ABSTRACT

**THE EVALUATION OF CARBON BENEFITS PRODUCED BY URBAN
STREET TREES**

**by
Hanyu Wang**

Urban tree service and urban forestry are important fields that focus on the care and management of trees in urban areas. Urban trees provide numerous benefits around all aspect, including carbon storage, improving air and water qualities. Carbon storage refers to the process of removing carbon dioxide (CO₂) from the atmosphere and storing it in various reservoirs, and in this case, in trees and forests.

i-Tree is a suite of software tools developed by the United States Forest Service that provides a range of resources for assessing and managing forests. i-Tree Eco is one of the more used tools from iTree suite. It is mainly used for assessing the structure and function of urban forests. In this project, i-Tree Eco is used to process data samples collected from the campus of New Jersey Institute of Technology (NJIT). iTree-Eco provides estimated calculations on multiple aspects. The evaluation will be more focused on the carbon sequestration and carbon storage of each species.

The overall objective of this thesis is to evaluate the current and potential carbon benefits produced by the trees of the NJIT campus, as a model of a typical urban campus. There are two sub objectives. One is to analyze the i-Tree package with provided documentation, trying to replicate some of the outputs using new written functions. Second is to analyze the reports generated by i-Tree Eco to making environmental plans.

BIOGRAPHICAL SKETCH

Author: Hanyu Wang
Degree: Master of Science
Date: May 2023

Undergraduate and Graduate Education:

- Master of Science in Biological Science,
New Jersey Institute of Technology, Newark, NJ, 2023
- Bachelor of Science in Biological Science,
University of Connecticut, Storrs, CT, 2020

Major: Biological Science

DEDICATION

I dedicate this thesis to my parents, who have been supportive all my life. I would never have made this far if it wasn't for them.

I also dedicate this work to all the people who have helped me over the years; professors, colleagues, friends, and even those cute animals on campus.

Thank you all for your love and support.

ACKNOWLEDGMENT

To start with, I would like to express my deepest gratitude to my thesis advisor, Dr. Gareth Russell, who's been extremely supportive through the years.

Also, I would like to thank the committee members Dr. Daniel Bunker, and Dr. Xiaonan Tai. Dr. Bunker also leads our Urban Ecology Lab group; he's helped me a lot through the year. Dr. Tai also have taught me in the GIS course, and I'm certain that the skills I acquired from the class will come in handy in my future career.

I would also like to thank all the other members in the Urban Ecology Lab: Dr, Maria Stanko, Dr. Caroline DeVan, and the other student members who have been in any sorts of help to me and to the UEL group.

Last but never the least, I will forever thank my parents for being supportive all my life.

CHAPTER 1

INTRODUCTION

1.1 Urban Forestry

Urban tree service and urban forestry are important fields that focus on the care and management of trees in urban areas. With increasing urbanization around the world, the importance of preserving and enhancing the green infrastructure in cities has become more prominent. Urban trees provide numerous benefits to the environment, including improving air and water quality, reducing the urban heat island effect, mitigating the impacts of climate change, and supporting biodiversity (Goddard et al., 2010; McPherson et al., 2013).

Urban tree service involves the maintenance and care of trees in urban areas, such as pruning, planting, and removal. This service is typically provided by certified arborists who have specialized training and experience in the care and maintenance of trees (ISA, 2021). The main aim of urban tree service is to protect urban trees at first while also enhancing their economic value and the benefits they produce to the environment and human society.

Urban forestry is a broader field that encompasses the management of urban trees and forests as a whole. This includes not only the care and maintenance of individual trees, but also the planning and implementation of urban forest programs and policies.

Urban forestry aims to create sustainable, healthy, and resilient urban forests that can provide long-term benefits to the community, the environment, and the economy (Nowak and Greenfield, 2018).

Overall, urban tree service and urban forestry play a crucial role in maintaining and enhancing the urban environment. Through careful planning, management, and care of urban trees and forests, we can create more livable and sustainable cities that benefit both people and the planet.

1.2 Carbon Storage

Carbon storage refers to the process of removing carbon dioxide (CO₂) from the atmosphere and storing it in various reservoirs, such as forests, oceans, soil, and rocks. Trees are one of the most effective natural systems for carbon storage, as they absorb CO₂ during photosynthesis and store it in their biomass and in the soil.

A mature tree can store a significant amount of carbon, with estimates varying depending on the species and other factors. On average, a mature tree can store between 100 and 1000 kilograms of carbon (IPCC, 2019). Trees also provide a range of other benefits, such as regulating water cycles, providing habitat for wildlife, and supporting human well-being (FAO, 2020).

The overall contribution of trees to global carbon sequestration is significant, but difficult to estimate precisely. According to the Intergovernmental Panel on Climate

Change (IPCC), forests and other vegetation currently absorb about 30% of anthropogenic CO₂ emissions (IPCC, 2019). This makes them one of the largest carbon sinks on Earth, along with the ocean and soil.

However, the contribution of trees to global carbon sequestration is also threatened by deforestation and other land-use changes. Deforestation has been estimated to contribute between 10-15% of total greenhouse gas emissions (IPCC, 2019). Conversely, reforestation and afforestation (planting trees in areas where there were no trees before) can help to sequester carbon and mitigate climate change. One study estimated that global reforestation could sequester up to 205 gigatons of carbon over the next century (Bastin et al., 2019).

In terms of urban trees, estimates suggest that about 8% of the world's tree cover is located in urban areas (Nowak et al., 2018). In the United States, urban trees comprise about 5% of the country's tree cover (Nowak et al., 2019). While urban trees may not sequester as much carbon as forests, they also provide a range of important ecosystem services, such as air pollution reduction, stormwater management, and urban heat island mitigation.

1.3 i-Tree

i-Tree is a suite of software tools developed by the United States Forest Service that provides a range of resources for assessing and managing forests.

One of the most widely used i-Tree modules is i-Tree Eco, which is a tool for assessing the structure and function of inventoried forests. i-Tree Eco uses field data to estimate the amount of carbon sequestered by trees, air pollution removal, and other ecosystem services (Nowak et al., 2008). It also addresses services unique to urban trees, such as reduction in the heat island effect and the savings in building cooling costs that come from the shade thrown by nearby trees.

i-Tree eco only *requires* two inputs: a tree's species identity and its diameter at breast height (dbh), although users can add optional additional information such as crown height, tree condition, or sun exposure. The outputs that are specifically used in this thesis are the composition and structure summary including leaf biomass, and the carbon benefits summary including carbon storage and sequestration and air pollution removal.

1.4 Objectives

The overall objective of this thesis is to evaluate the current and potential carbon benefits produced by the trees of the NJIT campus, as a model of a typical urban campus. A total of 254 trees were used for analysis, comprising almost all the trees within the perimeter of the main campus. Within this overall objective, there are two sub-objectives. One is to examine the i-Tree package by attempting to replicate some of its outputs using independent code based on the provided documentation, e.g., Understanding i-Tree:

2021 Summary of Programs and Methods (Nowak, 2021). The second objective is to use the reports generated by i-Tree Eco to quantify the carbon services provided by the current campus tree community, and to use these to make suggestions for campus management and planning going forward.

CHAPTER 2

UNPACKING THE I-TREE ‘BLACK BOX’

2.1 i-Tree Suite

i-Tree is a suite of software tools developed by the United States Forest Service that provides a range of resources for assessing and managing forests. Urban forests are an important component of cities, providing a range of ecosystem services, including air pollution reduction, temperature moderation, and carbon storage (Nowak et al., 2010). However, urban forests face a range of challenges, including fragmentation, pollution, and climate change, which can impact their structure and function (McDonald et al., 2021). The i-Tree suite is designed to help urban forestry professionals and city planners to understand and manage urban forests more effectively.

One of the more commonly used modules among i-Tree suite is i-Tree Eco. It can be used to generate reports that provide information on the value of urban forests in terms of ecosystem services, which can be used to inform policy decisions and management plans.

i-Tree Eco can perform analysis based on either complete inventory or plot samples. The software combines user input of a tree inventory with built-in databases of tree species information, as well as local weather data and pollution levels, to estimate several anatomical and physiological properties of the trees themselves (such as total biomass, growth rate, etc.), and consequently the ecosystem services provided by those

trees. These services are also converted to dollar values, which can be used to inform policy decisions and management plans.

i-Tree Eco can also be used to inform a range of management decisions related to urban forests by running ‘what if’ scenarios. For example, the tool can be used to estimate the carbon sequestration potential of alternative tree species or locations, which can be used to inform decisions about where to plant new trees or which trees to retain during development. It can also be used to estimate the impact of tree removal or pruning on ecosystem services.

