### ABSTRACT

Forestry companies have invested in genetic improvement to increase wood production in a shorter amount of time. Thus, studies are needed to compare the properties of clonal and seminal wood materials. The objective of this study was to analyze physical and mechanical properties of *Tectona grandis* from clonal (C1 and C2) and seminal (S) origin and evaluate the yield and quality of sawn wood subjected to outdoor and oven drying. Genetic material was collected from six, 15-year-old trees. Clone C2 presented the lowest amount of bark, and 51 % heartwood up to half the commercial height, while the heartwood of C1 and S went up to 25 % of the height. The three materials did not differ statistically for maximum angular deviation, pith eccentricity, basic density, Janka hardness, anisotropy, commercial income of sawn wood and the presence of knots. After the drying processes, the bowing and crooking indexes were less than 5 mm.m<sup>-1</sup>, however, the seminal material showed a higher cracking incidence after outdoor and oven drying. In conclusion, the wood properties of the three materials are similar. In addition, the oven drying process is recommended.

**Keywords:** Genetic enhancement, grain, sawnwood, teak, wood drying.

38  
39 **CALIDAD DE *Tectona grandis* PARA LA PRODUCCIÓN DE MADERA ASERRADA**

40  
41 **RESUMEN**

42  
43 Las empresas forestales han invertido en mejoramiento genético para aumentar la producción de  
44 madera en tiempo reducido. Por tanto, se necesitan estudios para comparar propiedades de maderas  
45 clonales y seminales. El objetivo de este trabajo fue analizar propiedades físicas y mecánicas de  
46 *Tectona grandis* de origen clonal (C1 y C2) y seminal (S) y evaluar el rendimiento y calidad de  
47 madera aserrada sometida a secado al aire libre y en estufa. Para cada material genético, se  
48 recolectaron muestras de seis árboles de 15 años. El clon C2 obtuvo menor proporción de corteza,  
49 con 51 % del duramen hasta la mitad de la altura comercial, mientras que el duramen de C1 y S  
50 obtuvo hasta 25 %. Estos materiales no difirieron estadísticamente en términos de desviación angular  
51 máxima, excentricidad de la médula, densidad básica, dureza Janka, anisotropía, rendimiento  
52 comercial de madera aserrada y presencia de nudos. Después de los procesos de secado, los índices  
53 de curvado y flexión fueron menores a 5 mm.m<sup>-1</sup>, sin embargo, el material seminal demostró mayor  
54 incidencia al agrietamiento después del secado al aire libre y en estufa. Las propiedades de la madera  
55 de los tres materiales, clonal y seminal, son similares. Se recomienda el proceso de secado en estufa.

70 **1. INTRODUCTION**

71 Teak, *Tectona grandis*, is one of the most valuable tropical woods in the world market due to  
72 its attractive characteristics such as unique coloring, design and brightness, in addition to high natural  
73 resistance (Kollert and Kleine 2017). In addition to these characteristics, teak wood is easy to cut and  
74 work with, so it is preferred for making furniture and carvings (Darmawan *et al.* 2021), boatbuilding,  
75 floors, doors, tubs, panels, among other noble uses (Arias and Monteuis 2013).

76 The average prices of teak logs and blocks are 420,50 and 499 US\$ per cubic meter,  
77 respectively (ITTO 2021). Since this wood is one of most expensive on the market, in addition to the  
78 natural teak forests in India, Laos, Myanmar and Thailand, the area used for teak plantations has been  
79 growing and occupies around 6,83 million hectares, with 80 % in Asia, 10 % in Africa and 6 % in  
80 America (Kollert and Kleine 2017). In 2018, there were approximately 94,000 hectares of this species  
81 in Brazil, with a 30% increase in the last decade and 6,21 % increase compared to 2017 (IBÁ 2019).

82 Short rotation plantations have the advantage of a shorter cycle, 15-20 years, lower proportion  
83 of branches and consequent knots in sawn wood, straight and cylindrical trunk (Martha *et al.* 2021).  
84 However, they have a high proportion of juvenile wood, which has shorter fibers with thinner walls  
85 and a larger microfibril angle (Martha *et al.* 2021). Short rotation wood has less heartwood and  
86 extractives but there are no significant differences compared to long rotation wood in swelling and  
87 mechanical properties (Rizanti *et al.* 2018), which indicates the need for care with outdoor use.

88 Up until a few years ago, most teak plantations in the world were planted using seedlings from  
89 seminal propagation (Oliveira 2003), which present disadvantages as restricted seed quantity per tree,  
90 low germination rates and considerable variability in important economic attributes between  
91 individuals (Monteuis and Maître 2006). Therefore, heterogeneous stands form in terms of wood  
92 growth and properties (Raposo *et al.* 2010). Nonetheless, to reduce the cutting cycle time and obtain  
93 trees with higher volumetric development and suitable wood properties, especially for lumber mills,  
94 forest producers have invested in genetic breeding programs. Thus, using clones stands out with

95 highly productive plantations in the same location, uniformity and high growth rates. As a result, the  
96 cutting cycles and production costs are reduced (Arias and Monteuis 2013).

97 Since clonal material presents accelerated wood growth and production, it is important to  
98 analyze whether they present higher defect rates in their final products, e.g., warping and cracking.  
99 Therefore, it is necessary to study the behavior of clonal wood in different drying processes. Loiola  
100 (2015) emphasized that the purpose of drying wood is to reduce the moisture content as soon as  
101 possible, avoiding defects that may interfere in the final use of wood. In addition, a homogeneous  
102 moisture content of wood is desirable for any final product, since the drying gradients are related to  
103 stresses and defects of the wood (Batista *et al.* 2016). Thus, the companies and researchers have been  
104 studying on drying kilns with more controlled atmospheric conditions to obtain high quality dried  
105 wood products.

106 Thus, to validate the genetic improvement for teak wood production and quality, studies  
107 focusing specifically on physical and mechanical properties and drying defects are needed. This is  
108 because, in addition to larger volumetric increments, clonal wood must have characteristics that are  
109 similar or superior to seminal wood, to be planted in new plantations and ensure that they can be used  
110 in products with greater value, e.g., furniture, floor, panels and boatbuilding.

