19 **RUNNING HEAD (SHORT TITLE):** Damaged latrines colonised by mosquitoes

20

21 **ABSTRACT**

22 During the resettlement of 6,500 persons living around the Nam Theun 2 hydroelectric project in Lao
23 PDR, more than 1,200 pour-flush latrines were constructed. To assess the role of these latrines as
24 productive larval habitats for mosquitoes, entomological investigations using CDC light traps, visual
25 inspection and emergence trapping were carried out in over 300 latrines during the 2008-2010 rainy
26 seasons. *Armigeres subalbatus* were nine times more likely to be found in latrines (mean catch =
27 3.09) compared with adjacent bedrooms (mean catch = 0.37; Odds Ratio (OR) = 9.08; 95% CI: 6.74 -
28 15.11) and mosquitoes were active in and around 59% of latrines at dusk. *Armigeres subalbatus* was
29 strongly associated with latrines which had damaged or improperly sealed septic-tank covers
30 (OR=5.44; 95% CI: 2.02 – 14.67; P<0.001). *Armigeres subalbatus* is a nuisance biter and a putative
31 vector for Japanese encephalitis and dengue viruses. Dengue virus serotype 3 was identified from a
32 single pool of non-blood fed female *Ar. subalbatus* using RT-PCR. Maintaining a good seal around
33 septic tanks is a simple intervention to block mosquito exit/entry and contribute to vector control in
34 the resettlement villages.

35

36 **MAIN TEXT**

37 Improved sanitation through the provision of latrines can contribute to a reduction in the incidence
38 of diarrhoeal disease and soil-transmitted helminthic infections (Strunz *et al.*, 2014). Under
39 Millennium Development Goal seven all United Nations member states agreed to halve the
40 proportion of the global population without sustainable access to safe drinking water and basic
41 sanitation. Between 1990 and 2012 nearly two billion people acquired access to improved sanitation
42 facilities, including latrines, thus progress towards meeting this target has been made, though the
43 target level of coverage will not be met by 2015.

44 Unfortunately, despite the extensive beneficial health outcomes associated with access to sanitation
45 facilities, if latrines are not properly maintained they can form a productive habitat for vector
46 mosquitoes. Mean catches in excess of 200 *Culex quinquefasciatus* per night have been reported for
47 CDC light traps set in latrines in Dar es Salaam, Tanzania (Chavasse *et al.*, 1995), with reports of as
48 many as 13, 000 mosquitoes from a single wet pit latrine on Zanzibar (Maxwell *et al.*, 1990).

49 As part of the resettlement programme of the Nam Theun 2 Hydroelectric Project (NT2), south-
50 central Lao PDR, over 1,200 families (6,500 persons) were relocated and provided with newly
51 constructed homes. Under the guidance of the millennium development goals, and with the desire
52 to improve hygiene and living conditions, each resettled household was provided with a pour-flush
53 latrine. We conducted investigations to determine whether latrines formed productive sources of
54 mosquitoes in the resettlement villages within 3 years of their construction.

55 Latrines constructed by the NT2 resettlement programme were based on the pour-flush pit latrine
56 design recommended by UNICEF ([www.unicef.org/eapro/unprotected-EDFchapter7-2\(1\).pdf](http://www.unicef.org/eapro/unprotected-EDFchapter7-2(1).pdf)). They
57 consisted of a water-sealed pan for defaecation, covered by a shelter built at ground level with
58 concrete and wood-walls and a corrugated iron roof. Waste is delivered to the septic-tank through a
59 pipe. The upper portion of the septic-tank was lined with a concrete ring of 80cm diameter with a
60 circular concrete cover placed on top of the septic-tank and sealed with cement. A plastic ventilation
61 pipe of 2cm diameter ran from the septic-tank to the top of the latrine wall (see Figure 1).

