17 **ABSTRACT**

18 We present the first integrated study of carbonate, hydroxyl, fluoride and chloride ion

19 partitioning in the apatite-melt system. We determined volatile partitioning behaviour

20 between apatite and silicate melt for both haplobasaltic andesite and trachyte bulk

21 compositions at 0.5-1 GPa and 1250 °C using the piston cylinder apparatus. All volatile

22 species were analysed directly in both apatite and glass using secondary ion mass

23 spectrometry (SIMS) and electron probe microanalysis. Distribution coefficients for OH-

24 halogen exchange are similar to those from previous studies, and together with literature

25   data, reveal a significant log-linear relationship with temperature, while the effects of

26   pressure and melt composition are minimal. Meanwhile, halogen-free experiments

27   generate very high C contents (up to 5000 ppm) in apatite. Stoichiometry calculations and

28   infrared spectra indicate that this C is mainly incorporated onto the channel volatile site

29   together with hydroxyl. In halogen-bearing experiments, apatite crystals contain

30   significantly lower C ($\leq$ 500 ppm) which may be partly incorporated onto the phosphate

31   site while the channel volatile site is filled by OH+F+Cl+C. Our experiments give the

32   first constraints on H_2O-CO_2 exchange between apatite and silicate melt, with a K_D of

33   0.355 $\pm$ 0.05 for the trachyte and 0.629 $\pm$ 0.08 for the haplobasaltic andesite. The new

34   constraints on the temperature-dependence of partitioning will enable quantitative

35   modelling of apatite-volatile exchange in igneous systems, while this new partitioning

36   data and method for direct, *in situ* analysis of C in apatite mark a significant advance that

37   will permit future studies of magmatic C and other volatiles. This has a broad range of

38   potential applications including magmatic differentiation, fractionation, and degassing;

39   quantification of volatile budgets in extra-terrestrial and deep earth environments; and

40   mineralisation processes.

41

42   **INTRODUCTION**

43   Volatile-bearing minerals such as apatite represent a useful source of information about

44   the volatile compositions of the systems from which they crystallise. Apatite has a very

45   flexible mineral structure and igneous apatites can accommodate all the major volatile

46   species of magmatic importance, i.e. H, C, F, Cl and S, as well as other trace volatile

47   species such as Br and I (e.g. Peng et al. 1997; Pan and Fleet 2002; Marks et al. 2012;

48   Konecke et al. 2017). With some knowledge of the partitioning properties of these

49   volatiles, apatite may therefore be able to provide quantitative information about multi-

50   component degassing, and other processes, in terrestrial magmas. The apatite crystal

51   formula is $Ca_5(PO_4)_3X$, where X represents the channel volatile site that runs parallel to

52   the crystallographic c-axis and is typically occupied by OH, F and Cl. While there are

53   several existing studies focusing on exchange between OH and halogens in the channel

54   site (e.g. Mathez and Webster 2005; Webster et al. 2009, 2017; Doherty et al. 2014; Li

55   and Hermann 2015, 2017; McCubbin et al. 2015; Potts et al. 2015), we are not aware of

56   any previous work quantitatively examining the partitioning behaviour of C between

57   apatite and a silicate melt. Knowledge of the C partitioning behaviour would be

58   particularly valuable for studies of terrestrial volcanism because magmatic CO_2 contents

59   are difficult to infer using traditional methods such as melt inclusions. The solubility of

60   CO_2 in silicate melts is strongly dependent on pressure, which means that CO_2 is typically

61   degassed very early during the magma ascent, and the highest (primary) CO_2 contents are

62   generally thought not to be trapped in melt inclusions or are lost to shrinkage bubbles

63   (e.g. Bureau et al. 1999; Wallace 2005; Blundy et al. 2010; Hartley et al. 2014; Moore et

64   al. 2015; Wallace et al. 2015; Aster et al. 2016). Furthermore, it is commonly not clear as

65   to the extent to which melt inclusions have been affected either by post-entrapment

66   diffusive modification (e.g. Gaetani et al. 2012) or by fluxing of CO_2-rich fluids through

67   the magma reservoir during entrapment (e.g. Spilliaert et al. 2006; Collins et al. 2009;

68   Blundy et al. 2010). The existing work on quantitative determination of carbonate

69   contents of apatite is based on FTIR using doubly polished, oriented wafers. This level of

70   sample preparation is almost prohibitively difficult for magmatic apatites, which are

71 typically small microphenocrysts or inclusions in other magmatic mineral phases. Here

72 we successfully determine C in apatite using secondary ion mass spectrometry, and

73 present data from a series of high pressure, high temperature experiments allowing us to

74 constrain the combined partitioning behaviour of H, C, F, and Cl between apatite and

75 silicate melts.

76

77   EXPERIMENTAL METHODS

78 Our experimental approach was to examine volatile partitioning and exchange equilibria

79 between apatite and silicate melts, with a particular focus on C and OH. We added

80 halogens (F and Cl) in a subset of runs, in order to evaluate the extent to which this

81 affects the partitioning of C and/or OH. The terminal run pressures (1.0 and 0.5 GPa) and

82 temperatures (1250 °C) employed represent reasonable storage conditions for mid- to

83 lower-crustal mafic magmas. Our chosen run conditions have the added advantages that

84 (a) apatite + melt are commonly the only phases present, and (b) the glass fraction of run

85 products is typically greater than 50% (e.g. Prowatke and Klemme 2006). These

86 conditions simplify interpretation of the partitioning data and ensure that suitably sized

87 areas of glass are available for ion microprobe analysis. Furthermore, it is helpful to

88 avoid crystallisation of other volatile-bearing phases (e.g. amphibole), which could

89 complicate analysis of the partitioning behaviour of volatiles between apatite and melt.

90

91 **Experimental starting materials**

92 We used two sets of synthetic starting materials ('BA' and 'BM'; Table 1), allowing us to

93 investigate the possible compositional effects on volatile partitioning. Both starting

4

94   materials are based on compositions used in previous experimental studies and were

95   chosen in order to take advantage of existing phase equilibrium constraints. Composition

96   'BA' is a haplobasaltic andesite equivalent to composition SH3 of Prowatke and Klemme

97   (2006). This composition produced large apatite crystals in trace element partitioning

98   experiments at similar temperatures and pressures (Prowatke and Klemme, 2006) and

99   enabled us to consider volatile partitioning in a simplified, Fe-free system in the first

100   instance. Composition 'BM' is a trachyte equivalent to the natural 'ZAC' obsidian

101   composition from Campi Flegrei, Naples, Italy (Fabbrizio and Carroll, 2008). The

102   nominal compositions of both starting materials are given in Table 1.

103   Starting materials were prepared as mechanical mixtures of reagent grade oxides

104   (Al_2O_3, SiO_2, MgO, MnO, FeO, Fe_2O_3, TiO_2) and carbonates (Na_2CO_3, K_2CO_3, $CaCO_3$)

105   subsequently doped with varying amounts of phosphate (added as $Ca_3(PO_4)_2$) and

106   volatiles (added as described below). Prior to mixing, all components were dried

107   overnight at 100 °C; the oxide powders SiO_2, Al_2O_3, MgO and TiO_2 were additionally

108   fired at 1000 °C to drive off residual moisture. Dried components were then mixed in the

109   desired proportions, ground under ethanol to produce homogenous powders, and slowly

110   decarbonated in a box furnace (600 °C to 1000 °C over 6 hours). For starting material

111   'BA,' four such powders were produced: a P-bearing split doped with ~25% $Ca_3(PO_4)_2$; a

112   P-free split equivalent to that reported in Table 1, but with added Ca; and carbonated

113   equivalents of both the P-free and P-bearing splits. Calcium was added to the P-free splits

114   such that all splits had equal bulk CaO contents. In the case of C-bearing splits, the

115   carbonate component was added following the decarbonation step. In this way, the bulk

116   proportions of P and C in each run were varied by varying the proportions of the different

117   splits added to each capsule. Fluorine and Cl were added directly to each capsule as Ca-,

118   K-, or Na-fluorides and chlorides. Because the quantity of F and Cl added was small

119   (typically < 1 wt%), these additions did not significantly affect the proportions of the

120   other components. Hydrogen, where present, was added as liquid water as described

121   below.

122   Starting material 'BM' was prepared as above, but with an additional glassing

123   step following decarbonation: splits were heated to 1400 °C for 30 minutes in a gas

124   mixing furnace, then ground dry to homogenise. The gas mixture was held near Ni-NiO

125   buffer conditions at the furnace temperature. This heating and grinding process was

126   repeated 1–3 times for each split. Fluorides and chlorides were added to prior to glassing,

127   with carbonate added afterward as above, and splits were mixed to yield the desired bulk

128   volatile proportions (excepting water) before being added to each capsule. These

129   additional steps were employed to ensure the thorough homogenisation of starting

130   materials as needed to aid apatite growth and equilibration in a companion study at lower

131   experimental temperatures and pressures. As we observe no systematic textural

132   differences between the apatites produced by the BA and BM starting materials, we

133   assume that the starting powders were sufficiently homogenised during equilibration at

134   high temperatures so as to negate any potential differences owing to the different

135   preparations of the two starting materials.