111 Therefore, this work aimed to analyze the production of heartwood, sapwood and bark and  
112 evaluate the physical and mechanical properties of *Tectona grandis* wood from seminal and clonal  
113 origins, as well as to evaluate the quality of sawn wood subjected to outdoor and oven drying.

## 114 **2. MATERIAL AND METHODS**

### 115 **2.1. Material collection**

116 In this study, we evaluated three different genetic materials: commercial clone (C1), test clone  
117 (C2) and seminal (S) from 15-year-old *Tectona grandis* L.f forest plantations. The three genetic  
118 materials were established at an initial spacing of 3 m x 3 m and thinning was done at four, six, and  
119 eight years. A total of five prunings were also made throughout the growth of the trees. The plantation  
120 belonged to Teak Resources Company (TRC) located in Cáceres city, state of Mato Grosso (MT),

121 Brazil (16°8'1,75" S and 58°31'1,77" W) with Tropical Savanna climate (Aw) (Köppen-Geiger 1936)  
122 and soil classification We – Eutric Planosols (FAO 1992).

123 From each genetic material, six individuals were selected, totaling 18 trees. The diameter at  
124 breast height (DBH) of each of these trees was measured. After cutting, the total and commercial  
125 heights were measured, with the first bifurcation of the trunk considered for the latter. Wood sampling  
126 in each tree is shown in Figure 1.

127

128 **Figure 1:** Diagram of sample removal from the three genetic materials of *Tectona grandis*.

## 129 2.2. Volumetric production and sawn wood yield

130 To calculate the commercial volume ( $V_c$ ) of the trees, rigorous cubing was performed through  
131 the Smalian method. Subsequently, the logs were split with a Vantec band saw (1,10 m steering wheel,  
132 locked and repressed saw teeth, 7-inch x 1,2 mm saw and 65 HP motor, 48,5 kW), tangential model  
133 sawing, on 3 cm x 15 cm x 100 cm boards. The number of tables varied according to each type of  
134 genetic material and log. After sawing, boards were visually analyzed to verify the presence of bark  
135 and pith and to calculate the commercial yield, which is the relationship between the volume of boards  
136 (without bark and pith) from the log's volume.

137 **2.3. Wood Properties**

138 The discs were identified and photographed for image analysis to quantify the areas of  
139 heartwood, sapwood and bark and determine pith eccentricity with image J software, using 0,5 cm  
140 calibration. These regions were macroscopically defined by color change. Then, the percentages of  
141 heartwood, sapwood and bark were calculated in relation to the total disk area.

142 Pith eccentricity (PS) was calculated according to the methodology described by Lima *et al.*  
143 (2007). The main formula is  $PS = PD/md * 100$ , where PS: pith eccentricity (%); PD: pith  
144 displacement given by the distance between the geometric center and the actual pith position (cm);  
145 and md: mean disc diameter (cm). Being,  $PD = Rm - R\bar{m}$ , where PD is pith displacement (cm); Rm  
146 is value of the greatest distance between the pith and the periphery of the disk (cm); and,  $R\bar{m}$  is value  
147 of the average distance of the four perpendicular rays between the pith and the periphery of the disk  
148 (cm). The four rays are obtained with the equation  $R\bar{m} = (RM + Rm + Rp1 + Rp2)/4$ , where RM  
149 is value of the greatest distance between the pith and the periphery of the disk; Rm is value of the  
150 shortest distance between the pith and the periphery of the disk; Rp1 is value of the perpendicular ray  
151 1 (cm); and, Rp2 is value of the perpendicular ray 2 (cm).

152 Subsequently, the discs were used to make the specimens, with the objective of evaluating the  
153 basic density and maximum angular deviation (MAD). For the MAD analysis, discs from the regions  
154 of 0 % and 25 % for the commercial height. From each of these discs, four specimens were made:  
155 two from the core region and two from the transition between heartwood and sapwood, with 5 cm x  
156 5 cm x 5 cm dimensions, following to the radial division method proposed by Webb (1969) and  
157 adapted by Hernández and Almeida (2003). The classification for maximum angular deviation  
158 followed Limaye (1954).

159 The basic wood density of the wood was calculated using the NBR 11941 technical standard  
160 method (ABNT 2003). To analyze compressive strength parallel to fibers and Janka hardness, defect-  
161 free specimens (knots and cracks) with 5 cm x 5 cm x 15 cm dimensions were cut, while 5 cm x 5 cm  
162 x 6,5 cm specimens and 2 cm x 3 cm x 5 cm specimens were cut to measure shear and dimensional

163 stability, respectively, thirty-six samples per treatment for each analysis, as determined by the NBR  
164 7190 standard (ABNT 1997). The anisotropy coefficient (or T/R shrinkage ratio) was determined by  
165 the ratio of tangential shrinkage and radial shrinkage.

#### 166 **2.4. Quality of sawn wood, drying processes and drying defects**

167 On the boards, knots were measured according to the NBR 9487 (1986) and classified as  
168 small, medium and large according to Arruda (2013). The quality of the material from both drying  
169 processes were analyzed after 75 days - warping (bowing and crooking) and splitting according to  
170 the technical standard NBR 14806 (ABNT 2002).

171 After, the boards were divided into two parts, with one dried in an oven, and the other dried  
172 outside. For the oven drying of the first batch of boards, a drying program lasting 200 hours  
173 (approximately eight days) was used. The maximum temperature was 60 °C and final wood moisture  
174 content of 8 %, with temperature, air velocity and humidity all controlled, according to the company's  
175 drying protocol. For the outdoor drying of the other batch of boards, they were packed in a covered  
176 shed in Cuiabá, MT (-15,5594 latitude and -56,0628 longitude), at 240 m altitude and average  
177 temperature and relative humidity of 23 °C and 72 %, respectively (Souza *et al.* 2016). This drying  
178 was conducted for 75 days, during May to July, when the wood reached the hygroscopic equilibrium  
179 moisture of 12 %.

180 After both drying processes, the quality of the boards was analyzed - warping (bowing and  
181 crooking) and splitting according to the technical standard NBR 14806 (ABNT 2002).

