21  ABSTRACT

22  Crystal growth is often described as either interface-controlled or diffusion-controlled. Here,

23  we study crystal growth in an intermediate scenario where reaction rates at the crystal-melt

24  interface are similar to the rates of diffusive transport of ions through the melt to the

25  advancing crystal surface. To this end, we experimentally investigated euhedral plagioclase

26  crystal shapes in dry mafic (basaltic) and hydrous silicic (haplodacitic) melts. Aspect ratios

27  and inferred relative growth rates of the 3D short ($S$) and intermediate ($I$) crystal dimensions

28  vary significantly between mafic and silicic melts, with $\delta S{:}\delta I = 1{:}6 – 1{:}20$ in basalt and $1{:}2.5$

29  $– 1{:}8$ in hydrous haplodacite. The lower aspect ratios of plagioclase grown in the silicic melt

30  coincide with 10-100x lower melt diffusion rates than in the mafic melt. Using an anisotropic

31  growth model, we show that such differences in melt diffusivity can explain the discrepancy

32  in plagioclase aspect ratios: if interface reaction and melt diffusion rates are of similar

33  magnitude, then the growth of a crystal facet with high interfacial reaction rates may be

34  limited by melt diffusion while another facet of the same crystal with lower interfacial

35  reaction rates may grow uninhibited by melt diffusivity. This selective control of melt

36  diffusion on crystal growth rates results in progressively more equant crystal shapes as

37  diffusivity decreases, consistent with our experimental observations. Importantly, crystals

38  formed in this diffusion-moderated, intermediate growth regime may not show any classical

39  diffusion-controlled growth features. The proposed model was developed for plagioclase

40  microlites, but should be generalisable to all anisotropic microlite growth in volcanic rocks.

41  **Keywords:** Crystal growth; crystal shape; interface kinetics; melt diffusivity; plagioclase

42  INTRODUCTION

43  Crystal growth rates and resulting crystal morphologies are controlled by two competing

44  factors: (i) interface reaction kinetics, i.e., the rates at which atoms move across the melt-

45    crystal interface; and (ii) diffusion in the melt, i.e., the rates of transport of atoms through the

46    melt to the advancing crystal surface (e.g., reviews by Kirkpatrick, 1975 and Dowty, 1980). If

47    the rates of interfacial reactions are much smaller than those of ion diffusion through the melt

48    (e.g., at low melt supersaturation), then chemical supply at the crystal-melt interface is

49    maintained and crystal growth rates are controlled by interface kinetics. In this *interface-*

50    *limited growth regime*, relative growth rates of different crystal facets reflect variations in

51    anisotropic crystal-melt interfacial energies, and the resulting crystal shapes are well-formed

52    (*euhedral;* e.g., Kirkpatrick et al., 1979; Muncill & Lasaga, 1987). On the other hand, if ion

53    diffusion through the melt is slower than interfacial reaction rates (e.g., at high melt

54    supersaturation), then compositional gradients develop in the melt and diffusion becomes the

55    rate limiting process. Crystals formed in this *diffusion-limited growth regime* are typically

56    skeletal, with acicular or bladed morphologies, or, in extreme cases, dendritic or spherulitic

57    (e.g., Lofgren, 1974; Kirkpatrick et al., 1979; Muncill & Lasaga, 1987; Hammer &

58    Rutherford, 2002; Duchene et al., 2008; Martel, 2012; Shea & Hammer, 2013). However,

59    crystal growth under conditions where interfacial reaction rates and ion diffusivities in the

60    melt are similar is less well understood. Here, we study plagioclase growth rates and resulting

61    crystal morphologies in this *intermediate growth regime* of competing melt diffusivities and

62    interfacial reaction rates. Firstly, we determine relative growth rates for the short and

63    intermediate crystallographic axes of plagioclase in mafic and silicic melts through a series of

64    novel crystallisation experiments. We then examine the relationship between relative crystal

65    growth rates (and resulting plagioclase shapes) and melt diffusivities, and we present an

66    anisotropic growth model predicting crystal shape as a function of competing interface

67    reaction kinetics and melt diffusivities. We find that for an anisotropic crystal formed in the

68    intermediate growth regime, some crystal faces may be affected by melt diffusion while

69    others are not, resulting in variations in euhedral crystal shapes without necessarily producing

70    typical diffusion-controlled textures.

