ABSTRACT

High-resolution backscatter and bathymetric maps created by multibeam sonar surveys were used to identify different seafloor bottom types within existing, potentially expanded, and newly proposed reef areas in New York waters. Existing sites included Smithtown in Long Island Sound (LIS), and Rockaway, Atlantic Beach, Hempstead, Yellowbar, Kismet, Fire Island, Twelve Mile along the South Shore. Potential expansions are proposed on the South Shore for McAllister, Moriches, and Shinnecock reefs in addition to a new site called Sixteen Fathom. In Long Island Sound, new sites are proposed for Huntington/Oyster Bay, Port Jefferson/Mount Sinai, and Mattituck. Grab samples were collected within these areas to characterize sediment properties and macrofauna. Multivariate analysis was used to identify important factors explaining variations in community structure. Sites within Long Island Sound had 3 to 10 bottom types (i.e., acoustic provinces), but sediments and benthic community structure was characterized by greater among site variation compared to within site variability. Sites along the South Shore had 4 to 12 bottom types (acoustic provinces), and although sediments were mostly sandy, there was substantial within site variation in benthic community structure.

INTRODUCTION

The New York State Department of Environmental Conservation (NYSDEC) has created and has managed artificial reef sites in marine waters off Long Island. These areas provide both ecosystem services and significant benefits to the recreational and commercial rod and reel fishing industry. As part of the permitting process, NYSDEC required detailed bathymetry, sonar backscatter, sediment grain-size, and benthic macrofauna information about the existing, potentially expanded, and newly proposed reef areas. Existing sites included Smithtown in Long Island Sound (LIS), and Rockaway, Atlantic Beach, Hempstead, Yellowbar, Kismet, Fire Island, Twelve Mile along the South Shore. Potential expansions are proposed on the South Shore for McAllister, Moriches, and Shinnecock reefs in addition to a new site called Sixteen Fathom. In Long Island Sound (LIS), new sites are proposed for Huntington/Oyster Bay, Port Jefferson/Mount Sinai, and Mattituck. Multibeam sonar mapping surveys conducted by Roger Flood of SoMAS collected high resolution bathymetry and backscatter data at all of the South Shore sites and Smithtown in LIS. In addition, existing NOAA sonar data were reprocessed and made available by Roger Flood for Huntington/Oyster Bay, Port Jefferson/Mount Sinai, and Mattituck in LIS. The backscatter data were used to guide ground-truth sampling in the present study.

Maps generated by sonar surveys are incredibly useful, enabling large areas to be surveyed at fine resolution in relatively short periods of time; however, these maps are not sufficient for predicting detailed bottom characteristics or the distribution of benthic communities, and at least one ground truth stage is required to link the acoustic survey maps with environmental and biological assemblages. Acoustic surveys can distinguish areas of different bottom type or character, but determining that those sites are, for example, rocky substrates, rippled sands, shelly sands, or muddy surfaces requires verification by direct sampling. Knowing the type of bottom present is an important indicator of the benthic community that may be present, but benthic communities are highly variable and cannot be accurately predicted based on bottom type alone. In addition, geophysical features detectable by acoustic surveys that appear to

characterize distinct sedimentary regions are not necessarily biologically relevant (Brown *et al.*, 2002).

The goal of the current study was to provide ground-truth data on seafloor sediment properties and information on the benthic macrofauna community characteristics of the reef areas. Sampling locations were determined by visual examination of high resolution backscatter maps created from the multibeam sonar surveys. The multibeam sonar surveys were conducted as part of a separate task, and these maps are not part of the current report.