#### 182 **2.5. Statistical analysis**

183 This study used a completely randomized design. Each genetic material was considered a  
184 treatment, with six replications (trees). The Shapiro-Wilk test was used for the analysis of the  
185 variables for the assumptions of normality of errors, at 5 % significance. The homogeneities of the  
186 variances were determined by the Bartlett test, at 5 % significance. When the F test of the variance  
187 analysis was significant, the means were compared by the Tukey test, at a level of 5 %. Statistical  
188 analyses were performed with the R version 3.6.1 software.

189 **3. RESULTS AND DISCUSSION**

190 **3.1. Volumetric production and sawn wood yield**

191 There were no statistical differences ( $p < 0,05$ ) for variables DBH, TH, CH, CVwb, and CY  
 192 (Table 1).

193 **Table 1:** Average values and standard deviation for the dendrometric variables and commercial yield  
 194 of sawn wood for the three genetic materials of *Tectona grandis*.

Treatment	DBH (m)	TH (m)	CH(m)	CVwb (m <sup>3</sup> )	CY (%)
<b>C1</b>	0,32 (6,66)	22,59 (2,64)	13,05 (3,39)	0,5841 (0,28)	60,71 (11,69)
<b>C2</b>	0,38 (6,74)	23,24 (2,23)	14,28 (2,02)	0,9918 (0,38)	53,51 (16,39)
<b>S</b>	0,32 (6,18)	20,74 (3,05)	11,42 (1,69)	0,7212 (0,32)	44,06 (22,82)
<b>Average</b>	0,34	22,18	12,91	0,7633	52,76

Diameter at breast height (DBH), total height (TH), commercial height (CH), commercial volume with bark (CVwb) and commercial yield (CY) per treatment and standard deviation.

195 The averages for the dendrometric variables (Table 1) were higher than those obtained by  
 196 Blanco-Flórez *et al.* (2014), who evaluated 14-year-old seminal teak and verified average values of  
 197 0,204 m for DBH, 12,49m for total height and 0,160 m<sup>3</sup>/tree of bark volume. On the other hand,  
 198 Benedetti (2018) also evaluated 14.4-year-old seminal teak and found average DBH of 0,28 m and  
 199 average volume per tree of 0,5768 m<sup>3</sup>. Thus, the clonal materials analyzed presented better  
 200 development.

201 Thulasidas and Baillères (2017) affirm that planting genetically improved materials with rapid  
 202 growth, associated with short rotations in populations, will produce trees with larger diameters. These  
 203 results (Table 1) agree with studies that have highlighted the superiority of clonal teak material in  
 204 relation to seminal teak material. Lemos *et al.* (2019) stated that clonal material produced 74,52 %  
 205 more volume than seminal material, while Medeiros *et al.* (2015) found that teak clones were 11 %  
 206 higher in height, 18 % in DBH, 34 % in basal area and 32 % by volume. Such characteristics are  
 207 interesting for the forestry sector as higher volumetric production of wood can lead to higher sawn  
 208 wood production per tree, if there are not many defects.

209 The average commercial yield in sawn wood was close to 55 %. The high value for teak wood  
 210 yield is due to the sapwood, which is used to produce edge glued panels (EGP), sold mainly in the

211 Brazilian market. When evaluating teak wood from different origins, Queiroz (2018) verified a  
 212 commercial yield of 38,89 % for 9-year-old trees from the same industry analyzed herein, which is  
 213 lower than the yield obtained herein. The volume of sawn wood with pith and bark for C1, C2 and S  
 214 materials was 23,37 %, 24,7 8 % and 26,55 %, respectively. The seminal material showed higher  
 215 percentages of pith and bark in boards, demonstrating better performance of clonal materials (Table  
 216 1). This is because pieces end up with smaller dimensions after secondary sawing to remove pith and  
 217 bark.

218 Table 2 presents some works that have evaluated the pith, heartwood, sapwood, and bark of  
 219 teak wood.

220 **Table 2:** Average values of pith, heartwood, sapwood and bark of teka trees.

Material Age	Pith (%)	Heartwood (%)	Sapwood (%)	Bark (%)	Authors
C1	0,18	46,34	37,26	16,22	This study
C2	0,13	46,60	42,55	10,72	
S	0,17	45,78	38,73	15,32	
Seminal teak (31)	-	68,00	53,95	-	Yang <i>et al.</i> (2020)
Seminal teak (14)	-	51,44	48,56	16,92	Blanco-Flórez <i>et al.</i> (2014)
Seminal teak (14,4)	0,16	47,99	43,52	8,33	Benedetti (2018)
Clone teak (8)	-	31,09	-	-	Rahmawati <i>et al.</i> (2022)