## EXPERIMENTAL APPROACH

72    To determine relative plagioclase growth rates in mafic and silicic melts, we conducted

73    crystallisation experiments at low to moderate undercoolings (~$0<\Delta T<70$°C) designed to

74    prevent diffusion-limited crystal growth. Absolute plagioclase growth rates derived from

75    crystallisation experiments show relatively small variations (factor of 2-3) at such

76    undercooling conditions for a given melt composition (Shea & Hammer, 2013). Assuming

77    that *relative* growth rates along different growth directions (e.g., along the 3D short [$S$],

78    intermediate [$I$] and long [$L$] growth direction) also remain approximately constant in this

79    undercooling window, such relative plagioclase growth rates $\delta S{:}\delta I{:}\delta L$ can be constrained by

80    characterising plagioclase shape as a function of crystal size. To this end, we ran a series of

81    high-temperature crystallisation experiments producing a total range of 2D crystal lengths $l$

82    from ~1 to 100 μm, with each experiment designed to produce *one* euhedral plagioclase

83    population of a given size and shape. Crystal size was primarily controlled by inducing

84    heterogeneous nucleation: at a given undercooling, crystals grow to smaller sizes as the

85    number of nuclei increases (e.g., Martel, 2012; Mangler et al., 2022), hence the higher the

86    number of nucleation sites in an experiment, the smaller the resulting crystals. The number of

87    available nucleation sites was adjusted by varying the particle size (i.e., surface area) of the

88    starting glass: fine powder has a higher surface area than mm-sized chips of starting glass,

89    and since each particle surface is a potential nucleation site (e.g., Zeng & Xu, 2015), starting

90    glass powder generates a significantly higher nucleation density than chips when heated to

91    (sub-) liquidus conditions. Additional controls used to modify final crystal size included

92    varying (1) pre-experimental heating ramps and annealing steps, (2) experimental

93    temperatures (i.e., undercooling), and (3) experimental durations (Table 1). An outline of

94 specific experimental conditions is given below and in Table 1, and detailed experimental and

95 analytical methods are provided in Supplementary File 1 and Tables S2 and S3.

96 For silicic compositions, we used a synthetic haplodacitic starting glass representative of

97 melts in natural intermediate volcanic rocks (Table S1). Isothermal and single-step cooling

98 experiments were conducted isobarically under $H_2O$-saturated conditions at 150 MPa and

99 temperatures of 830 to 900°C (~0<$\Delta T$<70°C) using a cold-seal pressure vessel at Durham

100 University, UK (Table 1). The plagioclase liquidus under these conditions was

101 experimentally determined to be at 890 ± 10°C. Two series of crystallisation experiments

102 were run: the first using finely powdered anhydrous starting glass to produce a high number

103 of nuclei and hence small plagioclase crystal sizes (*High-N experiments)*, and the second

104 using chips of hydrated starting glass to produce lower numbers of larger plagioclase crystals

105 (*Low-N experiments*; Table 1). In addition, pre-experimental heating ramps and dwells were

106 used to promote varying degrees of nucleation (e.g., Corrigan, 1982; Lofgren, 1983; First et

107 al., 2020), and experimental durations and temperatures were varied to probe different stages

108 of growth (Table 1).

109 For mafic compositions, anhydrous crystallisation experiments were conducted at atmos-

110 pheric pressure on a Linkam TS1500XY heating stage at Durham University using ≤60 μm

111 thin, double-polished wafers of naturally glassy "Blue Glassy Pahoehoe" basalt (Oze &

112 Winter, 2005; Table S1). The plagioclase liquidus under experimental conditions was

113 estimated to be ~1180 ± 5°C based on MELTS (Gualda et al., 2015) and experimental

114 observations (Geifman, 2022). Experiments were run at temperatures of 1180 to 1140°C

115 (~0<$\Delta T$<45°C; Table 1). Pre-experimental dwell times (1.5 to 10 min) and average cooling

116 rates (0 to 4.3°C/min) were modulated to induce varying degrees of nucleation, and

117 experiments were quenched after 2 to 142 min to capture different stages of plagioclase

118 growth. Crystallisation times were kept generally short to avoid overprinting of primary

119     plagioclase shapes by oxide growth, crystal agglomeration (e.g., Pupier et al., 2008) or other

120     maturation processes.

