Abstract

Objectives The aim of this cross-sectional study was to provide estimate of mid-buccal gingival recession (GR) according to the 2018 World Workshop Classification System and to explore GR risk indicators in a representative urban population in North-West of Italy.

Material and methods This is a secondary analysis using data collected in an epidemiological study enrolling a representative sample of 736 adults, living in Turin. GR prevalence was defined as the presence of at least one mid-buccal GR ≥ 1 mm. GRs were categorized according to the 2018 classification system (RT1, RT2, RT3) and to different severity cutoffs. Logistic regression analysis was performed to identify RT GR risk indicators.

Results Mid-buccal GR ≥ 1 mm affected 57.20% of subjects and 14.56% of teeth. When considering RT1 GRs, their prevalence was 40.90% and 6.29% at the patient and tooth level. RT2 and RT3 GRs affected 25.82% and 36.68% of the study population, respectively. RT1 GRs occurred mostly on maxillary and mandibular premolars and maxillary canines, while RT2 and RT3 GRs on maxillary molars and mandibular incisors. Older age, high education, and full-mouth plaque score (FMPS) $< 30\%$ were risk indicators for RT1 GRs, while older age, poor education, periodontitis, and FMPS $> 60\%$ were significant contributors to RT2 and RT3 GRs.

Conclusions RT1 and RT3 are fairly common findings in this Italian population and are significantly associated to different contributing factors and tooth type distribution pattern.

Clinical relevance Prevention strategies should target different socio-demographic, behavioral, and clinical risk indicators based on the RT classes.

Keywords Epidemiology · Gingival recession · Periodontitis · Prevalence · Risk indicators

Introduction

Gingival recession (GR) is defined as the exposure of the root surface due to the displacement of soft tissue margin beyond the cemento-enamel junction (CEJ) associated to clinical attachment loss [1]. GRs may be localized or generalized and can involve one or more surfaces. There are several potential factors that can lead to the apical shift of the gingival margin such as tooth malposition, thin scalloped phenotype, mechanical trauma, and plaque-induced inflammation [2]. Mid-buccal GR has received great attention in the scientific literature due to its negative impact on aesthetics and function but also due to the increased occurrence of carious and non-carious cervical and/or root lesions [3–5]. Indeed, periodontal plastic surgery procedures are applied

³ Section of Graduate Periodontology, Faculty of Odontology, University Complutense, Madrid, Spain

to overcome these consequences by achieving complete root coverage [6–8].

The presence of GR at buccal sites has been reported as highly prevalent in a recent systematic review [9]. However, large variation exists across different countries. The prevalence of adult subjects presenting at least one GR \geq 1 mm deep was 58% in the USA [10], 60.3% in Greece [11], 69.7% in Colombia [12], but higher in France (84.9%) [13] and Pomerania, a province in Eastern Germany (89.7%) [14], and included basically the whole sample in an urban area in Brazil (99.7%) [15]. For deeper GR in the 4–5-mm range, prevalence varied between 5.9 and 40.7% depending on the population surveyed [13, 15]. All these studies classified GR in terms of its vertical extension from the CEJ in millimeters using different severity thresholds.

Only one recent study [16] reported the prevalence of GR in the adult US population according to the 2018 World Workshop Classification System [1]. It distinguished among three GR types with reference to the amount of the interdental clinical attachment loss, as proposed by Cairo et al. in 2011 [17]:

- Recession type 1 (RT1) with no interproximal attachment loss;
- Recession type 2 (RT2) with the amount of attachment loss at interproximal sites being less or equal than that measured at the buccal site;
- Recession type 3 (RT3) with the amount of attachment loss at interproximal sites exceeding that at the buccal site.

Applying this classification to the NAHNES database, the estimated prevalence of RT1 recessions was 12.4%, which increased to 88.8% and 55.0% when considering RT2 and RT3 recessions, respectively [16].

Representative information about the occurrence and risk factors of GR according to the 2018 World Workshop Classification is lacking in Europe. Hence, the aims of this cross-sectional study were (1) to provide estimates of the prevalence of mid-buccal GR at the subject and tooth level considering both different severity cutoff values and the RT classification in a representative urban population in North-West Italy, and (2) to assess the association of potential risk indicators with the occurrence of GR in this population.