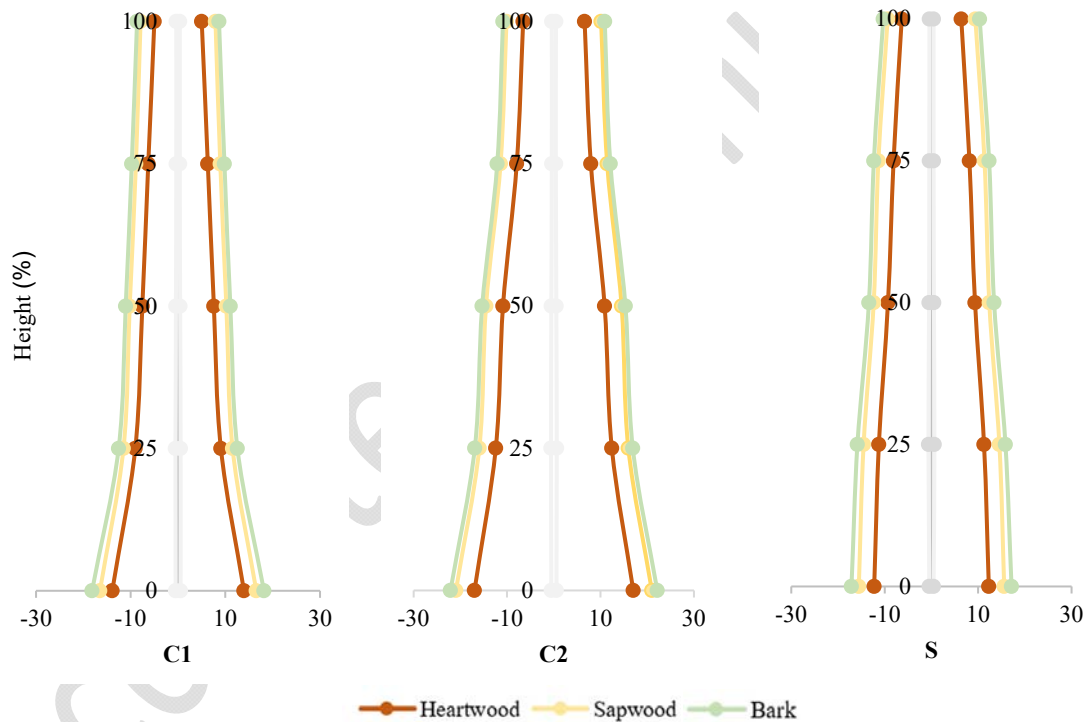

221

### 222 3.2. Wood properties

223

224 There were no significant differences ( $p < 0,05$ ) among the three genetic materials for total  
 225 percentage of heartwood and sapwood, which presented mean values of 46,16 % and 39,53 %, respectively.  
 226 Figure 2 shows the average values of heartwood, sapwood and bark along the trunk of C1, C2 and S teak trees.  
 227 Benedetti (2018) verified 47,99 % heartwood in seminal teak at 14,4 years and Lemos *et al.* (2019) found 15,24 %  
 228 higher heartwood production than that of seminal material when comparing seminal and clonal teak. Thus, the three materials had satisfactory heartwood  
 229 development for about 15-year-old material, with values similar to those found in 30-year-old teak  
 230 trees (maximum of 55 % heartwood) (Pérez and Kanninen 2003).  
 231

232 The C1 material stood out in heartwood production along the trunk compared to the seminal  
233 material (Figure 2). However, the C2 material outperformed the other materials with about 51 %  
234 heartwood in the longitudinal direction until halfway up the tree, while this percentage went up to 25  
235 % of the height for the other materials. The largest diameter associated with the largest percentage of  
236 heartwood is important for the lumber production sector, since this wood produces sawn wood with  
237 higher commercial value. Therefore, the larger the log diameter is, the more heartwood there is and,  
238 consequently, the higher the sawn heartwood yield is. The heartwood percentage is extremely  
239 important when determining sawn wood quality because the heartwood formation process changes  
240 the color of the wood and increases its natural durability (Blanco-Flórez 2014).

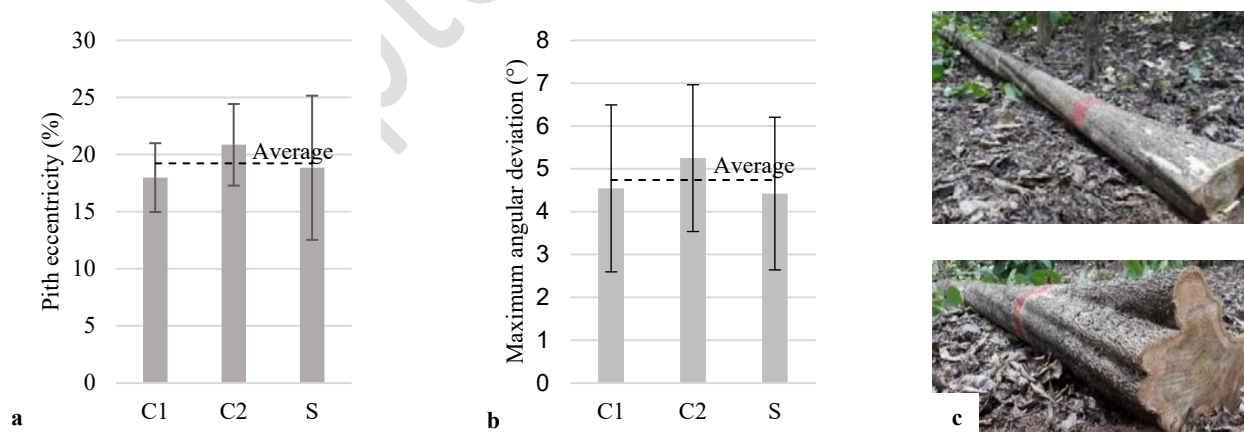

241 **Figure 2:** Average values of heartwood, sapwood and bark along the trunk of the three *Tectona*  
242 *grandis* genetic materials, in centimeters.

243  
244 The C2 material values were similar to those found by Blanco-Flórez *et al.* (2014), who  
245 evaluated 14-year-old seminal teak and found 51,44 % heartwood in the first two logs of the trees.  
246 Thus, the values found for the three materials corroborate with Gonçalves *et al.* (2010), who  
247 demonstrated the importance of heartwood and its application in furniture manufacturing, civil  
248 construction and in lumber products, thus adding value to the final product.

249 The average percentage of sapwood from the three materials was lower than those found by  
250 Blanco Flórez *et al.* (2014), who found 48,56 % sapwood for 14-year-old seminal teak, and Benedetti  
251 (2018), who verified 43,52 % sapwood in 14,4-year-old seminal teak. Lower amounts of sapwood in  
252 lumber products are more interesting for the lumber industry, as it has lower market value than  
253 heartwood. Therefore, it is essential to determine what by-products this material is going to be used  
254 e.g., production of solid wood panels or short pieces of sawn wood.

255 There were significant differences for the bark variable, in which the C2 material presented  
256 the lowest average value (10,72 %), followed by S material with 15,32 %, and C1 material with 16,38  
257 %. C2 material presented about 5 % Martha than the C1 and S materials. In addition to C2 having  
258 greater volumes than C1 and S (Table 1), it produced the least bark, that is, less waste will be  
259 generated when planting, transporting and processing this wood.