62 Informal discussions with the resettlement community during July 2008 (within one year of
63 resettlement), indicated that latrines may have been acting as breeding sites for mosquitoes. Small
64 holes (1-2cm diameter) beneath the concrete covers of septic-tanks were observed that may have
65 allowed mosquitoes access to the wastewater inside. During September 2008 (late rainy season) a
66 preliminary study was conducted in the bedrooms and latrine huts of 12 resettled households in
67 Nakai Tai village (17°45'04.3" N, 105°06'32.8" E, 553 m elevation). The study aimed to determine
68 which species of mosquito were collected in bedrooms of resettlement houses raised on stilts

69 approximately 2.5m above ground, as well as in ground-level latrine huts of the same houses. CDC
70 light traps (John W. Hock Co. Gainesville, FL) were set at dusk (between 18:00h and 19:00h) and
71 collected between 07:00h and 08:00h the following morning. Over successive four-nightly intervals,
72 each study house was sampled for three nights in the bedroom and once in the latrine. Traps in
73 bedrooms were positioned at the foot end of an occupied bed, with the light suspended 1.5 m above
74 the floor. Residents of all study houses were using insecticide-treated bed nets (B-52 Golden Horse
75 Brand, Netto Manufacturing Co. Ltd., Thailand). In latrine huts the traps were suspended from the
76 roof, 1 m distant from the latrine pan, with the light at 1.5 m above ground level. On any given night,
77 nine bedrooms and three latrines were sampled concurrently. Over 19 nights, a total of 224 trap
78 nights were successfully completed (4 traps failed and these data were excluded from further
79 analysis).

80 Between August and September 2009 an observational study was conducted in and around the
81 latrines of 50% of houses in three resettled villages (N=205 latrines): Done (17°40'07.1" N,
82 105°15'24.2" E, 551 m), Nakai Tai and NongBouaKham (17°49'15.8" N, 105°02'57.3" E, 544 m). In
83 each village the latrine of every second house along a pre-determined walking route, was subject to
84 a visual inspection at dusk. Each latrine was inspected for five minutes by a two-person team in
85 order to record the presence or absence of mosquitoes flying around the hut or near the septic tank
86 of the latrine. The presence of vegetation around the latrine hut, as well as any visible damage to the
87 septic-tank cover, was recorded.

88 After stratifying by household using a Mantel-Haenszel chi-square test, the relative abundance of
89 *Armigeres* mosquitoes caught in CDC light traps during 2008 was found to be significantly higher in
90 latrines than bedrooms. *Armigeres subalbatus* formed 51.7% of the total catch in latrines (N = 317
91 females of all species, 53 trap nights), compared with 11.4% of the total catch in bedrooms (N = 551
92 females, 171 trap nights, $\chi^2 = 165.0$, $P < 0.001$). Odds of capturing *Ar. subalbatus* were 9.08 times
93 higher in a latrine than in a bedroom (95% CI: 6.74 – 15.11) and the mean catch in latrines (mean

94 3.09, 95% CI: 2.30 – 3.89) was more than 8 times higher than in bedrooms (mean 0.37, 95% CI: 0.27
95 – 0.47) (GEE with negative binomial distribution and repeated measure for household, risk ratio (RR)
96 = 8.54, 95% CI: 5.58 - 13.08, $P < 0.001$) (see figure 2). Although the relative abundance of Japanese
97 encephalitis vectors (including *Culex tritaeniorhynchus*, *Cx. quinquefasciatus*, *Cx. vishnui*, *Cx. gelidus*,
98 *Cx. fuscocephala* and *Cx. bitaeniorhynchus*) and putative malaria vectors (any anopheline) differed
99 between latrines and bedrooms, mean catch sizes for these groups of species did not vary
100 significantly between the two locations (figure 2).

101 During the subsequent observational study in three villages, mosquitoes were observed flying in and
102 around 59% of 205 latrines at dusk. Damage to 17.6% of septic tanks was observed (N damaged =
103 36) and logistic regression analysis indicated that mosquitoes were more than five times as likely to
104 be found in or around latrines with damaged or improperly sealed tanks compared with latrines that
105 had intact tanks (OR = 5.44, 95% CI: 2.02 - 14.67, $P < 0.001$).

106 The results of these initial studies confirmed that mosquitoes were associated with latrines in the
107 resettlement villages, but further investigations were needed to determine whether mosquitoes
108 were newly emerging from the septic-tanks or merely resting in the dark, humid environments
109 provided by the tanks and latrine huts.

110 During May 2010 (early rainy season, two years post-resettlement) sampling using CDC light traps
111 took place in a randomly selected 40% of latrine huts in Nakai Tai village (N = 79 latrines) in order to
112 provide estimates of mosquito density and to identify latrines with the highest mosquito catch sizes.
113 The 36 latrines with the greatest mosquito catches were selected for subsequent sampling using
114 emergence traps in order to identify exit points for newly emerged adults. Exit points were
115 presumed to also form entry points for females searching for an oviposition site.