Materials and methods

Study design and population

This is a secondary analysis using existent data from a cross-sectional population-based epidemiological survey for periodontitis collected between December 1, 2009, and

July 31, 2010, by the Section of Periodontology, C.I.R. Dental School, Department of Surgical Sciences, University of Turin (Italy) [18]. The Institutional Ethics Committee approved the study protocol (Approval No. 0082388), and subjects who agreed to participate signed an informed consent form in accordance with the Declaration of Helsinki.

All adults aged more than 18 years with main residency in Turin, one of the largest cities in North-West of Italy, were eligible for participation. The sample size for the original study was estimated assuming a 15% prevalence of severe periodontitis [19], a confidence level of 95%, and a precision of 2.5%. Considering a response rate of 50%, 1600 individuals were randomly selected and invited to participate. This representative sample of the target population was obtained by applying a stratified two-stage probability strategy to the Health Regional Register of Piedmont. In the first stage, primary sampling units were general practitioners randomly selected after stratification into the four health care districts of Turin. The second stage consisted on a random selection of subjects cared for by each practitioner. The sampling method and sample size calculation are described in details in a previous publication [18].

The flow chart of the study is summarized in Appendix Figure 1. The net random sample comprised 736 dentate individuals, aged between 20 and 75 years.

Clinical examination

Patients enrolled into the study completed a self-administered questionnaire to collect information on socio-demographics, lifestyle factors (including educational level and smoking habit), and oral hygiene practices. Following completion, they were provided with a clinical examination that assessed their periodontal conditions. For consistency and to avoid inter-examiner variability, a single trained dental investigator performed all clinical examinations. Intra- and inter-examiner reliability for GR were assessed before the initiation of the study on 15 patients (387 teeth, 1161 buccal sites, 93 mid-buccal recession defects) at the medical office of a general practitioner not involved with the survey. Measurement of GR was performed twice with an interval of 24 h between the first and the second recording. Intra-examiner reliability revealed weighed (\pm 1 mm) *k* values of 0.96, and the inter-examiner agreement against a gold standard clinician was 0.87.

All fully erupted teeth, excluding third molars, were examined at six sites using a manual periodontal probe (PCPUNC15, Hu-Friedy®, Chicago, IL, USA). GR was defined as the distance from the CEJ to the free gingival margin (FGM), and probing depth (PD) represented the distance from FGM to the bottom of the sulcus/pocket. GR was scored as 0 if the FGM was located at the CEJ and was

assigned a negative sign if the FGM was coronal to the CEJ. In sites where the CEJ was not detectable, the CEJ level was estimated on the basis of the adjacent teeth [20].

Clinical attachment level (CAL) was derived for each examined site by the sum of GR and PD. Measurements were rounded to the lower whole millimeter. Furthermore, the percentages of sites harboring plaque (full-mouth plaque score (FMPS)) or bleeding on probing (full-mouth bleeding score (FMBS)) were recorded. No radiographic examination was made.

Periodontal status was established using the case definitions developed jointly by the US Centres for Disease Control and Prevention (CDC) and the American Academy of Periodontology (AAP) to describe the prevalence of moderate and severe periodontitis in health surveys [21, 22]. The classification of no/mild periodontitis was assigned to cases that did not qualify as having moderate or severe periodontitis.

Outcome definition

For the purpose of the study, only GRs at the mid-buccal sites were included in the analysis. Mid-buccal GRs were both categorized as ≥ 1 mm, ≥ 3 mm, ≥ 5 mm, and ≥ 7 mm according to their severity and as RT1, RT2, or RT3 using algorithms based on the operational definitions by Cairo et al. [17]. Furthermore, the following covariates were considered to define subpopulations and for the analytical epidemiological analysis:

- Subject level: age (categorized in three groups: 20–39 years, 40–59 years, 60–75 years), gender, educational level (categorized in three levels based on the Italian school system: low or primary and secondary school level, intermediate or high school diploma, high or education attainment beyond the high school level), periodontal status (no/mild periodontitis, moderate, severe periodontitis) [21, 22], smoking status (categorized in three levels: heavy smoker (≥ 10 cigarettes/day), light smoker (< 10 cigarettes/day), non-smoker) [23], FMPS (categorized in three levels: $< 30\%$, 30 to 60%, $> 60\%$ using an approximation of the subject distribution into tertiles and considering a percentage of sites harboring plaque $< 30\%$ as a tolerable level of oral hygiene among the general population) [24, 25], FMBS (categorized in three levels: $< 10\%$, 10 to 30%, $> 30\%$ according to the cutoff points for localized and generalized gingival inflammation) [26], self-reported toothbrushing frequency (categorized in 3 levels: not every day or once/day, twice/day, three or more times/day) [15], and professional scaling frequency (categorized in 2 levels: 12 months or less, more than 12 months) [16];

- Tooth level: tooth type (incisor, canine, premolar, molar), arch (maxilla, mandible), and mouth side (right, left).