2.2 The i-Tree Process

The first objective is to examine the i-Tree calculations by attempting to replicate its interior calculations using the information from the publication provided by i-Tree website, *Understanding i-Tree: 2021 Summary of Programs and Methods* (Nowak, 2021), and references therein. As this is the official reference, it ought to be possible. As i-Tree can perform its calculations using inputs of just species name and dbh, we start with that. Our starting goal was to replicate each stage of the calculations up to the final estimates of carbon storage and sequestration. (We did not try any of the economic conversions.)

Tree biomass is in direct relationship to carbon storage. In general, the more biomass a tree has, the more carbon it will store (wood dry biomass is approximately 50%

carbon, but see below). The i-Tree documentation mentions two biomasses being used for the calculation of carbon storage, tree biomass and leaf biomass.

Tree biomass means the total tree dry weight biomass. Dry weight biomass is a measure of the weight of organic matter in a tree after all water has been removed, and it is closely related to the amount of carbon stored in the tree. The amount of carbon stored in a tree can be estimated by multiplying the dry weight biomass of the tree by a carbon fraction, which is the proportion of carbon in the dry weight biomass. The carbon fraction varies depending on the tree species, but typically ranges from 0.45 to 0.5 (Nowak et al., 2010). The documentation provides allometric equations for the calculation of dry weight biomass for each of a number of species, based on its measured dbh (Appendix A).

Leaf biomass means the total weight of dry leaves. It is calculated from leaf area estimates using species-specific conversion factors (Appendix B). To get the leaf biomass, we just multiply the leaf area by the species-specific conversion constant. Before that, we do need to use other equations in order to get the leaf area first.

Leaf area is defined as the total surface area of leaves on a tree. Leaf area of individual open-grown (high crown light exposure), deciduous trees is calculated using a regression equation (Nowak, 2021):

$$\ln Y = -4.3309 + 0.2942H + 0.7312D + 5.7217S + -0.0148C$$

Where Y is leaf area (m²),

H is crown height (m),

D is average crown diameter (m),

S is the average shading factor for the individual species, and

C is based on the outer surface area of the tree crown ($\pi D (H + D) / 2$).

Therefore, in order to calculate the leaf area (Y), we need to estimate the crown height (H), crown width (D), shading factor (S), and ground surface area (C), which is based on crown width (D). In this case, the shading factor (S) is based on the dbh and species shading coefficient, which is a species-specific constant (Appendix C).

$$S = 0.0617 \ln(\text{dbh}) + 0.615 + \text{species-specific shading coefficient}$$

As for the crown height (H) and the crown width (W), we either have to measure the data during sampling, or to use equations that estimate these values from the dbh. These equations are not provided in the documentation, so we requested a copy of the equation sheets that lists the all conversion between dbh and crown height or crown width from the i-Tree staff (Appendix D).

Table 2.1 Summary of which Directly Field-measured Characteristics are Used to Estimate Derived Variables and Ecosystem Services. (D = directly used; I = indirectly used; C = conditionally used.)

DIRECT MEASURES	DERIVED VARIABLES		ECOSYSTEM SERVICES										
	Leaf Area	Leaf Biomass	Carbon Storage	Gross Carbon Sequestration	Net Carbon Sequestration	Energy Effects	Air Pollution Removal	Avoided Runoff	Transpiration	VOC Emissions	Compensatory Value	Wildlife Suitability	UV Effects
Species	D	D	D	D	D	D	I	I	I	D	D		
Diameter at breast height (d.b.h.)			D	D	D						D	D	
Total height	D	D	C	C	C	D	I	I	I	I		D	
Crown base height	D	D	C				I	I	I	I			
Crown width	D	D	C				I	I	I	I			
Crown light exposure			C	D	D

Percent building cover						D							
Ground cover composition							I					D	

Source: Nowak, D. J. (2021). Understanding i-Tree: 2021 Summary of Programs and Methods. [Brochure]. US Forest Service.

Once we manage to calculate the numbers like crown width and crown height, we can track back to this Table 2.2.1 provided by i-Tree. We can see that all the required measurements, either directly used or conditionally used, we can all manage to calculate based on only species name and dbh.

2.3 Results of Coding Replication

A series of functions were written to replicate the calculations behind i-Tree Eco based on the report published on the i-Tree website, Understanding i-Tree: 2021 Summary of Programs and Methods (Nowak, 2021). These functions were applied to hypothetical trees, such as “Red Maple, dbh 15cm”, and the results compared to the corresponding i-Tree output.

Following the instructions from the documentation, two sets of functions were written; one to calculate the tree biomass, the other to calculate the leaf biomass.

As discussed in the last section tree biomass means the total tree dry weight biomass. A series of allometric equations is provided by the documentation to calculate the dry weight biomass. The codes serve as a way to help find the suited equation in order to calculate the biomass using species name and dbh. In this case, we want to find the right equation in the tree biomass table (Appendix A).

```
dryBiomass[dbh_, species_] := Module[{biomassData, a, b, c, d, e, f, g},
  biomassData = findBestMatch[species, biomassEquationTable];
  (*Print[biomassData];*)
  If[biomassData === {Missing[]}, Missing[],
  Which[
    biomassData[[2]] === "Y=10(A+(B*log(x)))",
    {a, b} = biomassData[[{3, 4}]];
    10^(a + (b * Log[10, dbh])),
    biomassData[[2]] === "Y=10((A*log(x))-B)",
    {a, b} = biomassData[[{3, 4}]];
    10^((a * Log[10, dbh]) - b),
    biomassData[[2]] === "Y=10AxB",
    {a, b} = biomassData[[{3, 4}]];
    (10^a) * (dbh^b),
```

Figure 2.1 Partial codes on the calculation of tree biomass. (Full codes available if requested).

For example, Figure 2.1 shows a function which finds the best match for a species in the table, extracts the corresponding dry biomass scaling equation, and then applies it to the dbh input.

The biggest issue we faced was that the data table does not contain all the species in the US, or even all the species we have in our inventory. What is worse, other calculations reference different tables that have different collections of species. In order to partially fix this issue, we extended our lookup code to allow us to find the closest name choice when the exact species name is not in the species list. For example, in the tree biomass table, if we directly search for *Quercus palustris* (pin oak), there will be no match. With the updated codes it will automatically find the closest match, which is *Quercus spp.* in this case. When looking for the closest match, we follow the sequence of exact species, genus average, family average, and finally similar species in the same genus or family.

However, even this does not solve all the problems. Take the same tree biomass table for example. Even with the help of the filter to find similar species, there still are a number of species for which there isn't even a family match. This includes some of the common species on campus, such as *Ginkgo biloba*, *Pyrus calleryana* (Callery pear) and *Gleditsia triacanthos* (honey locust). Test of the functions therefore yields results like those below (Figure 2.2).

```
dryBiomass[25, "Acer rubrum"]
354.21

dryBiomass[25, "Ginkgo biloba"]
Missing[]

dryBiomass[25, "Fagus sylvatica"]
412.086
```

Figure 2.2 Test result of the functions to calculate the tree dry biomass. The two inputs are dbh in cm and the scientific name of the species. The output is total tree dry weight biomass in kg.

As we can see from Figure 2.2, the result for the search for “*Ginkgo biloba*” is “Missing[]”. This means that we can’t find the species of *Ginkgo biloba*, of the genus *Ginkgo*, the family *Ginkgoaceae*, or any other species in those taxa.

While the calculations for tree biomass is not available, we still have the report from i-Tree Eco to test. i-Tree Eco has its own calculation codes set within the system, some of which are detailed explained in the manuscript (Koeser et al., 2021). As a result, a written report along with detailed individual results were generated by the system. According to the report, with a provided species name and “DBH”, i-Tree Eco managed to calculate the result of “Crown height”, “Crown width”, “Canopy cover”, “Leaf area”, “Leaf biomass” and other carbon benefits data.

In order to test the result from i-Tree Eco, two methods were taken to confirm the calculation.

In the first method, a sensitive test was taken with an extra input of the estimated “Total height” added to the data base. This way allows a comparison between the two sets

of end results, one with the system calculated height, the other with the human estimated height. With the first method, a first difference is noticed between the estimated height and system calculated height. In most cases (out of the 254), the system calculated height is way higher than human estimated height, which at the same time also makes other categories higher. One potential explanation of this could be that the i-Tree calculation was initially built on forest data, while the samples in this project was more focused on urban trees.

In the second method, a similar set of code are written. Instead of trying to get the tree biomass, these codes are built to calculate the composition and structure summary such as crown height and width (Appendix D). With the second the method, a comparison is made between the written codes and the i-Tree built-in calculation. There still are quite a variance between the two outcomes with the i-Tree Eco estimates are higher than human function estimates. Therefore, there is not yet a conclusion to made regarding the code replication on i-Tree. The main reason behind this could be that i-Tree is not sharing all the calculation basics. This makes this i-Tree system still somewhat remain as a “black box”.