121     All experimental run products were sectioned, polished in $\gamma$-$Al_2O_3$ slurry and imaged on a

122     Hitachi SU-70 field emission scanning electron microscope at Durham University. Crystal

123     area as well as 2D lengths (*l*) and widths *(w)* were extracted manually using ImageJ

124     (Schneider et al. 2012; Supplementary File 2). 3D crystal shapes for each sample were

125     estimated from 2D *l* and *w* data using 2D-to-3D projection software *ShapeCalc* (Mangler et

126     al., 2022). Since 3D crystal length (*L*) is poorly constrained by 2D intersection data (Higgins,

127     2000), the most significant morphological parameter is the ratio of 3D short/intermediate

128     dimensions (*S/I*), and we therefore focus on relative growth rates $\delta S{:}\delta I$ and aspect ratios *S:I*

129     as a proxy for plagioclase shape in this study. Plagioclase size is expressed as the average

130     crystal volume (Tables S2, S3, Figs. 1, 2 & 4), which is the inverse of the ratio of volumetric

131     plagioclase number density $N_{V,plag}$ to plagioclase volume fraction $\varphi_{plag}$.

## PLAGIOCLASE SHAPE EVOLUTION DURING GROWTH

133     The experiments produced plagioclase number densities of $10^3$-$10^7$ mm$^{-3}$ and average crystal

134     lengths of 2-44 µm (Tables 1, S2 & S3), covering the range of microlite populations found in

135     natural volcanic rocks (Cashman, 2020). Plagioclase crystal shapes are euhedral in all of our

136     experiments, and textures indicative of diffusion-controlled growth are rare (Fig. 1). Crystal

137     shapes in the haplodacite (blue in Fig. 1) vary from prismatic (*S/I* = 0.5 or *S:I* = 1:2) to

138     tabular (*S/I* = 0.2; *S:I* = 1:5) with increasing size, consistent with observations in natural

139     samples (Mangler et al., 2022). Contrary to previous experimental studies (e.g., Lofgren,

140     1974; Shea & Hammer, 2013), we did not find a correlation between crystal shapes and

141     nominal undercooling conditions (Fig. S1a), and there is also no clear correlation with

142     plagioclase major element compositions (Fig. S1b; Supplementary Files 1 & 3). Plagioclase

143  crystallised from basaltic melt (red in Fig. 1) shows an analogous trend from more prismatic

144  ($S/I$ = 0.26; $S{:}I$ = 1:4) to more tabular shapes ($S/I$ = 0.05; $S{:}I$ = 1:20) with increasing size, but

145  at generally lower $S/I$ than in the haplodacite. This offset to lower $S/I$ in the basaltic melt is

146  consistent with our first-order petrographic observation that plagioclase generally forms

147  thinner tablets in basalts than in rhyolites.

## RELATIVE GROWTH RATES AND STEADY-STATE CRYSTAL SHAPES

149  Our knowledge about relative growth rates of different crystal facets in silicate minerals is

150  limited. Mangler et al. (2022) showed that the change from prismatic to tabular plagioclase

151  shapes with increasing microlite size can be reproduced by modelling crystal shape as a

152  function of its growth volume, assuming a prismatic initial shape ($S/I$ = 1; $S{:}I$ = 1:1) and 10x

153  faster growth of the intermediate dimension than of the short dimension (i.e., relative growth

154  rates $\delta S{:}\delta I$ = 1:10; $\delta S/\delta I$ = 0.1). These relative growth rates were determined by finding a

155  fit to a complex natural dataset and are subject to large uncertainties. Here, we apply the same

156  model to our more tightly controlled experimental size-shape data to infer robust constraints

157  on relative growth rates along the short and intermediate crystallographic axes for plagioclase

158  in basaltic and silicic melts (Fig. 2a & b). The growth model geometrically calculates the 3D

159  shape change of a crystal with a given starting size and shape $S{:}I{:}L$ as it grows at given

160  relative growth rates $\delta S{:}\delta I{:}\delta L$ (Fig. S3). Following Mangler et al. (2022), we modelled

161  crystal shape evolution for a 'proto-crystal' with an initial volume of 0.1 $\mu m^3$, a prismatic

162  starting shape ($S/I$ = 1; $S{:}I$ = 1:1), and relative growth rates $\delta S{:}\delta I$ of between 1:1.5 and 1:20

163  (Fig. 2a). The size-shape data for plagioclase crystallised from mafic melts show a good fit to

164  models using relative growth rates $\delta S{:}\delta I$ of between 1:6 and 1:20 (shaded red in Fig. 2a &

165  b). In contrast, best model fits for the haplodacite data suggests relative plagioclase growth

166  rates of between 1:2.5 and 1:8 in the silicic melt (shaded blue in Fig. 2a & b).