Statistical analysis

At subject level, the prevalence of GR was defined as the percentage of the population presenting at least one tooth with GR equal or higher than different depth thresholds (1, 3, 5, and 7 mm) or at least one mid-buccal site with RT1, RT2, or RT3 recession. Extent was classified as localized or generalized if GR ≥ 1 mm involved $< 15\%$ or $\geq 15\%$ of teeth, respectively [16].

At tooth level, the prevalence of mid-buccal GR was calculated based on different vertical cutoff values and RT classes considering all teeth and then categorized by tooth type, arch, and side [27, 28]. Complex survey commands were used in all analyses to account for cluster correlations expected for the multistage sampling strategy used in the study.

A multiple multinomial logistic regression analysis was designed to assess the contribution of the independent variables to the probability of occurrence of RT1 or RT2/RT3 recessions in at least one tooth. Individuals without GR ≥ 1 mm were used as the reference group. Univariable models were fitted for each independent variable and those presenting P values < 0.25 were entered in the multivariable regression model. A backward selection procedure with a P value cutoff at 0.05 was used to identify the set of independent predictors. Using this approach, age, educational level, smoking habit, periodontal status, and FMPS remained in the final model. Due to the collinearity between FMPS and FMBS, only FMPS was maintained. Odds ratios (OR) were calculated with 95% CI. Data analysis was performed using SAS (version 9.4, SAS Institute) and SPSS (version 25, IBM) package.

Results

Prevalence and severity of mid-buccal gingival recessions

As summarized in Table 1, the presence of mid-buccal GR ≥ 1 mm was detected in more than half of the study population with 57.20% of subjects having at least one site affected and 33.56% having multiple recessions. Additionally, 42.12%, 8.83%, and 1.77% of the individuals presented at least one mid-buccal site with GR ≥ 3 mm, ≥ 5 mm, and ≥ 7 mm, respectively. The prevalence of GR increased with aging: in the age range 20–39, it was 34.18% and in the age group 60–75, it reached above 70%. It was also higher in heavy smokers, males, and individuals with severe periodontitis, mainly for higher thresholds of GR. Poor oral hygiene was

GR, gingival recession; SE, standard error

associated to both GR severity and extent, whereas gingival inflammation only to severity.

The prevalence of GRs according to the types defined in the 2018 Classification System is reported in Table 2. RT1 and RT3 classes showed similar prevalence in the population (40.90% versus 36.68%), while RT2 was less frequently detected (25.82%). In particular, RT2 and RT3 recessions were more often found among individuals suffering from severe periodontitis, with low education and heavy smokers. Furthermore, they were more prevalent among those with higher percentage of plaque (FMPS > 30%) and generalized gingival inflammation

(FMBS > 30%). When considering the distribution of interdental sulci/pockets in relation to PD severity and RT classes, PDs ≤ 3 mm were more frequently associated with RT2 than RT3 recessions (57% versus 39%), and moderate pockets of 4–5 mm were equally distributed (38% versus 37%), while severe pockets ≥ 6 mm deep were proportionately less prevalent at the interproximal sites of RT2 defects (5% versus 24%).

As depicted in Figure 1, only a minority of the subjects had exclusively one RT class of recession (14.9% RT1, 3.1% RT2, and 6.7% RT3), whereas the majority had a combination of them.

GR, gingival recession; RT, recession type classification; SE, standard error

Fig. 1 Distribution of RT classes of recession and their combination at the subject level

Prevalence and severity of mid-buccal gingival recessions by tooth type

A total of 17,433 teeth were examined for the presence of GRs. Table 3 shows that 14.56% of them had the buccal surface affected by GR ≥ 1 mm and 6.79% by GR ≥ 3 mm, most of them being RT1 (prevalence of RT1: 6.29%). Recession thresholds ≥ 5 mm and ≥ 7 mm affected only a small percentage of the teeth. Higher frequency of GRs was found on the right side of the upper and lower jaw.

