17 **ABSTRACT**

18 **Critical to understanding the development of active continental margins is knowledge of**
19 **the crustal basement on which magmatic arcs are built. This study reports results from**
20 **a whole rock geochemical and zircon U-Pb geochronological study of a suite of crustal**
21 **xenoliths from the Bolivian Altiplano, Central Andes that provide new insight into the**
22 **evolution and composition of the continental basement beneath the region. The**
23 **xenoliths are hosted in Plio-Pleistocene trachyandesitic/dacitic lavas which erupted**
24 **from monogenetic volcanic centres in the Andean back-arc region and comprise both**
25 **igneous and metamorphic lithologies including diorites, microgranites, gneisses, garnet-**

26 mica schists, granulites, quartzites, and dacites. The xenolith suite exhibits significant
27 Sr-isotopic heterogeneity with values extending from 0.7105 to 0.7368. Pb isotopic
28 signatures reflect the crustal domains previously constrained from scattered exposures
29 of basement rocks throughout the region. Ion microprobe U-Pb dating of cores and rims
30 from zircon separates from two of the sampled xenoliths reveal predominant Early
31 Phanerozoic age peaks (*c.* 500 Ma; population 1), Late Mesoproterozoic (1.0-1.2 Ga;
32 population 2) and Palaeoproterozoic (1.7-1.9 Ga; population 3). Populations 1 and 2 are
33 well-documented throughout the Andes and correspond to periods of supercontinent
34 formation (e.g. Rodinia at *c.* 1.0 Ga) and break-up. Population 3, poorly represented in
35 the zircon record of the Andes as a whole, may record geological events during the
36 construction of the Palaeoproterozoic Amazonian craton. The presence of the three age
37 peaks in the zircon record of a single crustal xenolith demonstrates the important role
38 of crustal recycling in the construction of the modern day Andean margin. The
39 character of the xenoliths and their detrital zircon record is also inconsistent with
40 current understanding of the eastern extent of the Arequipa-Antofalla Basement (AAB)
41 block beneath the Bolivian Altiplano.

42

43 INTRODUCTION

44 The basement to continental arcs deserves study for two principal reasons; 1) its
45 composition and structure dictate the potential effects on continental arc magmas as they
46 ascend through, and differentiate within, the crust, e.g. enriched LILE, depleted HFSE,
47 Davidson et al. 2005), and 2) the composition, ages and structures are key to determining the
48 geological and plate tectonic development of an active continental margin.

49 Although it is generally recognized that the western margin of South America has been the
50 type example of an active continental margin for most of the Phanerozoic at least, to date,

51 incomplete knowledge of the continental crust in the Central Andes, hampers our efforts to
52 constrain and refine both palaeo-plate reconstruction models (e.g. Dalziel, 1997; Loewy et
53 al., 2004) and the extent of crust-mantle interaction in Central Andean magmas (e.g.
54 Sørensen and Holm, 2008; Mamani et al., 2010). Current tectonic models for the
55 Neoproterozoic and early Palaeozoic history of the western margin of the South American
56 continent have proposed a collision between the eastern Laurentian Craton and the western
57 margin of Gondwana, of which modern-day South America was a part (Cordani et al., 2005).
58 Fundamental to refining these models and associated terrane maps is knowledge of the
59 continental crust, yet surface exposures of the Central Andean basement are rare due to the
60 lack of tectonically-driven exhumation of basement rocks across the Altiplano region and the
61 extensive Tertiary sedimentary sequences that blanket the region today. Many geochemical
62 studies of volcanic rocks throughout the Central Andes have invoked the variable role of the
63 continental crust during the petrogenesis of magmatic rocks across the region in order to
64 account for the geochemical differences observed within and between magmas
65 erupted/emplaced along and across strike of the active arc (Davidson et al., 1991; Wörner et
66 al., 1992; Aitcheson et al., 1995; Davidson and de Silva, 1995; Caffè et al., 2002). The
67 compositions of potential crustal contaminants however remain poorly constrained.

68 Studies of crustal xenoliths brought to the surface by ascending magmas during the most
69 recent phase of volcanism (Plio-Pleistocene) have the potential to provide a unique cross
70 section of the continental basement that will provide additional constraints to regional
71 tectonic models and offer new insights to the composition of the Central Andean crust. The
72 crustal xenoliths that are the focus of this research represent a region of the Central Andes
73 where the continental basement has not previously been sampled through studies of surface
74 exposures and/or drill cores. Thus, the objectives of this study are threefold; (1) to present
75 long sought after compositions for the crustal components in Central Andean magmas; (2) to

76 contribute geochronological constraints on the evolution of the western margin of the South
77 American continent to explore the roles of crustal recycling in construction of the Central
78 Andean basement; and (3) to help constrain existing basement terrane models for this region
79 of the Andes.

80

81 **GEOLOGIC SETTING AND PREVIOUS WORK**

82 This study focuses on a suite of entrained crustal xenoliths hosted in Plio-Pleistocene lavas
83 which have erupted from two monogenetic centres at Pampas Aullagas (PA; 19°S, 67°W) and
84 Quillacas (QL; 19°S, 66°W) on the Bolivian Altiplano (Fig 1a, b). Both centres consist of
85 several lava flows which have erupted along NW-SE trending faults and form part of a
86 lineament of minor volcanic centres which runs subparallel to the volcanic front (Davidson
87 and de Silva, 1995).

