption) and core-side zoning (bottom row of garnets with no Mn back-
141 diffusion during resorption) by fluctuating garnet stability (growth–resorption cycles) in
142 response to pressure pulses. Blue stars mark onset of undrained conditions at the start of a
143 phase of fluid overpressure development and garnet growth. Orange stars mark full
144 overpressure conditions at the end of a growth phase (immediately prior to an earthquake
145 event), fracturing due to dynamic stresses and relief of overpressure.

146

Interrogating pressure pulses by spectroscopic methods

148

Raman barometry uses the pressure dependence of the position of peaks in the Raman spectra for an included mineral to calculate a residual pressure in the inclusion (e.g. Kohn, 2014). This residual pressure results from differential expansion/contraction of host and inclusion following cooling and exhumation and, knowing the thermo-elastic properties of the two minerals, can be used to calculate the *P–T* conditions of inclusion overgrowth by host. The properties of quartz and garnet yield an inclusion–host system far more sensitive to overgrowth pressure than temperature, meaning that the quartz-in-garnet system makes a good barometer (e.g. Ashley et al., 2016). The position of (nominal 464 cm^{-1}) quartz Raman A1g-mode peaks were measured in triplicate for 80 quartz-in-garnet inclusions across samples CA13-01 and CA13-05A. Images of quartz inclusions are provided in Fig. 3a–c and detailed methods are provided in the Materials and Methods section. Repeat analyses produced consistent results, yielding 2σ reproducibility of ± 0.3 cm^{-1} (Fig. 3d). With exposed, cracked or compound inclusions (n = 12) excluded, analyses from the two rocks show a significant spread in A1g-mode peak position (4.2–7.2 cm^{-1} above atmospheric for CA13-01, and 3.5–6.5 cm^{-1} above atmospheric for CA13-05A; Fig. 3d). Variable Raman A1g-mode peak position reflects variable residual pressure resulting from different overgrowth pressure. Using the calibration of Schmidt & Ziemann (2000), the elastic model of Guiraud & Powell (2006) and mineral properties recommended by Holland & Powell (2011), the ranges of Raman A1g-mode peak shifts suggest *P* = 1.4–2.1 GPa (median 1.9 GPa) for CA13-01 and *P* = 1.25–1.95 GPa (median 1.5 GPa) for CA13-05A. Spatially, Raman A1g-mode peak position varies by 0.5–1.5 cm^{-1} over garnet radial distances of 10–50 μm and in association with the major-element growth zoning (Fig. 1); we infer that garnet growth–dissolution was associated with fluctuations in metamorphic pressure of magnitude 100–350 MPa.

171
Fig. 3. (a–c) transmitted-light photomicrographs of some analyzed quartz inclusions in garnet. (d) Positions for the nominally 464 cm^{-1} A1g Raman peak for quartz inclusions in garnet from Ring Mountain, analyzed in triplicate. Inclusion circled in pink displays an abnormally low peak position despite lack of evidence that it was exposed during polishing or associated with visible cracks in garnet. Yellow-to-red background coloring for reference to spot colors on garnet x-ray count maps in Fig. 1.

Raman barometry can only be applied where suitable inclusions occur. In order to obtain more complete records of pressure fluctuations during garnet growth/resorption, we also applied an exploratory FTIR absorption spectroscopy for simultaneous garnet barometry and hygrometry. Experimental work has demonstrated a positive relationship between growth pressure and the OH content of pyrope garnet (at mantle pressures; Lu & Keppler, 1997; Withers et al., 1998), and the presence of non-structural (molecular) H_2O in garnet (an impurity) may also act as a proxy for activity (partial pressure) of H_2O (a hygrometer) during garnet growth. Structural OH and molecular H_2O in garnet are associated with independent FTIR spectral peaks within the mid-IR range. Interrogation of the fine major-element zoning in the Franciscan H*P*/L*T* garnets by FTIR spectroscopy requires high-spatial-resolution and high-sensitivity measurement of a component that occurs in extremely low concentrations (< 100 ppm; garnet is nominally anhydrous), meaning that the technique requires an IR source with brightness only offered by synchrotron light. Transmission synchrotron FTIR microspectroscopy was performed on three garnets from CA13-01 and two from CA13-05A, at the Australian Synchrotron and Diamond Light Source, UK. Detailed methods and results are provided in the Materials and Methods section.