The distribution of GRs varied according to the type of teeth. Mandibular incisors, premolars, and maxillary molars presented the highest frequencies of GR ≥ 1 mm and ≥ 3 mm. Maxillary incisors and mandibular molars had the lowest prevalence of GR.

Among teeth with RT1, the most commonly affected were the mandibular premolars followed by the maxillary canines and premolars. Teeth showing the highest percentage of RT2 and RT3 recessions were the maxillary molars and the mandibular incisors. Figure 2 supports the greater involvement of the right side of the jaw with the maxillary first molar,

GR, gingival recession

Fig. 2 Prevalence of RT recessions according to tooth types

the mandibular first and second premolars, and the maxillary first premolar being the most predisposed teeth.

Factors associated with mid-buccal RT gingival recessions

In the multiple logistic regression analysis (Table 4), younger age and low educational level were significantly associated with lower chance of RT1 recessions at mid-buccal sites. Conversely, better performance in oral hygiene was significantly associated with the presence of RT1 recessions.

When considering RT2 and RT3 recessions, low and intermediate educational levels and suffering from severe periodontitis were significant risk indicators, while younger age and FMPS percentages < 30% had a protective effect. Self-reported frequency of toothbrushing, professional

scaling frequency, and smoking habits were not significantly associated with the presence of GR.

Discussion

This is the first epidemiological study focusing on mid-buccal GR in a representative sample of an adult Italian population according to both severity thresholds and RT classification system. GR ≥ 1 mm affected 57.20% of this population with 35% of them suffering from multiple GRs. In most cases, GR was between 1 and 4 mm of severity (46.6%). The prevalence of GR ≥ 1 mm, ≥ 3 mm, and ≥ 5 mm increased through the age groups, whereas this age-dependent distribution was less pronounced when considering GR ≥ 7 mm.

Table 4 Multiple multinomial regression models of factors associated with the presence of mid-buccal RT1 or mid-buccal RT2/RT3 gingival recessions in at least one tooth (adjusted for gender)

GR, gingival recession; OR, odds ratio; 95% IC, 95% confidence interval; ref, reference

GR frequencies documented in the literature are largely heterogeneous with percentages ranging from 25% of regular dental clinic attendants in Sweden [24] to 99.7% of adults over 35 years in Brazil [15] and 100% of subjects aged from 18 to 35 years in the UK [29]. In line with the present data, the prevalence of buccal GR was estimated to be 57.9% for persons over 30 years of age in the NHANES III US survey [10], and 68.7% among Colombian adults between 18 and 75 years of age [12]. Data from Italy reported prevalence ranging between 39 and 64% among undergraduate dental students [30–32].

Although these differences may be in part attributed to methodological issues (partial recording protocols, convenience samples), it is reasonable to infer that they may be also explained by different age ranges of the cohorts, periodontal profile, possible ethnic/genetic determinants, oral hygiene habits, and exposure to risk factors.

The current data showed that RT1 recession affected 41% of the study population, while RT2 and RT3 recessions were found to be less prevalent with a frequency of 25.8% and 36.7%, respectively. Noteworthy, this is the second study using the RT system introduced by Cairo et al. [17]. In a

recent national population-based survey, Romandini et al. [16] reported lower estimates of RT1 (12.4%), but higher frequency for RT2 and RT3 recessions (88.8% and 55.0%) among adults of 30 years and older living in the USA. This different pattern of recession between the two surveys may be related to the characteristics of the participants. Our cohort was less large, younger in age, composed of only Caucasians with lower educational status than the US sampled population. Furthermore, it was representative of citizens living in an urban industrialized area from North-West Italy. Previous evidence supported a different distribution of GR by geographic area with people living in rural areas displaying significantly greater maximum recession scores [29].

The prevalence of mid-buccal GR demonstrated great differences according to the type of teeth. In line with findings from previously published reports [10, 12, 15, 33], the most affected teeth were mandibular incisors, mandibular premolars, and maxillary molars, while the least affected ones were the maxillary incisors. In contrast, Sarfati et al. [13] did not find any specific distribution pattern for GR according to tooth types and Serino et al. [24] referred to incisors and canines as the most affected teeth in young subjects, and to premolars in older ones.