167   The model results further show that crystal shapes rapidly approach aspect ratios defined by

168   the relative growth rates after nucleation: once a crystal reaches a volume of ~100 μm$^3$

169   (corresponding to 2D crystal intersection lengths $l$ of >5-15 μm), its shape $S{:}I$ is predicted to

170   become constant and reflect its relative growth rates $\delta S{:}\delta I$ (Fig. 2a & b). This is because the

171   crystal volume added during growth is orders of magnitude larger than the proto-crystal

172   volume, such that the initial shape is overprinted. Consistently, using a more tabular starting

173   shape ($S/I$ = 0.75; $S{:}I$ = 1:1.3) does not significantly affect the fit of the model to our

174   experimental data (Fig. 2b). Post-nucleation growth therefore leads to stable crystal shapes

175   that reflect the relative growth rates along crystallographic axes ($S{:}I \approx \delta S{:}\delta I$), and we will

176   refer to such crystal morphologies as *steady-state crystal shapes*. We suggest that euhedral

177   microlites with volumes >100 μm$^3$ generally exhibit such steady-state shapes, unless they are

178   modified by a subsequent process (e.g., resorption and new growth with different $\delta S{:}\delta I$, or

179   post-impingement growth). On the other hand, euhedral crystals with volumes <100 μm$^3$ ($l$

180   <5-15 μm) show transient morphologies tracing their evolution from proto-crystal to steady-

181   state shapes.

182   MELT DIFFUSIVITY AFFECTS EUHEDRAL CRYSTAL GROWTH

183   Our experiments show that plagioclase morphology evolves during growth towards a steady-

184   state crystal shape reflecting relative growth rates, which are different for mafic ($S/I \approx 0.05$;

185   $S{:}I \approx 1{:}20$) and silicic melts ($S/I \approx 0.2$; $S{:}I \approx 1{:}5$). This difference in relative growth rates

186   $\delta S{:}\delta I$ for plagioclase crystallised from mafic and silicic melts may reflect changes in the

187   interfacial reaction rates of the short and intermediate growth directions. For example,

188   temperature (Zanotto & James, 1985, Deubener & Weinberg, 1998; Hammer, 2008), relative

189   crystal and melt compositions (Takei & Shimizu, 2003) and melt water content (Davis et al.,

190   1997; Hammer, 2004; Hammer, 2008; Mollard et al., 2020) can all affect crystal-melt

191   interfacial energies $\sigma$, and may thus affect reaction rates. These parameters all have

192 significantly different values for mafic and silicic systems and may therefore account for

193 differences in total interfacial reaction rates. Importantly, such variations in $\sigma$ would likely be

194 anisotropic in nature, so they could explain differences in $\delta S : \delta I$ between mafic and silicic

195 melts. However, interfacial energies of individual crystal faces of rock-forming minerals are

196 unquantified except for olivine (Wanamaker & Kohlstedt, 1991; Watson et al., 1997; Bruno

197 et al., 2014), precluding a quantitative assessment of the potential magnitude of these factors.

198 On the other hand, melt diffusivities are also strikingly different between the basalt and

199 haplodacite. We used the Eyring equation to calculate the 'network diffusivity' at

200 experimental conditions, which is analogous to the Si and O diffusivities in the melts

201 (Glasstone et al., 1941; Dingwell, 1990). Silicon and oxygen are the slowest diffusing

202 elements of relevance and therefore limit chemical supply to the crystal-melt interface:

$$D_{Eyring} = \frac{k_B T}{\lambda \eta} \qquad (1)$$

203 where $k_B$ is the Boltzmann constant, $T$ is the experimental temperature, $\lambda$ is the diameter of

204 the diffusing element (here set to 0.14 nm for $O^{2-}$; Watkins et al., 2009), and $\eta$ is the melt

205 viscosity at experimental conditions calculated after Giordano et al. (2008). Eyring

206 diffusivities are more than an order of magnitude lower in the hydrous haplodacite (between

207 $4 \cdot 10^{-15}$ and $1 \cdot 10^{-14}$ m$^2$/s) than in the basalt (between $2 \cdot 10^{-13}$ and $5 \cdot 10^{-13}$ m$^2$/s; Tables S2 & S3).