136

137   **Piston cylinder experiments**

138   Starting powders were loaded into 3 mm diameter Pt capsules. In water-bearing

139   experiments, distilled, deionised water was first added to the base of each capsule using a

140 micro-syringe. Capsules were welded shut, then pressed into cylinders approximately

141 4mm in length, and placed into 4 mm diameter outer Pt capsules containing identical

142 proportions of starting powders ± H_2O. The outer capsule was then welded shut and

143 pressed into a cylindrical shape approximately 7 – 8mm in length. Pressing of inner and

144 outer capsules helped to ensure an even distribution of surrounding materials in the

145 nested assembly. The double-capsule technique employed is essential when using Pt

146 capsules, in order to reduce gradients in the chemical potentials of H and C adjacent to

147 the sample, and thus limit the rate of H_2 and C exchange between the sample and the

148 apparatus (Hall et al. 2004, Brooker 1998). In lieu of a solid buffer, this method also

149 helps to maintain a fixed $f O_2$ (or $f H_2$) in the inner capsule and helps to minimise volatile

150 loss or gain during runs. After each welding step (inner and outer capsule), capsules were

151 weighed to check for water loss, then heated and reweighed to ensure the integrity of the

152 weld seal.

153   All experiments were run in end-loaded piston cylinder apparatus (Boyd and

154 England 1960) at the University of Bristol. A conventional ½ inch diameter bomb and

155 piston was used for runs at 1 GPa. A ¾ inch diameter bomb was used for two runs at

156 lower pressure (0.5 GPa). The complete sample assembly consisted of the 4 mm diameter

157 outer Pt capsule surrounded by crushable MgO (½ inch diameter setup; for the geometry

158 of this setup, see McDade et al., 2002, their figure 1d) or Al_2O_3 (¾ inch diameter setup,

159 for the geometry of this setup, see McDade et al., 2002, their figure 1e) spacers

160 positioned to centre the capsule in the hot spot of the graphite furnace. The furnace +

161 capsule assembly was fitted within a pyrex sheath and an outer NaCl (½ inch) or talc (¾

162 inch) sleeve. Loaded assemblies were then heated and pressurised according to a 'hot

7

163   piston in' routine. After applying an initial pressure load, the assembly was allowed to

164   settle for at least 20 minutes. Temperature and pressure were then increased

165   simultaneously, with the final pressure applied upon reaching the run temperature. This

166   routine is in keeping with that used to determine the talc- and salt-pyrex friction

167   correction for set pressures (~3%, McDade et al. 2002). Pressure was maintained by

168   means of an automated pressure regulator to within ±1 psi of the target run pressure,

169   yielding pressure variations of <<1% relative. Run temperature was monitored using

170   $W_{97}Re_3$–$W_{75}Re_{25}$ (D-type) thermocouples, inserted along the assembly axis adjacent to

171   the top of the charge. Temperature was maintained by automated adjustment of the

172   operating power via a Eurotherm, with typical deviations from target of <1 °C. No

173   attempt was made to correct temperatures for a pressure-dependence of e.m.f., although

174   this effect is generally considered negligible for the type of thermocouple used here

175   (Brooker and Kjarsgaard 2011).

176   To encourage growth of experimental apatites, runs were first heated to super-

177   liquidus temperatures (1450–1500 °C), then cooled at a constant rate to a terminal

178   temperature of 1250 °C, following Prowatke and Klemme (2006). Super-liquidus heating

179   reduces the availability of nuclei and/or secondary nucleation sites for crystallising

180   phases, fostering the growth of fewer, larger crystals. A slow cooling ramp results in

181   lower degrees of undercooling and thus further favours crystal growth over nucleation

182   (e.g. Swanson 1977). Typical cooling rates were 20 °C/hr or 50 °C/hr, depending on the

183   bulk water content. Even lower cooling rates (≤ 10 °C/hr) were applied to some runs with

184   lower bulk phosphate contents or nominally zero bulk OH contents (Table 2). Samples

185   were then allowed to equilibrate at the final run temperature, during which time a small

186 temperature cycle was applied (±10 °C at 1 °C per minute) to enhance crystal growth

187 (e.g. Mills and Glazner 2013). Total run times ranged from 20–24 hours and were chosen

188 to provide sufficient time for crystal-melt equilibration, as evidenced by experiments at

189 similar conditions (Prowatke and Klemme 2006), whilst minimising the time available

190 for diffusive exchange at high temperatures. At the end of each run, charges were

191 quenched isobarically by cutting the operating power while manually maintaining the

192 terminal run pressure.

193   Following quench, capsules were removed from the assembly and sectioned using

194 a micro-saw. In order to preserve the double capsule assembly, it was not possible to

195 pierce inner capsules to test for the presence of a free fluid phase, and instead we take the

196 absence of vesicles or gas pockets in most experiments as evidence of volatile

197 undersaturation (three 'BM' samples containing minor vesicles are indicated in Table 2).

198 Sectioned capsules were ground using abrasive SiC papers (220 to 1200 grit) and

199 progressively polished using diamond suspensions (6, 3, and 1 μm). Polished capsules

200 were then mounted either in In metal or a thin layer of EpoFix resin, with the aim of

201 minimising H backgrounds during subsequent ion microprobe analysis.

202

203   **ANALYTICAL METHODS**

204 **Electron probe microanalysis**

205 Apatite and glass major element compositions were determined by electron probe

206 microanalysis using a Cameca SX100 5-spectrometer instrument at the University of

207 Bristol. Glasses were analysed using a 15 kV, 2 nA electron beam defocused to a 15 μm

208 spot, with Na analysed first to minimise alkali migration (Morgan and London 1996;

209 Humphreys et al. 2006). Apatites were analysed using a 15 kV, 10 nA beam defocused to

210 10 μm to minimise migration of halogens yet still enable accurate determination of minor

211 elements (e.g. Goldoff et al. 2012; Stock et al. 2015; see supplementary methods for

212 details of analytical protocol). Calibration standards were albite for Na and Si; St. Johns

213 olivine for Mg; sanidine for Al and K; Durango apatite for P; wollastonite or Durango

214 apatite for Ca; ilmenite for Ti and Fe; Mn metal for Mn; MgF_2 for F; and NaCl for Cl.

215 Count times were 30 s on peak for all elements except Fe and Mn (60 s on peak) and Cl

216 and F (120 s on peak). Resulting detection limits for volatile elements in apatite were

217 typically ~120 ppm for Cl and ~500 ppm for F, whereas in glass the detection limits were

218 typically ~300 ppm for Cl and ~900 ppm for F (for full analytical conditions see

219 supplementary materials). Raw data were processed using a PAP matrix correction

220 scheme. Accuracy and precision of the analytical setup were monitored by repeated

221 analysis of well-characterised secondary standards (KN18, BCR2, and synthetic F-

222 bearing haplobasalt for glasses; oriented Durango and Wilberforce apatite crystals for

223 apatite).

224

225 **Secondary ion mass spectrometry**

226 Volatile compositions of apatite and coexisting glass were determined by secondary ion

227 mass spectrometry using a Cameca ims-4f instrument at the NERC ion microprobe

228 facility at the University of Edinburgh. The instrument is run utilizing Charles Evans and

229 Associates PXT interface and software.

230   For apatite, a 5 nA $^{16}O^-$ primary beam with a net impact energy of 14.5 keV was

231 accelerated onto the sample. An energy window of 75 ± 20 V was applied. The spot size

232   was ~15 – 20 μm. A circular field aperture with an effective radius of 8 μm was used to

233   lower H and C backgrounds coming from the edge of the sputtering pit. Backgrounds

234   were monitored using either end-member (H-free) apatites from Schettler et al. (2011) or

235   a piece of quartz embedded within each sample mount.

236   In addition, a 4-minute pre-sputter period at a raster size of 20 μm was employed

237   to minimise contamination from the sample surface. The secondary ions $^1H^+$, $^{12}C^+$,

238    $^{25}Mg^{2+}$, $^{19}F^+$, $^{23}Na^+$, $^{26}Mg^+$, $^{30}Si^+$, $^{31}P^+$, $^{35}Cl^+$, $^{39}K^+$, and $^{44}Ca^+$ were collected for 5s, 10s,

239   6s, 10s, 2s, 5s, 2s, 2s, 10s, 3s, and 2s, respectively, for each 6 cycles of the magnet. Only

240   H_2O, CO_2, F, P_2O_5, and Cl were quantified. Other elements were used to monitor for

241   contamination with the silicate glass. The OH and CO_3^{2-} contents of apatite were

242   determined using daily working curves of $^1H/^{44}Ca$ vs. OH and $^{12}C/^{44}Ca$ vs. C acquired for

243   a suite of natural apatite standards (supplementary information), after correction for

244   isobaric interference by $^{24}Mg^{2+}$ on ^{12}C (correction generally < 5%, except in the most C-

245   poor samples up to 15%). The same approach was taken for both F and Cl, with 95%

246   prediction intervals calculated for every calibration line (supplementary materials). For a

247   small subset of apatite crystals (< 15 μm in smallest dimension), the beam current was

248   reduced to 2 nA resulting in a spot size of <10 μm. This process reduced the number of

249   ions counted, but had no appreciable effect on the calibration curve slopes. Halogens

250   were also quantified for halogen-free experiments as a check for contamination. No effect

251   of apatite orientation (parallel vs. perpendicular to the c-axis) on working curves for H_2O,

252   CO_2, F, and Cl was detected, consistent with the findings of Stock et al. (2015).

253   For the glass, a similar analytical setup and procedures were used as for apatite,

254   apart from using a 50 ± 20 V energy window for C analysis (a 75 ± 20 V energy window