260 Blanco Flórez *et al.* (2014) obtained an average bark value of 16,92 %, which is close to the  
261 C1 material. However, herein, the bark values for the three materials were lower than those found by  
262 Pérez and Kanninen (2003), who verified 20 % bark for teak trees between 10 and 15 years of age.  
263 Average values of pith eccentricity and maximum angular deviation of wood from materials C1, C2  
264 and S are presented in Figure 3.

265 **Figure 3:** Average values and standard deviation of pith eccentricity (%) (a), and maximum angular  
266 deviation - MAD (°) (b) for the three genetic materials of *Tectona grandis* and spiral grain of C2  
267 material (c).  
268

269 There were no statistical differences ( $p < 0,05$ ) among the three materials for pith eccentricity,  
270 with an average value of 19,23 %. Figure 3a shows that the clonal materials presented a coefficient  
271 of variation  $< 20$  %, while that of the seminal material was 33,51 %, attesting to the homogeneity of  
272 C1 and C2; an important result for the standardization of industry equipment for higher sawn wood  
273 productivity and yield.

274 C1, C2 and S materials presented average pith eccentricity values that were higher than those  
275 of the studies developed by Benedetti (2018) and Blanco-Flórez *et al.* (2014), being 5,35 % and 9 %,  
276 respectively. According to Boschetti *et al.* (2015), the higher the trunk inclination is, the greater the  
277 pith eccentricity is, due to how trees react to winds and the slope of the terrain and the species'  
278 genetics, which is called reaction wood (Burger and Richter 1991). However, the region where C1,  
279 C2 and S were planted had a low slope. Thus, the high values of pith eccentricity are likely correlated  
280 to the characteristics of the genetic materials.

281 The average MAD values of the three genetic materials did not differ statistically, with an  
282 average value of  $4,74^\circ$  (Figure 3b). According to Limaye (1954)'s classification, the three genetic  
283 materials fall into the moderately intercrossed class ( $3,64^\circ$ - $5,44^\circ$ ). However, C2 is different from the  
284 other materials since the trunk bends on its own axis (Figure 3c), which characterizes a spiral grain.

285 Coelho *et al.* (2015) verified an average MAD of  $4,09^\circ$  for teak, with standard deviation of  
286  $2,59^\circ$ , which is lower than that found herein. However, all these values fall within the range from  
287 Limaye's classification (1954). The MAD value affects the surface finish of the wood, since higher  
288 angulation of the fibers causes its surface to have "roughness" (Vidaurre *et al.* 2017); an aspect that  
289 is not suitable for teak wood because it is used to make noble products such as furniture. In addition,  
290 workability can be impaired, as drying and machining of wood can cause major defects such as  
291 cracking and warping.

292 Therefore, according to NBR 7190 (1997), the three materials presented satisfactory quality,  
293 as they fall within the angulation limit of fibers up to  $6,00^\circ$ . Anything above this angulation  
294 significantly interferes with the wood properties, because the inclination of cellular elements causes

295 defects in wood, e.g., warping and decreased mechanical resistance, and causes cracks to form, which  
 296 interferes in the finishing of sawn wood (Panshin and De Zeeuw 1980; Coelho *et al.* 2015).

297 Coelho *et al.* (2015) highlighted the importance of identifying the MAD of wood because it  
 298 helps make decisions regarding sawing, re-sawing, drying, and finishing techniques. According to  
 299 these authors, MAD is also important for the workability of wood for various uses, mainly civil  
 300 construction, due to the correlation between grain type and dimensional stability and mechanical  
 301 strength of the wood. C1, C2 and S materials present grain classification that is superior to  
 302 commercially valued species, with MAD close to 15, and is considered a strongly intercrossed grain  
 303 (Hernández and Almeida 2003).

304 The results of basic density, compressive strength parallel to fibers, Janka hardness and shear  
 305 strength of C1, C2 and S materials are presented in Table 3.

306 **Table 3:** Average values and standard deviation of basic density ( $\rho_{\text{bas}}$ ) compression resistance  
 307 parallel to the fibers ( $f_{\text{wc},0}$ ), Janka hardness ( $f_{\text{wH}}$ ), shear strength ( $f_{\text{wv},0}$ ), tangential shrinkage ( $\epsilon_{r,3}$ ) and  
 308 radial shrinkage ( $\epsilon_{r,2}$ ) of the wood from the three genetic materials of *Tectona grandis*.

Treatment	$\rho_{\text{bas}}$ ( $\text{g}\cdot\text{cm}^{-3}$ )	$f_{\text{wc},0}$ (MPa)	$f_{\text{wH}}$ (MPa)	$f_{\text{wv},0}$ (MPa)	$\epsilon_{r,3}$ (%)	$\epsilon_{r,2}$ (%)	Anisotropy Factor
C1	0,51 a (0,02)	45,12 b (1,96)	40,36 a (8,67)	9,49 a (0,83)	4,64 a (0,51)	2,29 a (0,42)	2,08 a (0,36)
C2	0,52 a (0,02)	42,84 b (2,40)	43,07 a (11,50)	9,47 a (0,56)	3,88 a (0,48)	1,76 a (0,25)	2,26 a (0,47)
S	0,54 a (0,04)	48,89 a (2,35)	45,72 a (8,93)	10,61 a (0,87)	4,13 a (0,92)	2,25 a (0,29)	1,85 a (0,41)
<b>Average</b>	0,52	-	43,04	9,86	4,21	2,09	2,07

Means followed by the same letter do not differ statistically from each other by the Tukey test at 5% significance. (...) Standard deviation.

309  
 310 The materials did not differ statistically ( $p < 0,05$ ) for basic density and presented an average  
 311 value of  $0,52 \text{ g}\cdot\text{cm}^{-3}$ . “Therefore, they are classified as moderate (range  $0,5 \text{ g}\cdot\text{cm}^{-3} - 0,75 \text{ g}\cdot\text{cm}^{-3}$ ),  
 312 according to the Csanády *et al.* (2015). The basic density found herein was close to that found for 15  
 313 year old teak planted in Minas Gerais by Motta (2011), and those obtained by Blanco-Flórez *et al.*  
 314 (2014) and Benedetti (2018), who found basic densities of  $0,54 \text{ g}\cdot\text{cm}^{-3}$ ,  $0,52 \text{ g}\cdot\text{cm}^{-3}$ , and  $0,55 \text{ g}\cdot\text{cm}^{-3}$ ,  
 315 respectively.