Back to the original tree biomass calculation (Figure 2.2), in order to test the results of the other two available outcomes, we also compare our calculated values to the ‘carbon’ outcomes from the i-Tree software after putting in the same species name and dbh (Figure 2.3).

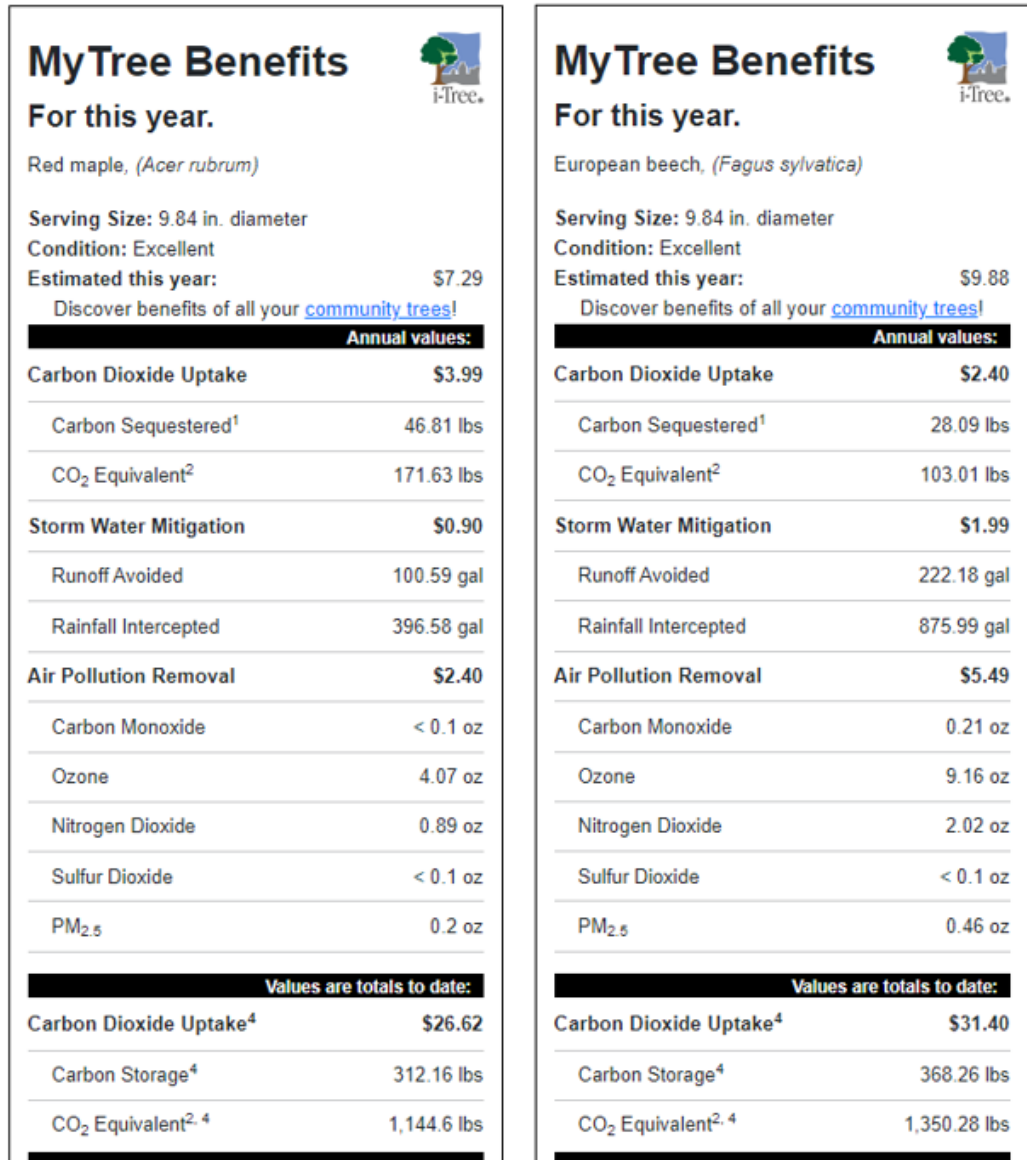

Figure 2.3 Test results from i-Tree software. The inputs are the same species name and dbh as the previous test.

For our two example inputs, i-Tree gives us the total carbon storage in lb: 312.16lb for the red maple and 368.26lb for the European beech (Figure 2.3). We convert our own tree biomass calculations into carbon storage to compare to the i-Tree outputs. The estimated tree biomass for red maple is 354.21kg; for European beech is 412.086kg.

We convert these two numbers into pounds and then multiply by the carbon fraction rate (the approximate conversion rates between tree biomass and carbon storage discussed earlier) of 0.5. This gives estimated carbon storages of 390.4lb for red maple, and 454.3lb for European beech.

As we can see from the two sets of result, the numbers from the written functions are relatively larger than the outcomes from the i-Tree software. We repeated these tests with various different species and dbh values. The results from our code generally follow the same trend as the results from i-Tree but are always larger.

There are several possible explanations for this outcome. One is that the i-Tree software has done more calculations behind the scenes, such as including the sun exposure (it does require a geographic location at first), or a non-zero crown damage value, and so on. Also, the carbon fraction rate may vary for different species (although it does not seem to vary enough to explain the discrepancies). Meanwhile, Open-grown, maintained trees tend to have less biomass than predicted by forest-derived biomass equations (Nowak 1994). Therefore, there should be another factor that would show the difference between urban trees and street trees.

Unfortunately, we are not able to test these hypotheses because those additional calculations, if being performed, are not explained in the i-Tree documentation. Therefore, despite our best efforts, i-Tree remains in large part a “black box”.

CHAPTER 3

NJIT CAMPUS CARBON BENEFITS

Even though we were not able to precisely reproduce the i-Tree calculations, we proceeded to examine the i-Tree Eco reports based on our campus tree inventory. i-Tree is used by professionals all over the country, and we don't feel that we have sufficient evidence (yet) to invalidate it.

3.1 Campus Survey

In order to test the carbon services, along with the economic benefit, of NJIT's trees, a tree survey was performed within the campus area of NJIT. With the help of i-naturalist, the following data were collected for all the tree species within the area, "Scientific name", "Common name", "DBH" (diameter at breast height), and "Location" (latitude and longitude). Where possible "Total height" and "Crown height" were also estimated, sometimes using an inclinometer, and sometimes with dead reckoning. There are two reasons why "Total height" and "Crown height" were not measured precisely. One is because it's relatively harder to precisely measure the height than it is to measure the diameter of a tree. The second reason is because i-Tree can perform its own calculations to convert "DBH" into various height and other morphological measurements for a known tree species. Further comparison and analysis shall be discussed later on.

Altogether, 254 trees were censused within the campus of NJIT, comprising almost all the trees within the main campus boundary (Figure 3.1).