255   was used for analysis of H and other elements). To ensure accurate determination of C

256   contents in the Mg-rich glass, an initial set of analyses was collected at sufficient mass

257   resolution to separate the $^{12}C^+$ and $^{24}Mg^{2+}$ peaks, with secondary ions collected at $^{24}Mg^{2+}$,

258    $^{12}C^+$, $^{26}Mg^+$, and $^{30}Si^+$ for 5s, 10s, 3s, and 2s, respectively, for each of 10 cycles of the

259   magnet. In a second set of analyses on the same spot (with a 2-minute pre-sputter period

260   and 20 μm raster), the secondary ions $^1H^+$, $^{11}B^+$, $^{19}F^+$, $^{26}Mg^+$, $^{30}Si^+$, and $^{35}Cl^+$ were

261   collected for 3s, 3s, 6s, 2s, 2s, and 6s, respectively (over 10 magnet cycles). As with

262   apatite, H_2O and CO_2 contents of the glasses were determined using daily working curves

263   of $^1H/^{30}Si$ vs. H_2O and $^{12}C/^{30}Si*SiO_2$ vs. CO_2, respectively, generated from standard

264   glasses including basalts and phonolites. The calibration glasses included samples from

265   Shishkina et al. (2010), Hauri et al. (2002), Mangan and Sisson (2000), and Brooker et al.

266   (1999), (see supplementary information for details). A field aperture was used to reduce

267   backgrounds for H and C, which were monitored using either a volatile-free glass from

268   Shishkina et al. (2010) or a piece of quartz embedded within each sample mount.

269   Halogens were calculated using Lipari glass (Hunt and Hill 1993) as the primary

270   calibration standard for Cl, and NIST SRM610 glass as the primary calibration standard

271   for F. Halogens were also quantified for halogen-free experiments as a check for possible

272   contamination. Values were checked against internal secondary glass standards and

273   synthetic halogen-rich glasses synthesised using the starting material SH3. SIMS glass

274   halogen concentrations were also checked and compared against EPMA.

275

276   **Secondary electron microscopy (SEM)**

277   Back-scattered SEM images of polished, mounted samples were collected using a Hitachi

278   S-3500N scanning electron microscope at the University of Bristol, with a $15 - 20$ kV

279   accelerating voltage and 15 mm working distance. All samples were imaged prior to

280   SIMS analysis in order to identify the phases present, produce image maps for sample

281   navigation, and locate areas of apatite and glass suitable for ion microprobe work

282   (sufficiently large and free from cracks and inclusions). To avoid contaminating the

283   sample surface with C in advance of SIMS analysis, samples were not C coated prior to

284   imaging in low vacuum mode. Run products were imaged again following ion

285   microprobe work to confirm the location of sputter craters.

286

287   **Apatite stoichiometry**

288   We followed the calculation scheme of Ketcham (2015) for stoichiometric calculations,

289   with formula proportions calculated on a 25-oxygen basis. We placed Mg, Mn, Fe, and

290   Na on the Ca site, and Si onto the phosphate site. Any deficiency in P on the phosphate

291   site was filled with carbonate where possible; any remaining carbonate was placed onto

292   the channel volatile site together with F, Cl, and hydroxyl (Table 3). Stoichiometric totals

293   are generally good, with the Ca-site contents 9.967 ± 0.070, P-site contents $6.037 \pm$

294   0.030, and average X-site totals for the halogen-bearing experiments of 1.913 ± 0.087

295   (Table 3), although halogen-free experiments have lower totals (see below). There is also

296   a correlation between the measured OH and OH calculated by difference (see later

297   discussion).

298

299   **RESULTS**

Experimental run products

300   Experimental run products for both starting materials typically comprise microlite-free

302   glass + apatite, with a minority of samples also containing clinopyroxene ± fluid (see

303   Table 2; Fig. 1). The experiments were designed to be volatile-undersaturated, because of

304   the difficulty of constraining the composition of any fluid(s). The two experiments run at

305   0.5 GPa contain sparse vesicles, which may indicate that these samples had just reached

306   volatile saturation. Apatites are large and euhedral (typically up to 100 μm perpendicular

307   to c-axis and up to 1 mm parallel to the c-axis) and commonly contain melt inclusions

308   that are visible in sections cut perpendicular to the c-axis (Fig. 1). Experiments run at

309   lower pressures or higher cooling rates formed apatites with more skeletal or hopper

310   textures.

311   *Glasses*

312   Experimental glasses from the "BA" experiments are Al-rich haplobasalts with ~5 wt%

313   total alkalis, 9 – 10 wt% MgO, 14 – 16 wt% Al_2O_3, and 18 – 30 wt% CaO on an

314   anhydrous basis (Table 4). Silica contents are 44.4 – 49.6 wt% SiO_2, normalised to 100%

315   on an H- and C-free basis. The glasses have high volatile concentrations, as expected

316   given the experimental run pressure of 1 GPa and nominal bulk volatile compositions

317   (Table 2). Some CO_2 was found even in the nominally C-free runs, which we attribute to

318   infiltration of C through the Pt capsule walls during the course of the experiment

319   (Brooker et al. 1998) or possibly incomplete decarbonation of the starting material and/or

320   atmospheric contamination. H_2O contents are in the range 0.7 – 7.1 wt%, and CO_2

321   concentrations range from 300 ppm to 1.3 wt% (Table 4). Halogen concentrations in the

322   glass are 0.8 – 1.6 wt% F and ~0.8 wt% Cl (Table 4).

323   The "BM" experiments formed phonolitic glasses with 57.2 – 61.8 wt% SiO_2 and

324   12.6 – 16.3 wt% total alkalis (Table 4). For the halogen-bearing "BM" experiments,

325   halogens were added in the form of NaCl and NaF, so the melts for these experiments

326   have correspondingly higher Na_2O contents (Table 4). H_2O concentrations are in the

327   range 1.3 – 7.1 wt% and CO_2 concentrations are 1600 – 7100 ppm, consistent with

328   volatile concentrations in the BA experimental glasses. Fluorine contents are also similar

329   to those in the BA glasses (0.85 – 1.0 wt% F) but Cl concentrations are higher (1.25 wt%

330   Cl) for the same nominal bulk Cl added. Glasses are homogeneous throughout each

331   sample, with typical relative standard deviations of approximately 1.2% for CO_2, H_2O, F,

332   and Cl. This is smaller than the analytical uncertainty, and we therefore used the

333   analytical uncertainty to estimate and propagate errors in the partitioning data.

334   *Apatites*

335   Experimental apatites from the halogen-free BA experiments are hydroxy-apatites with

336   0.7 – 1.7 wt% H_2O and a wide range of C contents up to 1.80 wt% (C expressed as CO_2)

337   (Table 3). Apatites from the halogen-bearing experiments are hydroxyl-bearing fluor-

338   apatite, with $\geq$ 2 wt% F and compositions systematically shifted to lower OH and C

339   contents ($\leq$ 0.8 wt% H_2O and $\leq$ 0.22 wt% CO_2, Table 3). Apatites from these halogen-

340   bearing experiments have volatile contents of F > Cl >> OH > C, even when these

341   components were added in the same concentrations to the starting mixture (e.g. BA12,

342   which had 1 wt% each of F, Cl, and OH in the starting material, Tables 2 and 3). In the

343   halogen-free experiments, the apatite H_2O and CO_2 contents increase with increasing

344   dissolved H_2O and CO_2 in the coexisting glass, respectively, and the CO_2 content

345   increases with increasing $CO_2/(H_2O+CO_2)$ in the glass (Fig. 2). The same pattern is

346 observed in the halogen-bearing experiments, but with lower overall OH and C contents

347 as described above. Similarly, experimental apatites from the BM experiments show high

348 H_2O and CO_2 contents in the halogen-free runs, (0.7–1.2 wt% H_2O and up to 1.2 wt%

349 CO_2) and significantly lower concentrations in the halogen-bearing experiments, which

350 routinely produced fluor-apatite with >2.5 wt% F (Table 3). Carbon contents increase

351 with increasing concentration of the minor elements (Mg, Na, and Si; Fig. 3).

352 The stoichiometry calculations suggest that, for the halogen-free experiments,

353 there is no space on the phosphate site for carbonate, such that all the carbonate and

354 hydroxyl are accommodated on the channel site (Table 3). In contrast, for some of the

355 halogen-bearing experiments, there is sufficient space on the phosphate site to assign

356 some of the carbonate, with the channel site occupied by the remaining carbonate,

357 halogens, and hydroxyl.

358 Minor element concentrations in the apatites are clearly related to the host melt

359 composition. Apatites from the BM experiments typically contain higher alkalis and

360 lower Mg compared with those from the BA experiments (Table 3).

361

362 **Partitioning data**

363 We used the experimental apatite and glass compositions to calculate the apparent Nernst

364 partition coefficients, $D_i = \frac{c_i^{ap}}{c_i^{m}}$, where C is the concentration of element i in wt%. This

365 representation allows the distribution of volatile species between apatite and melt to be

366 directly compared with other literature data (in the case of H, F, and Cl), and to give the

367 first experimentally-determined partitioning data for C between apatite and silicate melts.