208 Such a large difference in melt diffusivity is likely to have an effect on crystal growth

209 kinetics: the slower melt diffusion rates in the haplodacite could affect the melt composition

210 at the advancing crystal-melt interface and therefore control absolute and relative growth

211 rates. In fact, the two parallel size-shape trends for plagioclase crystallised from basalt and

212 haplodacite (Fig. 1) collapse into a single correlation when normalised to the Eyring

213 diffusivity for each experiment (Fig. 2c). This implies significant diffusion control on

214 euhedral crystal growth. In other words, our experimental dataset offers a unique opportunity

215 to study the *intermediate growth regime*, where diffusion competes with interfacial reaction

216 as the rate-limiting process. In the following, we use a simple model to predict crystal shape

217 as a function of melt diffusion and anisotropic interfacial reaction rates, and we examine our

218 experimental data using the model.

## INTERFACE REACTION V. DIFFUSION: A CRYSTAL GROWTH MODEL

220 In their work exploring effects of anisotropic Ostwald ripening in ceramics, Kitayama et al.

221 (1998) introduced an equation to describe material flux across an interface $i$ controlled by

222 both diffusion in the melt and interfacial reaction:

$$J_i = -\frac{\Delta\mu_i}{k_b TV}\frac{DK_i}{D + K_i\Delta x} \tag{2}$$

223 where $T$ is the temperature, $V$ is the molar volume of the solid, $D$ is the melt diffusion

224 constant, $\Delta x$ is the diffusion length, $K_i$ is the interfacial reaction rate constant (c.f. Lai and

225 Tien, 1993), and $\Delta\mu_i$ is the chemical potential difference between the melt phase and the

226 crystal face $i$. Using the simplified assumption that $\Delta\mu_i$ is identical for all crystal-melt

227 interfaces $i$ (i.e., assuming that $\Delta\mu$ is not surface curvature dependent), we obtain a size-

228 independent model describing relative growth rates of an anisotropic crystal as a function of

229 diffusion and interface reaction rates:

$$\frac{\delta S}{\delta I} = \frac{K_S}{K_I} \cdot \frac{D + K_I\Delta x}{D + K_S\Delta x} \tag{3}$$

230 where $\delta S/\delta I$ describes the relative growth rates of the short ($S$) and intermediate ($I$) growth

231 directions in terms of growth increments $\delta S$ and $\delta I$. $K_S$ and $K_I$ are the interfacial reaction rate

232 constants for $S$ and $I$. A detailed derivation of and rationale for eq. (3) can be found in

233 Supplementary File 1.

234    Firstly, we explore how the competition of melt diffusivity and interfacial reaction affects

235    steady-state shapes using variable $K_S$, $K_I$, $D$ and $\Delta x$ in equation (3) (Fig. 3a & b). Following

236    Kitayama et al. (1998), in order to directly compare melt diffusion $D$ [m$^2$/s] with interface

237    reaction $K_S$ and $K_I$ [m/s], we examine the quantity $D/\Delta x$, which has units of [m/s]. It is clear

238    from Fig. 3a & b that steady-state crystal shapes only show purely interface-controlled

239    morphologies (i.e., $\delta S/\delta I = K_S/K_I$) if melt diffusion is at least ~10x faster than interfacial

240    reaction ($D/\Delta x = 10K$). Significant deviations from purely interface-controlled

241    morphologies are therefore possible even if melt diffusivities are higher than interface

242    reaction rates. Crucially, the point at which diffusion rates and interfacial reaction rates are

243    equal (i.e., $D/\Delta x = K$, yellow curve in Fig. 3a & b) is reached at higher melt diffusivity for

244    growth of the intermediate dimension than for the short dimension, as $K_I$ is larger than $K_S$. In