197 Our new, qualitative synchrotron FTIR barometry and hygrometry technique identified regions
198 with steep OH (and to a lesser extent H_2O) concentration gradients in garnet (Fig. 4). These
199 breaks in OH match the locations of the steep compositional gradients that mark garnet growth
200 'unconformities' (Fig. 4). The correlation is with zoning in Mg and Mn but not Ca, suggesting
201 fluctuations in OH do not simply reflect changes in proportion of the garnet end members that
202 are most commonly hydrated (i.e. grossular/andradite). Regardless of the polarity of Mn
203 change across the 'unconformities' in rim-side (CA13-01) and core-side (CA13-05A) zoning, OH
204 content uniformly shows a sharp rim-side decrease (Fig. 4). This result is consistent with garnet
205 growth (following dissolution) resuming at lower pressure than recorded in the garnet
206 immediately core-side of the growth 'unconformity'—i.e., the synchrotron FTIR results indicate
207 that dissolution was associated with a pressure drop. The synchrotron FTIR results demonstrate
208 the linkage between pressure fluctuations and growth–dissolution cycles proposed in the
209 model for development of the fine-scale, rhythmic compositional zoning in the garnets (Fig. 2).
210 The relationship between OH and H_2O in the garnets is complex, displaying covariance or anti-
211 correlation in some regions, and apparent independence in others. For these rocks, if
212 systematic mechanistic linkages between pressure and fluid activity exist, the synchrotron FTIR
213 approach was unable to resolve them.
214
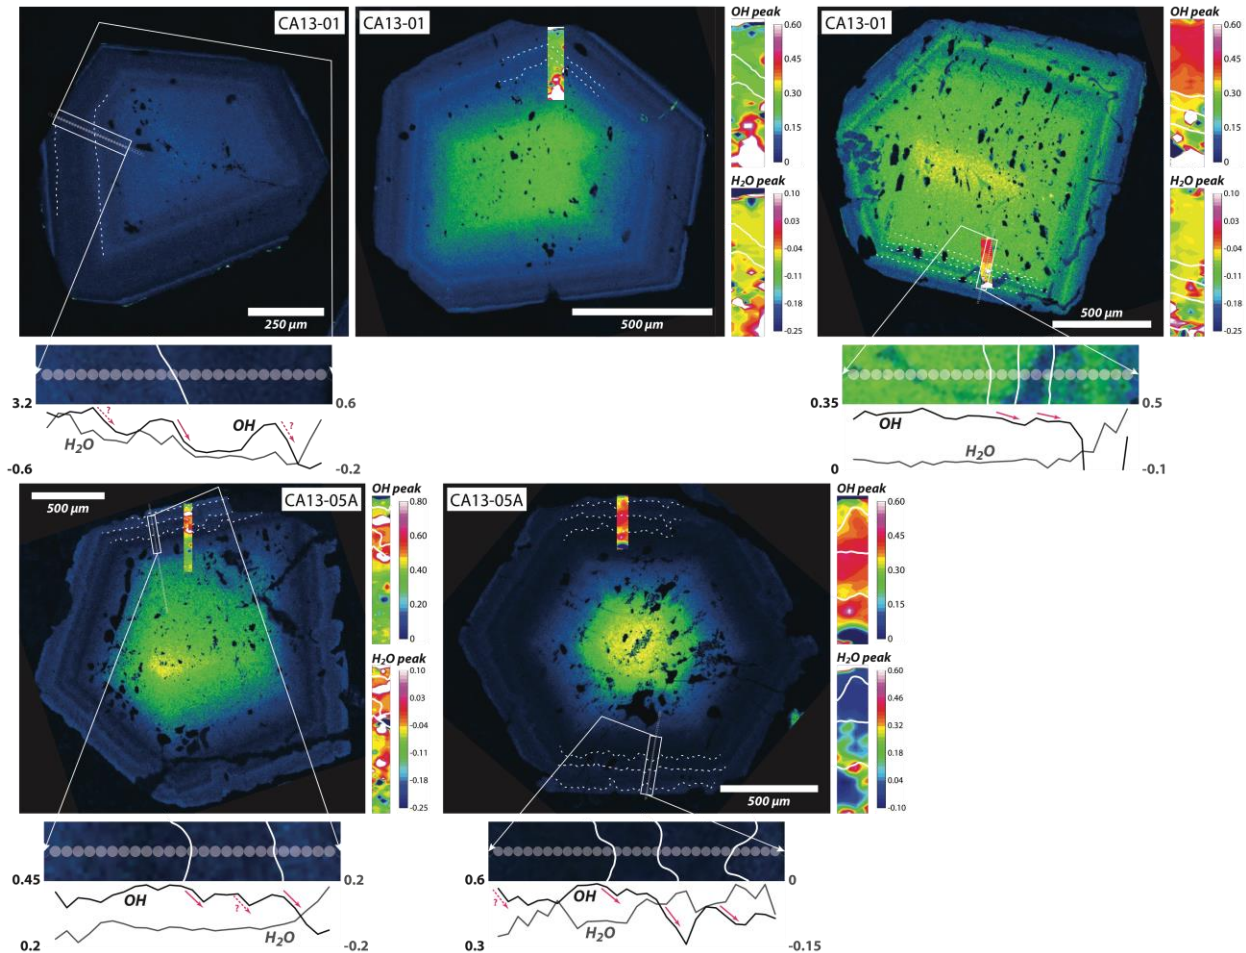

215
216 **Fig. 4.** X-ray count maps for Mn in garnet, synchrotron Fourier transform infrared (FTIR) analysis

217   1D traverses (bottom of each Mn map) and 2D maps (right of each Mn map) for OH and H_2O.
218   Dashed white lines on Mn maps indicate the position of garnet growth 'unconformities' and
219   correspond to the white lines on the 1D FTIR traverses and 2D FTIR maps. Vertical axis on 1D
220   traverse plots and colors of the 2D FTIR maps correspond to integrated intensity in the 3520–
221   3620 cm^{-1} region for OH (a dimensionless measure of OH abundance) and in the 3350–3450 cm^{-1}
222   region for H_2O (a dimensionless measure of H_2O abundance). Pink arrows on 1D traverse plots
223   indicate regions of decreasing OH in vicinity of garnet growth 'unconformities'.
224

225   ***Short time scales for multiple pressure pulses***
226

227   The presence of rutile and Ca–Na amphibole in CA13-05A constrain peak T = 535–595 °C at P =
228   1.2–1.8 GPa, and the presence of glaucophane and absence of chlorite in CA13-01 constrain
229   peak T = 555–585 °C for P = 1.4–1.95 GPa (see metamorphic assemblage diagrams in the
230   Materials and Methods section). The presence of rutile inclusions at the edge of garnet rims is
231   consistent with garnet zoning having developed during the peak-T phase of the metamorphism
232   (T > 550 °C), in agreement with other work on Ring Mountain HP/LT garnets (Tsujimori et al.,
233   2006a), but in contrast to Franciscan HP/LT garnets with retrograde rims from Healdsburg (Page
234   et al., 2007, 2014) and Jenner (Krogh et al., 1994). The absence of lawsonite in both rocks
235   suggests slightly lower maximum pressure than calculated from Raman barometry (< 1.8–2.0
236   GPa v. 1.9–2.1 GPa). The counter-clockwise P–T path experienced by these rocks involved
237   relatively isobaric refrigeration after peak P–T, followed by monotonic cooling during
238   exhumation (Wakabayashi et al., 1990; Tsujimori et al., 2006a; Page et al., 2007). Preservation
239   of fine-scale diffusion textures in garnet that developed during the peak-T, garnet rim-growth
240   phase of the metamorphism (≤ 10 μm, Fig. 1) means that there was negligible modification
241   during exhumation, despite evidence for a protracted exhumation (cooling) history
242   (Anczkiewicz et al., 2004; Page et al., 2014).
243

244   We use an error function approximation to 1D (radial) diffusion [equation of the form $c(x,t) \propto$
245   erf ($x/\sqrt{4Dt}$), where c, x, t and D are concentration, position, time and diffusivity, respectively]
246   to reproduce Mn diffusion length scales associated with the garnet growth 'unconformities' (≤
247   10 μm, Fig. 1), and thereby constrain time scales for formation of the garnet zoning at near-
248   peak metamorphic conditions. This approach assumes an initial step change in Mn
249   concentration associated with the overgrowth/dissolution surface, and no cutting effects or
250   spatial homogenization due to spot size; the calculated estimates are therefore significantly
251   biased toward longer durations. The Mn-in-garnet Arrhenius parameters of Chu & Ague (2015)
252   yield time scales of < 300 kyr for T > 550 °C, P < 2.0 GPa; all of the pressure-driven growth–
253   dissolution cycles must have occurred within this timeframe. Varying the overgrowth P–T from
254   550 to 590 °C and 1.2 to 2.0 GPa expands the estimate range to < 30–300 kyr. Allowing for Mn-
255   in-garnet Arrhenius parameter values between the most diffusive (Chakraborty & Ganguly,
256   1992) and the most retentive (Carlson, 2006) published expands the range to < 0.04–1.2 Myr
257   (for mean P–T conditions; T = 570 °C, P = 1.6 GPa). This range is compatible with global
258   subduction speeds (Syracuse & Abers, 2006), indicating that most subducting crust passes
259   through blueschist facies conditions in ~1 Myr.
260