368 Note that to maintain consistency with previous studies (e.g. McCubbin et al. 2015), we

369   have calculated the partition coefficients between volatile abundances in apatite and melt

370   as the same species, i.e. OH in apatite is calculated as the equivalent H_2O content,

371   whereas CO_3^{2-} in apatite is calculated as the equivalent CO_2 content, on a concentration

372   (wt%) basis. Our calculated Ds show, as expected, that F is highly compatible in apatite,

373   with D_F between 1.3 and 3.6 (average = 2.2). Chlorine is moderately compatible (D_{Cl} =

374   0.7 to 2.2), and OH is generally incompatible (D_{OH} = 0.06 to 0.97; average = 0.27) (Table

375   5), although its compatibility varies with a bulk mixed volatile content. $D_{CO_3^{2-}}$ is

376   variable, with values ranging from 0.05 to 2.1. Notably, CO_3^{2-} was actually compatible in

377   apatite in several of the halogen-free experiments. Both $D_{CO_3^{2-}}$ and D_{OH} are significantly

378   higher in the halogen-free runs.

379   Although Nernst partition coefficients (D) have been widely reported in studies of

380   volatile partitioning in apatite, the more appropriate measure of partitioning for major

381   chemical components competing for the same crystallographic site, such as F, Cl, and OH

382   in apatite, is the exchange coefficient, K_D (e.g. Roeder and Emslie 1970), defined as the

383   ratio of partition coefficients of two species, e.g.:

384        $K_D^{OH-Cl} = (OH_{ap}/OH_m)/(Cl_{ap}/Cl_m) = (OH_{ap}/Cl_{ap})/(OH_m/Cl_m)$ (1)

385   According to the strict definition of these distribution coefficients, the volatile

386   components should be calculated using activity (or mole fraction if assuming ideal

387   behaviour). However, it is not obvious that this approach brings greater clarity to the

388   results of these experiments. In particular, the high pressures and range of melt

389   compositions used means that there is some considerable uncertainty concerning the

390   validity of models describing the distribution of dissolved water and C species in the melt

391   (e.g. Brooker et al. 1999; Sowerby and Keppler 1999; Morizet et al. 2002; Hui et al.

392   2008), even if the apatite behaviour is ideal at high pressure and temperature (see Li and

393   Hermann 2017 for a discussion). For completeness, we give apatite-melt K_D^{OH-Cl}, K_D^{OH-F},

394   and K_D^{Cl-F} in mole fraction form (supplementary information) using the same water

395   speciation model as Li and Hermann (2017) for consistency with their approach, though

396   this may not be the most appropriate for the range of melt compositions included. These

397   K_D's are calculated by normalising the volatile site contents such that $X_{OH} + X_F + X_{Cl} =$

398   1, excluding carbonate (supplementary information). For OH-carbonate exchange,

399   however, we present only K_D's calculated on a concentration basis in order to avoid

400   introducing errors as a result of the poorly understood variation in C speciation in silicate

401   melts (e.g., Morizet et al. 2002).

402   From our experiments, the resulting distribution coefficients (calculated following

403   McCubbin et al. 2015 as the ratio of partition coefficients) are $K_D^{H2O-F} = 0.023–0.08$,

404     $K_D^{H2O-Cl} = 0.08–0.11$, and $K_D^{Cl-F} = 0.27–0.98$ (Table 5). Apatite-melt distribution

405   coefficients for H_2O-CO_2 exchange are defined more rigorously in Figure 4 through

406     $logK_D^{H2O-CO2} = logD_{H2O} − logD_{CO2}$, where $logK_D$ is the intercept. This gives $K_D^{H2O-CO2} =$

407     $0.355 ± 0.05$ for the 'BM' experiments and $0.629 ± 0.08$ for the 'BA' experiments

408   (uncertainties represent a 95% prediction interval). This suggests a dependence on the

409   melt major element composition, with systematically higher K_D's (as calculated for

410   individual experiments) in the BM system (Fig. 4). The gradient in Figure 4 is

411   approximately 0.65 for both the BM and BA experiments, whereas for an ideal system it

412   should be equal to 1.0. This suggests that C-H partitioning may be non-ideal for high-

413   temperature igneous apatites, which would be consistent with the development of

414   significant vacancy concentrations in the more carbonate-rich apatites (see below).

415

416   DISCUSSION

417   **CO_3^{2-} in apatite**

418   Our primary focus was to define the carbonate partitioning behaviour between hydroxyl-

419   bearing apatite and hydrous silicate melt. The apatites themselves contain quite high

420   carbonate concentrations, typically several hundred to a few thousand ppm, even in the

421   halogen-bearing experiments. This is in contrast with natural silicate melts, which

422   commonly record magmatic volatile concentrations only after significant degassing of

423   CO_2, either into a fluid phase or during post-entrapment modification and formation of a

424   shrinkage bubble, resulting in lower CO_2 contents of typically a few hundred ppm

425   (Wallace 2005; Blundy et al. 2010; Hudgins et al. 2015; Tuohy et al. 2016; Maclennan

426   2017). The K_D's for OH-carbonate exchange ($K_D^{H2O-CO2}$) appear to be dependent on the

427   melt major element composition, with higher values in the BM experiments than in the

428   BA experiments (see Fig. 4; Table 5). In contrast, the apparent carbonate-halogen

429   exchange coefficients are very low, with $K_D^{CO_2-Cl} < 0.17$ and $K_D^{CO_2-F} < 0.11$ (Table 5).

430   To the best of our knowledge, these are the first experimental constraints on carbonate

431   partitioning in igneous apatite, so we are unable to compare our data with those of other

432   studies. The advantage of SIMS analysis is that the total C concentration is technically

433   easy to measure *in situ* on unoriented grains, although it cannot provide structural

434   information related to site occupancy, which requires techniques such as FTIR, XRD or

435   NMR (e.g., Fleet, 2017).

436

437   **Incorporation of CO_3^{2-} in experimental igneous apatites**

438   Previous work has identified that carbonate can be accommodated in apatite *via* two key

439   substitution mechanisms. In 'Type A' apatite, carbonate is incorporated by exchange of a

440   hydroxyl ion for a carbonate anion within the c-axis channel site, plus an OH^- vacancy for

441   charge compensation (e.g. LeGeros et al. 1969; Bonel 1972; Young et al. 1981):

442         $$CO_3^{2-} + \square = 2(OH^-,F^-,Cl^-) \qquad\qquad (2)$$

443   In 'Type B' carbonate, the CO_3^{2-} ion is substituted for PO_4^{3-}, as demonstrated by

444   substantially lower P concentrations in carbonated apatite. This substitution may be

445   charge-balanced according to the mechanism

446         $$PO_4^{3-} = CO_3^{2-} + F^- \qquad\qquad (3)$$

447   (e.g. Binder and Troll 1989), although NMR work shows that the charge-balancing F^- is

448   not directly interacting with carbonate as a tetrahedal complex (Mason et al. 2009).

449   Various other substitution mechanisms are also possible (e.g. Pan and Fleet 2002):

450         $$Ca^{2+} + 2PO_4^{3-} = \square^{Ca} + 2CO_3^{2-} \qquad\qquad (4)$$

451         $$Ca^{2+} + PO_4^{3-} = Na^+ + CO_3^{2-} \qquad\qquad (5)$$

452         $$Ca^{2+} + F^- = REE^{3+} + CO_3^{2-} \qquad\qquad (6)$$

453

454   Apatite data from our halogen-free experiments indicate that the Type A substitution

455   mechanism is the dominant one for the carbonate anion. Both the carbonate and OH

456   contents of apatite vary systematically with increasing $CO_2/(H_2O+CO_2)$ in the host melt

457   (see Fig. 2). This indicates that the apatite carbonate concentrations are directly linked to

458   the volatile composition of the melt. Since OH is well known to occupy the channel site,

459   this indicates that carbonate is also incorporated into the channel site. The stoichiometry

460   calculations also indicate that there is insufficient space on the phosphate site to

20

461 accommodate any significant Type B carbonate, and therefore the carbonate should sit on

462 the X-site (Type A; see Table 3). This has been confirmed using FTIR (see

463 supplementary Figure 1) where the positions of the carbonate $\nu 3$ vibrational peaks are

464 consistent with dominantly A site occupation (e.g. Fleet et al. 2004; Fleet 2017).

465 However, while OH calculated by charge balance in the channel site is equivalent to

466 measured OH in the most OH-rich samples, for samples with higher carbonate contents

467 the measured OH is significantly lower than OH calculated by charge balance (Fig. 5).

468 This suggests that the incorporation of carbonate into igneous apatite at high temperatures

469 may involve the creation of vacancies, significantly greater than the number of OH$^-$

470 vacancies predicted to charge balance CO_3^{2-} via equation (2). The presence of structural

471 H_2O in the channel site (e.g. Mason et al. 2009; Yoder et al. 2012) seems unlikely given

472 the high run temperatures of the experiments.

473 In fact, the under-occupancy of the X-site suggests the formation of a significant

474 "oxyapatite" component, with O^{2-} (and a vacancy) substituting for 2OH$^-$ within the

475 channel site (Trombe and Montel 1978; Young et al. 1981; Schettler et al., 2011). First

476 principles calculations support the idea that significant defects on the channel site can be

477 formed at high temperatures (> 1000K), including the formation of oxyapatite coupled to

478 OH$^-$ vacancies, resulting in significant non-stoichiometry at high temperatures

479 (Matsunaga and Kuwabara 2007; Kubota et al. 2014). This deviation from stoichiometric

480 mineral formulae is consistent with our interpretation that C-H exchange is non-ideal.