88 Based on previous studies, the PA and QL centres are located on the Arequipa-Antofalla
89 Basement (AAB) block (Fig. 1c; Loewy et al., 2004; Ramos, 2008; Chew et al., 2011). This
90 crustal block can be divided into the northern Arequipa Massif, described as the best-
91 preserved basement inlier throughout the central Andes (Ramos, 2008), and the southern
92 Antofalla basement block. Collectively they are comprised of three distinct domains based
93 Pb-isotopic signatures (after Loewy et al., 2004) the Northern (Arequipa) and the Central and
94 Southern (Antofalla) Domains. These domains young to the south and are exposed
95 intermittently along the Arica embayment (Fig. 1c). Western Bolivia and southern Peru are
96 underlain by the Northern Domain that consists of Palaeoproterozoic (2.02-1.79 Ga)
97 intrusions that were later metamorphosed between 1.82 and 1.79 Ga (Loewy et al., 2004).
98 The oldest rocks in the Central Domain are constrained to Mesoproterozoic age with
99 crystallisation of migmatites and orthogneisses at ~1.25 Ga and ~1.21 Ga respectively. The
100 Central and Northern Domains subsequently underwent metamorphism between 1.20 and

101 0.94 Ga, whereas the Southern Domain in northern Chile and north-western Argentina is
102 composed of Ordovician rocks and experienced metamorphism at 440 Ma (Loewy et al.,
103 2004). To the east of the AAB lies the cratonic nucleus of South America, the Amazonian
104 Craton which consists of several Archaean and Proterozoic domains (Chew et al., 2011).
105 Several workers inferred an allochthonous origin for the AAB and have suggested that it
106 accreted to the South American margin at the time of the Sunsás Orogeny during assembly of
107 Rodinia (1.2-1 Ga: Loewy et al., 2004; Chew et al., 2007a; Ramos, 2008). The continental
108 basement between the AAB and Amazonian Craton is poorly characterised at this latitude in
109 the Central Andes (Fig. 1c) due to limited tectonic activity and recent sedimentation
110 (identified as “metamorphic basement and Ordovician clastic platform deposits” by Ramos,
111 2008). Volcano-sedimentary sequences deposited after 320 Ma, and which were subsequently
112 metamorphosed (310 Ma), have been identified to the north of the study area in the Eastern
113 Peruvian Andes (Cardona et al. 2009).

114 Basement surface exposure in Bolivia is constrained to a single outcrop at Cerro Uyarani on
115 the Western Altiplano (18°30'S, 68°40'W, Fig. 1c) where granulites, charnockites and rare
116 amphibolites with early Proterozoic protoliths have been identified (Wörner et al., 2000).
117 Evernden et al. (1977) reported clasts of red gneiss (K-Ar age of 647 Ma) and granite within
118 the Azurita Conglomerate ~200 km south of La Paz which are inferred to have been derived
119 from western Bolivia. These clasts, in addition to those found in the Mauri formation near
120 Berenguela, western Bolivia, were found to be Mesoproterozoic in age and characteristic of
121 the northern part of the AAB (Loewy et al., 2004). The location of the PA and QL centres
122 and the entrained xenoliths within erupted lavas will therefore allow characterisation of the
123 continental basement in a region of the Central Andes where surface exposure is rare and will
124 provide constraints on the eastward extent of the AAB basement block.

125

126 **ANALYTICAL PROCEDURES**

127 Rock powders were produced from rock chips free of weathered material. Sr-Nd isotopic
128 analyses were determined on a multicollector VG mass spectrometer (TIMS) at the
129 University of California, Los Angeles (UCLA, see Davidson and de Silva, 1995).
130 Additional Sr, Nd and also Pb isotopic compositions were measured on a plasma ionization
131 multicollector mass spectrometer (PIMMS) using the ThermoElectron Neptune instrument at
132 the Arthur Holmes Isotope Geology Laboratory (AHIGL), part of NCIET, at Durham
133 University, UK. Electron microprobe analyses of biotites and garnets were undertaken at the
134 School of Geosciences, University of Edinburgh using the CAMECA SX100 instrument.
135 Secondary ionization mass spectrometry (SIMS) analyses for U-Pb ages in zircons were
136 performed at the UCLA Department of Earth and Space Sciences using a CAMECA ims1270
137 ion microprobe (SIMS). Sample preparation for each of the analytical techniques, details of
138 standards run throughout this study and all whole rock sample data are provided in the
139 supplementary material. Results from SIMS analyses are presented in Tables 1 and 2.

140 Corresponding major and trace element data are presented in the supplementary material.
141 Major element and selected trace element abundances were determined by XRF at the
142 University of Edinburgh using the Panalytical PW2404 wavelength-dispersive sequential X-
143 ray spectrometer. Additional trace element concentrations were measured at NCIET
144 (Northern Centre of Isotopic and Elemental Tracing) at Durham University, UK by
145 inductively coupled plasma mass spectrometry (ICPMS) on a Perkin Elmer-Sciex Elan 6000.
146 Where reported, Zr (ppm) data is XRF data due to the difficulty of dissolving zircon
147 encountered during dissolution of whole rocks powders for ICPMS analysis. For this reason,
148 no Hf data are reported

149

150 **GEOCHEMISTRY**

151 The xenolith suite consists of eight lithologies of which average modal mineralogical
152 abundances are presented in Fig. 2 and key characteristics are described here.