Discussion

The diffusion length scale data indicate that at least four cycles of pressure fluctuation (of magnitude 100–350 MPa) occurred during HP/LT metamorphism, net garnet growth length scales of < 100–300 μm and metamorphic time scales very likely << 1 Myr. On the basis of major-element zoning in HP/LT garnets from Cuba, García-Casco et al. (2002) hypothesized pressure fluctuations of similar magnitude during subduction, relating them to small-scale (physical) exhumation events during prograde metamorphism. The << 1 Myr time scales for garnet zoning development are significantly shorter than hypothesized time scales for multiple burial–exhumation cycles in HP/LT rocks that have been related to i) 'yo-yo tectonics', involving (local or regional) switches between shortening and extension (e.g. Beltrando et al., 2007; Kabir & Takasu, 2010; Rubatto et al., 2011; Lister & Forster, 2016), ii) exhumation–erosion–deposition–subduction cycles (Wakabayashi et al., 2012), and iii) numerically simulated 'chaotic' mixing as a result of convection within a putative subduction channel (e.g. Gerya et al., 2002; Gerya & Stöckhert, 2006; Blanco-Quintero et al., 2011; Li et al., 2016). These 'lithostatic pressure' models are limited by maximum rates of burial/exhumation; e.g., four 7.5 km (mean magnitude; 225 MPa) burial–exhumation cycles at vertical movement rates approximating tectonic plate velocities—i.e., 30 mm yr^{-1}, as in the subduction convection model of Gerya & Stöckhert, 2006—require at least 2 Myr. It should be noted, however, that modeling of convection within the subduction channel also predicts periodic stalling of particles, yielding more likely time scales of 5–10 Myr per 200–500 MPa physical burial–exhumation cycle (e.g. Gerya & Stöckhert, 2006, Fig. 4, 7, p. 259, 262).
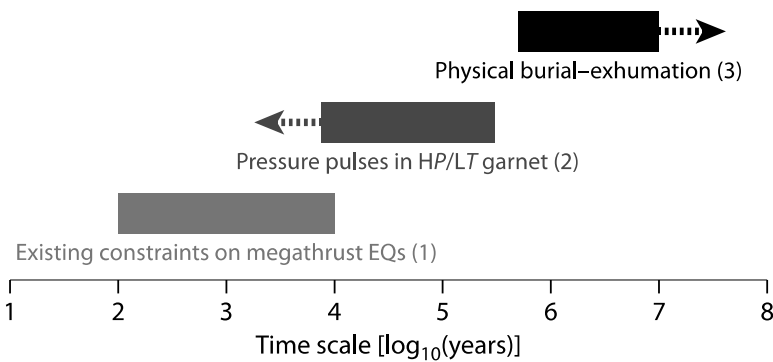

Garnet zoning marks seismic cycles during subduction

Fig. 5 compares time scales for (1) megathrust earthquake recurrence, (2) individual P pulses recorded in the HP/LT garnets of this study, and (3) small-scale physical burial–exhumation cycles, showing that these constraints are most consistent with a seismic cycle origin for the garnet P pulse records. We relate rhythmic major-element zoning in the Franciscan garnets to cycles of pore-fluid overpressure development–dissipation, linked to a seismically-induced switch from locally undrained to drained conditions (i.e., dynamic cracking and permeability changes following large earthquakes; see Brenguier et al., 2014; Chaves & Schwartz, 2016).

Physical burial–exhumation (3)

Pressure pulses in HP/LT garnet (2)

Existing constraints on megathrust EQs (1)

Time scale [log$_{10}$(years)]

295 **Fig. 5.** Time scales for individual cycles relating to: (1) megathrust earthquake (EQ) events from
296 tsunami and turbidite deposits and subsidence/uplift histories; (2) garnet dissolution–growth
297 and associated *P* pulses as recorded in the garnets of this study, and (3) physical burial–
298 exhumation cycles relating to 'yo-yo' tectonics, exhumation–erosion–deposition–subduction
299 cycles or convection within a putative subduction channel. Note, time scales for (2) are
300 maximum values due to bias toward overestimation in the approach used and the possibility
301 that *P* pulses were significantly more numerous than recorded in the garnets (see text).
302
303 Though rocks do not typically have unconfined strength greater than 100–200 MPa, the effects
304 of confinement and undrained conditions may allow pore fluid pressure excess (overpressure)
305 to attain more significant values (e.g. Vrijmoed et al., 2009; Padrón-Navarta et al., 2011;
306 Nabelek, 2015). Transient pressure pulses may mark porosity waves that transit the rock
307 volume, or cycles of overpressure development–dissipation linked to subduction-zone
308 seismicity. Porosity waves are only theorized to exist, whereas subduction zone seismicity is an
309 observed phenomenon that has been associated with pore fluid overpressure (e.g. Green &
310 Houston, 1995; Kirby et al., 1996; Hacker et al., 2003; Preston et al., 2003; Jung et al., 2004) and
311 occurs at the depth and location of H*P*/L*T* metamorphism.
312
313 Our model for Franciscan garnet zoning invokes widespread rock fracture with passing seismic
314 waves as the trigger for overpressure relief; changes in seismic velocity following megathrust
315 earthquakes have been related to this mechanism of pore-fluid pressure relief (Brenguier et al.,
316 2014; Chaves & Schwartz, 2016). Rock fracture in response to dynamic stresses induced by a
317 large earthquake may also produce a widespread permeability spike. Once fault healing and
318 sealing is complete and conditions again become undrained, feedback between dehydration
319 reactions and increasing metamorphic pressure—due to metamorphic pore-fluid production—
320 can lead to overpressure development and recommenced garnet growth, until dynamic
321 stresses associated with a subsequent large earthquake again cause rock fracture and
322 permeability increase. Not all earthquake events need be recorded and those that were do not
323 need to have been proximal; dynamic stresses and therefore likelihood of local fracturing and
324 overpressure relief would be greatest for the most energetic events (e.g. megathrusts). The
325 model is consistent with our FTIR observation of a decrease in OH across the growth
326 'unconformity' (Fig. 4). Intimate garnet growth-zone $\delta^{18}O$ variation in the Franciscan garnets (cf.
327 Page et al., 2014) may also be expected for cycles of pore-fluid purging with rock fracture,
328 pressure drop and permeability increase, followed by metamorphic dehydration and
329 overpressure development under undrained conditions. Such work may offer a means to test
330 the fluid overpressure relief (following large earthquakes) model presented here.
331
332 Multiple, rapid pressure fluctuations of 100–350 MPa, as observed here in association with
333 garnet zoning, can be achieved by seismic cycles in subduction zones. Large earthquakes have
334 recurrence intervals of 100–10,000 yr (e.g. Taylor, 1990; Goldfinger et al., 2003; Nanayama et
335 al., 2003; Cisternas et al., 2005; Monecke et al., 2008; Gràcia et al., 2010). Though there is some
336 overlap, the H*P*/L*T* garnets studied record frequencies mostly outside of this recurrence range
337 (see Fig. 5). Not every earthquake will cause fracturing and overpressure dissipation; records
338 are only made for those that produced sufficient seismic energy, directed at the rock volume.