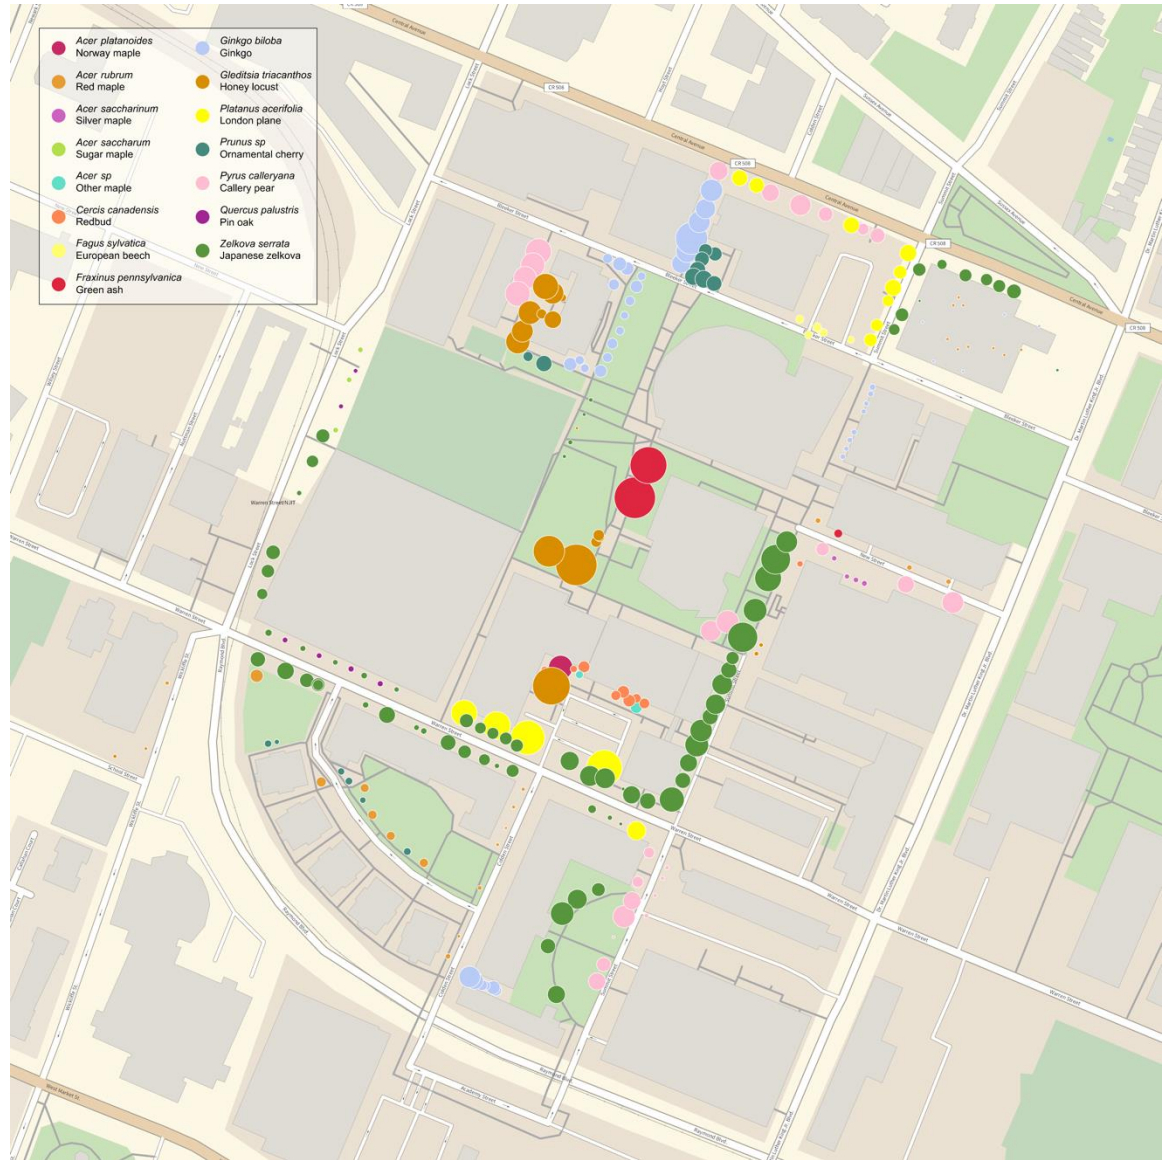

Figure 3.1 All trees included in these analyses, located on a street map of NJIT.

Within that census were thirteen distinct species, with two trees identified only as genus *Acer*, and all types of ornamental cherry recorded only as genus *Prunus*. The thirteen species were *Zelkova serrata* (Japanese zelkova), *Ginkgo biloba*, *Quercus palustris* (pin

oak), *Pyrus calleryana* (Callery pear), *Platanus x hybrida* (London plane), *Gleditsia triacanthos* (honey locust), *Fraxinus pennsylvanica* (green ash), *Fagus sylvatica* (European beech), *Cercis canadensis* (eastern redbud), *Acer rubrum* (red maple), *Acer saccharum* (sugar maple), *Acer saccharinum* (silver maple) and *Acer platanoides* (Norway maple). The abundance of species varied considerably, with the three most common species being Japanese zelkova (28.7 percent), ginkgo (15.7 percent), and red maple (10.6 percent)(Figure 3.2).

Figure 3.2 Tree species composition in NJIT.

Urban forests are typically composed of a mix of native and non-native tree species, and therefore have the potential for a tree diversity that is higher than surrounding native landscapes. Significant tree diversity can minimize the overall impact or destruction by a species-specific insect or disease. In practice though, trees used in urban settings, especially ‘street trees,’ are usually selected from a relatively small pool

of candidates based on their tolerance for various stressors, and urban tree diversity can also be low. In addition, non-native species can pose a risk to native plants, and local ecosystems more generally, if they are capable of propagating into nearby green spaces. Non-native species are considered invasive if they can out-compete and displace native species. Invasive plant species are often characterized by their vigor, ability to adapt, reproductive capacity, and general lack of natural enemies.

In the NJIT tree inventory (Figure 3.3), about 30 percent of the trees are species native to North America, with 23 percent native specifically to New Jersey. Species non-native to North America make up 70 percent of the population. Most of the non-native tree species have an origin in Asia (55 percent of the species).

Figure 3.3 Percentage of live tree population by area of native origin in NJIT. X-axis represents the origin of the trees. Y-axis shows the percentage of the trees originating in that particular area. The plus sign (+) indicates the tree species is native to another continent other than the ones listed in the grouping.

Three of the species in NJIT, Japanese zelkova, Callery pear, and Norway maple, are identified as invasive species by the State of New Jersey (New Jersey Invasive Species Strike Team, 2022). In this case, Callery pear and Norway maple are considered more concerning as they are marked as “Widespread,” while Japanese zelkova is only at “Stage 0”.

Based on the information from the New Jersey Invasive Species Strike Team, a pie figure is made to have a clearer view among native, non-native, and invasive species (Figure 3.4).

Percentage of live tree population by area of native origin in NJIT.

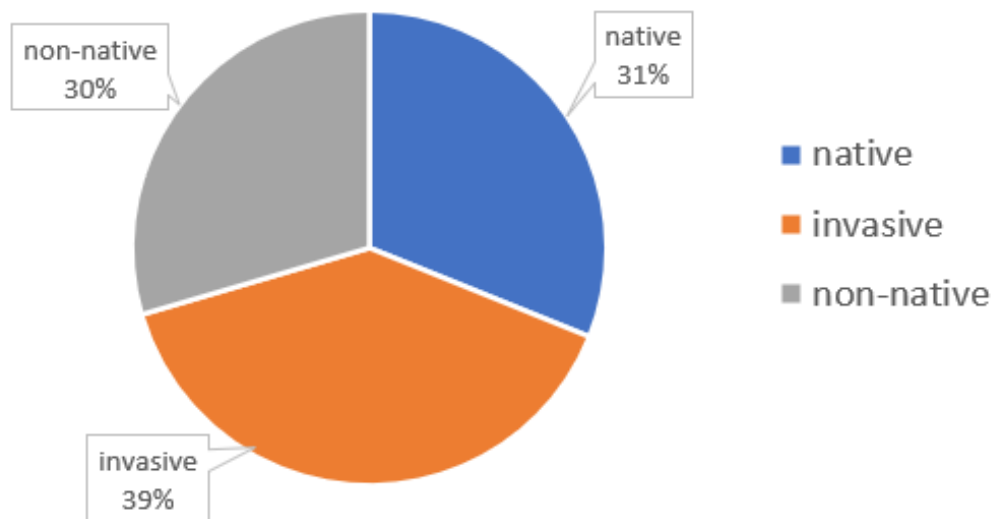

Figure 3.4 Pie graph of percentage of live tree population by area of native origin in NJIT.

3.2 Carbon Storage and Carbon Sequestration

As mentioned earlier, both carbon storage and carbon sequestration are closely tied to overall tree biomass (Figures 3.5 and 3.6). The largest trees store over 1000 times the carbon of the smallest trees, and sequester over 200 times more.

Figure 3.5 NJIT campus map of all species showing the carbon storage (lb) of all trees. The shade of the color shows the carbon storage. The size of the dot is in relation to the square root of the “DBH” of each tree.

Figure 3.6 NJIT campus map of all species showing the carbon sequestration (lb/yr) of all trees. The shade of the color shows the carbon sequestration. The size of the dot is in relation to the square root of the “DBH” of each tree.

To further examine the difference in size dependence of carbon storage vs annual sequestration, and also look at species-specific differences, we plotted each carbon value against DBH raised to a power that would make the relationship linear. Across all species in this study, carbon storage scales with DBH raised to the power 2.5 (Figure 3.7), which is less than the power of 3 that would be expected if tree volume (and therefore wood biomass) scaled isometrically with DBH. By observation, smaller trees tend to be narrower and proportionally taller than mature trees, in which case they will contain more wood volume relative to the trunk cross-sectional area.

Carbon sequestration, however, scales with DBH raised only to the power 1.5 (Figure 3.8). This is presumably because carbon sequestration is a function of photosynthetic activity, best measured by total leaf area. Since leaf size doesn’t change with tree age, total

leaf area will be mainly a function of the number of leaves, and as leaves occur on towards the tips of branches, they will scale closer to canopy area than to total tree volume.