153

154 **Major and trace elements**

155 Sampled diorites are the most mafic of the sampled suite ranging from 52.7 to 57.7 SiO₂ at
156 higher MgO (2.8-5.7); Fe₂O₃ (7.2-8.4) and K₂O (2.6-6.9) than the majority of the other
157 xenoliths. These samples also exhibit some of the highest Cr and Ni abundances. They are
158 characterised by abundant hornblende, plagioclase and biotite with biotite displaying
159 alteration to orthopyroxene, consistent with biotite breakdown (plus melt). Microgranitic and
160 dacitic xenoliths are characterised by plagioclase, biotite ± alkali feldspar and up to 60%
161 quartz. Samples consistently display very similar major element chemical signatures over a
162 restricted range of SiO₂ (66.7 to 69.3) and high Na₂O + K₂O at ~8 wt. %. The remaining
163 xenoliths show high Al₂O₃ contents which, coupled with the high abundance of aluminous
164 minerals (garnet, sillimanite, biotite) indicate the aluminous nature of the probable pelitic
165 protoliths. Specifically, gneisses and garnet-mica schists are characterised by regular
166 alternating layers of biotite-sillimanite ± garnet melanosomes and quartzofeldspathic
167 leucosomes. Sampled garnets in the mica-schists are almandine (Py₁₅Alm₇₀Gr₅Sp₁₀-
168 Py₁₆Alm₇₆Gr₄Sp₄) as would be expected of garnet produced during regional metamorphism
169 of argillaceous sediments (i.e. a pelitic protolith, Deer et al., 1992). A few of the sampled
170 granulites and gneisses show evidence for partial melting in the form of quenched glass
171 (estimated at ≤2 vol. % where present), which is interpreted as having formed during
172 entrainment of the xenoliths within their host lavas. Within the glass phase, very fine grained
173 (<200 μm) acicular crystals of anatase (TiO₂) are present (McLeod et al., 2012). Subsequent
174 (partial) extraction of this melt phase during entrainment is likely to have contributed to the

175 high percentage of residual quartz and high bulk SiO₂ contents (up to 88 wt. %) observed in
176 these particular samples.

177 Dacites and microgranites display LILE enrichment (e.g. Rb, Ba) and exhibit broadly
178 similar enrichment signatures from Ba through to Sm. There are notable peaks at U, K and Pb
179 and troughs at Nb-Ta and Sr. The majority of xenoliths have Sm/Nd ~0.2 (see supplementary
180 information, Fig. i.) similar to that of the upper (and middle) continental crust (Rudnick and
181 Gao, 2003). The majority of samples, to a greater or lesser degree, exhibit a negative Eu
182 anomaly which is again, akin to REE patterns of the upper (and middle) continental crust
183 (Rudnick and Fountain, 1995; Rudnick and Gao, 2003).

184

185 **Sr-Nd-Pb isotopes**

186 18 xenoliths were chosen for Sr-Nd isotopic analysis. Fig. 3a shows the xenoliths and the Sr-
187 Nd isotope compositional fields for sampled crustal basement rocks in neighbouring Chile
188 and Argentina. The xenoliths overlap compositions from previous basement studies, exhibit
189 slightly higher ⁸⁷Sr/⁸⁶Sr at lower ¹⁴³Nd/¹⁴⁴Nd but do not extend to the extreme ⁸⁷Sr/⁸⁶Sr values
190 of Palaeozoic Argentinian gneisses. Fig. 3b shows the variation in ⁸⁷Sr/⁸⁶Sr signatures of
191 recent (<60 Ma) volcanic rocks erupted along the Andean Cordillera. Regional variation is
192 attributed to the difference in continental crustal composition, age and thickness: Mafic,
193 Cretaceous and younger between 50 km (recent mapping of the Moho by the European Space
194 Agency) and 70 km (from gravity data; Feininger and Seguin, 1983) thick in the NVZ;
195 Palaeozoic with mafic and felsic components and up to 40 km thick in the SVZ (Hildreth and
196 Moorbath, 1988); Proterozoic and younger, predominantly felsic and thick, up to 80 km (e.g.
197 Thorpe and Francis, 1979; Zandt et al., 1994) in the CVZ. Volcanic rocks in the Central
198 Andes extend to more crust-like ⁸⁷Sr/⁸⁶Sr compositions than in the northern and southern
199 zones but not to the extremely high ⁸⁷Sr/⁸⁶Sr of the crustal xenoliths of this study or those of

200 crustal rocks from the Central Andes previously investigated (Fig. 3). 20 xenoliths were
201 chosen for Pb isotopic analysis. The microgranites are relatively non-radiogenic with
202 characteristically low Pb isotopic ratios at $^{206}\text{Pb}/^{204}\text{Pb} < 17.77$; $^{207}\text{Pb}/^{204}\text{Pb} < 15.61$; and
203 $^{208}\text{Pb}/^{204}\text{Pb} < 38.49$ (Fig. 4a, b). The remaining xenoliths exhibit $^{206}\text{Pb}/^{204}\text{Pb}$ values from 18.17
204 to 18.93; $^{207}\text{Pb}/^{204}\text{Pb}$ values from 15.64 to 15.69; $^{208}\text{Pb}/^{204}\text{Pb}$ values from 38.66-39.46, which
205 fall near upper crustal evolution trends. Aside from adding to the limited knowledge on the
206 compositions of the rock types which comprise the Central Andean continental basement, the
207 geochemical database presented here offers much needed constraints on the crustal
208 component(s) involved during petrogenesis of Central Andean magmas, a process which has
209 been, and is currently, extensively investigated and modelled (Davidson and de Silva, 1992;
210 1995; Sørensen and Holm, 2008; Mamani et al., 2010; Kay et al., 2010; Caffè et al., 2012).