316 The mean values of compression strength parallel to the wood fibers of the three genetic  
317 materials differed statistically. S material was higher than C1 and C2 by 7,71 % and 12,38 %,  
318 respectively (Table 3). The mean values of compressive strength parallel to the fibers were close to  
319 those found by Zahabu *et al.* (2015), with 40,12 MPa for 14-year-old teak wood in Tanzania, and by  
320 Blanco-Flórez *et al.* (2014), with 46,58 MPa for 13-year-old teak. Additionally, it was higher than  
321 the value found by Benedetti (2018) (38,54 MPa), and lower than those obtained by Valero *et al.*  
322 (2005) (52,24 MPa) for 20-year-old seminal teak in Barinas, Venezuela, and Motta (2011) (54,23  
323 MPa) for 15-year-old wood.

324 Nogueira (2007) affirmed that the grain inclination significantly interferes with the  
325 mechanical properties of wood at different magnitudes, which was verified herein with an inverse  
326 correction of 0,60 for these variables. The C2 material presented the highest grain angulation (5,25°)  
327 (Figure 3b), and the lowest compressive strength value parallel to the fibers (Table 3), while the  
328 seminal material presented the lowest grain inclination (4,42°; Figure 3b), and higher compression  
329 strength parallel to the fibers (Table 3).

330 There were no significant differences ( $p < 0,05$ ) between the three materials for Janka  
331 hardness, with an average value of 43,05 MPa. Thus, they were all classified as moderately soft,  
332 following FPL-0171(1973). The average Janka hardness of the three materials was similar to those  
333 found by Motta (2011) and Blanco-Flórez *et al.* (2014), being 48,15 MPa and 46,58 MPa,  
334 respectively. When comparing the mechanical properties of teak with those of other forest species,  
335 Benedetti (2018) found that young teak wood is not indicated for flooring production. Similarly, the  
336 three evaluated materials should be used for civil construction (doors and windows), panels and  
337 furniture, however, 15-years-old teak are not recommended for flooring. The low hardness of teak is  
338 related to workability and it is important for traditionally uses, i.e decorative portals (Arias and  
339 Monteuis 2013), however, makes it not suitable for floors and decks.

340 The average shear strength of wood from the three genetic materials did not differ statistically  
341 and was 9,66 MPa. This value was close to that found by Zahabu *et al.* (2015) (8,7 MPa) and by

342 Valero *et al.* (2005) (10,49 MPa). These authors consider this value low for shear strength. The values  
343 found herein were lower than those found by Benetti (2018) and Motta (2011), which were 16,41  
344 MPa and 12,25 MPa, respectively.

345 The characteristic values of parallel to the grain compression strength ( $f_{c0,k}$ ) for C1, C2 and S  
346 materials were 45,76 MPa, 43,67 MPa and 49,12 MPa, respectively. They also presented average  
347 values for basic density and characteristic shear strength values of  $0,52 \text{ g}\cdot\text{cm}^{-3}$  and 12,43 MPa,  
348 respectively. When considering these three variables, the three materials fall into the C20 class,  
349 according to NBR 7190 (1997). It should be pointed out that when considering only the value of  $f_{c0,k}$   
350 we could classify teak wood in the C40 class ( $f_{c0,k}= 40\text{MPa}$ ) for hardwoods (ABNT 1997), but due to  
351 the basic density criterion, we have to classify it as C20 (basic density =  $0,5 \text{ g}\cdot\text{cm}^{-3}$ ). For C40, in  
352 addition to  $f_{c0,k}$ , the basic density should  $\geq 0,75 \text{ g}\cdot\text{cm}^{-3}$ . Valero *et al.* (2005) highlight the use of teak  
353 for carpentry purposes in general, such as lathing.

354 There were no statistical differences ( $p < 0,05$ ) for anisotropy factor, volumetric shrinkage,  
355 tangential shrinkage and radial shrinkage, with average values of 2,07 %, 6,62 %, 4,21 % and 2,09  
356 %, respectively. The mean values for anisotropy coefficient of teakwood range from 2,08 to 1,88;  
357 1,17 % to 1,89 % for radial shrinkage, and 2,30 % to 3,57 % for tangential shrinkage, while the  
358 volumetric shrinkage is on the order of 3,57 % to 6,07 % (Blanco Flórez *et al.* 2014; Lengowski *et*  
359 *al.* 2021).

360 The shrinkage found in the present work are close to those reported in the literature, but the  
361 tangential shrinkage and volumetric shrinkage are higher. According to the anisotropy factor  
362 classification, Nock *et al.* (1975), teak wood is classified as normal (1,5-2,0), thus, it can be used for  
363 furniture manufacturing and other uses that allow small warping.

364 Teak wood is classified as resistance class 20 (ABNT 1997), thus, Queiroz (2018) suggested  
365 using it in the light construction sector, as well as for decorative pieces, sheets, panels, laminated  
366 plywood and framed plywood. This wood can also be used to manufacture frames, doors, or as slats,  
367 baseboards, boards and to manufacture fine furniture.

368 **3.3. Quality of sawnwood and drying defects**

369 Table 4 shows the percentage of boards with and without knots along with knot classification  
 370 according to Arruda (2013).

371 **Table 4:** Percentage of boards with and without living knots and knot classification for the three  
 372 genetic materials of *Tectona grandis*.

	C1	C2	S
<b>Absence of knots (%)</b>	37,78	34,33	47,50
<b>Presence of knots (%)</b>	62,22	65,67	52,50
<b>Class of knots (%)</b>			
<b>Small</b> (0 to 2 cm in diameter)	42,86	24,44	19,05
<b>Medium</b> (2 to 5 cm in diameter)	35,71	42,22	47,62
<b>Large</b> (above 5 cm in diameter)	21,43	33,33	33,33

373

374 There were no statistical differences ( $p < 0,05$ ) between the three materials regarding the  
 375 presence of living knots. However, the clonal materials presented knot incidences above 60 % in the  
 376 boards, while the seminal material presented almost 50 %. The C2 material showed a higher incidence  
 377 of knots concentrated in the medium and large size classes, while C1 presented the lowest number of  
 378 knots in the large class and the seminal material in the small class. Although the C2 material presented  
 379 a higher number of knots in the middle class, their maximum diameter was 2 cm.