481 Our observations are also consistent with experiments that resulted in the

482 formation of Type A carbonate apatite by the reaction of hydroxyapatite with dry CO_2

483 (Bonel 1972); and with first principles calculations that indicate a greater stability of the

484   Type A substitution at high temperatures (Kubota et al. 2014). The lack of negative

485   correlation between CO_3^{2-} and Ca or P also argues against a significant B-type

486   substitution (de Maeyer et al. 1993). However, the highest total carbonate contents are

487   also associated with high minor element concentrations (e.g. Mg, Na), which suggests a

488   subsidiary Type B substitution similar to (5) or (6). Peroos et al. (2006) showed that

489   although the Type A substitution was energetically favourable, a Type B substitution,

490   charge balanced by Na^+, was also favourable when Type-A carbonate was already

491   present.

492   In contrast, the stoichiometry of apatites from our halogen-bearing experiments

493   suggests the additional formation of some B-type carbonate apatite. In some of these

494   apatites, the phosphate site has enough space to accommodate some carbonate, and the

495   channel site incorporates the remainder plus halogens and OH (Table 3). In contrast with

496   apatites from the halogen-free experiments, there is good agreement between OH

497   contents calculated by difference and measured OH for the halogen-bearing experiments

498   (Fig. 5). This suggests that these calculated site assignments are reasonable, and

499   consistent with calculations showing that at high temperatures the Type A carbonate

500   substitution should be more stable than Type B (e.g. Kubota et al. 2014). However, we

501   suggest that in the presence of abundant halogens, the formation of F-Cl-OH apatite is the

502   most energetically favourable, and that carbonate can be shifted onto the phosphate site.

503

504   **OH-Cl-F distribution between apatite and silicate melt**

505   The OH-F-Cl apatite-melt exchange coefficients calculated from our experimental data

506   are consistent with those of other studies, but with some significant differences. There are

22

only two other experimental Cl-OH-F apatite-melt partitioning studies with direct measurements of all channel site components. The extended abstract by Potts et al. (2015) reported experiments conducted at 1 GPa and 1350 – 1450 °C with a composition similar to the mesostasis of lunar basalts, while McCubbin et al. (2015) performed apatite-melt experiments at 1 – 1.2 GPa and 950 – 1000 °C using an Fe-rich basalt. Our calculated nominal D_F, D_{Cl}, and D_{OH} are within the range reported by these and other previous studies (Fig. 6; Table 7). This includes experiments without direct measurement of OH, for which we calculated nominal D_{OH} 'by difference' (see Table 7; Doherty et al. 2014, rhyodacite at 50 MPa, 850 – 950 °C; Webster et al. 2009, rhyodacite at 200 MPa, ~900 °C; Mathez and Webster 2005, basalt, 1050-1150 °C; Webster et al. 2017, rhyolite at 50 – 200 MPa and 700 – 1000 °C; and Li and Hermann 2015 and 2017, 'pelite' melts at 2.5 – 4.5 GPa and 600-900 °C). This was done assuming a stoichiometric channel site containing no carbonate (see earlier discussion) and calculating $H_2O_{(m)}$ by difference where necessary. These 'by difference' calculations are subject to a significant uncertainty (e.g. Devine et al. 1995; Humphreys et al. 2006), and the direct analysis of all volatile components in both melt and apatite is strongly encouraged for future work. The dataset also includes a mixture of volatile-saturated and volatile-undersaturated experiments (see Table 7), and at least some of the volatile-saturated experiments are rich enough in Cl that fluid immiscibility is likely (e.g., Webster et al. 2017). These results, perhaps not surprisingly, are strongly scattered and cover a wide compositional range (Figs. 6-8). The variation in starting materials and experimental conditions suggests that some of this variability may be due to the effects of changing melt composition or pressure and temperature. This is supported by a systematic decrease in both D_F and, to a

530   lesser extent, D_{Cl}, with increasing temperature and increasing melt CaO content in the

531   compiled literature dataset. Increasing experimental pressure causes only a minimal

532   decrease in $D_{F,Cl}^{ap-m}$.

533   As with Figure 4, the distribution coefficients for OH-halogen exchange are

534   equivalent to the intercept in Figure 6. Thus, our calculated K_D^{OH-F} are slightly lower than

535   those of Potts et al. (2015) but higher than those of (McCubbin et al. 2015). Each study

536   was conducted at the same pressure (1 GPa), so we interpret these differences in K_D as

537   predominantly a result of differences in temperature (in the range 950 °C to 1450 °C).

538   This is borne out by the results of a multiple regression analysis of the full literature

539   dataset, including our new experiments (Fig. 8), to an equation of the form

540          $\log K_D = a + b/T + c(P-1)/T$ (7)

541   following the approach of Piccoli and Candela (1994). This shows a clear log-linear

542   increase in $K_D^{OH-halogen}$ with increasing temperature, which indicates a preference for the

543   OH end-member at higher temperatures for a given melt composition. Despite the

544   inclusion of both volatile-saturated and volatile-undersaturated experiments from rhyolite

545   to basalt, the relative consistency of the published $K_{D}S$, as a function of temperature, is

546   striking, and confirms that temperature is the dominant overall control on apatite-melt

547   volatile partitioning. The CaO content in the melt was not a significant variable,

548   presumably due to covariation with temperature. The pressure term was of subsidiary

549   significance and we obtained better confidence on the parameter values by excluding the

550   third term in equation (2) (Table 6). For OH-Cl exchange, the results gave $a = 1.0729 \pm$

551   0.2353 and $b = -2938.4 \pm 282.3$ whereas for OH-F exchange, $a = 1.2590 \pm 0.2942$ and b

552    $= -3853.6 \pm 367.8$ (Fig. 8, Table 6).

553   We compared these results with earlier thermodynamic expressions derived by

554   Piccoli and Candela (1994) for the system apatite-fluid. Their $K_D^{ap\text{-}fl}$ were calculated

555   using the thermodynamic data of Zhu and Sverjensky (1991) to give the fugacity ratio for

556   the coexisting aqueous fluid, with aqueous species data derived from Robie et al. (1978)

557   and Stull and Prophet (1971). High-temperature values for $K_D^{OH\text{-}Cl}$ are up to an order of

558   magnitude lower for the apatite-fluid than for the apatite-melt K_D exchange data, but

559   there is better agreement between the two systems at low temperatures (Fig. 8). There is

560   also agreement on the direction of change of K_D with temperature (cf. Li and Hermann

561   2015). In contrast, the values for $K_D^{OH\text{-}F}$ are 2-3 orders of magnitude lower for apatite-

562   fluid (Piccoli and Candela, 1994) than for apatite-melt (see literature data compilation in

563   Fig. 8). The cause of this mismatch for $K_D^{OH\text{-}F}$ is unclear, particularly given that there is

564   relatively good agreement for $K_D^{OH\text{-}Cl}$ at low temperatures (where one or more fluid

565   phases are most likely to be present). Calculating K_Ds using OH and halogen mole

566   fractions instead of H_2O_t results in higher values in Figure 8. The experiments do not

567   contain any other phases that could incorporate significant F. Our calculations (together

568   with those of the other studies in the literature) were done using melt F concentrations

569   instead of activities, and fluoride activity varies with both melt composition (e.g. Scaillet

570   and Macdonald 2004) and temperature (e.g. Webster 1990). Piccoli and Candela (1994)

571   attempted to apply their method to the Bishop Tuff and found similar problems, with

572   good agreement between predicted (from apatite) and measured (from melt inclusions) Cl

573   concentrations, but a much wider discrepancy for F, which they interpreted as a problem

574   with the assumption that F is present only as HF in the fluid. We therefore suggest that

25

575   improved fluoride activity and speciation models for silicate melts and fluids may help to

576   resolve this problem.

577

578   **Implications**

579   Recent experimental students of apatite–melt partitioning have greatly enhanced the

580   potential of apatite as a tool for interpreting magmatic volatile contents, in both terrestrial

581   and planetary settings (Piccoli and Candela, 1994; Boyce and Hervig, 2008; McCubbin et

582   al. 2015). The results presented here extend this work to the important magmatic volatile

583   C, which records key information regarding deep magma storage and early degassing

584   processes. Our new partitioning experiments on haplobasaltic andesite and trachyte melts

585   provide the first constraints on partitioning mechanisms and exchange coefficients for C

586   in high-temperature igneous apatite. Stoichiometry calculations and preliminary FTIR-

587   ATR analysis indicates that carbonate is accommodated primarily in the c-axis channel in

588   our experiments. OH calculated by difference agrees relatively well with measured OH

589   for the halogen-bearing experiments but is systematically low for the halogen-free

590   experiments. This suggests the presence of a significant oxyapatite component at high

591   temperatures, and emphasises that calculations of OH by difference should be treated

592   with care. Analysis of C in apatite represents a potential new route to better

593   understanding the original CO_2 contents of melts, particularly in arc systems, where melt

594   inclusion CO_2 concentrations likely represent a significant underestimate of CO_2 in the

595   un-degassed melt. The ease of SIMS analysis, as demonstrated here, should facilitate this

596   goal, particularly for small natural crystals and inclusions within phenocrysts. We

597   encourage future work comparing CO_2 in arc melt inclusions with CO_2 inferred from

598 coexisting apatite inclusions, and suggest that this may help to improve our understanding

599 of volatile fluxes at subduction zones.