211

212 **Geochronology**

213 Zircon is a useful mineral for U-Pb geochronology as it has a closure temperature in excess
214 of typical zircon dissolution temperatures for continental crustal compositions (Cherniak and
215 Watson, 2001), and it is physically and chemically robust, incorporating U and Th but little
216 (if any) common Pb. $^{207}\text{Pb}/^{235}\text{U}$ and $^{206}\text{Pb}/^{238}\text{U}$ ion microprobe data on U-Pb concordia plots
217 for 64 interior and rim analyses from 31 zircon crystals derived from two xenoliths of this
218 study are presented on figures 5a and b and in Tables 1 and 2.

219 From sample BC93PAX14 (garnet-sillimanite granulite), three ages were discordant, likely
220 reflecting Pb loss from the system. From 34 concordant ages, the oldest ages cluster at $1857 \pm$
221 17 Ma and the youngest at 380 ± 14 Ma. The oldest ages define a small peak from ~ 1.7 to
222 ~ 1.9 Ga with one age at 1611 ± 21 Ma. A prominent age population is present between ~ 1.0
223 and ~ 1.2 Ga and the most significant population of Ordovician ages (11) is present between
224 439 ± 13 Ma and 487 ± 14 Ma (see inset graph in Fig. 5a). Additionally, two analyses yielded

225 upper Devonian ages of 385 ± 11 Ma and 380 ± 14 Ma ($^{206}\text{Pb}/^{238}\text{U}$). The zircons analysed
226 from sample BC10QSX107 (garnet granulite) yield predominantly concordant ages with
227 significant age peaks from approximately 1.7 to 1.9 Ga and 1.0 to 1.2 Ga (see inset graph in
228 Fig. 5b). A third clustering of ages is present between 417 ± 17 Ma and 495 ± 17 Ma. Five
229 ages fall outside these populations with three showing late Neoproterozoic ages (average 653
230 ± 56 Ma) and two normally discordant analyses exhibiting early Palaeoproterozoic ages
231 (2178 ± 7 Ma and 2503 ± 10 Ma). Thus, of the 64 ages yielded from the two chosen samples,
232 59 are concordant from which three age peaks at *c.* 500 (population 1), 1.0-1.2 (population 2)
233 and 1.7-1.9 Ga (population 3) can be identified.

234 There is no systematic age relationship between the sampled zircons as rim ages differ
235 between grains hosted in the same crustal xenolith. Age data constrains a minimum age of *c.*
236 420 Ma and *c.* 380 Ma for the garnet granulite and the garnet-sillimanite granulite
237 respectively. This clearly demonstrates the detrital origin of the zircons and indicates that the
238 sampled xenoliths may have originally been post Devonian sediments. Core-rim age
239 relationships also vary between grains within the same xenolith implying that the zircon
240 population may represent derivation from numerous source regions (see Tables 1 and 2).

241

242 **DISCUSSION**

243 **Insight into basement domains as inferred from bulk Pb isotopes and Nd model ages**

244 From previous work, the location of the volcanic centres at PA and QL are inferred to have
245 erupted through the Arequipa-Antofalla basement (AAB) block (Fig. 1c; e.g. Ramos, 1988;
246 2008). The evolutionary history of this basement block will be discussed in detail later. In
247 relation to three previously identified crustal domains within the AAB block (after Loewy et
248 al., 2004), the Pb-isotopic compositions of the xenoliths plot mainly in the Central Domain
249 which stretches from $\sim 18^\circ\text{S}$ to $\sim 22^\circ\text{S}$ consistent with the location of PA and QL (figures 6a

250 and b). A subset of samples display relatively radiogenic $^{208}\text{Pb}/^{204}\text{Pb}$ signatures akin to those
251 of the Northern Domain present north of $\sim 18^\circ\text{S}$ to $\sim 14^\circ\text{S}$ and that incorporates the
252 Precambrian Arequipa Massif. This suggests one of several possibilities; 1) local
253 compositional heterogeneity with respect to $^{208}\text{Pb}/^{204}\text{Pb}$ within the Central Domain, 2)
254 involvement of crustal basement to the east of the Arequipa-Antofalla basement where the
255 continental crust is uncharacterised, or 3) the domain boundary between the Northern and
256 Central Domain is much more complex and extends further south than thought. Previous
257 work on the Pb-isotopic composition of the continental basement in this region supports a
258 complex transition between the northern and central domains (Wörner et al., 1992; de Silva et
259 al., 1993; Davidson and de Silva, 1995); a shallow southward-dipping, complexly interleaved
260 inter-crustal domain boundary has been suggested to exist beneath the PA and QL centres
261 thus both domains may be sampled by vertical conduits.