Some of the biggest trees on campus are honey locusts, and these also have relatively high carbon storage relative to their trunk diameter (Figure 3.7). Overall, differences in this rate reflect differences in tree shapes.

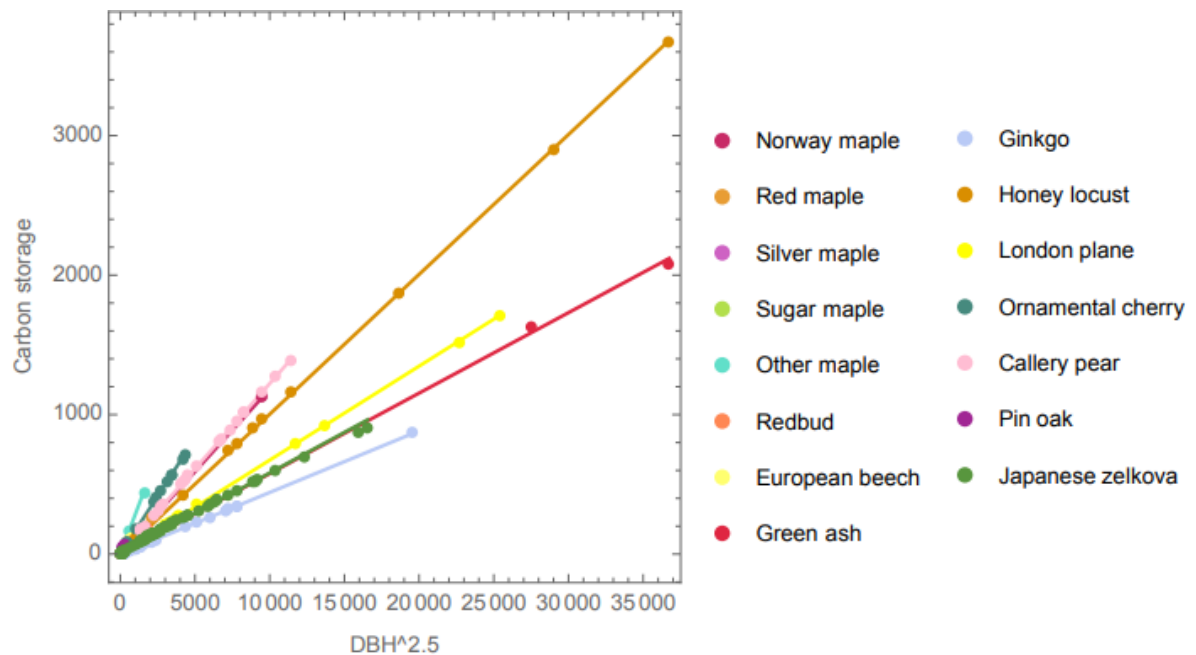

Figure 3.7 Carbon storage for different species versus different “dbh^{2.5}”. Different species are marked with different color.

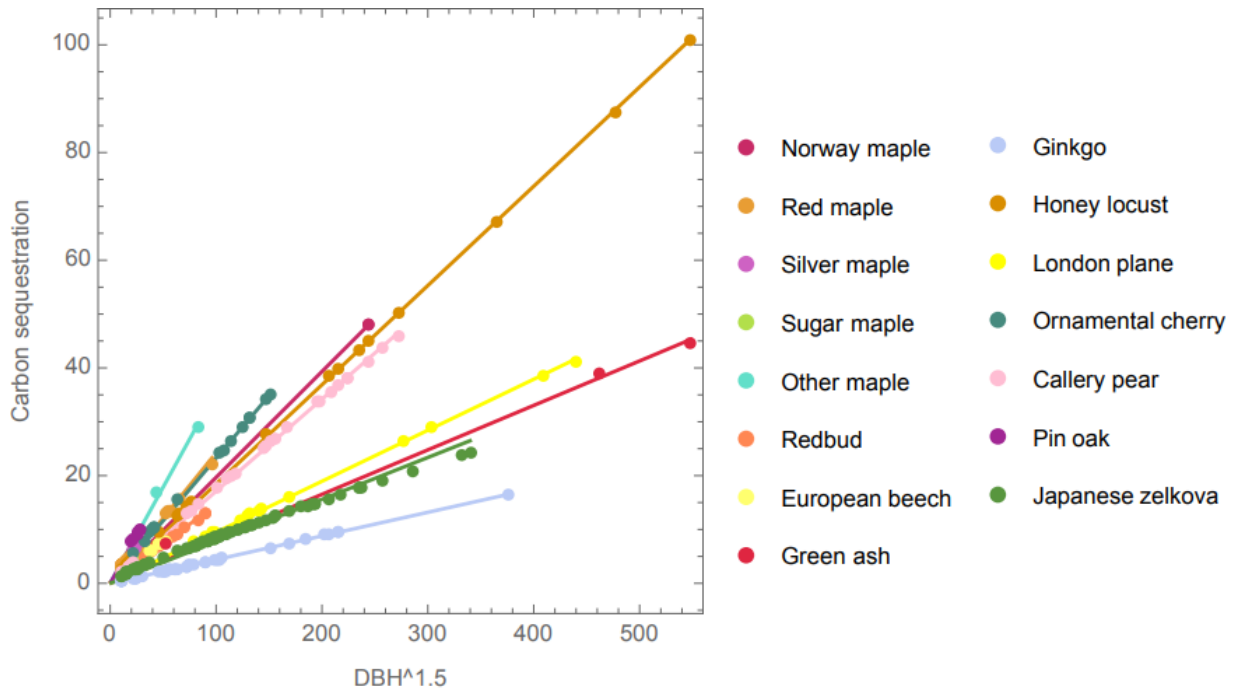

Figure 3.8 Carbon sequestration for different species versus different “ $dbh^{1.5}$ ”. Different species are marked with different color.

The same is broadly true for annual carbon sequestration (Figure 3.8). Much more interesting would be to plot the carbon values against tree age, as this would reveal expected rates of carbon capture as a function of time. We can do this by applying species-specific growth rate factors gleaned from the literature to convert dbh to age (Figures 3.9 and 3.10).

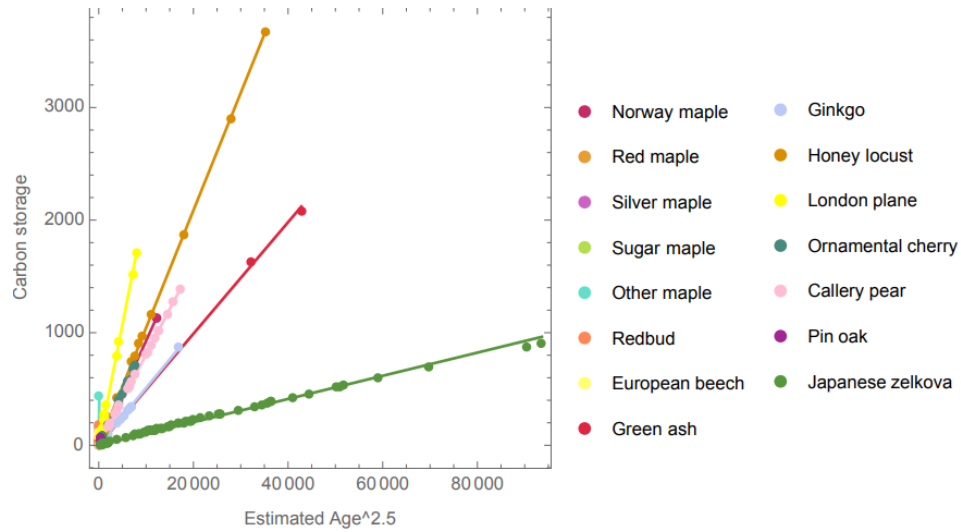

Figure 3.9 Carbon storage for different species versus different “age^{2.5}”. Different species are marked with different color. Ages were estimated based on measured dbh.

Figure 3.10 Carbon sequestration for different species versus different “age^{1.5}”. Different species are marked with different color. Ages were estimated based on measured dbh.

Non-native Japanese zelkova seems to have by far the lowest rate rates of overall carbon storage and annual sequestration, with similarly non-native Ginkgo also low in sequestration. Other non-native species such as Callery pear and Norway maple, as well as various native species (e.g., honey locust, red maple and redbud) have much higher rates. One

thing worth noting, however, is that the growth rate conversion factors that estimate age from dbh are extremely coarse, with different sources often providing quite different factors. Thus these ‘species rankings’ should be regarded a tentative.