600   Regression of our new partitioning data, alongside previously published

601 experimental data in the system apatite–silicate melt, shows that while measurements of

602 Cl–OH exchange are in good agreement with existing estimates for the system apatite–

603 fluid (Piccoli and Candela, 1994), there is a large discrepancy for F–OH exchange, which

604 may be due a to relatively poor understanding of the fluoride activity and speciation in

605 silicate melts and fluids. This highlights the need for further experimental work focused

606 on clarifying the mobility and compatibility of halogens between solids, melt, and fluids

607 close to the magmatic-hydrothermal transition. Nonetheless, the current study marks a

608 significant advance in the understanding of volatile partitioning in high-temperature

609 igneous apatites and opens up the potential for quantitative analysis and modelling of

610 magmatic volatile systematics in both terrestrial and extra-terrestrial environments.

611 Apatite can accommodate the full range of volatile elements and, in our view, future

612 work should focus on the quantitative modelling of variations in apatite composition

613 during common igneous processes such as cooling, ascent, and degassing of fluid(s), with

614 the aim of fully developing apatite as a tool for investigating magmatic storage and

615 degassing processes.

837

838

839   Figure 1. Experimental run products from BA experiments showing glass-rich materials

840   and large, equant apatite crystals. Left: BA1 (H-C). Right: BA15 (HCFCl), the most

841   strongly crystallised experiment containing glass + clinopyroxene + apatite.

842

843   Figure 2. Apatite CO_3^{2-} content, expressed as apfu (ions per formula unit) as a function of

844   the CO_2:H_2O ratio of the host melt.

845

846   Figure 3. Apatite carbonate concentrations increase systematically with Mg, Si, and Na

847   contents in apatite. Minor element concentrations, overall, reflect the composition of the

848   host melt. (a) 'BA' haplobasaltic andesite experiments. (b) 'BM' Breccia Museo

849   (trachyte) experiments.

850

851   Figure 4. Partitioning data for H-C exchange between apatite and melt, calculated on the

852   basis of wt% CO_2 and H_2O in both phases. Circles: 'BM' (trachyte) series; squares: 'BA'

853   (haplobasaltic andesite) series. Open symbols are halogen-free experiments. Closed

854   symbols are halogen-bearing experiments. Solid line - best fit; short-dashed line - 95%

855   confidence limits on the fit. Uncertainties on individual data points represent accuracy

856   based on 95% prediction intervals from SIMS working curves (and are much larger than

857   the precision, which is very good).

858

859   Figure 5. Comparison of measured OH contents (pfu) with OH 'by difference' from the

860   sum of the volatile site. Apatite from halogen-bearing experiments (filled symbols) and

861   from halogen-free experiments, but with low carbonate contents, show reasonably good

862   correspondence, whereas the carbonate-rich apatites show a significantly lower measured

863   OH content, indicating the presence of vacancies.

864

865   Figure 6. Nominal partition coefficients for OH, Cl, and F, from this study and from the

866   literature, wt% basis. Grey dashes, Webster et al. (2017); grey crosses, Webster et al.

867   (2009); grey triangles, Doherty et al. (2014); open circles, Mathez and Webster et al.

868   (2005); filled circles, McCubbin et al. (2015); pluses, Potts et al. (2015). Black diamonds

869   - 'BA' experiments; black squares - 'BM' experiments.

870

871   Figure 7. Experimentally derived distribution coefficients for OH-halogen exchange

872   between apatite and silicate melt (calculated on a wt% basis), in comparison with K_{DS}

873   from the literature. Symbols are the same as for Figure 6.

874

875   Figure 8. Regression analyses of experimentally determined halogen-OH distribution

876   coefficients for apatite-melt (wt% basis), with dependence on both P and T ($\log K_D = a +$

877    $b/T + c(P-1)/T$) or temperature only ($\log K_D = a + b/T$). Regression coefficients for T-only

878   analysis are given. Data symbols are the same as for Figure 6. Dark grey lines, predicted

879   variations at 1 GPa (solid) and 50 MPa (dashed). Light grey lines, predicted variations for

880   the system apatite-fluid from Piccoli and Candela (1994) at 1 GPa (dashed) and 50 MPa

881   (dotted). Black dotted line shows the T-only regression. Grey fields show the

882   experimental range of Li and Hermann (2017; 2.5 GPa). Dashed light grey outlines show

883   the experimental range of Li and Hermann (2015; 2.5-4.5 GPa).

884

885 Supplementary Figure 1. Infrared spectra of the carbonate region in apatite from sample

886 BA7. Melt and apatite spectra were acquired from grains mounted in In metal, using an

887 ATR attachment on a Nicolet i10 infrared microscope with the signal coming from a

888 ~8μm area. The CHAP (carbonate-bearing hydroxyapatites) spectra are from Fleet (2017)

889 who used powered samples in a KBr pellet. The AB CHAP is reported to have 66%

890 carbonate on the A site, the rest on the B site. A CHAP is pure A site carbonate. It is clear

891 that sample BA7 is dominated by A-site carbonate with only a very minor contribution

892 from B-site carbonate.

893
Figure 1
Experimental run products from BA experiments, showing
glass-rich materials and large, equant apatite crystals. Left:
BA1 (H-C). Right: BA15 (HCFCl), the most strongly crystal-
lised experiment containing glass + clinopyroxene + apatite.
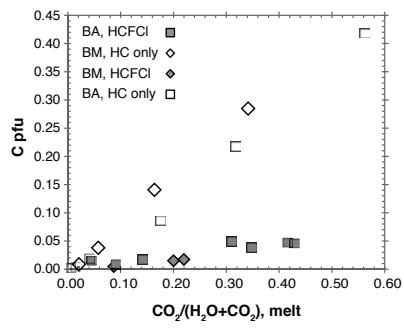

Figure 2.
Variation of apatite CO_3^{2-} content (ions per formula unit) as a function of the CO_2:H_2O ratio of the host melt.
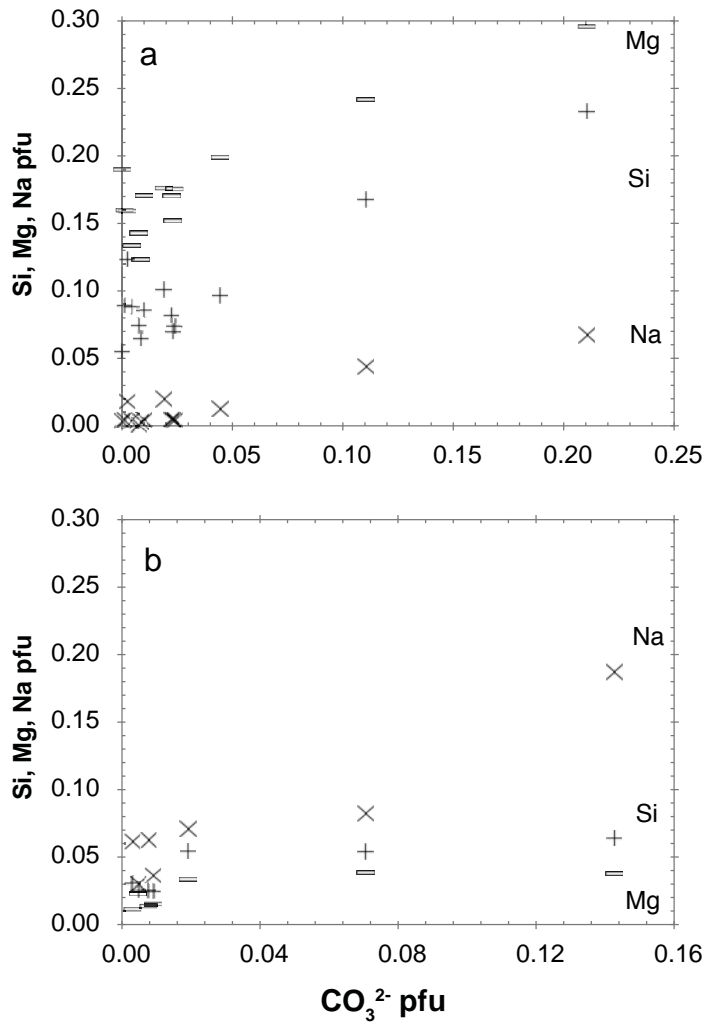

Figure 3.
Apatite carbonate concentrations increase systematically with Mg, Si and Na contents in apatite. Minor element concentrations overall reflect the composition of the host melt. (a) 'BA' haplo-basaltic andesite experiments. (b) 'BM' Breccia Museo (trachyte) experiments.
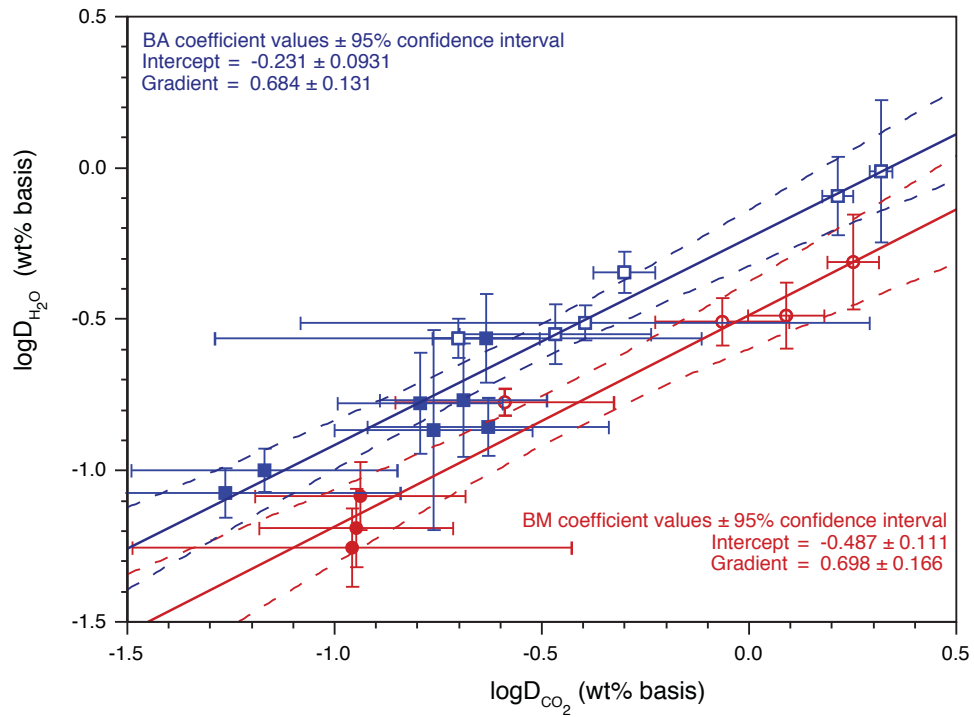

Figure 4.