262 In terms of $^{206}\text{Pb}/^{204}\text{Pb}$ vs. $^{207}\text{Pb}/^{204}\text{Pb}$ all samples are distinct from the Southern Domain
263 which is present south of $\sim 22^\circ\text{S}$ in Chile and Argentina. Fig. 6c shows Pb isotopic data from
264 this study combined with data from previous Central Andean studies on basement rocks
265 (Tosdal, 1996; Wörner et al., 2000; Loewy et al., 2004). All sampled xenoliths follow the
266 Arequipa-Brazilian Shield trend, above the Stacey and Kramers (1975) bulk crustal evolution
267 curve and just above the Pb isotopic evolution curve at $\mu=10$. All sampled basement rocks
268 from the Central Andes, including the xenoliths of this study, fall distinctly outside the Pb
269 isotopic domain of Laurentian crust at $\mu=9.3$ to which Argentinian Precordillera rocks have
270 been found to show affinity (Thomas et al., 2002). This excludes the role of any Laurentian
271 crust (either as reworked crustal material or as protoliths) in the genesis of the continental
272 crust in this region of the Central Andes.

273 Calculated xenolith ϵNd values range from -7.5 to -15.8. Calculated T_{DM} ages for the
274 sampled xenolith suite form a continuous range from 2.6 to 1.0 Ga, with a peak at *c.* 1.9 Ga

275 (with the exception of the garnet mica schist at *c.* 4.0 Ga and one diorite at *c.* 2.9 Ga). This is
276 comparable with the range exhibited by Central Andean basement rocks (1.7-2.0 Ga, see
277 compilation by Becchio et al., 2011). T_{DM} ages are broadly comparable to T_{DM} ages of the
278 Northern and Central Domains of the Arequipa-Antofalla basement that range from 2.3 to 1.9
279 Ga and 2.2 to 1.3 Ga respectively (Loewy et al., 2004). T_{DM} ages in the younger Southern
280 Domain range widely from 1.9 to 0.5 Ga. Sample BC93PAX14 (garnet-sillimanite granulite)
281 has a T_{DM} age of 2.34 Ga however; multiple analyses for the U-Pb ages in its zircons reveal
282 events at *c.* 1.8, 1.0 and 0.5 Ga. The crystallisation age of these zircons range from the Late
283 Palaeoproterozoic to Early Devonian and clearly demonstrate the role of extensive crustal
284 reworking. Given that the (proto) Andean margin has been an active site of orogenesis and
285 magmatism since at least the mid-Proterozoic (see discussion below) calculated T_{DM} ages are
286 likely an average age derived from both crustal and mantle sources and thus highlight the role
287 of crustal recycling throughout the history of the western South American margin.

288

289 **Insight into basement domain models from Zircon U-Pb ages**

290 Constraining the evolution of the Central Andean continental basement is challenging due to
291 1) the accretion of several allochthonous and autochthonous tectonic blocks to the South
292 American margin, 2) the fact that each of these blocks has a unique geological history and 3)
293 that each will have experienced multiple orogenic events throughout the Phanerozoic.
294 Perhaps more importantly however, is the lack of exposure of Precambrian age basement
295 rocks throughout the modern Central Andean Cordillera. As shown previously, concordant
296 U-Pb zircon ages of this study exhibit three prominent age populations at the late
297 Palaeoproterozoic (population 3) late Mesoproterozoic (population 2) and early Phanerozoic
298 (population 1, Fig. 7a). Fig. 7b and c show concordant U-Pb zircon ages from provenance
299 and basement studies across the Central Andes and throughout the Andean Cordillera where

300 prominent age peaks are identified at *c.* 500 Ma (population 1 of this study) and *c.* 1.1 Ga
301 (population 2) and a scattering of ages exists throughout the Palaeoproterozoic and into the
302 Archean (e.g. Beccio et al., 2011). Despite the comparatively small sample size of this study,
303 it is significant that the overall age pattern previously identified throughout the entire Central
304 Andes is imprinted in the zircon record of the two xenoliths selected for analysis. This further
305 attests to extensive crustal recycling, but also speaks to the refractory and reliable nature of
306 zircon as a recorder of crustal evolution. Below we examine the implications of our data for
307 current models of basement domains in the Central Andes.

308

309 *Palaeoproterozoic ages (Population 3)*

310 Material older than ~1.7 Ga is typically lacking from Central Andean U-Pb zircon data sets
311 which has led to the suggestion that the Sunsás orogen (1.2 to 0.9 Ga; Grenville age) acted as
312 a topographic barrier preventing the supply of material from the Amazonian craton, which
313 forms the continental “nucleus” of South America (Chew et al., 2007b; 2011). A similar
314 scenario has been invoked for the evolution of Newfoundland and the Appalachian mountain
315 chains (Cawood et al., 2007). The craton is comprised of two Archean and five Proterozoic
316 crustal provinces with crustal growth patterns suggesting that domains young with distance
317 from the cratonic interior, the youngest being the Sunsás (1.28-0.95 Ga) exposed in Eastern
318 Bolivia (see Fig. 1c; Chew et al. 2011).