339 This, partnered with potential for garnet dissolution to remove evidence for earlier garnet
340 growth–dissolution cycles (cannibalization of records of *P* pulses), can explain much of the
341 potential discrepancy between time scales for H*P*/L*T* garnet records of *P* pulses and recurrence
342 intervals for large subduction-zone earthquakes (Fig. 5).
343
344 We conclude that major-element zoning in the H*P*/L*T* garnets records seismic cycles within the
345 Franciscan subduction zone. Such metamorphic features are common in H*P*/L*T* metamorphic
346 rocks worldwide. In time, geochemical features of H*P*/L*T* garnets (and other minerals) may offer
347 important new insights on the nature of subduction zone (paleo)seismicity, and associations
348 among stress evolution, earthquake magnitude and recurrence, and fluid transport/mobility in
349 the crust.
350
351 **Materials and Methods**
352
353 ***Sample descriptions***
354
355 The manuscript focuses on two rocks from Ring Mountain, San Francisco Bay, California. Sample
356 CA13-01 [GPS: 37° 55.073' N, 122° 29.583' W] is an eclogite–blueschist with 11 vol.% garnet.
357 Sample CA13-05A [GPS: 37° 54.729' N, 122° 29.122' W] is a garnet-rich (32 vol.%) amphibolite–
358 blueschist. Garnet populations in both rocks are not uniform, with grain size in each varying
359 from < 0.5 mm to approximately 2 mm across. Both rocks are heterogeneous on a scale of 1–10
360 mm; CA13-01 has blueschist and eclogite layers, CA13-05A has interfingered amphibolite and
361 blueschist domains. Garnet in CA13-01 is commonly surrounded by phengite, whereas many
362 garnets in CA13-05A are surrounded by clots of chlorite. Mineralogy for each sample is given
363 below. Cross-polarized-light microphotographs are provided in Fig. S1.
364
365 (CA13-01)   omphacite + garnet + glaucophane + phengite + titanite + zoisite + quartz + rutile
366 (CA13-05A)   hornblende + garnet + glaucophane + zoisite + chlorite + rutile + phengite +
367 omphacite + titanite
368
369 Tsujimori et al. (2006a) provided detailed descriptions of three high pressure-low temperature
370 (H*P*/L*T*) rocks from Ring Mountain. Their sample A is incredibly similar in mineralogy and
371 appearance to our CA13-05A. For that sample, Tsujimori et al. (2006a) used petrography,
372 garnet–omphacite–phengite thermobarometry and equilibrium phase assemblage modeling to
373 constrain garnet rim growth to the peak-metamorphic phase, at *T* = 550–620 °C and *P* = 2.2–2.5
374 GPa. Titanite overgrows rutile in both CA13-01 and CA13-05A, and chlorite overgrows garnet in
375 CA13-05A. The Ring Mountain H*P*/L*T* rocks record a counter-clockwise *P*–*T* path, with a
376 metamorphic overprint relating to refrigeration prior to exhumation (Wakabayashi et al., 1990;
377 Tsujimori et al., 2006a). Chlorite and titanite in CA13-01 and titanite in CA13-05A are texturally
378 post-peak metamorphic and grew during the exhumation (and refrigeration) phase of the rock
379 history.
380
Fig. S1. Cross-polarized-light photomicrographs of samples CA13-01 and CA13-05A. For each rock, some of the garnets mapped for major elements are circled in red.

Electron microprobe methods, mineral chemistry and zoning, and Mn sources

Electron microprobe mapping method and results

Wavelength-dispersive spectrometer (WDS) x-ray count maps for Al, Ca, Fe, Mg and Mn were produced for seven garnets from CA13-01 and six garnets for CA13-05A. Measurements were made simultaneously on the five spectrometers of the Cameca SX 100 electron microprobe in the Department of Earth Science, University of California, Santa Barbara; Al, Ca, Fe, Mg and Mn measurements were made on TAP, LPET, LLIF, LTAP and LLIFF crystals, respectively. Run conditions were 15 keV and 200 nA, and pixel dwell times were 50 ms for all maps except for CA13-01 garnet 2.3, which used 100 ms. Mapping resolution was 2–5 µm, depending on the size of the garnet, and uniform in x and y. Color overlayed maps for all garnets are provided at the end of this document.

Electron microprobe quantitative analysis method and results

Quantitative WDS analyses were produced for three radial garnet traverses (n = 670), a cluster of zoned zoisites from each of CA13-01 and CA13-05A (n = 24), and selected additional minerals from each sample (n = 36). All analyses were performed on the JEOL JXA 8600 electron microprobe in the Department of Earth & Planetary Sciences, Johns Hopkins University. Calibration used multiple natural reference materials. Garnet traverses were run at 15 keV and 40 nA, and used a 1 µm spot size at 1 µm centers and 30 s on-peak and 10 s background counting times. All other analyses were run at 15 keV and 20 nA, and used a 5 µm spot size and 30 s on-peak and 15 s background counting times.

410 Results for the radial garnet traverses are provided in Fig. 1. Compositions of typical examples
411 of minerals from CA13-01 and CA13-05A are provided in Tables S1 and S2. The subsequent
412 section discusses mineral chemical variability and zoning. All quantitative electron microprobe
413 results are provided in a separate supplementary file.
414
415 **Table S1.** Stoichiometric mineral compositions for CA13-01, based on assumed number of
416 oxygen atoms shown. Note, Fe in zoisite was assumed 100% Fe^{3+}, Fe in all other minerals was
417 assumed 100% Fe^{2+}. Gln = glaucophane; Omph = omphacite; Phe = phengite; Zo = zoisite.