116 Three types of emergence trap were used during the third stage of the study (see figure 1): (i) whole
117 hut enclosed with the ventilation pipe open, (ii) whole hut enclosed with ventilation pipe sealed, and

118 (iii) an emergence trap enclosing only the cover of the septic-tank. Each of the 36 latrines was
119 sampled over three consecutive nights, using a different type of trap each night. Any indoor-resting
120 mosquitoes were removed from the latrine hut before setting the emergence trap. The presence of
121 vegetation around the latrine, water for flushing, and any damage to the waste delivery pipe and/or
122 septic-tank was recorded. A door sealed with cord ties was incorporated into the design of the large
123 emergence trap so that people could access the latrine during the night. Two of each type of trap
124 were set before dusk each night (N = 6 traps per night) and mosquitoes were collected from all traps
125 between 07:00h and 08:00h the morning after the trap was set.

126 Over 108 trap nights a total of 1,866 mosquitoes (59.5% female, of which 98.5% were unfed and
127 1.5% blood fed or gravid) were collected from the three types of emergence trap. *Armigeres*
128 *subalbatus* comprised 88.7% of females and 91.1% of males, whilst *Culex quinquefasciatus*
129 comprised 10.8% of the female catch and 8.9% of males. Although mosquitoes of either sex or
130 species were found in at least one emergence trap at 34 of the latrines, the total catch was highly
131 skewed; with 5 latrines producing most of the total *Ar.subalbatus* catch.

132 Analysis using a negative binomial regression model with household-level clustering, revealed that
133 fifteen times more female *Ar. subalbatus* were caught in emergence traps positioned directly over
134 the septic-tank cover, compared with traps positioned over the latrine hut with the ventilation pipe
135 open (RR = 15.25, 95% CI: 3.17-73.36, P = 0.001). A maximum of 496 females were captured in one
136 night in this type of emergence trap. Fourteen times more males were collected from septic-tank
137 emergence traps, compared with traps covering latrine huts with open ventilation pipes (RR = 13.75,
138 95% CI: 2.7 – 70.13, P = 0.002). This result indicated that ventilation pipes did not form an access
139 point to septic-tanks for mosquitoes in the resettlement villages.

140 Despite the wide variation in catch sizes, damaged septic-tank covers (N = 6) were significantly
141 associated with female *Ar. subalbatus* catch sizes that were almost five times greater than catches
142 from undamaged septic-tanks (N = 21) (RR = 4.82, 95% CI: 1.31-17.72, P = 0.019). Males were also

143 more likely to be caught in emergence traps at latrines with damaged septic-tanks compared with
144 tanks that had intact covers, but this difference was not statistically significant (RR = 3.49, 95% CI:
145 0.70 – 17.33, P = 0.122). In latrines where the tank cover was buried completely below the ground (N
146 = 9) the likelihood of capturing female *Ar. subalbatus* was substantially reduced, compared with
147 latrines where the cover was visible but intact (RR = 0.07, 95% CI: 0.02 – 0.31, P = 0.001). The same
148 was true for males, though the variation in catch sizes was much greater (RR = 0.13, 95% CI: 0.02 –
149 0.86, P = 0.035). The absence of water for flushing the latrine was not associated with a reduced
150 likelihood of finding mosquitoes in an emergence trap.

151 *Armigeres subalbatus* captured in latrine CDC light traps were pooled and frozen at -80°C for further
152 virological analysis given their putative role in flavivirus transmission. A total of 1,175 specimens
153 (983 females, 192 males) were sorted and pooled by date and capture site. A total of 101 pools
154 (females: 70; males: 31) were processed for total RNA extraction as previously described (Pagès *et*
155 *al.*, 2009). Purified RNA was submitted to a first screening by a pan-*flavivirus* RT-nested PCR
156 (Sánchez-Seco *et al.*, 2005). Among the pools tested, five were positive for the presence of *flavivirus*
157 sequences (4.9% of pools; females: 4 positive; males: 1 positive pool). All positive samples were
158 submitted to a second battery of specific real time RT-PCR to attempt virus identification, including a
159 standard approach to test samples for dengue virus and to determine the virus serotype (Lao *et al.*,
160 2014). Dengue virus serotype 3 was identified using RT-PCR from a single pool of non-blood fed
161 female *Ar. subalbatus*. The four remaining pools were negative for all specific RT-PCR tested viruses
162 (dengue; West Nile; Japanese encephalitis). Subsequently, a dengue virus 3 serotype was isolated
163 from the RT-PCR positive pool homogenate following inoculation onto C6/36 cells. This viral isolation
164 formally excludes a possible RT-PCR cross contamination. Although this result does not demonstrate
165 the direct role of this species as a vector of dengue, it at least demonstrates the active replication of
166 dengue 3 virus in *Ar. subalbatus* tissues.