319 Palaeoproterozoic ages from this study range predominantly from 1.9 to 1.7 Ga with late to
320 mid Mesoproterozoic data (1.7-1.2 Ga) almost completely absent. Similar zircon ages have
321 been identified elsewhere throughout the Andean Cordillera (e.g. Peru, Loewy et al., 2004;
322 Chew et al., 2008). During the mid Palaeoproterozoic, the Trans-Amazonian Belt developed
323 from northern Amazonia to Argentina as a tectonic collage and is understood to have been
324 established by ~1.8 Ga. Following this, a series of tectonic events dominated by post-

325 orogenic granitic plutonism, explosive and extrusive volcanism, crustal-scale shearing and
326 rifting associated with the formation of volcano-sedimentary basins occurred from 1.8 to 1.6
327 Ga (de Almeida et al., 2000). These events could potentially account for the >1600 Ma
328 Palaeoproterozoic ages detected in our study and others, and implies that pre-
329 Mesoproterozoic Amazonian cratonic material was available during the development of the
330 Andean margin. This requires re-examination of the Sunsás orogeny topographic barrier
331 hypothesis.

332

333 *Mesoproterozoic ages (Population 2)*

334 At approximately 1 Ga a single supercontinental mass, Rodinia, is hypothesised to have
335 existed (McMenamin and McMenamin, 1990). Grenvillian aged belts produced during the
336 Mesoproterozoic and hence prior to supercontinent formation exist as scattered fragments
337 across the continents on earth today and have been used to reconstruct the paleogeography of
338 Rodinia (e.g. Hoffman, 1991). This reconstruction, alongside more recent efforts, juxtapose
339 the western margin of the Amazonian craton (Palaeoproterozoic to Archean in age) against
340 Laurentia's eastern (Appalachian) margin (e.g. Torsvik, 2003). The Arequipa-Antofalla
341 Basement (AAB) block of the Central Andes (after Loewy et al., 2004) is considered to
342 represent a fragment of a Mesoproterozoic, Grenvillian-aged, orogenic belt which is
343 allochthonous to Amazonia (Ramos, 1988; Dalziel, 1994; Fuck et al., 2008). Its accretion to
344 the proto-Andean margin has been proposed at 1000-1300 Ma during the Sunsás orogenic
345 episode and the building of the Rodinian supercontinent implying a major crustal domain
346 boundary separates the two (Wörner et al., 2000; Loewy et al., 2004)). The prominent age
347 peak between 1 and 1.2 Ga observed within the sampled zircon suite of this study, and others
348 (Fig. 7) is therefore attributable to the Grenville-aged Sunsás orogenic source associated with
349 the construction of Rodinia and is consistent with an AAB origin. Syn and post tectonic

350 Sunsás related deformation and orogenesis has recently been identified between 1105 and
351 1014 Ma in zircons derived from intrusive rocks within the Sunsás belt (Chew et al., 2011
352 and references therein). This age peak coincides extremely well with age peaks derived from
353 numerous other U-Pb detrital zircon studies aimed at reconstructing Rodinia e.g. California,
354 Arizona and the Mojave Province, north-western Mexico (Stewart et al., 2001; Farmer et al.,
355 2005); south-western Africa and Uruguay (Basei et al. 2005); Mongolia (LaiCheng et al.,
356 2007); Scotland, Newfoundland and the Appalachians (Cawood et al., 2007).

357

358 *Neoproterozoic and Early Phanerozoic ages (Population 1)*

359 Rifting of the Rodinian supercontinent is understood to have been multi-stage and may have
360 occurred as early as ~850 Ma (Torsvik, 2008) with the eventual formation of the Iapetus
361 Ocean as Laurentia separated from western Gondwana (Fig. 8). Paleontological evidence for
362 the link between the proto-Andean margin and the Iapetus Ocean is provided by brachiopods
363 in Argentina, Bolivia and Peru (Benedetto, 1998). Remnant basement blocks from the Sierra
364 Pampeanas, Argentina, indicate active arc magmatism between 650 and 530 Ma on the
365 western margin of Gondwana during Iapetus times, which is considerably earlier than that
366 recorded on Laurentia (~500 Ma and younger, Chew et al., 2008). Mid-Late Neoproterozoic
367 U-Pb ages from our detrital zircon study (and those of the (Central) Andean record) can be
368 inferred to record the Pampean-Brasiliano orogenic cycle during which a magmatic arc is
369 understood to have developed on the proto-Andean margin (0.5-0.7 Ga, Loewy et al., 2004;
370 Chew et al., 2008; Wotzlaw et al., 2011). This orogenic belt is understood to have developed
371 during the assembly of western Gondwana as allochthonous terranes converged on the
372 Amazonian craton (Fig. 8). However, the present day expression of this orogeny in Bolivia
373 (the Tucavaca Belt at ~16°S, 65°W, see Fig. 1c) is composed of deformed sedimentary
374 sequences and not oceanic lithosphere (Pimentel et al., 1999). A potential source for the Mid-

375 Late Neoproterozoic ages in the detrital zircon record of this study may therefore be the
376 Brasília Belt that lies to the northeast of the Tucavaca Belt where syn-collisional and arc-
377 related (granitoid) magmatism has been dated between 0.9 to 0.63 Ga (Chew et al., 2008).

378 At the onset of the Phanerozoic, the western margin of Gondwana was active (Fig. 8) but the
379 number and associated ages of orogenic events throughout the Palaeozoic is poorly
380 constrained (Chew et al., 2007b). A subduction regime is thought to have been established
381 along the western Gondwana margin during the Cambrian, which defined a convergent
382 tectonic regime between the margins of eastern Laurentia and western Gondwana. At this
383 time, rifted fragments of Laurentian crust are thought to have accreted to the western
384 Gondwana margin as recorded by the Laurentian Precordillera terrane in northwest
385 Argentina, (Fig. 6c, Kay et al., 1996; Thomas et al., 2002). However, involvement of
386 Laurentian crust is not recorded in the Pb-isotopic compositions of sampled xenoliths (Fig.
387 5a, b) suggesting there was limited, if any, accretion of Laurentian derived material to the
388 continental basement of the western South American margin at modern-day latitudes (based
389 on data currently available).