3.3 Carbon Benefits in Invasive Species

Analysis of the tree on the NJIT campus shows that our ‘urban forest’ consists of a mix of both native and non-native tree species. While this arguably increases tree diversity, it might also pose a risk to native plants if non-native species are invasive and out-compete native species. Invasive species sometimes can cause significant harm to the environment, economy, or human health. However, from the carbon storage perspective, there isn’t a clear distinction between native and non-native species (Figure 3.11 and 3.12). Especially when we put the other two invasive species, Norway maple and Callery pear, into consideration, these two species fall right among the rest native species. Therefore, this low carbon benefits of Japanese zelkova are more likely to be an outlier. Even if it is indeed is producing less, it is unlikely due to it being non-native species.

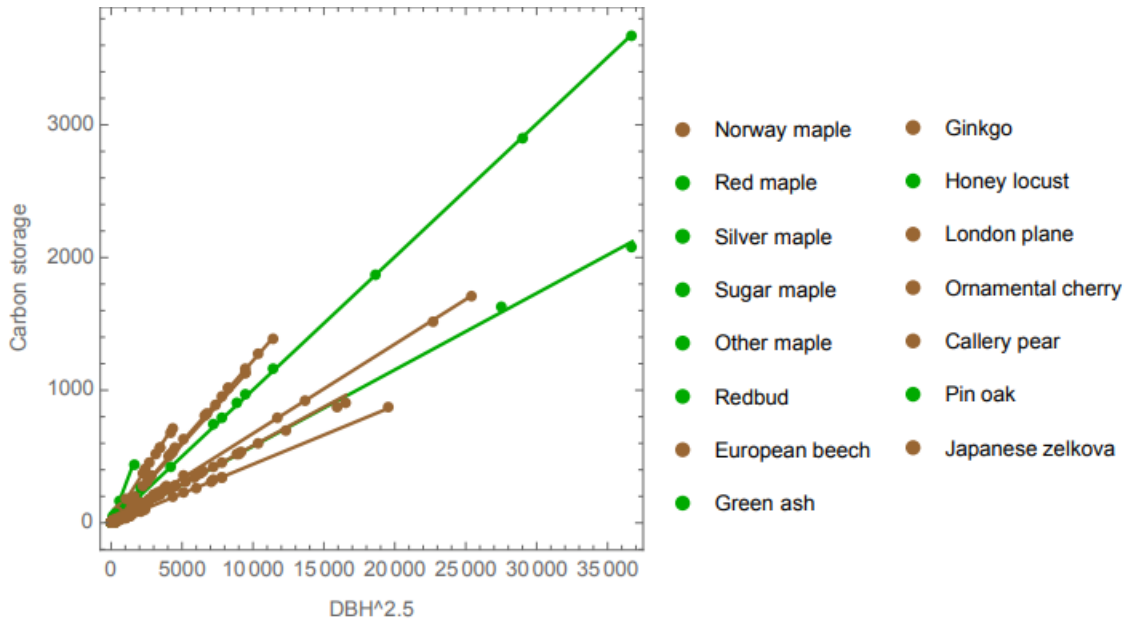

Figure 3.11 Carbon storage for different species in terms of native and non-native.

Green represents native species. Brown represents non-native species.

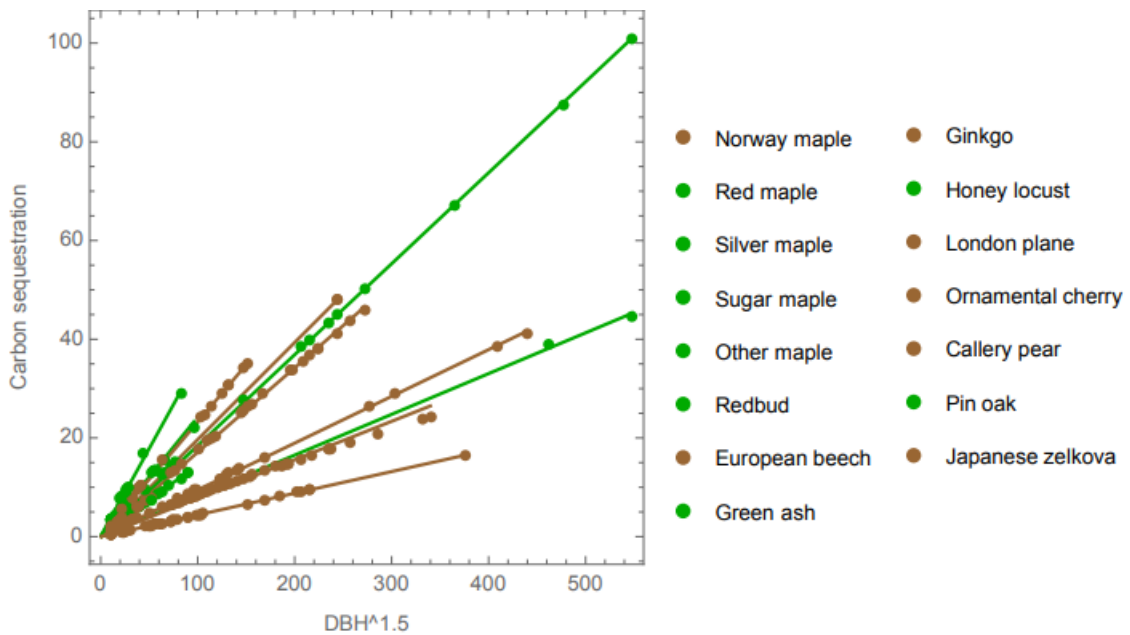

Figure 3.12 Carbon sequestration for different species in terms of native and non-native.

Green represents native species. Brown represents non-native species.

3.4 Carbon Benefits in Different Tree Sizes

If the distinction between native and non-native species is inconclusive from a carbon storage perspective, it's a whole different story when it comes to removing or replacing existing trees and adding new ones.

As shown in the previous (Figures 3.5 and 3.6). The largest trees store over 1000 times the carbon of the smallest trees, and sequester over 200 times more. In fact, the twenty-six largest trees (just over ten percent) constitute fifty percent of the total carbon storage, whereas the smallest hundred and eleven trees (~44%) constitute only five percent (Figure 3.13)

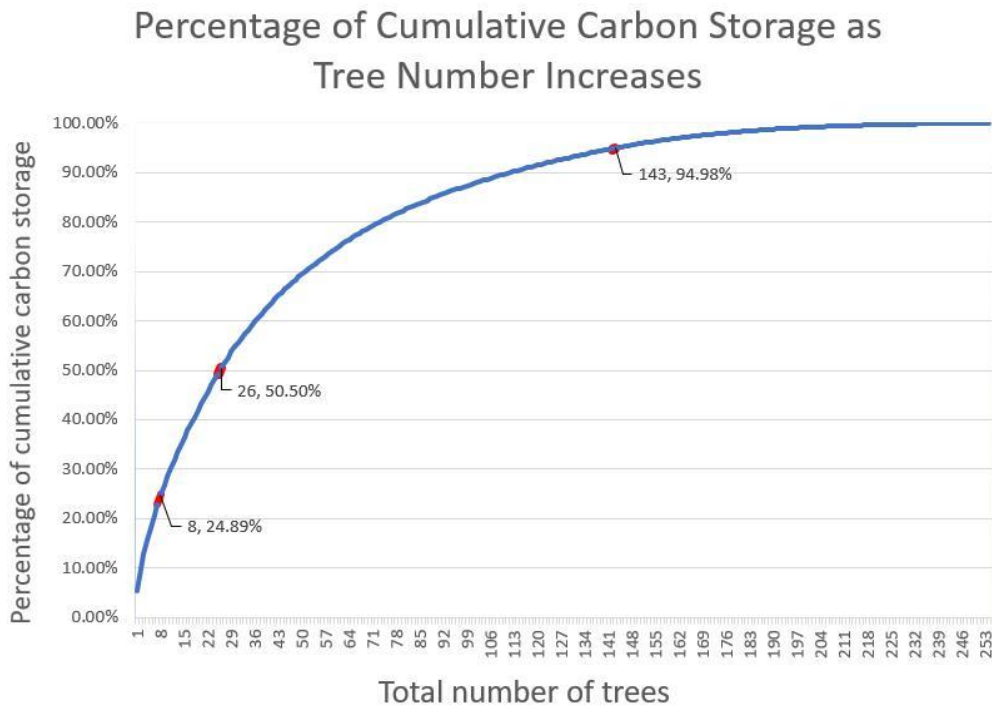

Figure 3.13 Percentage of cumulative carbon storage as tree number increases. X-axis represents the total number of trees starting with the largest. Y-axis represents the percentage of cumulative carbon storage.

For sequestration, the disparity is less dramatic, with the 42 biggest trees providing fifty percent of total carbon sequestration and the smallest 65 small trees providing five percent (Figure 3.14).