423

424 ### _Solid solution, mineral zoning and Mn sources_

425

426 Quantitative analyses demonstrate variability in composition for all minerals analyzed. Zoning
427 in individual minerals can capture the full range of compositional variation observed for
428 omphacite and zoisite in CA13-01, and hornblende and zoisite in CA13-05A. Amphiboles from
429 CA13-01 are glaucophane, with Na/(Na + Ca) ≈ 94% (Fig. S2a). One population of amphibole in
430 CA13-05A has similar glaucophane chemistry, whereas the other is a hornblende, with
431 composition between actinolite and pargasite (Fig. S2a). Clinopyroxene in CA13-01 is
432 omphacite, with 39–53 mol.% jadeite (Fig. S2b). Chlorite in CA13-05A varies in composition,
433 with Fe/(Fe + Mg) in the range 37–45% and Si increasing with Fe (Fig. S2c). White mica in CA13-
434 01 also varies in composition, potentially defining two (phengitic) compositional arrays
435 between celadonite and muscovite/paragonite (Fig. S2d). Phengite in CA13-01 has Si content
436 3.34–3.54 p.f.u.

437
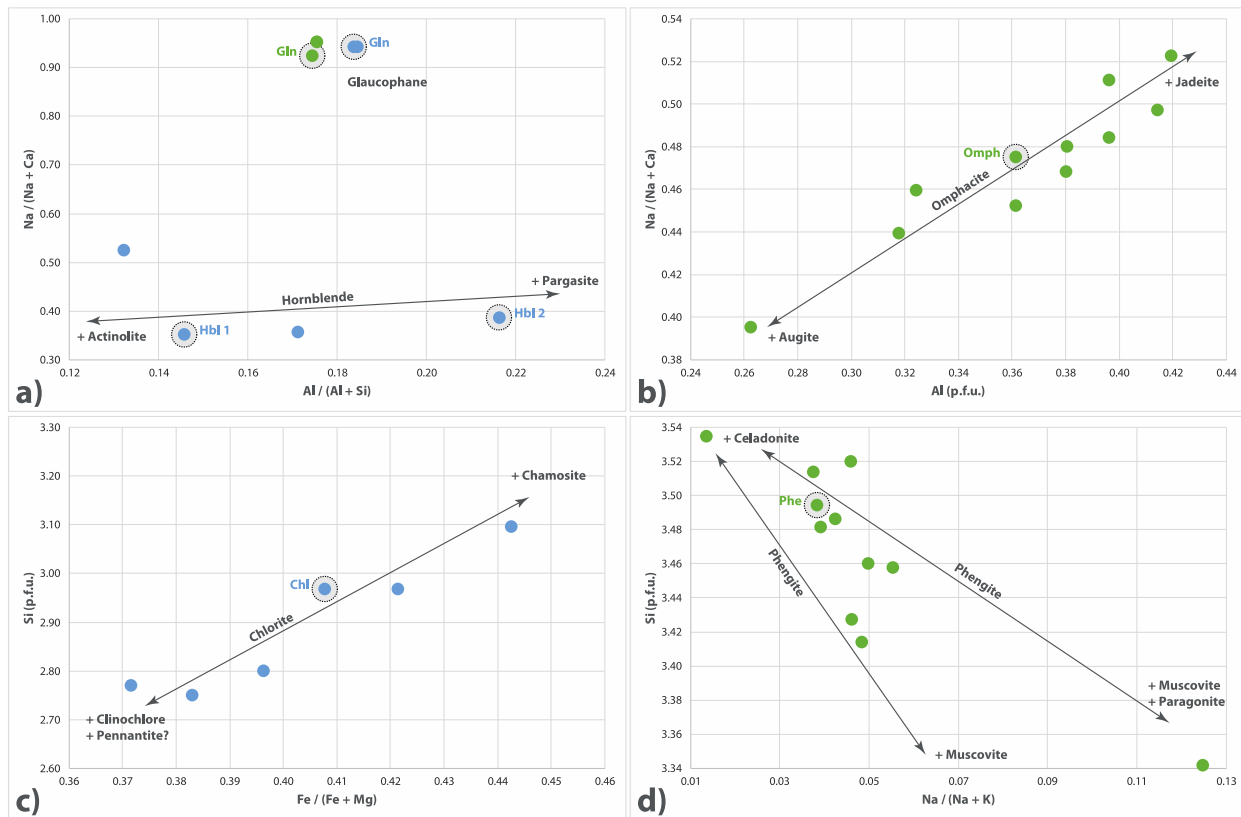

438
439 **Fig. S2.** Plots showing solid solution for (a) amphibole, (b) clinopyroxene, (c) chlorite, and (d)
440 white mica. Green data are for CA13-01, blue data for CA13-05A. Circled points are those
441 whose geochemistry is given in Tables S1 and S2.

442

443 The compositional arrays and populations of Fig. S2 are reflected in back-scattered electron
444 (BSE) zoning in amphibole and omphacite. In addition, zoisite has fine-scale, oscillatory BSE
445 zoning (Fig. S3). The zoning principally relates to Fe^{3+} and Al substitution in the epidote–zoisite