390 Mid Palaeozoic ages recorded in the detrital zircon record of this study (495-380 Ma) could
391 reflect magmatism related to the Famatinian orogeny (*c.* 480 Ma) during which the Iapetus
392 Ocean closed. However, the southern Laurentian margin is thought to have eventually
393 collided with the northern margin of South America meaning that the western margin has
394 remained active since early Palaeozoic times (Thomas and Astini, 2003).

395 In summary, U-Pb zircon data from crustal xenoliths hosted in Quaternary lavas from the
396 Bolivian Altiplano, supports previous work by indicating the presence of Grenville-aged
397 crustal basement in the Central Andes and the potential derivation of material from the
398 Amazonian craton, Grenville-aged (Sunsás) and Famatinian-aged peaks in the analysed
399 zircon populations implies the availability of these sources to supply material to Palaeozoic

400 strata. Today these belts may form, at least part of, the crust on which the modern day
401 Andean mountain chain is built and may have been buried as recently as the Eocene-
402 Oligocene (Chew et al., 2008). The presence of all three age populations within the detrital
403 U-Pb zircon record from the same crustal xenolith clearly indicates the important role of
404 crustal recycling during the evolution of the (Central) Andean continental margin.
405 Furthermore, given the lack of a systematic age relationship between the detrital grains
406 sampled by this study and the age constraints emplaced by the youngest observed ages (c.
407 420 and 320 Ma), the host xenoliths likely represent post Silurian and/or post Devonian
408 sediments. On a separate note, the prominent age peaks of zircon population 2 and 3 found in
409 this study and throughout the Andean Cordillera can also be attributed to significant periods
410 of continental crustal growth at 1.9 and 1.2 Ga (c.f. Condie, 1998).

411

412 **Implications for the Arequipa-Antofalla Basement block of the Central Andes.**

413 The U-Pb zircon record of the (Central) Andes in this study complements and enhances
414 previous work that demonstrates the development of the Andean margin from pre-Grenville
415 times to the establishment of the modern-day tectonic regime through a sequence of
416 supercontinent construction, subsequent break up, the docking of exotic crustal terrane blocks
417 and the important role of crustal recycling. Below we evaluate the implications of our work
418 for the Arequipa-Antofalla Basement (AAB) block – the putative local basement to the study
419 area on the Bolivian Altiplano.

420 From previous work, the AAB block is inferred to underlie the volcanic centres at PA and
421 QL (see Fig. 1c). Early studies of basement inliers in this region suggested the AAB was one
422 coherent basement domain (Ramos, 1988) but more recent work has indicated that the
423 Antofalla Basement is distinct from the northern, nonradiogenic Precambrian Arequipa
424 Massif (Ramos, 2008) despite both exhibiting similar Palaeoproterozoic protoliths ages (c.

425 1900 Ma; Loewy et al., 2004). The Arequipa Massif is characterised by granulites, gneisses,
426 dioritic gneisses, foliated migmatites, mylonites and meta-igneous basic rocks (Ramos,
427 2008). The Antofalla Basement is comparatively radiogenic (Fig. 6a, b) but like the Arequipa
428 Massif, exhibits similar high-grade Mesoproterozoic metamorphic ages (e.g. Wasteneys et
429 al., 1995) indicating that the two blocks, at least in part, share a common history. Antofalla
430 rock types preserved in the scattered surface outcrops are dominated by Proterozoic gneisses
431 (orthogneisses, quartz-biotite paragneisses granodioritic orthogneisses, migmatitic gneisses)
432 muscovite schists and amphibolites (Wörner et al., 2000; Loewy et al., 2004). Rifting
433 associated with the break-up of Rodinia is inferred to have partially detached the AAB from
434 the Amazonian margin (Fig. 9a in Ramos, 2008) and established a passive margin regime
435 during the Neoproterozoic (the Puncoviscana Basin, see Fig. 1c; Cawood et al., 2001).
436 During the Cambrian and preceding the assembly of Gondwana, the tectonic regime changed
437 to one of subduction during which the AAB was re-accreted to Amazonia during the
438 Famatinian orogeny (Ramos, 2008). The distinct Pb isotopic composition of the southern
439 Antofalla (Southern Domain after Loewy et al., 2004) has been attributed to the
440 counterclockwise separation from Gondwana following early Cambrian re-accretion such
441 that, although dominated by an extensional regime, oceanic crust did not develop in the
442 northern Antofalla (Central Domain after Loewy et al., 2004). Ramos (2008) inferred that
443 following cessation of continental rifting, the Antofalla was re-accreted to the continental
444 margin again.