167 During November 2011 (end of the rainy season) a follow-up study was conducted in Done village in
168 order to investigate whether burying septic-tank covers beneath a layer of earth could prevent them
169 from becoming oviposition sites. Eighty households were randomly selected for inclusion in the
170 study and emergence traps were positioned over the septic-tank cover of each latrine for one night.
171 Tank covers were classified as: completely covered by soil (buried), visible and intact, visible and
172 damaged or the tank location could not be found and an emergence trap was not set. In agreement
173 with the findings of the previous year, when tanks were completely buried below ground (N = 10
174 latrines) no male or female *Ar. subalbatus* were caught in emergence nets. Where tank covers were
175 damaged, female catch rates were 78 times higher than in intact tanks (RR = 77.6, 95% CI: 29.6 –
176 203.0, P < 0.001) and male catch rates were 104 times higher (RR = 103.5, 95% CI: 36.6 – 292.9,
177 P<0.001) than in intact tanks.

178 **Discussion:**

179 During the course of a number of studies between 2008 and 2011 it was demonstrated that if septic-
180 tank covers are damaged, even newly constructed latrines can be highly productive habitats for *Ar.*
181 *subalbatus* mosquitoes.

182 During the first year following latrine construction and population resettlement, *Ar. subalbatus* were
183 found in latrine huts, but rarely in bedrooms. It is possible that the small volume of the latrine hut,
184 or position low to the ground, might explain increased catch sizes due to the higher concentration of
185 attractive odours in a room of smaller volume compared with a bedroom. Ground-level latrine huts
186 may also have been more accessible when compared with bedrooms that were in houses raised
187 above ground on stilts (Charlwood *et al.*, 2003; Lee *et al.*, 2006). However, this theory would imply
188 that catch sizes of putative JE and malaria vectors would also be greater in latrines compared to
189 bedrooms, which was not the case.

190 During the observational study, mosquitoes were seen flying around latrine huts at dusk, an
191 observation which is in line with previous studies on mosquito time of emergence (de Meillon *et al.*,
192 1967). This supports the conclusion that these were newly emerged mosquitoes.

193 During the emergence trapping study a large number of males were captured (40.5% of the total
194 catch), indicative that the catches represented emergence from a larval habitat, rather than captures
195 from a resting site where females were digesting blood. It is assumed that the slight female bias was
196 due to trapping of females which entered the septic tank to oviposit before the emergence trap was
197 set. It is unlikely that septic tanks formed an important resting site as most captured females were
198 unfed (only 1.5% were blood fed or gravid). Emergence trap catches were highest in traps that were
199 positioned over damaged septic-tank covers, indicating that small gaps in the concrete cover formed
200 the exit, and presumably entry point, for *Ar. subalbatus*. Trapping using large emergence nets
201 enclosing the entire latrine hut with the ventilation pipe open, did not suggest that mosquitoes were
202 exiting septic-tanks via this route.

203 While the vectorial status of *Ar. subalbatus* in the Lao PDR is not confirmed, Japanese encephalitis
204 virus (JEV) has been detected in *Ar. subalbatus* from Taiwan and Yunnan Province, China (Chen *et al.*,
205 2000; Feng *et al.*, 2012; Liu *et al.*, 2013). After feeding *Ar. subalbatus* on a suspension of JEV which
206 had been isolated from a sympatric region of Taiwan, 79% of females were found to have
207 disseminated virus in the salivary glands (Chen *et al.*, 2000), a strong indicator that this mosquito
208 could act as a vector. As JEV has been shown to circulate among the NT2 resettlement population
209 (Hiscox *et al.*, 2010) the increased abundance of this non-conventional vector species could facilitate
210 increased transmission of the disease. Among the pools of mosquitoes collected in the resettlement
211 villages, nearly 5% were positive for flavivirus sequences, but direct identification of a virus species
212 (i.e. dengue) was established from only one pool. A number of mosquito species, including *Ar.*
213 *subalbatus*, have been reported to harbour either viral or insect-specific flavivirus sequences
214 (Takhampunya *et al.*, 2014). Despite being negative for known flaviviruses by RT-PCR, the other

215 panflavi-positive pools warrant further sequencing in this specific context where high *Ar. subalbatus*
216 populations are coexisting with humans. Detection and isolation of dengue virus serotype 3 from a
217 pool of non-blood fed females demonstrates the possible infection of *Ar. subalbatus* by dengue, but
218 does not allow us to confirm its competence nor the role of this species as a vector for dengue virus.
219 However, this aspect should be investigated more thoroughly to determine its putative
220 epidemiological impact on dengue transmission in areas, or during periods where conventional
221 vectors densities are naturally or artificially low. This will allow us to better determine the role of *Ar.*
222 *subalbatus* as a possible vector.