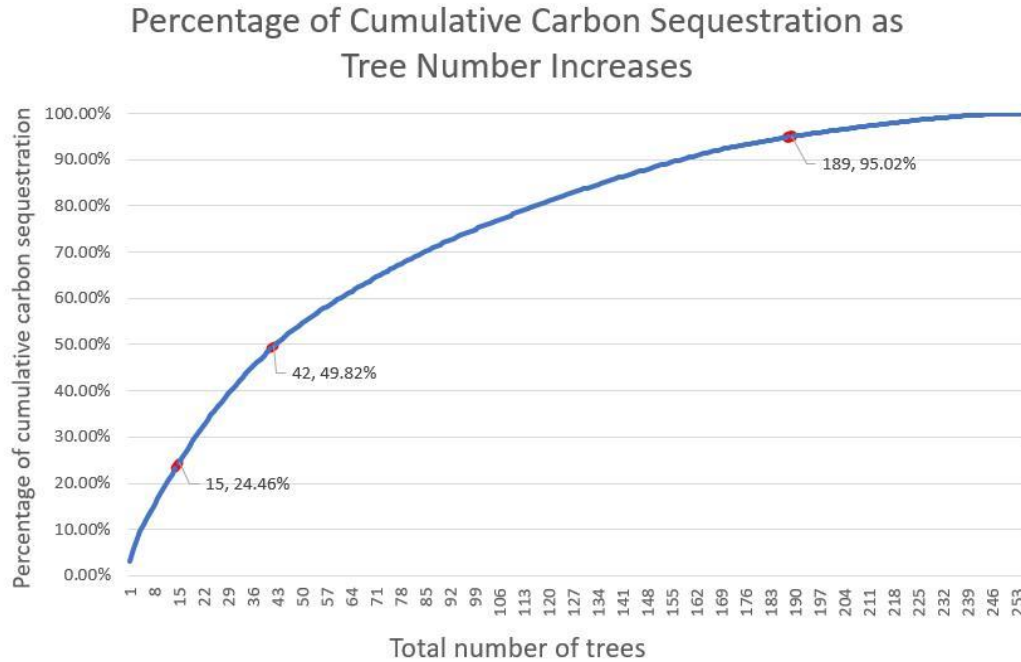

Figure 3.14 Percentage of cumulative carbon sequestration as tree number increases. X-axis represents the total number of trees starting with the largest. Y-axis represents the percentage of cumulative carbon sequestration.

Figure 3.15 is the same curve that was shown previously but with different selected points. From the figure we can tell that the single largest tree on campus, which is a honey locust, contributes 3.18% of the total carbon sequestration. It takes 48 of the smallest trees on campus to match this, or about three of the twentieth largest trees combined. This means that it is more than difficult to replace one of the larger trees on campus if we want to maintain the carbon sequestration each year. Even, if we just want to replace the twentieth biggest tree on campus, which is still one of those honey locusts,

we need about a dozen of smaller trees to match its carbon sequestration. Therefore, large trees should not be removed unless it is absolutely necessary; and when it is, it proposes big challenges in find the number and places for small trees to offset the loss.

Figure 3.15 New percentage of cumulative carbon sequestration as tree number increases.

3.5 The Economic Value in Carbon

Urban trees help mitigate climate change by sequestering atmospheric carbon (from carbon dioxide) in tissue and by altering energy use in buildings, and consequently altering carbon dioxide emissions from fossil-fuel based power sources (Abdollahi et al 2000). Trees reduce the amount of carbon in the atmosphere by sequestering carbon in new growth every year. The amount of carbon annually sequestered increases with the size and health of the trees. According to the calculations of i-Tree Eco, the gross sequestration of the inventoried trees at NJIT is 1.585 tons of carbon per year, which has an associated value (today) of \$270 (Figure 3.16).

Carbon storage is another way trees can influence global climate change. As a tree grows, it stores more carbon by holding it in its accumulated tissue. As a tree dies and decays, it releases much of the stored carbon back into the atmosphere. Thus, carbon storage is an indication of the amount of carbon that can be released if trees are allowed to die and decompose. Maintaining healthy trees will keep the carbon stored in trees, but tree maintenance can contribute to carbon emissions (Nowak et al 2002).

All of the sample trees in NJIT are estimated to store 33.7 tons of carbon, with a value of \$5,750 (Figure 3.17). Because it is the most common tree, Japanese zelkova stores and sequesters the most carbon, with an 21.1% of the total stored and 20.6% of the annual sequestration.

Figure 3.16 Estimated carbon storage (triangles) and values (bars) for urban tree species with the greatest storage in the sample trees in NJIT.

Figure 3.17 Estimated annual gross carbon sequestration (triangles) and values (bars) for urban tree species with the greatest storage in the sample trees in NJIT.

CHAPTER 4

DISCUSSION

This thesis presents two sets of analysis regarding the evaluation of the carbon benefits produced by urban street trees.

The first analysis is on the interior calculation of the software i-Tree. The result proves that i-Tree does involve the calculation from all aspects. While there are some concerning area where the i-Tree calculation is not completely transparent. This includes the extra calculation which is not explained in the documents, and the inconsistent species list where some of the species are not found in some of the reference tables. Also, the difference between urban trees and forest trees are not clearly explained in details (numbers), which also makes it challenging to convert.

The second analysis is based on the campus survey. The result proves the carbon benefits produced by the campus street trees with the economic benefits along with it. The discussion between native species and non-native species shows that there is not a significant different between native species and non-native or invasive species. Therefore, if we were to replace some of the invasive species on our campus due to some other impacts on ecosystem, we will not have to worry about the drop in carbon benefits as long as we replace them with similar sized trees.

However, in case of replacing larger sized trees, it will be more challenging. Sometimes, it's inevitable when large trees grow old or die. As proven in previous

chapters, a large tree would take about forty small trees or three medium trees to balance the carbon loss. Even for a medium sized tree, it still would take about ten small trees to cut the loss. This would require a lot panning ahead of the action as the carbon benefits is also proven to be directly connect to actual money.

APPENDIX A

TREE BIOMASS EQUATIONS

Dry weight biomass equations, by species, used in i-Tree. x = d.b.h. in cm unless otherwise noted; Y = total tree dry weight biomass in kg unless otherwise noted. DHT: x = d.b.h.² (cm²) x total tree height (m); AGB = aboveground dry weight biomass.

These equations were derived from Understanding i-Tree: 2021 Summary of Programs and Methods (Nowak, 2021).

APPENDIX B

CONVERSION FACTORS FOR LEAF AREA TO BIOMASS

Conversion factors used to estimate leaf biomass (g) from leaf area (m²) for individual species are shown in below. Values are based on averages from numerous unpublished field studies.

Species	g/m ²
<i>Abies balsamea</i>	104.17
<i>Abies lasiocarpa</i>	217.39
<i>Acacia aneura</i>	476.19
<i>Acacia melanoxylon</i>	161.94
<i>Acer buergerianum</i>	123.46
<i>Acer mono</i>	37.17
<i>Acer negundo</i>	91.48
<i>Acer pensylvanicum</i>	32.57
<i>Acer platanoides</i>	53.97
<i>Acer pseudoplatanus</i>	69.93
<i>Acer rubrum</i>	67.34
<i>Acer saccharinum</i>	52.63
<i>Acer saccharum</i>	60.24
<i>Aesculus californica</i>	88.11
<i>Aesculus flava</i>	65.15
<i>Aesculus hippocastanum</i>	69.93
<i>Albizia julibrissin</i>	43.48
<i>Alnus incana ssp. Rugosa</i>	85.84
<i>Alnus rhombifolia</i>	87.72
<i>Alnus species</i>	55.25
<i>Amelanchier alnifolia</i>	100
<i>Amelanchier arborea</i>	60.98
<i>Arecastrum romanzoffianum</i>	183.49

<i>Artemisia tridentata</i>	312.5
<i>Asimina triloba</i>	167.76
<i>Atriplex canescens</i>	119.05
<i>Atriplex polycarpa</i>	253.16
<i>Baccharis pilularis</i>	192.31
<i>Betula alleghaniensis</i>	41.41
<i>Betula nigra</i>	77.51
<i>Betula papyrifera</i>	69.93
<i>Betula species</i>	62.5
<i>Bischofia polycarpa</i>	178.57
<i>Brachychiton populneus</i>	87.53
<i>Broussonetia papyrifera</i>	57.47
<i>Caesalpinia gilliesii</i>	89.29
<i>Carpinus caroliniana</i>	60.24
<i>Carya alba</i>	57.31
<i>Carya aquatica</i>	232.27
<i>Carya cordiformis</i>	62.86
<i>Carya glabra</i>	19.06
<i>Carya illinoensis</i>	69.54
<i>Carya ovata</i>	73.24
<i>Carya pallida</i>	59.88
<i>Carya species</i>	56.26
<i>Cassia nemophila</i>	259.74
<i>Castanea dentata</i>	45.66
<i>Castanea pumila</i>	150.86
<i>Catalpa bignonioides</i>	53.33
<i>Catalpa species</i>	70.92
<i>Celtis laevigata</i>	67.99
<i>Celtis occidentalis</i>	52.03
<i>Cercis canadensis</i>	64.04
<i>Cercocarpus montanus</i>	123.46
<i>Chamaecyparis obtusa</i>	250
<i>Chamaedaphne calyculata</i>	84.75
<i>Cinnamomum camphora</i>	67.57
<i>Citrullus lanatus</i>	85.47
<i>Citrus limon</i>	147.06
<i>Citrus sinensis</i>	124.61
<i>Cornus alternifolia</i>	66.67
<i>Cornus florida</i>	58.1
<i>Cornus mas</i>	66.23