445 Cardona et al. (2009) recently studied the Marañón Complex in the Eastern Cordillera of the
446 Peruvian Andes. This complex encompasses all the metamorphic basement rocks of the
447 Eastern Cordillera and is characterised by low to middle-grade metamorphic units in two
448 basins of volcano-sedimentary origin, which are inferred to have developed in an arc-related
449 tectonic regime during the late Palaeozoic. From detrital zircons and stratigraphic age

450 relationships, sedimentation was constrained to 318-300 Ma for the western basin (450-420
451 Ma in the east). Metamorphism of these deposited sequences, attributed to terrane accretion
452 or a change in the subduction regime, has been constrained to 300-310 Ma in exposed schists
453 with evidence for younger granitoid intrusions during the Triassic (Cardona et al., 2009).

454

455 From our perspective, the youngest detrital zircon age obtained by this study is 380 Ma.
456 This constrains the age of the host garnet-sillimanite granulite xenolith to $< c. 380$ Ma ($< c.$
457 420 Ma for the garnet granulite). The high wt. % Al_2O_3 contents in the majority of the
458 sampled xenoliths and the high abundance of aluminous minerals present (garnet, sillimanite,
459 biotite) are indicative of the aluminous nature of potential pelitic protolith(s). Furthermore,
460 the almandine-rich nature of sampled garnets (schists only) can be used to infer garnet growth
461 during regional metamorphism of argillaceous sediments (Deer et al., 1992). These
462 observations and constraints present difficulty when attempting to reconcile these xenoliths
463 within the evolutionary history of the AAB given that our observations indicate that 1) the
464 Central Domain is predominantly characterised by gneissose lithologies (Loewy et al, 2004)
465 and 2) source regions to the detrital zircons must have been available until at least 380 Ma.
466 This is in contrast to current thinking about the AAB, which is composed predominantly of
467 Proterozoic gneisses (and thus devoid of Phanerozoic material) and only affected by
468 magmatism during the Early Palaeozoic (Loewy et al., 2004). Thus, whilst the sampled
469 zircon suite shares a similar U-Pb age record as that observed in the AAB (Fig, 7b), we
470 suggest that the sampled xenoliths of this study are not derived from the continental basement
471 of the AAB. Instead, we infer that the sampled crustal suite represents the meta volcano-
472 sedimentary continental basement of the Eastern Bolivian Cordillera, the composition of
473 which may be similar to that identified in the Peruvian Eastern Cordillera by Cardona et al.

474 (2009). The eastern terrane boundary of the AAB may therefore be further west than inferred
475 by previous studies (Fig, 1c).

476

477 **CONCLUSIONS**

478 The crustal xenoliths from the back-arc region of the modern-day active Central Andean
479 margin reveal significant lithological heterogeneity exists within the continental basement.
480 Measured major and trace element concentrations and Sr-Nd-Pb isotopic compositions place
481 important constraints on the characteristics of the Central Andean crust. The data presented
482 provides an absolute, comprehensive geochemical dataset of potential crustal contaminants
483 for studies of crustal contamination which aim to evaluate the role of the continental crust
484 during petrogenesis of Central Andean magmas.

485 The sampled xenoliths are entrained within *c.* 2 Ma lavas which erupted from two
486 monogenetic volcanic centres on the Bolivian Altiplano beneath which, based on previous
487 work, the Central Domain of the Precambrian Arequipa-Antofalla Basement (AAB) block is
488 thought to exist. The Pb isotopic characteristics of the xenolith suite overlap the Pb
489 compositions of the Central (and Northern) AAB Domain and are compositionally distinct
490 from Laurentian crust, thus suggesting a limited contribution from Laurentian-derived
491 material, at least in this region of the Central Andes, to the continental basement.

492 The detrital U-Pb zircon record from two of the xenoliths reveal three populations with age
493 peaks at *c.* 1.8 Ga, *c.* 1.1 Ga and *c.* 0.5 Ga and demonstrate the important role of crustal
494 recycling during the growth of the Central Andean margin. These ages can be reconciled with
495 periods of supercontinent formation, subsequent break-up and active margin magmatism. The
496 core-rim age relationships vary between grains implying numerous sources contributed to the
497 detrital record. The age constraints implied by the detrital record and the aluminous nature of
498 inferred pelitic protoliths indicate that these xenoliths represent post Silurian and/or post

499 Devonian sediments. This interpretation is difficult to reconcile within the evolutionary
500 history of the AAB and suggests these xenoliths are sampling the meta volcano-sedimentary
501 continental basement of the Bolivian Eastern Cordillera. This further implies that the eastern
502 extent of the Proterozoic AAB Central Domain is further west than previously thought.

503

504 **ACKNOWLEDGEMENTS**

505 Financial support was provided to C. L. McLeod by NERC studentship NE/G524036/1.
506 Davidson and de Silva acknowledge National Science Foundation (EAR 8916496, 0838536
507 and 0908324) support for past and current work in the Central Andes. The ion microprobe
508 facility at UCLA is partly supported by a grant from the Instrumentation and Facilities
509 Program, Division of Earth Sciences, National Science Foundation. Additional thanks are
510 extended to the Bolivian Geological Survey (GEOBOL) who provided assistance with the
511 original fieldwork and the Durham Volcanology Group for discussions throughout this study.
512 Nic Odling at Edinburgh University and Chris Ottley at Durham University are thanked for
513 guidance throughout sample preparation for XRF and ICPMS analysis. Thanks are due to
514 Jamie Kern, Jason Kaiser and Rodrigo Iriarte for zircon preparation and subsequent
515 assistance during U-Pb analysis at Oregon State University and UCLA respectively.

516