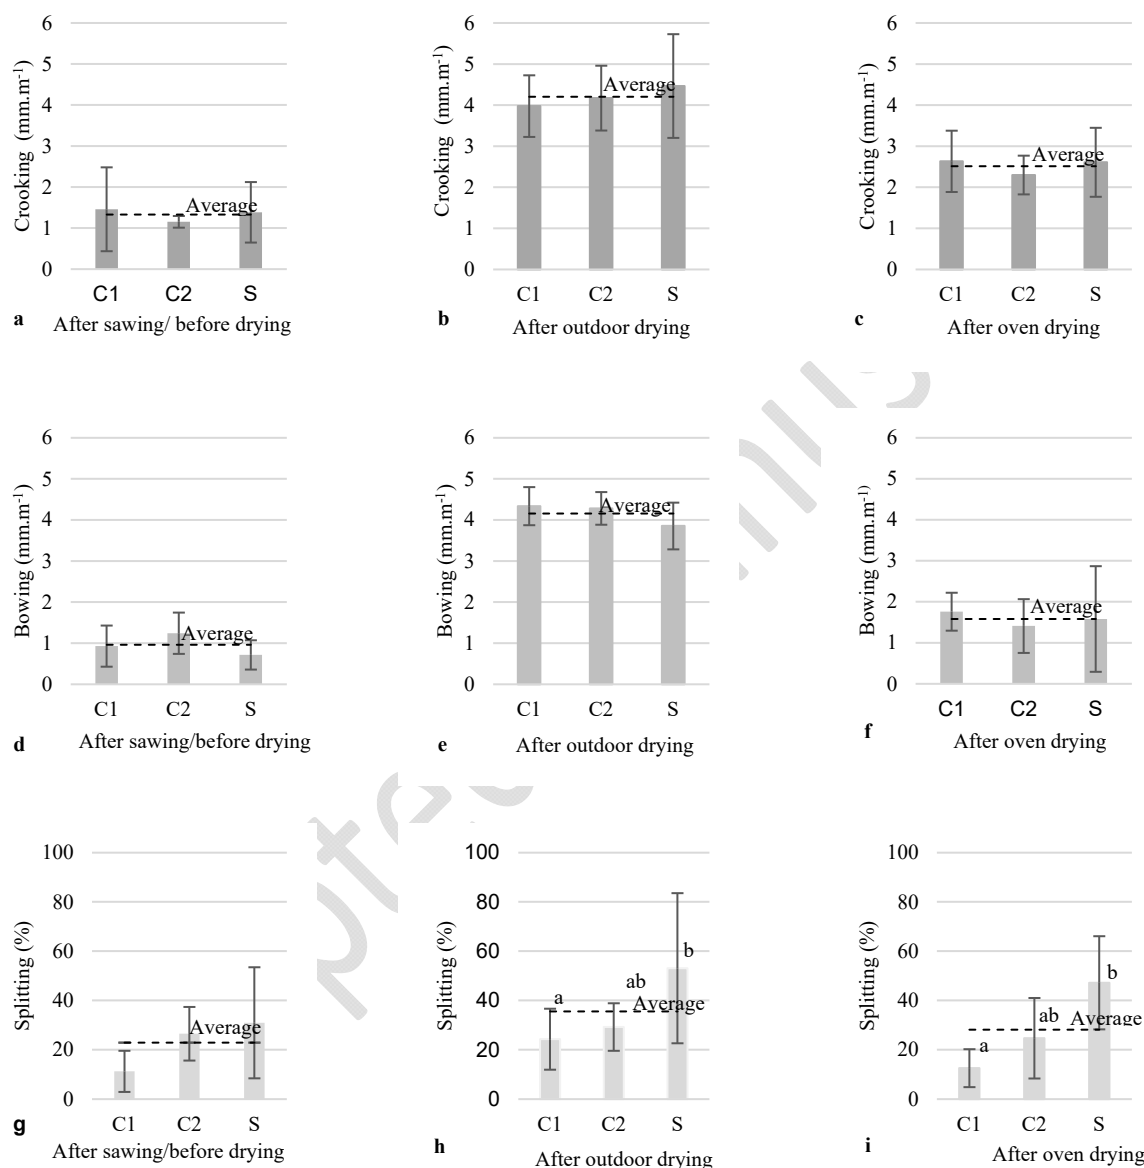

380 With knot development, there is greater inclination of the grain angle around it, which results  
 381 in a striking design with decorative value that is determined by the individual preference of the final  
 382 user (Wiedenhoeft 2010). However, the presence of a knot changes the direction of wood fibers, and  
 383 thus, most mechanical properties are lower in these regions (Kretschmann 2010).

384 There were no statistical differences between the three genetic materials for knots diameter,  
 385 with an average of 3,24 cm, and are classified as medium diameter knots according to Arruda (2013).  
 386 According to the IBDF (1984), the three materials would fit into the first quality class, because the  
 387 sum of the diameters of each genetic material is less than one tenth of the length of the board. Forestry  
 388 practices, such as pruning and thinning, are recommended to reduce the incidence and diameter of  
 389 knots, which can increase the yield and classification of wood, since better quality logs result in higher  
 390 wood yield rates (Tze 1999).

391 There were no statistical differences ( $p < 0,05$ ) between the three genetic materials for bowing,  
 392 crooking and splitting after the sawing process, with averages of  $1,33 \text{ mm}\cdot\text{m}^{-1}$ ,  $0,96 \text{ mm}\cdot\text{m}^{-1}$  and  
 393  $22,89 \%$ , respectively (Figure 4).

394

395 **Figure 4:** Average values and standard deviation of crooking (a, b and c), bowing (d, e and f) and  
 396 splitting (g, h and i) after sawing/before drying, after outdoor drying and after oven drying of the  
 397 three genetic materials of *Tectona grandis*. Averages followed by the same letter do not differ  
 398 statistically from each other with 5 % significance by the Tukey test.