Partitioning data for H-C exchange between apatite and melt, calculated on basis of wt% CO_2 and H_2O in both phases. Circles: 'BM' (trachyte) series; squares: 'BA' (haplo-basaltic andesite) series. Open symbols are halogen-free experiments; closed symbols are halogen-bearing experiments. Solid line - best fit; short-dashed line - 95% confidence limits on the fit.
Figure 5

Comparison of measured OH contents (pfu) with OH 'by difference' from the sum of the volatile site. Apatite from halogen-bearing experiments (filled symbols) and from halogen-free experiments but with low carbonate contents show reasonably good correspondence, whereas carbonate-rich apatites show a significantly lower measured OH, indicating the presence of vacancies.
Figure 6.
Nominal partition coefficients for OH, Cl and F, from this study and from the literature, wt% basis. Grey dashes, Webster et al. (2017); grey crosses, Webster et al. (2009); grey triangles, Doherty et al. (2014); open circles, Mathez & Webster et al. (2005); filled circles, McCubbin et al. (2015); pluses, Potts et al. (2015). Black diamonds - 'BA' experiments; black squares - 'BM' experiments.
Figure 7.
Experimentally derived distribution coefficients for OH-halogen exchange between apatite and silicate melt (calculated on wt% basis), in comparison with K_Ds from the literature. Symbols as for figure 6.
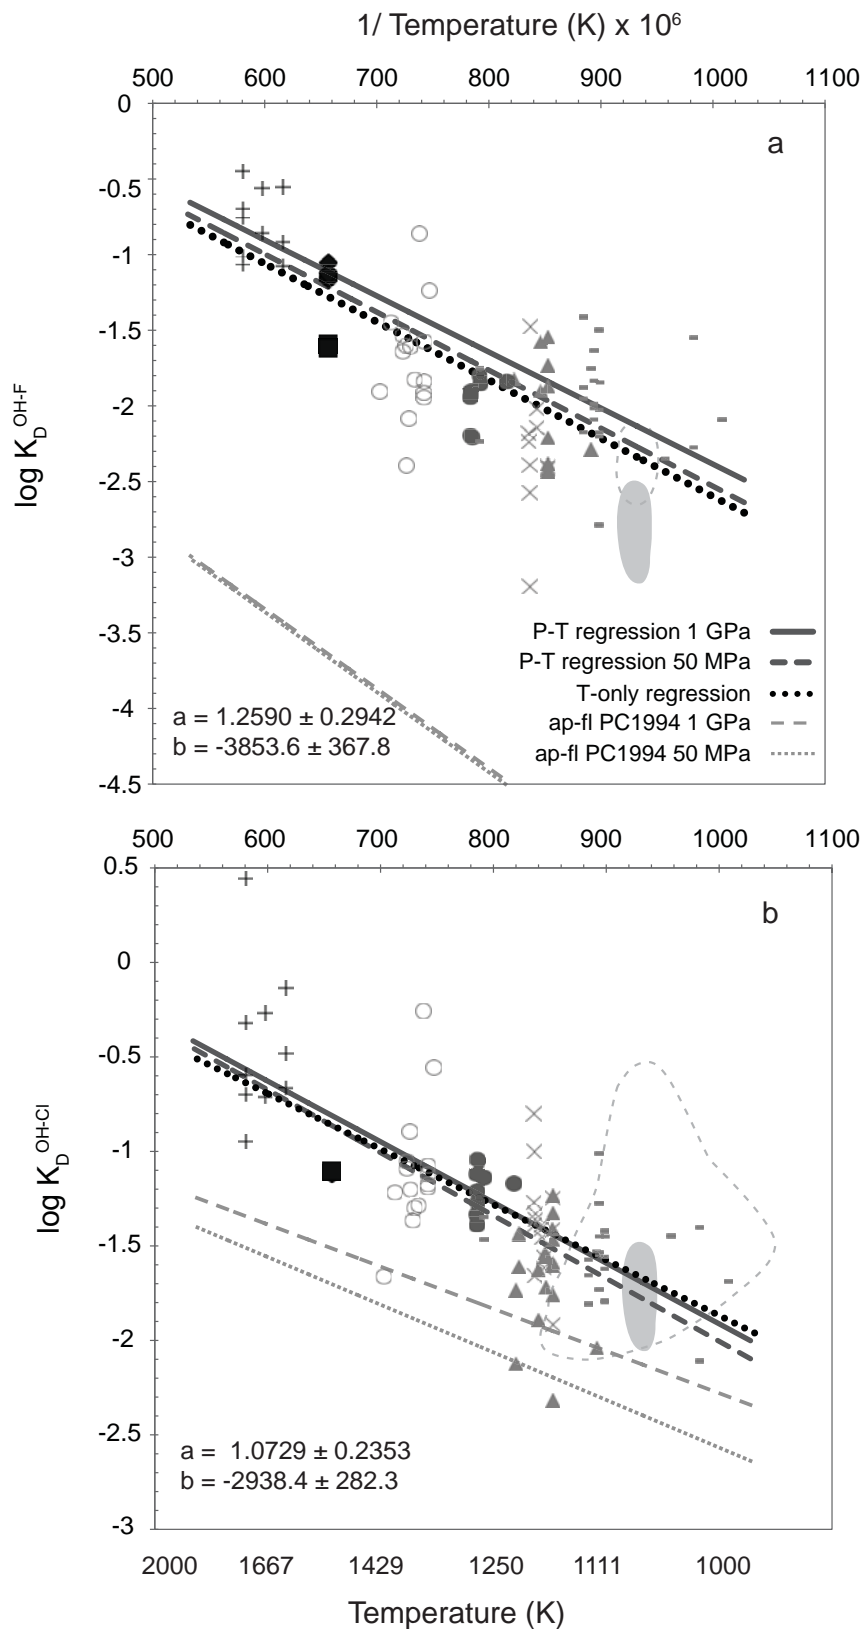

Figure 8. Regression analyses of experimentally determined halogen-OH distribution coefficients for apatite-melt (wt% basis), with dependence on both P and T ($logK_D = a + b/T + c(P-1)/T$) or temperature only ($logK_D = a + b/T$). Regression coefficients for T-only analysis are given. Data symbols as for figure 6. Dark grey lines, predicted variations at 1 GPa (solid) and 50 MPa (dashed). Light grey lines, predicted variations for the system apatite-fluid from Piccoli & Candela (1994) at 1 GPa (dashed) and 50 MPa (dotted). Black dotted line shows the T-only regression. Grey fields show the experimental range of Li & Hermann (2017; 2.5 GPa). Dashed light grey outlines show the experimental range of Li & Hermann (2015; 2.5-4.5 GPa).

Notes: 1 sigma uncertainties relate to the variability of multiple analyses within a given sample. Mole fraction apatite volatile compositions are calculated from stoichiometry a
Uncertainties on the partition coefficients are calculated by standard error propagation methods. Melt mole fraction calculations were done using the method of Li & Hermann
Molecular weight of 36.1g was used for both halogen-bearing compositions. Water speciation is calculated using Hui et al. (2008).

[a] Analytical session refers to the calibration data provided in the supplementary information. 95% prediction intervals provided are also derived from this.

b	-3853.6	368	-2938	282

Table 7 - summary of experimental conditions for studies included in multiple regression analysis.