Interestingly, RT1 recession occurred mostly at the buccal surface of maxillary and mandibular premolars and maxillary canines, while RT2 and RT3 recessions on maxillary molars and mandibular incisors. This is supported by data from epidemiological studies indicating that posterior sites are more prone to periodontal disease and that interdental sites at incisor and molar teeth experience more severe attachment loss in periodontitis patients [34]. However, Romandini et al. [16] observed that RT1 recession was more prevalent on maxillary and mandibular incisors, and that RT2 and RT3 recessions were evenly distributed among the dentition with a slight predilection for mandibular premolars and molars.

With respect to the symmetry along the dental midline, we detected a higher prevalence of gingival recessions on the right side and Addy et al. [35] on the left side, while Romandini et al. [16] and Sarfati et al. [13] reported a quite symmetric distribution. Although this study lacks information on toothbrushing techniques and hand preference, Tezel et al. [36] reported that right-handed subjects had more GRs in the premolar and canine region of the upper and lower right jaws.

Multivariable logistic regression analysis was carried out to identify risk indicators for RT1 recession and for RT2 and RT3 recessions, which were pooled together because both were associated with interdental attachment loss. Older age, lower percentage of plaque, and high education were found to be significant risk indicators of RT1 recession, while older age, severe periodontitis, low education, and poor oral

hygiene were associated with RT2 and RT3 recessions. It has been previously demonstrated that age is one of the main contributors for the development of buccal recessions [10, 13, 14, 16, 33] and the present findings provide additional evidence. This could be reflective of the cumulative periodontal tissue loss and exposure to environmental risk factors across the lifespan, although it cannot be ruled out that the aging process leading to low-grade systemic inflammation and immune senescence could contribute to the development and progression of periodontal tissue damage [37, 38].

It is noteworthy that percentages of FMPS > 60% were significantly associated with higher odds of buccal RT2 or RT3 recessions, while percentages < 30% with higher odds of buccal RT1 recessions. These results support the speculation of Løe et al. [39], which refers to two possible types of GR associated with good and poor oral hygiene practices. Although clinical evidences indicate a positive correlation between buccal GRs, high standards of home oral hygiene and traumatic toothbrushing [30, 33, 40, 41] in the present study data on toothbrushing methods and brush hardness were not available.

In line with previous epidemiological studies [12, 15], there was an association between educational level and recessions. This finding may be explained by the fact that educated individuals are more aware of the importance of proper home plaque control and regular dental office attendance to maintain oral health conditions than their less-educated counterparts. Consistently, they are more prone to develop RT1 recessions, in contrast to moderately and lowly educated people who are more likely to experience RT2 or RT3 recessions.

Finally, considering that the RT classification system [17] refers to the loss of interproximal periodontal support, it is reasonable to consider RT2 and RT3 as a related phenomenon to advanced forms of periodontitis. Serino et al. [24] found that interdental attachment loss was associated with GR at the buccal surface and Yoneyama et al. [42] suggested that GR is the major feature of the progression of destructive periodontal disease with age. Indeed, this study suggests that the risk indicators for RT2 and RT3 recessions are similar to those traditionally associated to severe periodontitis [18]. We used the CDC/AAP periodontitis case definition, which was recommended in population-based epidemiological surveys [43]. Severe periodontitis was defined by the presence of both pathologic periodontal pockets and clinical attachment loss on interdental tooth surfaces [21, 22], allowing discrimination between periodontal atrophy and destructive periodontal disease [44].

The present study, although being the first survey using the RT classification in Europe, has some limitations. As this research was a secondary data analysis, the sample

size was not calculated specifically to estimate GR prevalence. In addition, it was not possible to evaluate some variables inherent to oral hygiene methods and oral habits. Furthermore, neither the frequency of unidentifiable CEJ nor the different lesion morphologies of hard dental tissue in the cervical area were recorded [45]. In sites where CEJ was undetectable, we used the level of the CEJ on the adjacent teeth as reference [20]. Thus, we cannot rule out that the prevalence of shallow GRs (≤ 2 mm) could be underestimated. Lastly, this study is based on a representative sample of an industrialized city in North Italy; thus, findings cannot be generalized to other populations, and its cross-sectional design does not allow any conclusion regarding the temporality of the associations.

In conclusion, buccal GR is a fairly common finding in this Italian population and it is significantly associated to different contributing factors and tooth type distribution pattern according to the RT recession classes. This information can guide to identifying individual risk factor profiles and to implementing practical management and personalized prevention strategies for both clinical and surveillance purposes.