223 In addition to the potential capacity of *Ar. subalbatus* to act as a disease vector in these villages,
224 informal discussions with members of the community revealed that substantial levels of nuisance
225 biting are experienced in latrines. If nuisance biting were to deter people from using latrines, the
226 knock-on effect of mosquito breeding could be an increase in the transmission of soil-transmitted
227 helminthic infections and diarrhoeal disease in the resettlement population.

228 The application of a floating layer of polystyrene beads has been used to control breeding of *Cx.*
229 *quinquefasciatus* in soakage pits and wet pit latrines in Tanzania and India (Curtis *et al.*, 2002) and
230 the use of this technique has been suggested for *Ar. subalbatus* (Sivagnaname *et al.*, 2005).
231 Unfortunately application of this technique to latrines in the NT2 resettlement area would be
232 hindered by the small size of openings (often only 1-2cm diameter) through which mosquitoes
233 access the latrines. Concrete septic-tank covers are sealed in place and cannot be easily removed in
234 order to apply the beads. An alternative, cheap and environmentally friendly approach to vector
235 control would be to ensure that septic-tanks are fully covered with earth, thus blocking any small
236 holes in the septic-tank covers. During our studies of 2010 and 2011, septic-tanks that were buried
237 below the ground were devoid of mosquito breeding. Household owners could do the covering at
238 the time of installation, or at a later date, and minimal training would be needed to explain this
239 simple process to the community.

240 In conclusion, despite large improvements in health to be gained through the provision of sanitation
241 facilities, poor maintenance can lead to pour-flush latrines becoming highly productive mosquito
242 habitats. Simply covering septic tanks with a layer of soil should dramatically reduce the number of
243 mosquitoes produced, but field data is needed in order to validate this recommendation. As the NT2
244 resettlement programme followed a latrine design which was recommended by UNICEF, the Asian
245 Development Bank and the World Bank, the implications of these findings could be far reaching as
246 similar latrine designs are used all over the world.

247 **ACKNOWLEDGEMENTS**

248 The authors would like to thank Mr. Joy of Nakai district health office as well as Amphone
249 Bounmanosin and Nengyang Wangkou of IP Laos for their support in the field activities. Thanks also
250 to Jeroen Ensink for useful discussions about the topic. Most importantly we would like to thank,
251 Nam Theun 2 Power Company (NTPC) for allowing this study to take place and the residents of the
252 resettlement villages for allowing us to work in and around their homes and for their subsequent
253 follow-up work to repair the latrine covers. Special thanks are extended to Mr. Ruedi Luthi, former
254 director of the Environment and Social Division at NTPC, for his support. This study was funded by
255 grants from the Foundation of Electricité de France (EDF) and NTPC .

300 **FIGURE LEGENDS**

301 **Figure 1:** Emergence traps used to capture mosquitoes in latrine huts and septic-tanks. A: side
 302 section of a latrine hut with blue ventilation pipe enclosed in an emergence trap and the septic-tank
 303 outside the emergence trap, B: front section of a latrine hut covered in an emergence trap showing
 304 the door flap used to keep the trap closed but allow access to the latrine hut, C: emergence trap
 305 covering a septic-tank, D: photograph of the same view shown in B, a latrine hut covered by an
 306 emergence trap.

307 **Figure 2:** Mean CDC light trap catches for putative vectors of malaria (any anopheline), Japanese
 308 encephalitis (including *Culex tritaeniorhynchus*, *Cx. quinquefasciatus*, *Cx. vishnui*, *Cx. gelidus*, *Cx.*
 309 *fuscocephala* and *Cx. bitaeniorhynchus*) and *Armigeres subalbatus* in latrines and bedrooms of Nakai

310 Tai village. Error bars indicate 95% confidence intervals for the mean, P-values are for the difference
311 between in mean catches between bedrooms and latrines for each species, N = 53 trap nights in
312 latrines and 171 in bedrooms.