399 However, there was a higher incidence of splitting the boards from seminal material, in  
 400 addition to high variation of the material (Figure 4 g, h and i). This makes it difficult to use the entire  
 401 piece of wood, consequently, generates damages for forest producers.

402 Defects were greater after drying (Figure 4), when compared to defects after sawing. There  
403 were no significant differences ( $p < 0,05$ ) for warping between the three materials in outdoor drying,  
404 and the average crooking and bowing were  $4,20 \text{ mm}\cdot\text{m}^{-1}$  and  $4,04 \text{ mm}\cdot\text{m}^{-1}$ , respectively.

405 There was also no significant statistical effect ( $p < 0,05$ ) between the three materials for oven  
406 drying, both for crooking and for bowing, and the mean values were  $2,51 \text{ mm}\cdot\text{m}^{-1}$  and  $1,58 \text{ mm}\cdot\text{m}^{-1}$ ,  
407 respectively. When evaluating the drying process of 20-year-old *T. grandis* in a conventional camera  
408 Loiola (2015) obtained an average value of  $0,40 \text{ mm}\cdot\text{m}^{-1}$  for crooking and  $0,30 \text{ mm}\cdot\text{m}^{-1}$  for bowing,  
409 which are lower than the values found herein.

410 Figure 4 shows that the average values of the bowing index were higher than those of crooking  
411 both in outdoor drying and in oven drying. This same result was found by Berrocal *et al.* (2017), who  
412 evaluated different drying programs for 11-year-old teak and verified that the wood presented a higher  
413 bowing than crooking. Arruda (2013) states that bowing can be minimized by adding weight to the  
414 wood pile.

415 According to the NBR 14806 (2002), there is a quality class tolerance for the bowing and  
416 crooking in hardwood of up to  $5 \text{ mm}\cdot\text{m}^{-1}$ . Hence, the crooking index was 16 % lower than the  
417 stipulated limit for outdoor drying, while bowing was 19,2 % lower. On the other hand, oven drying  
418 showed a better response because the average crooking and bowing values were 49,8 % and 68,45  
419 %, respectively, which is below the established limit.

420 According to the IBDF (1984), regarding the aspect of bowing and crooking, the boards of  
421 the three genetic materials fall into the first class since all presented values below  $5 \text{ mm}\cdot\text{m}^{-1}$ .  
422 However, woods that were dried in the oven had a lower incidence of bowing and crooking defects.  
423 Therefore, the oven drying process is advantageous as it presents fewer defects and shorter drying  
424 time, demonstrating that the drying program used by the company is effective for the teak species.

425 This result contradicts Betancur *et al.* (2000), who evaluated different drying processes in teak  
426 wood and obtained better results in the outdoor drying process, with final dry material presenting

427 fewer defects. Nonetheless, regardless of the genetic material, all the boards submitted to the drying  
428 processes herein are suitable for manufacturing and commercialization.

429 After the artificial drying process 25 % of the samples did not present any kind of defect, and  
430 for crooking, bowing and splitting were 3,95 %, 18,42 % and 2,63 %, respectively. While in the air  
431 drying process, only 11,43 % did not have splitting, that is, they had the development of warping.  
432 Trujillo *et al.* (2021) evaluating the artificial drying of teak boards obtained from 33 year-old trees,  
433 observed that 61 % of the evaluated boards showed no deformation, however, among those that  
434 suffered deformation, only 3,5 % were rejected, that is, they had indexes above the acceptable by the  
435 standard, resulting in a percentage of 96,5 % of boards accepted for commercialization after drying.

436 There was a significant effect ( $p > 0,05$ ) of the materials for splitting, and the seminal material  
437 presented higher values for both outdoor drying and oven drying. For all materials, the outdoor drying  
438 process had the highest incidence of splitting, demonstrating that the oven drying process met the  
439 drying requirements with lower defect index, even with higher temperature and air circulation.

440 When evaluating different drying processes in teak, Berrocal *et al.* (2017) obtained a splitting  
441 index between 10 % and 35 %. The C1 boards submitted to the oven drying process presented a value  
442 close to 10 %, while those from seminal material presented average values higher than 40 %, and  
443 those from C2 material presented intermediate behavior in relation to the other materials, in both  
444 drying processes.

445 The greatest variation in drying type occurred with C1 material, with a difference of 48,46 %.  
446 Yet, C1 presented the lowest percentage of splitting of all three materials. The C2 and S materials  
447 showed variation between the drying processes of 15,51 % and 11,13 %, respectively. According to  
448 the IBDF classification (1984), C1 material would fit into the fourth class, due to its splitting value  
449 of  $< 20$  %. The other materials did not fit any classification, as they presented values  $> 20$  %.  
450 However, it was the most significant defect in the wood from the three genetic materials.

451 **4. CONCLUSIONS**

452 The wood properties of the three genetic materials (two clones and one seminal) are similar,  
453 but C2 showed higher volumetric production of heartwood in the basal region of the tree, above 50  
454 % heartwood until half of the commercial height.

455 The three materials did not differ significantly ( $p < 0,05$ ) for maximum angular deviation and  
456 basic density. They were classified with moderately intercrossed grain and presented an average basic  
457 density of  $0,52 \text{ g}\cdot\text{cm}^{-3}$ .

458 The seminal material was superior to materials C1 and C2 for fiber parallel compressive  
459 strength, however the three materials did not differ for Janka hardness and shear strength. The wood  
460 from the genetic materials evaluated can be intended for decorative purposes, furniture  
461 manufacturing, and the light civil construction sector.

462 The incidence of knots did not differ among the genetic materials and was higher than 50 %,  
463 but with knots of medium diameter (3,24 cm). Compared to seminal material, the clonal materials  
464 presented higher yields of sawn wood and lower incidences of defects, mainly for splitting, despite  
465 lower mechanical strength, demonstrating the sawn wood with the best quality.

466 The oven drying process is recommended, as it proved to be more efficient and generated the  
467 lowest defect rates.