446   solid solution (Fig S3; Tables S1 and S2), but also maps with Mn content, particularly in CA13-
447   05A (Fig S3). Complementary Mn zoning in zoisite to that observed in garnet (see Results
448   section) suggests zoisite growth may have partially balanced garnet dissolution (and vice versa).
449   This observation is consistent with parallelism of modal garnet and zoisite contours (Fig. S4).
450   Garnet breakdown in the presence of H_2O produces zoisite only if other reactants are able to
451   balance the remaining chemistry. Garnet growth–dissolution reactions that mark P pulses
452   (seismic loading–rupture cycles) may have involved garnet, jadeite, quartz and H_2O to yield Na
453   amphibole and zoisite (and vice versa) in CA13-05C, and garnet, Na amphibole and H_2O to yield
454   Na–Ca amphibole and zoisite (and vice versa) in CA13-01.
455
456   The predicted garnet-growth to zoisite-dissolution ratio for an isothermal, 250 MPa P pulse
457   starting at T = 570 °C, P = 1.55 GPa is greater for CA13-01 (5:1.25) than CA13-05A (9:4) (Fig. S4).
458   The Mn-in-garnet to Mn-in-zoisite ratio is also greater for CA13-01 (approx. 1.0:0.1) than CA13-
459   05A (approx. 0.5:0.2). Hornblende, a product of garnet breakdown in CA13-05A, has up to 0.11
460   wt.% Mn. More accommodating hosts for Mn liberated during breakdown of garnet in CA13-
461   05A may account for limited Mn back-diffusion during garnet dissolution in CA13-05A (relative
462   to CA13-01) and thus development of core-side rather than rim-side zoning in those garnets
463   (see Fig. 2).
464
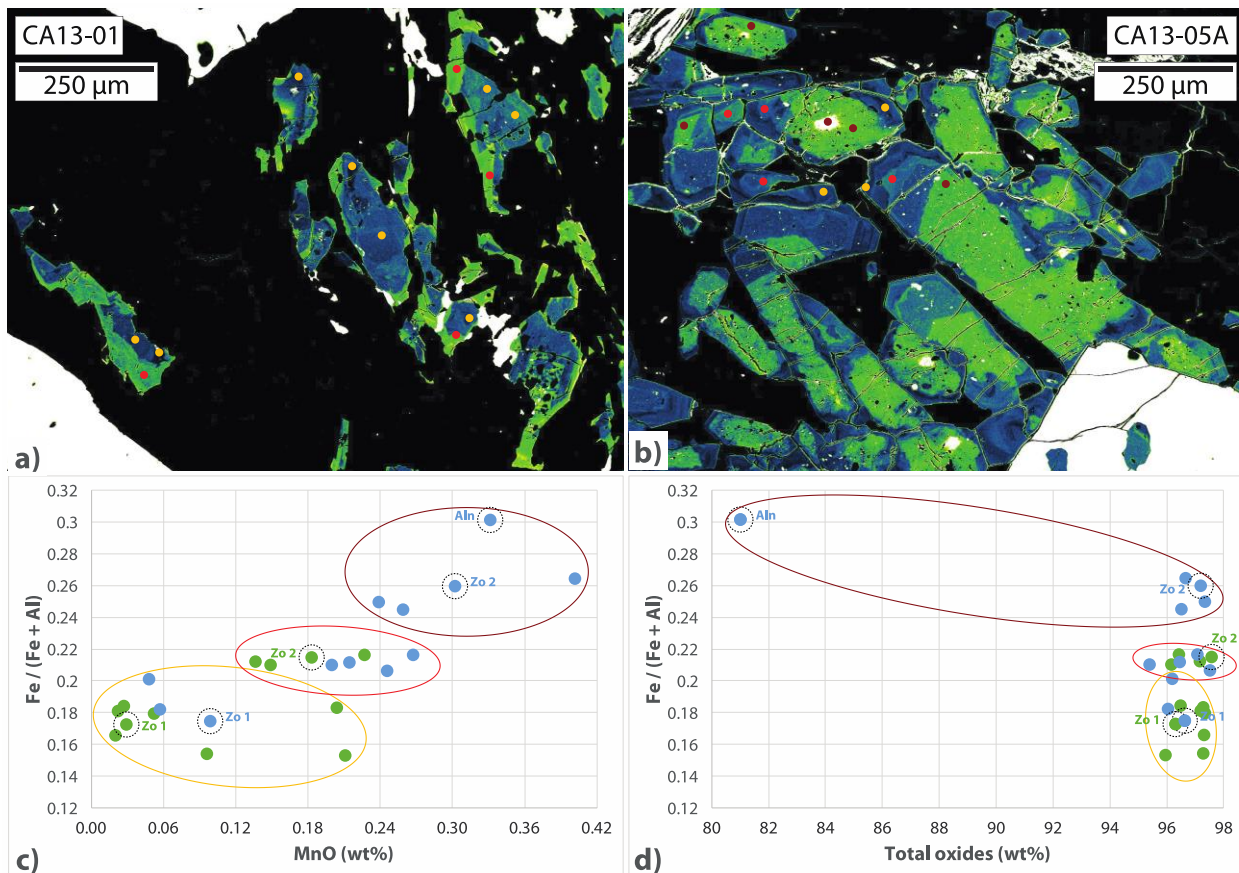

465
466   **Fig. S3.** (a and b) color-overlayed BSE maps for zoisite in CA13-01 and CA13-05A, highlighting
467   fine-scale oscillatory zoning. (c) shows a positive correlation between Fe/(Fe + Al) and MnO in

468 zoisite. (d) shows one analysis with lower oxide totals than all others; an allanite that contains a
469 high proportion of trace elements not analyzed for. Green data are for CA13-01, blue data for
470 CA13-05A. Yellow, red and maroon groupings match the color of analysis spots and low to high
471 BSE response, respectively, in the maps. Spots on maps are three times larger than actual
472 analyses.

473

474 ***Whole-rock geochemistry, and thermodynamic modeling method and results***

475

476 <u>*Whole-rock geochemistry*</u>

477

478 Approximately 20 g of fresh and representative material from each of CA13-01 and CA13-05A
479 was ground to powder in a tungsten carbide ring-and-puck mill. Lithium borate fused glass
480 beads were prepared for analysis with a sample (powder) to flux ratio of 1:5. Whole-rock
481 geochemical analyses for major elements were performed on the PANalytical Axios Advanced x-
482 ray fluorescence (XRF) spectrometer in the Department of Geology, University of Leicester.
483 Results from the XRF work are provided in Table S3.

484

485 **Table S3.** Whole-rock geochemistry determined by XRF (values in wt.%).

	SiO_2	TiO_2	Al_2O_3	Fe_2O_3	MnO	MgO	CaO	Na_2O	K_2O	P_2O_5	SO_3	LOI	Total
CA13-01	48.09	1.53	15.78	9.90	0.19	5.38	10.74	3.49	1.54	0.12	<0.002	1.26	98.02
CA13-05A	40.85	2.84	16.43	17.23	0.35	6.36	12.53	1.11	0.13	0.10	0.112	1.28	99.32