245    other words, ion supply from the melt to the crystal-melt interface may slow down the

246    advancement of fast growing crystal faces, whilst slower growing interfaces remain

247    unaffected by melt diffusion. This qualitatively explains why lower melt diffusivities lead to

248    crystals with lower aspect ratios (i.e., higher *S/I*). Finally, we point out that diffusion-limited

249    growth *sensu stricto* ($D/\Delta x \ll K$) would theoretically result in isotropic relative growth rates

250    (i.e., $\delta S/\delta I = 1$, Fig. 3a & b). Strictly speaking, the *intermediate growth regime* therefore

251    spans a large range (white area in Fig. 3a & b) and likely characterises most natural crystal

252    growth. For practical use, we suggest a narrower definition of the intermediate growth regime

253    as the case when melt diffusion is slower than interface reaction on some faces of a given

254    crystal, but faster on other interfaces of the same crystal (e.g., $D/\Delta x < K_I$ but $D/\Delta x > K_S$,

255    shown by the yellow area in Fig. 3c & d).

256    Next, we use equation (3) to examine how the competition between diffusion in the melt and

257    interface kinetics might have shaped the steady-state crystal morphologies obtained in our

258    mafic and silicic experiments (Fig. 3c & d). The interfacial reaction constants $K_S$ and $K_I$

259 depend on multiple parameters including the respective crystal-melt interfacial energies (Lai

260 & Tien, 1993), which are unknown for plagioclase, and therefore $K_S$ and $K_I$ cannot be

261 independently constrained. Therefore, we used representative experimental average

262 plagioclase growth rates (c.f. Hammer, 2008) and set $K_I$ to be 20 times higher than $K_S$ ($K_S =$

263 $1 \cdot 10^{-8}$ m/s; $K_I = 2 \cdot 10^{-7}$ m/s), matching the maximum relative growth rates obtained in mafic

264 experiments ($\delta S : \delta I = 1 : 20$, Fig. 2). Diffusivities $D$ were varied between $10^{-11}$ and $10^{-16}$ m$^2$/s

265 to encompass Eyring diffusivities of our basaltic and haplodacitic experimental melts (Tables

266 S2 & S3). The diffusion length can be expressed as $\Delta x = \sqrt{4Dt}$, and we used respective

267 Eyring diffusivities and a diffusion time of $t = 1$ second to estimate diffusion lengths $\Delta x$ of 2

268 μm for basaltic melts and 0.2 μm for silicic melts. Model results are shown in Fig. 3c and d

269 for basaltic and silicic melts, respectively. Steady-state crystal shapes predicted for the

270 respective experimental melt diffusivities are in good agreement with experimental steady-

271 state plagioclase shapes for both mafic (shaded red in Fig. 3c) and silicic melts (shaded blue

272 in Fig. 3d). The model therefore shows that the changes in plagioclase crystal shapes

273 between mafic and silicic melts can be explained by variations in melt diffusivity alone, and

274 variations in interfacial reaction rates are not required. We note, however, that $K_S$ and $K_I$ are

275 *likely* to vary, as there is ample evidence that interfacial energies depend on curvature,

276 temperature and composition (Davis et al., 1997; Deubener & Weinberg, 1998; Takei &

277 Shimizu, 2003; Hammer, 2008; Schmelzer et al., 2018; Mollard et al., 2020). Nonetheless,

278 based on our experimental data and model, we suggest that melt diffusivity plays a more

279 important role in controlling euhedral crystal shapes than previously acknowledged. Lastly,

280 we note that absolute plagioclase growth rates predicted by the model are about one to two

281 orders of magnitude slower for silicic than for mafic melts, consistent with observations of

282 lower plagioclase growth rates in rhyolitic than in andesitic experiments (Shea & Hammer,

283 2013). We therefore hypothesise that the well-documented differences in plagioclase growth

284 rates for different melt compositions may be controlled by melt diffusivities.