Reference	Bulk composition	Melt CaO (wt%)	T (°C)	P (MPa)	Apatite measured	Melt measured	Fluid measured	Volatile state
This study	Haplo-basaltic andesite	15 7 - 19.0	1250	1000	OH, F, Cl, C (SIMS); F, Cl (EPMA)	H_2O, F, Cl, C (SIMS); F, Cl (EPMA)	n/a	Volatile-undersaturated
This study	Trachyte	2.4 - 3.3	1250	1000	OH, F, Cl, C (SIMS); F, Cl (EPMA)	H_2O, F, Cl, C (SIMS); F, Cl (EPMA)	n/a	Volatile-undersaturated
Doherty et al. (2014)	Rhyodacite	0.4 - 3.1	849 - 947	50 - 52	F, Cl (EPMA)	H_2O (FTIR); F, Cl (EPMA)	Cl (mass balance)	Mostly volatile-saturated
Li & Hermann (2015)	Pelite	2.3 - 2.5	630 - 900	2500-4500	F, Cl (EPMA)	F, Cl (EPMA); H_2O (mass balance)	n/a	Volatile-undersaturated
Li & Hermann (2017)	Pelite	2.4	800	2500	F, Cl (EPMA)	F, Cl (EPMA); H_2O (mass balance)	n/a	Volatile-undersaturated
Mathez & Webster (2005)	Basalt	5.3 - 16.9	1066 - 1150	200	F, Cl (EPMA)	F, Cl (EPMA)	Cl (chloridometer)	Mostly volatile-saturated
McCubbin et al. (2014)	Fe-rich basalt	3.8 - 9.0	950 - 1000	1000 - 1200	OH, F, Cl (SIMS)	H_2O, F, Cl (SIMS)	n/a	Volatile-undersaturated
Potts et al. (2015)	Lunar basalt mesostasis	8.0 - 9.0	1350 - 1450	1000	OH, F, Cl (SIMS)	H_2O, F, Cl (SIMS)	n/a	Volatile-undersaturated
Webster et al. (2009)	Rhyodacite to rhyolite	0.5 - 2.4	900 - 923	198 - 205	F, Cl (EPMA)	F, Cl (EPMA)	Cl (chloridometer)	Volatile-saturated
Webster et al. (2017) [a]	High-Si rhyolite	0.1 - 2.1	722 - 1000	49 - 202	F, Cl (EPMA)	H_2O (FTIR); F, Cl (EPMA)	Cl (chloridometer)	Volatile-saturated

[a] These runs typically contained <25 ppm CO_2 as contaminant (not studied)
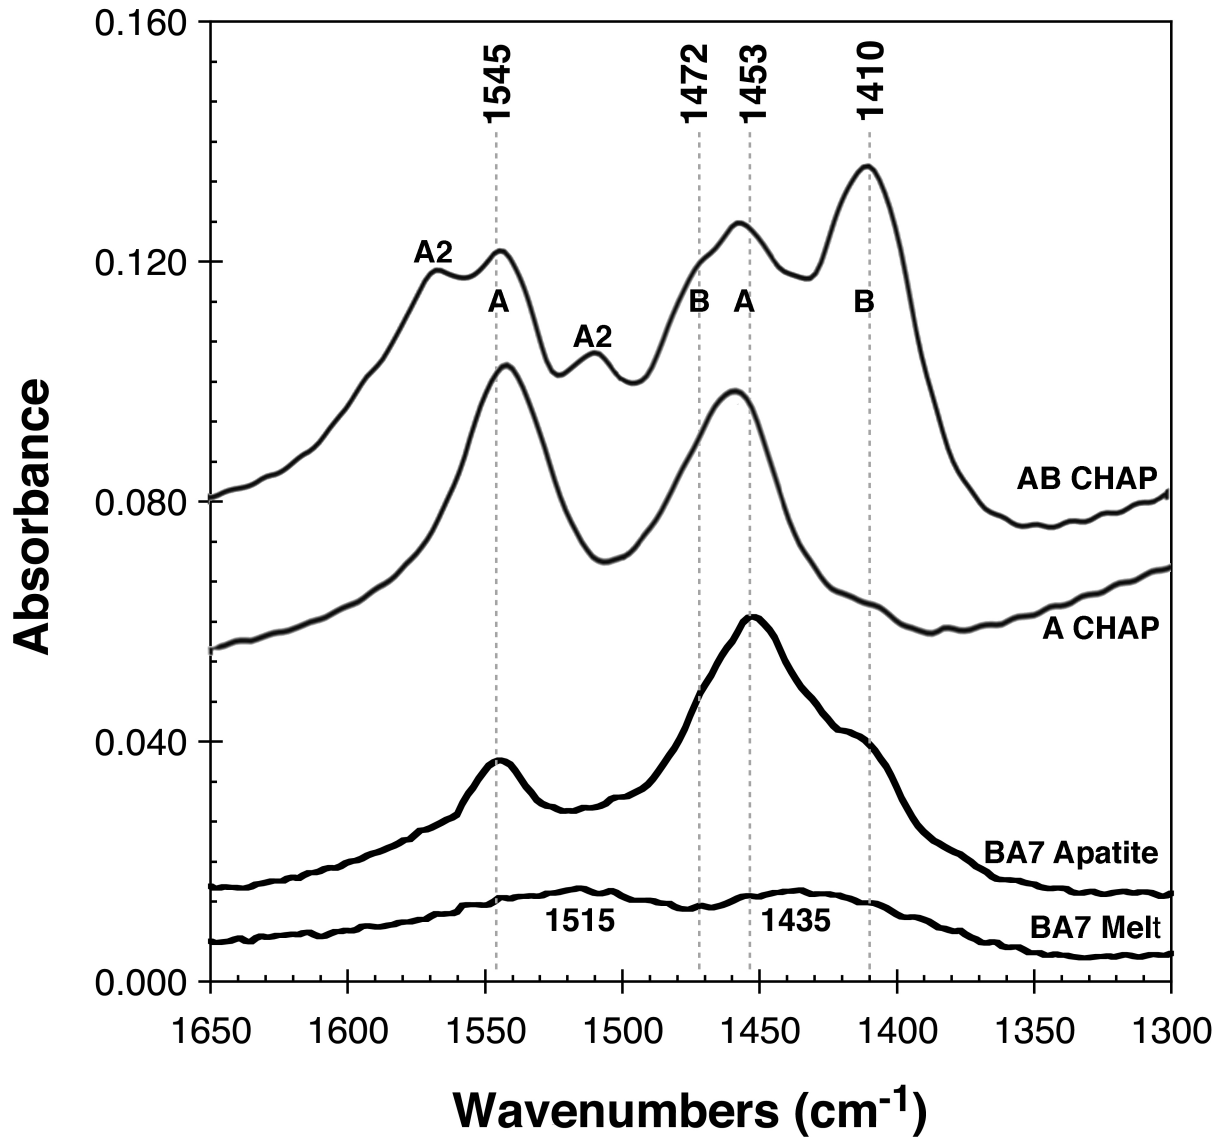

Supplementary materials – Riker et al.

EPMA analytical conditions - apatite
Our standard analytical setup for electron probe microanalysis of apatite using the 5-spectrometer Cameca SX-100 electron microprobe at University of Bristol was (peak counting times given for each element; background counting times half as long):

Spectrometer 1 [LPET]:   Cl (120 s)
Spectrometer 2 [PC1]:   F (120 s)
Spectrometer 3 [LPET]:   Ca (30 s)   P (30 s)   K (30 s)   Ti (30 s)
Spectrometer 4 [TAP]:   Na (60 s)   Si (30 s)   Al (30 s)   Mg (60 s)
Spectrometer 5 [LLIF]:   Fe (60 s)   Mn (60 s)

A 15 kV, 10 nA, 10 μm electron beam was used as a pragmatic compromise between the need for accurate analyses and the need to mitigate sample damage (e.g. Stormer et al. 1983; Goldoff et al. 2012; Stock et al. 2015). Na was calibrated on albite; Si and Mg on St John's Island olivine; Cl on NaCl; F on MgF_2; P and Ca on Durango apatite; K and Al on sanidine; Mn on Mn metal and Ti and Fe on ilmenite. Oriented secondary standards of Durango (Young et al. 1969) and Wilberforce apatite were analysed before, during and after every run.

EPMA analytical conditions - glass
Our standard analytical setup for electron probe microanalysis of hydrous glass using the 5-spectrometer Cameca SX-100 electron microprobe at University of Bristol was (peak counting times given for each element; background counting times half as long):

Spectrometer 1 [LPET]:   Cl (120 s)
Spectrometer 2 [PC1, or PC0 for Fe-bearing glasses]:   F (120 s)
Spectrometer 3 [LPET]:   Ca (30 s)   P (30 s)   K (30 s)   Ti (30 s)
Spectrometer 4 [TAP]:   Na (60 s)   Si (30 s)   Al (30 s)   Mg (30 s)
Spectrometer 5 [LLIF]:   Fe (60 s)   Mn (60 s)

We used a 15 kV, 2 nA, 15 μm electron beam to mitigate sample damage (e.g. Devine et al. 1995; Humphreys et al. 2006). Na and Si were calibrated on albite; Mg on St John's Island olivine; Cl on NaCl; F on MgF_2; P on Durango apatite; Ca on wollastonite; K and Al on sanidine; Mn on Mn metal and Ti and Fe on ilmenite. Secondary standards KN18 (Nielsen & Sigurdsson 1981) and BCR were analysed before, during and after every analytical run, together with Durango apatite and three synthetic, fluorine-bearing basaltic glasses prepared using starting material SH3.

K2 = 68.153 ± 78.8

H_2O apatite, session 3, day 4

gradient = 1.9807e+06 ± 1.81e+04

CO2 apatite, session 3

gradient = 109.03 ± 1.45

F apatite, session 3, day 1

wt% F

F/Ca

gradient = 112.17 ± 0.972

F apatite, session 3, day 2

gradient = 115.24 ± 1.29

F apatite, session 3, day 3

gradient = 104.07 ± 0.7

wt% Cl

Cl apatite, session 3, day 2

Cl/Ca

gradient = 103.75 ± 0.733

Cl apatite, session 3, day 3

wt% Cl

Cl/Ca

gradient = 104.32 ± 0.634

Cl apatite, session 3, day 4

gradient = 2.6657 ± 0.0669

H2O glass, session 3