486

487 <u>*Perple_X thermodynamic modeling of metamorphic phase equilibria*</u>

488

489 Thermodynamic modeling of metamorphic phase equilibria was performed in the
490 MnNCKFMASHT system, using the whole-rock compositions in Table S3. Whole-rock
491 compositions were considered in preference to porphyroblast-subtracted compositions as the
492 modeling was performed to interrogate sensitivity of garnet content (and growth or
493 dissolution) to changes in *P–T*; a highly responsive, porphyroblast-involved system is assumed.
494 For each model, the rock was considered saturated in H_2O (set to 10 wt.%) and Fe determined
495 from XRF was recalculated to 100% ferrous (FeO); the only mineral in the rock with significant
496 Fe^{3+} is epidote and that accounts for only a limited proportion of the zoisite (see Fig. S3).
497 Modeling used version 6.6.6 of the Perple_X program (Connolly, 2005, 2009), the 2004 update
498 of the thermodynamic dataset of Holland & Powell (1998), and solution models for amphibole
499 (Wei & Powell, 2003; White et al., 2003), biotite (Powell & Holland, 1999; White et al., 2000),
500 chlorite (Holland et al., 1998), clinopyroxene (Green et al., 2007; Diener & Powell, 2012),
501 feldspar (Fuhrman & Lindsley, 1998), fluid (Connolly & Trommsdorf, 1991), garnet (White et al.,
502 2000), ilmenite (White et al., 2000), melt (Holland & Powell, 2001; White et al., 2001) and white
503 mica (Coggon & Holland, 2002; Auzanneau et al., 2010). Modeling was performed in the range *T*
504 = 525–625 °C and *P* = 1.4–2.4 GPa for CA13-01, and *T* = 525–625 °C and *P* = 1.2–2.2 GPa for
505 CA13-05A. Fig. S4 shows metamorphic assemblage diagrams for both samples, with modal
506 abundance contours for both garnet and zoisite (Fig. S4a and b) and Mg garnet (pyrope) and
507 Mn garnet (spessartine) (Fig. S4c and d) overlain.

508

### *Raman thermobarometry method and results*

510

511   Raman spectroscopy was performed on quartz inclusions in garnet using a Horiba Jobin–Yvon
512   LabRAM HR Raman microscope in the Department of Chemistry, Durham University. All
513   analyses used an 1800 grid (1800 grooves mm^{-1} grating), centered at 470 cm^{-1}. For each quartz
514   inclusion analysis, a 100x confocal objective lens was used to focus the 632.8 nm (red) HeNe
515   laser to a spot size of 1 μm, centered in the inclusion. Quartz inclusions were inspected for
516   exposure and/or cross-cutting cracks, and analysed in triplicate (three measurements in
517   separate sessions). Precise peak positions were obtained by fitting of Lorenzian curves to the
518   nominal 464 cm^{-1} A1g-mode quartz Raman peak (for unknowns), using the software package
519   Igor Pro. Curve fitting to the nominal 464 cm^{-1} A1g-mode peak in quartz used the portion of the
520   spectrum 12 grid points either side of the maximum intensity position, representing a total
521   range of ~7.6 cm^{-1}.

522

523   Instrument drift due to internal temperature equilibration was corrected for by quasi-hourly
524   (duplicate) measurement of a pure sulfur Raman spectroscopy standard. Analyses on sulfur
525   standards used a 50x objective and the same 632.8 nm (red) HeNe laser, focused to the
526   position within the homogeneous standard that produced maximum spectrum intensity. For
527   the sulfur standard spectra, curve fitting to the nominal 384.1 cm^{-1} mode peak used the portion
528   of the spectra eight grid points either side of the maximum intensity position (total range of
529   ~5.1 cm^{-1}), a Lorenzian form and the software package Igor Pro. Drift in the position of the
530   nominal 384.1 cm^{-1} sulfur peak during each Raman session was characterized by an equation of
531   the form [$y = -A \exp(-t / b) + c$], where y is the measured peak position minus the nominal
532   384.1 cm^{-1} value, t is time since the first measurement of the session, A and b are shape
533   constants and c is a vertical shift constant. Values of A, b and c for each session were calculated
534   from a fit to the sulfur data for that session. Following correction for instrument drift at the
535   time of measurement, unknowns were found to have an overall 2σ reproducibility of ± 0.3 cm^{-1}
536   for the peak position of the nominal 464 cm^{-1} A1g-mode quartz Raman peak, despite
537   measurements being made on separate days (see Results section and Fig. 3). Uncorrected
538   spectra (with time stamps) for both quartz inclusions (unknowns) and sulfur standards are
539   available at https://doi.org/10.7281/T1/SP6KO3.