285 Finally, we draw attention to the fact that in our experiments on both mafic and silicic melts,

286 plagioclase appears to crystallise predominantly in the intermediate growth regime (i.e.,

287 $D/\Delta x < K_I$ but $D/\Delta x > K_S$, yellow area in Fig. 3c & d). This means that growth of the short

288 crystal dimension $S$ via interfacial reaction is slower than and unaffected by melt diffusion

289 rates, whereas interface kinetics of the intermediate growth dimension $I$ are faster than ion

290 supply rates from the melt to the crystal-melt interface, and diffusion is thus limiting the

291 intermediate growth rate. The result of this slowing down of $\delta I$ relative to $\delta S$ is a decrease in

292 the aspect ratio of steady-state crystals, and it becomes more pronounced as melt diffusivity

293 decreases (shown schematically in Fig. 3d). In addition, as $D$ becomes increasingly rate-

294 limiting, Mullins-Sekerka instabilities (swallowtails) may begin to form on the faster growing

295 interface (Fig. 3d), as commonly seen in natural volcanic rocks and occasionally in our

296 experiments (Fig. 1e).

## IMPLICATIONS FOR THE CRYSTALLISATION OF SILICATE MELTS

298 This study offers new insights into the crystallisation of silicate melts, with important

299 implications for the interpretation of natural and experimental igneous rock textures.

300 1) There is no straightforward quantitative correlation between magma undercooling and

301 crystal shape when nucleation is not exclusively homogeneous. Our experiments show that

302 different crystal shapes (and sizes) form at identical undercoolings if the nucleation density is

303 varied. Therefore, heterogeneous nucleation and pre-existing crystal cargo in natural magmas

304 will also affect crystal sizes and shapes, calling for extreme caution when using crystal

305 textures to constrain undercooling conditions. This is particularly important at low

306 undercoolings, for which heterogeneous nucleation is know to dominate (e.g., Fletcher, 1958;

307 Chernov, 1984; Liu, 2002).

308 2) Small microlites ($l$<5-15 μm) show *transient growth morphologies* evolving from proto-

309 crystal shapes towards aspect ratios reflecting the relative growth rates of their

310 crystallographic axes. Larger euhedral crystals ($l$>5-15 μm) exhibit *steady-state crystal*

311 *shapes*, which reflect the relative growth rates that formed them.

312 3) Euhedral crystals may predominantly grow in an *intermediate growth regime* characterised

313 by the competition between interface reaction rates and melt diffusivities, which control the

314 rate of ion supply to the crystal-melt interface. Specifically, for anisotropic crystals, slower-

315 growing crystal faces may grow uninhibited by melt diffusion kinetics, whereas faster-

316 growing ones may already be limited by diffusion. This effect results in progressively lower

317 aspect ratios as melt diffusivities decrease, and it can explain plagioclase shapes in natural

318 magmas. In mafic melts, relatively high melt diffusivities will produce euhedral plagioclase

319 morphologies approximating interfacial reaction rates. In more evolved silicate melts (e.g.,

320 dacite), melt diffusivities are lower and limit the growth rates of the fastest-growing crystal

321 facets, thereby reducing the aspect ratios of steady-state shapes – without necessarily

322 producing any of the classical diffusion-limited growth textures. Conversely, for a given melt

323 diffusivity, higher absolute interface reaction rates (even if the ratio $K_S/K_I$ remains constant)

324 will result in an earlier onset of diffusion-moderated growth and therefore lower aspect ratio

325 (higher $S/I$) crystals. The general model proposed here of diffusion-moderated crystal growth

326 in an intermediate growth regime likely also applies to other anisotropic mineral phases (e.g.,

327 clinopyroxene and olivine).

328 4) Relative growth rates for plagioclase presented here describe post-nucleation growth

329 outside the diffusion-controlled regime. The resulting steady-state crystal shapes are the first

330 iteration of a crystal's morphology during its lifetime: our experiments chart plagioclase

331 shape evolution during the initial two hours for basaltic melts (142 min, Table 1), and three

332 weeks for silicic melts. Upon longer storage and textural maturation in magmatic systems,

333 further modifications to crystal shapes are to be expected, such as heterogeneous nucleation

334 on existing grains, post-impingement growth (Holness, 2014), crystal agglomeration (Pupier

335 et al., 2008), or resorption. Hence, in order to better understand crystal shape and its

336 petrological significance in volcanic rocks, more work is required to constrain textural

337 maturation mechanisms and their timescales.