<i>Cornus racemosa</i>	47.73
<i>Cornus sericea</i>	57.22
<i>Corylus cornuta</i>	69.44
<i>Crataegus marshallii</i>	245.23
<i>Crataegus monogyna</i>	125.79
<i>Crataegus species</i>	35.97
<i>Ericameria nauseosa</i>	180.51
<i>Eucalyptus camaldulensis</i>	138.41
<i>Eucalyptus grandis</i>	115.61
<i>Eucalyptus sideroxylon</i>	136.99
<i>Euryops pectinatus</i>	224.72
<i>Fagus crenata</i>	60.61
<i>Fagus grandifolia</i>	42.61
<i>Fraxinus americana</i>	56.82
<i>Fraxinus excelsior</i>	106.38
<i>Fraxinus nigra</i>	59.52
<i>Fraxinus pennsylvanica</i>	65.22
<i>Fraxinus species</i>	90.09
<i>Garrya flavescens</i>	217.39
<i>Ginkgo biloba</i>	44.09
<i>Gleditsia triacanthos</i>	104.71
<i>Gossypium hirsutum</i>	69.32
<i>Grevillea robusta</i>	121.58
<i>Hamamelis virginiana</i>	58.82
<i>Hibiscus rosa-sinensis</i>	85.11
<i>Hibiscus syriacus</i>	48.31
<i>Ilex opaca</i>	133.69
<i>Juglans nigra</i>	80.14
<i>Juglans regia</i>	42.15
<i>Juniperus species</i>	277.78
<i>Kalmia latifolia</i>	120.48
<i>Koelreuteria paniculata</i>	80.81
<i>Larix laricina</i>	46.3
<i>Larix leptolepis</i>	64.52
<i>Ledum groenlandicum</i>	107.53
<i>Ligustrum lucidum</i>	90.91
<i>Liquidambar styraciflua</i>	45.91
<i>Liriodendron tulipifera</i>	58.95
<i>Lonicera x bella</i>	49.26
<i>Lycopersicon esculentum</i>	79.21
<i>Lysiloma watsonii</i>	105.82

<i>Maclura pomifera</i>	100.53
<i>Magnolia acuminata</i>	32.79
<i>Magnolia grandiflora</i>	135.04
<i>Magnolia virginiana</i>	142.92
<i>Mahonia bealei</i>	86.21
<i>Malus pumila</i>	86.21
<i>Metasequoia glyptostroboides</i>	56.5
<i>Morella cerifera</i>	344.09
<i>Morus alba</i>	73.15
<i>Morus rubra</i>	99.32
<i>Nerium oleander</i>	148.7
<i>Nyssa sylvatica</i>	34.59
<i>Osmanthus fragrans</i>	86.96
<i>Ostrya virginiana</i>	65.28
<i>Oxydendrum arboreum</i>	30.44
<i>Parthenocissus tricuspidata</i>	49.18
<i>Photinia serratifolia</i>	102.04
<i>Picea abies</i>	166.67
<i>Picea abies x asperata</i>	178.57
<i>Picea asperata</i>	99.5
<i>Picea bicolor</i>	194.17
<i>Picea engelmannii</i>	212.77
<i>Picea glauca</i>	160.64
<i>Picea glehnii</i>	229.89
<i>Picea jezoensis</i>	487.8
<i>Picea koraiensis</i>	95.24
<i>Picea koyamai</i>	204.08
<i>Picea mariana</i>	188.68
<i>Picea montigena</i>	153.85
<i>Picea omorika</i>	188.68
<i>Pinus banksiana</i>	83.33
<i>Pinus contorta</i>	192.31
<i>Pinus resinosa</i>	147.06
<i>Pinus strobus</i>	64.31
<i>Pinus taeda</i>	81.11
<i>Pistacia chinensis</i>	76.34
<i>Pistacia vera</i>	155.04
<i>Platanus hybrida</i>	43.67
<i>Platanus occidentalis</i>	48.45
<i>Populus alba</i>	86.96

<i>Populus angustifolia</i>	87.72
<i>Populus balsamifera trichoca</i>	54.05
<i>Populus fremontii</i>	86.58
<i>Populus grandidentata</i>	51.02
<i>Populus nigra</i>	72.12
<i>Populus species</i>	67.57
<i>Populus tremuloides</i>	78.74
<i>Populus x canadensis</i>	92.42
<i>Prunus alleghaniensis</i>	212.77
<i>Prunus cerasifera</i>	60.75
<i>Prunus dulcis</i>	101.27
<i>Prunus pensylvanica</i>	48.27
<i>Prunus serotina</i>	77.55
<i>Prunus virginiana</i>	77.52
<i>Pterocarya stenoptera</i>	80
<i>Pueraria lobata</i>	30.03
<i>Quercus agrifolia</i>	141.68
<i>Quercus alba</i>	72.74
<i>Quercus berberidifolia</i>	149.32
<i>Quercus chrysolepis</i>	168.94
<i>Quercus coccinea</i>	72.87
<i>Quercus douglasii</i>	121.41
<i>Quercus ellipsoidalis</i>	103.09
<i>Quercus engelmannii</i>	151.16
<i>Quercus falcata</i>	77.98
<i>Quercus gambelii</i>	133.33
<i>Quercus kelloggii</i>	102.89
<i>Quercus lobata</i>	101.12
<i>Quercus michauxii</i>	60.21
<i>Quercus nigra</i>	94.56
<i>Quercus pagoda</i>	112.82
<i>Quercus palustris</i>	90.5
<i>Quercus phellos</i>	88.71
<i>Quercus prinus</i>	78.59
<i>Quercus robur</i>	66.58
<i>Quercus rubra</i>	79.68
<i>Quercus stellata</i>	85.11
<i>Quercus suber</i>	177.78
<i>Quercus velutina</i>	70.67
<i>Quercus virginiana</i>	209.93

<i>Quercus wislizeni</i>	148.36
<i>Rhamnus cathartica</i>	44.44
<i>Rhododendron maximum</i>	200
<i>Rhus glabra</i>	55.14
<i>Rhus lancea</i>	122.7
<i>Rhus ovata</i>	320
<i>Rhus species</i>	80
<i>Robinia pseudoacacia</i>	53.84
<i>Rosmarinus officinalis</i>	275.86
<i>Rubus species</i>	37.31
<i>Salix sericea</i>	65.05
<i>Salix species</i>	61.73
<i>Salvia leucophylla</i>	246.91
<i>Sassafras albidum</i>	49.18
<i>Senna artemisioides</i>	186.05
<i>Sophora japonica</i>	113.64
<i>Sorbus species</i>	79.37
<i>Spartium junceum</i>	291.97
<i>Symphoricarpos occidentalis</i>	55.87
<i>Syringa vulgaris</i>	96.46
<i>Thuja occidentalis</i>	192.31
<i>Tilia americana</i>	29.2
<i>Tilia cordata</i>	74.91
<i>Tilia platyphyllos</i>	59.17
<i>Tsuga canadensis</i>	92.88
<i>Tsuga heterophylla</i>	55.25
<i>Ulmus alata</i>	72.25
<i>Ulmus americana</i>	72.73
<i>Ulmus parvifolia</i>	113.64
<i>Ulmus rubra</i>	44.77
<i>Vitex agnus-castus</i>	133.78
<i>Vitis vinifera</i>	66.67
<i>Washingtonia robusta</i>	154.44

APPENDIX C
SHADING COEFFICIENTS

The shading coefficient (y) is based species-specific coefficients (Table 11) and d.b.h., based on the formula: $y = 0.0617 * \ln(x) + 0.615 + \text{species-specific shading coefficient}$

Where: x = d.b.h in cm.

Species	Coefficient
<i>Acacia farnesiana</i>	0.006476
<i>Acacia melanoxylon</i>	0.033203
<i>Acacia salicina</i>	0.036297