540

541
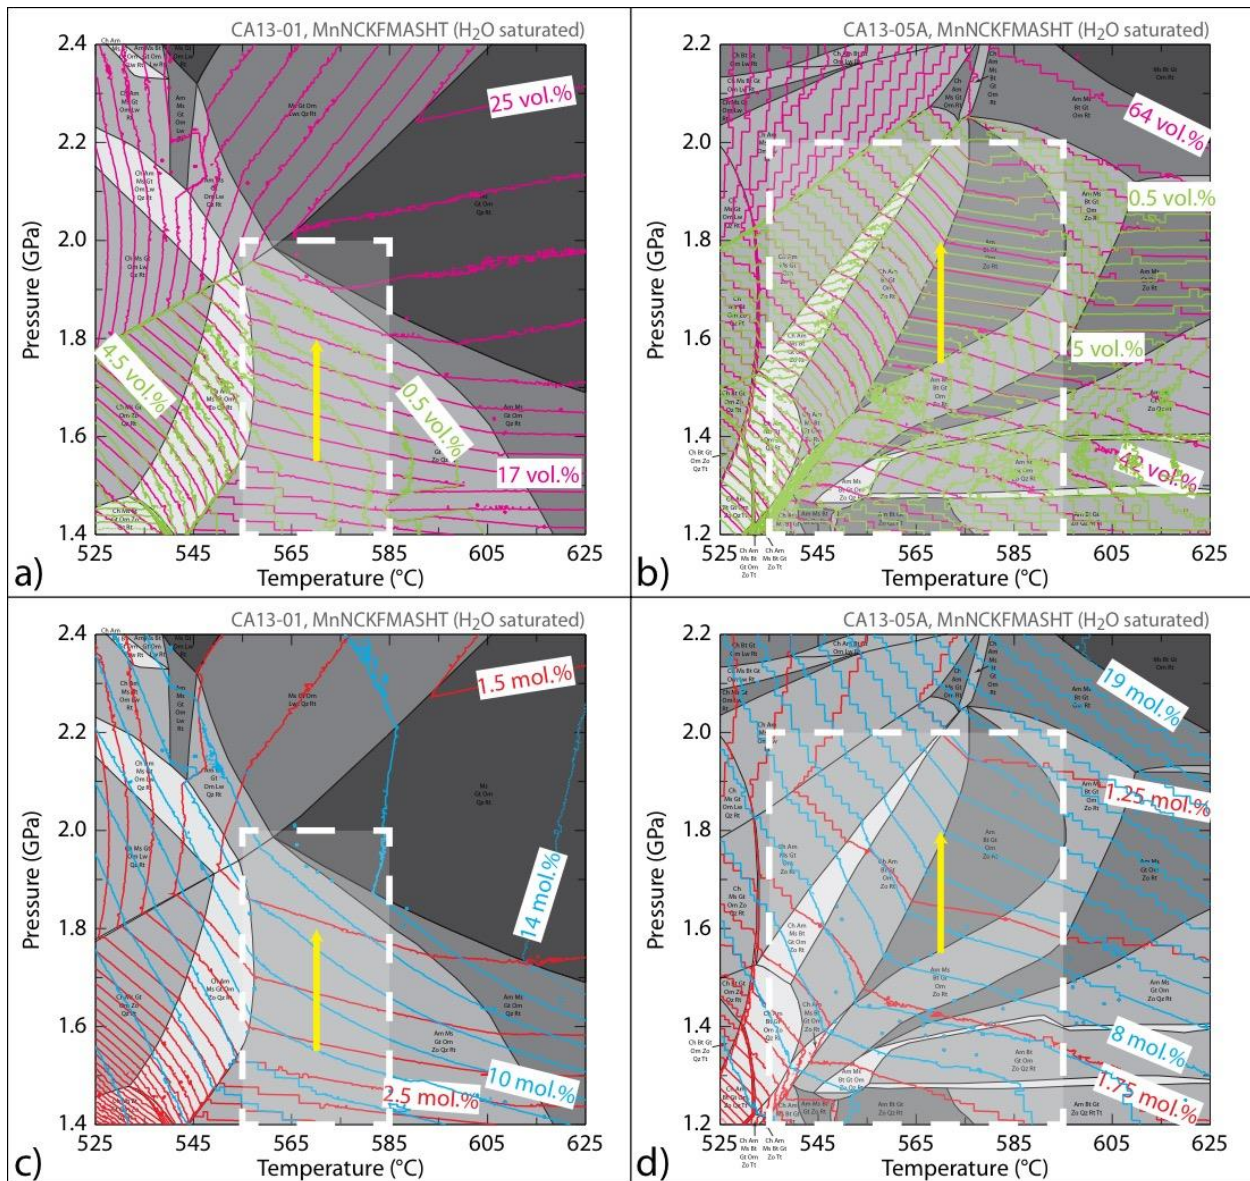

Fig. S4. MnNCKFMASHT metamorphic assemblage diagrams for (a and c) CA13-01 and (b and d) CA13-05A. Phase assemblage fields and labels redrafted from the Perple_X output. White dashed box indicates approximate equilibrium *P–T* range of the peak-metamorphic assemblage in each rock. Green and pink contours in a and b are for modal zoisite and garnet, respectively; contour intervals of 0.5 vol.% used for zoisite, and 1 and 2 vol.% for garnet in CA13-01 and CA13-05A, respectively. Note significant congruence between zoisite and garnet contours, suggesting a metamorphic relationship between the phases (i.e. dissolution of one partially accommodates growth of the other). Yellow arrow shows 250 MPa isothermal *P* increase (starting at *T* = 570 °C, *P* = 1.55 GPa), associated with an absolute gain of 5 vol.% garnet and loss of 1.25 vol.% zoisite for CA13-01, and an absolute gain of 9 vol.% garnet and loss of 4 vol.% zoisite for CA13-05A. Blue and red contours in c and d are for proportion of Mg garnet (pyrope) and Mn garnet (spessartine), respectively; contour intervals of 1 mol.% used for pyrope and 0.25 mol.% for spessartine.

556 Calculation of overgrowth P and T used the MATLAB QuiBCalc program of Ashley et al. (2014),
557 quartz Raman calibration of Schmidt & Ziemann (2000), mineral properties compiled in Powell
558 & Holland (2011) and the elastic model of Guiraud & Powell (2006). Properties of garnet were
559 calculated by linear interpolation between almandine, grossular, pyrope and spessartine, using
560 respective molar ratios of 59:26:11:4 for CA13-01 and 56:28:15:1 for CA13-05A. These garnet
561 compositions match microprobe-determined rim compositions for the garnets (see Fig. 1). For
562 the same Raman shifts, the elastic model of Zhang (1998) yields P estimates that are
563 systematically higher, by 100–200 MPa.
564
565 ***Synchrotron Fourier transform infrared (FTIR) method and results***
566
567 Microanalyses made at the Diamond Light Source were performed in transmission mode, with
568 spectral resolution of 16 cm^{-1} and phase resolution of 128, using a 700–3200 cm^{-1} window.
569 Analyses used a 36x objective and 10 x 10 µm square slit size defining the detected area at the
570 sample. Each spectrum was produced from 3000 scans and backgrounds were collected prior to
571 each traverse. Four traverses were run radially across the zoning at the garnet edge, using 10
572 µm centers; n = 39 for CA13-01 G1T2, n = 35 for CA13-01 G2T1, n = 76 for CA13-05A G1T1, n =
573 46 for CA13-05A G2T1. Microanalyses made at The Australian Synchrotron were also performed
574 in transmission mode, with spectral resolution of 16 cm^{-1} and phase resolution of 128, using a
575 700–3200 cm^{-1} window. Analyses again used a 36x objective, but a circular spot size of 11.6 µm.
576 Each spectrum was produced from 512 scans, and backgrounds were collected prior to each
577 map. The 2D maps approximated 1D radial traverses, forming elongate grids with dimension 6 x
578 44 (n = 264) for CA13-01 G1T3, 5 x 39 (n = 195) for CA13-01 G2T2, 6 x 45 (n = 270) for CA13-01
579 G3T1, 6 x 81 (n = 486) for CA13-05A G1T2, 6 x 48 (n = 288) for CA13-05A G2T2. All line maps
580 used 12 µm centers in the 'circumferential' direction and 6 µm centers (approximate 2x
581 oversampling) in the radial direction. CA13-01 garnet 2, map G2T2, collected at The Australian
582 Synchrotron, experienced irrecoverable issues with background correction.
583
584 In total, analyses were performed in transmission mode on three garnets from a clean, ~225
585 µm-thick wafer of sample CA13-01 and two garnets from a clean, ~280 µm-thick wafer of
586 sample CA13-05A. Relative OH and H_2O contents were calculated from the integrated intensity
587 of the background-subtracted spectra in the 3520–3620 cm^{-1} and 3350–3450 cm^{-1} mid-IR
588 regions, respectively. Integrated intensity calculations were performed with the OPUS software
589 package, using a linear integration baseline. Processed data for the integrated intensities of OH
590 and H_2O in the five garnets analyzed by synchrotron FTIR spectroscopy are provided in Fig. 4.
591 Raw data (as OPUS files) for all synchrotron FTIR analyses are available at
592 https://doi.org/10.7281/T1/SP6KO3.