## FIGURE CAPTIONS

**Fig. 1.** *Results of plagioclase crystallisation experiments. Crystal shape, expressed as the ratio of 3D short axis/intermediate axis (S/I ± 1SD) becomes more tabular with increasing crystal volume, represented by the ratio of plagioclase number density $N_V$ and crystallinity $\varphi$. Each datapoint reflects a single experiment, with the exception of 21-CSA-01 and 21-CSB-12, which are represented with two datapoints each to reflect their significant textural heterogeneity (Fig. S2). The range of plagioclase sizes and shapes is exemplified in (**a**)-(**c**) for basaltic experiments and in (**d**)-(**f**) for haplodacitic experiments. Note that plagioclase appears darker than the melt in basalt but slightly lighter in haplodacite due to the difference in melt compositions. Other minerals include Fe-Ti-oxides (bright crystals in (a) and (b)) and amphibole (bright crystals in (f)).*

**Fig. 2.** (**a**) and (**b**) *Models of crystal shape evolution with increasing volume for a range of growth rates $\delta S : \delta I$ for 3D relative short (S) and intermediate (I) dimensions ($\delta S : \delta I = 1:20 - 1:1.5$). Starting point of the growth models is a crystal with a volume of 0.1 $\mu m^3$ and a 3D start shape of (**a**) S/I = 1 and (**b**) S/I = 0.75. Relative growth rates for plagioclase grown from basaltic melt vary between $\delta S : \delta I = 1:6 - 1:20$, whereas those for plagioclase crystallised from haplodacitic melt range from $\delta S : \delta I = 1:2.5 - 1:8$. Note that shapes of crystals $> 100 \ \mu m^3$ reflect relative growth rates ("steady-state crystal shapes"), and that variations of start shape do not significantly change outcomes. (**c**) The offset between the size-shape relationships of basaltic and haplodacitic experiments is removed by dividing the crystal volume factor $\frac{N_V}{\varphi}$ by Eyring diffusivities of the melt. This suggests a kinetic control on euhedral crystal shapes. See text for discussion.*

**Fig. 3** *Anisotropic growth modelling using equation (3). (**a**) and (**b**) Effect of melt diffusivities $D/\Delta x$ on resulting steady-state crystal shapes $\delta S / \delta I$ for a given interfacial reaction rate ratio*

527  $K_S/K_I$. (**a**) melt diffusivity relative to interface kinetics $K_I$ of the intermediate growth

528  dimension; (**b**) melt diffusivity relative to interface kinetics $K_S$ of the short growth dimension.

529  If diffusion is much faster than interfacial reaction ($D/\Delta x > 10K$), resulting steady-state

530  crystal shapes approximate aspect ratios $\delta S/\delta I$ approaching $K_S/K_I$ (dashed 1:1 line).

531  Diffusion begins to affect crystal shapes even when $D/\Delta x > K$, and the point at which $D/\Delta x =$

532  $K$ (orange curves) is reached earlier for the faster reacting intermediate growth direction

533  than for the slower reacting short direction. Hence, growth of the intermediate crystal

534  dimension is slowed down more significantly by melt diffusivity than growth of the short

535  crystal dimension, resulting in increasing $\delta S/\delta I$ (i.e., lower aspect ratios) with decreasing

536  diffusivity at a given $K_S/K_I$. Crystal shapes approach aspect ratios of 1 if melt diffusivity is

537  much slower than interface kinetics ($D/\Delta x < 0.01K$), consistent with a completely diffusion-

538  controlled growth regime (dashed vertical line). (**c**) and (**d**) Effect of varying melt diffusivity

539  at fixed interfacial reaction constants $K_S$:$K_I$=1:20 ($K_S = 1\cdot10^{-8}$ m/s; $K_I = 2\cdot10^{-7}$ m/s) on

540  steady-state crystal shape. Experimental melt diffusivities and steady-state plagioclase

541  shapes are reproduced for (**a**) mafic experiments (red) at a diffusion length $\Delta x$ of 2 μm and

542  (**b**) silicic experiments (blue) at a diffusion length $\Delta x$ of 0.2 μm. The yellow shaded area

543  designates the intermediate growth regime in which melt diffusion is slower than interface

544  kinetics of the intermediate growth direction but faster than interface kinetics of the slow

545  growth direction. Resulting crystal morphologies with decreasing melt diffusivity are shown

546  schematically to the right of panel d.