METHODS

Study Areas and Sampling Locations

This study was carried out at fifteen existing, potentially expanded, and newly proposed reef areas in New York waters and adjacent areas in Long Island Sound and on the South Shore of Long Island (Figure 1). Stratification of the reef areas into bottom type provinces was conducted by visual examination of preliminary 300 kHz multibeam backscatter data collected by Roger Flood (SoMAS) for all of the South Shore sites and Smithtown in LIS. In addition, existing NOAA sonar data were reprocessed and made available for the current study by Roger Flood for Huntington/Oyster Bay, Port Jefferson/Mount Sinai, and Mattituck in LIS. In the stratification process, acoustic backscatter was taken as a proxy for bottom type or habitat. Flanagan, et al. (2019) found that habitats visually characterized based on an examination of backscatter intensity and texture in this way explained more of the infaunal community variation than any analysis that used a combination of other environmental variables (e.g., water depth & sediment grain size) or those constructed using categorical habitat classes from existing habitat classification schemes. A polygon feature class consisting of the bottom type provinces was created in ArcGIS 10.7.1 (ESRI, Redlands CA). Bottom type provinces were assigned a two-character site code (e.g., AB = Atlantic Beach) and an arbitrarily defined, single character province code of A, B, C, etc. reflecting the number of provinces within a site. Polygons in the GIS feature class were clipped to conform to the outline of the designated reef areas allowing an estimate of strata areas in square kilometers.

Budget considerations allowed ground-truth grab sampling at bottom type provinces consisting of 7 samples at each of the existing reef sites (Smithtown, Rockaway, Atlantic Beach, Hempstead, Yellowbar, Kismet, Fire Island, and Twelve Mile) and 14 samples at each of the potential expansion sites (McAllister, Mорiches, and Shinnecock) and the new sites (Sixteen Fathom, Huntington/Oyster Bay, Port Jefferson/Mount Sinai, and Mattituck). Sampling stations were randomly positioned within each province using the “Create Random Points” tool in ArcGIS 10.7.1 (ESRI, Redlands CA). Not all provinces could be sampled since the study had constraints on the number of samples at each site, but an attempt was made to sample as many bottom provinces as possible. Bottom type provinces and ground-truth sampling locations are identified in Figure 2.

Sediment and Fauna Sampling

Bottom samples for sediments and fauna were collected on June 29-30, 2021 in Long Island Sound and August 10-13, 2020 along the South Shore using a modified van Veen grab (0.04 m^2). A total of 49 samples were collected at the four Long Island Sound reefs and 105 samples at the eleven South Shore reefs. Subsamples of sediments for grain size were drawn from each grab sample. The remaining sediment was washed through a 0.5 mm sieve for fauna. All material left on the sieve was preserved in 10% buffered formalin and stained with rose bengal. Faunal samples were rewashed in the lab and transferred to 70% ethanol before sorting and identification. Individual organisms were identified to species level whenever possible and the total for each taxon enumerated. Unless otherwise noted, all abundances in this report are expressed as the number of individuals per sample (i.e., per 0.04 m^2).

Sediment grain size analysis followed methodology in Folk (1974) to estimate percent composition by weight of major size-fractions (gravel, sand, silt-clay or mud). Samples were initially partitioned into three size-fractions by adding 50 ml of a 1% Calgon solution to the sample, mixing to disaggregate the particles in the sample, and wet sieving with distilled water through a combination of 2 mm and 63 micron sieves. The $>2\text{ mm}$ (gravel) and $2\text{ mm}-63\text{ micron}$ (sand) fractions were placed in a drying oven at 60° C for at least 48 hours to obtain dry weights. Water containing the $<63\text{ micron}$ fraction (silt-clay or mud) was brought up to 1000 ml total volume by adding distilled water in a graduated cylinder, mixed thoroughly, and subsampled with a 20 ml pipette at a depth of 20 cm, 20 seconds after mixing to obtain an estimate of mud. Pipette samples were placed in a drying oven at 60° C for at least 48 hours to obtain dry weight estimates. Weight estimates for mud (silt-clay) included a correction for the amount of Calgon introduced to the samples.

Data Entry and Summary

Data were entered into Microsoft Excel spreadsheets, and faunal data were summarized by using PC-ORD (MJM Software Design, Gleneden Beach, OR). This summary and subsequent data analyses required assigning a unique 4-character code for each species. This was created in most cases by using the first 2 characters in both the genus and species name. Faunal data at each sampling station were summarized by calculating the abundance (total number of individuals per grab), species richness S (number of species per grab), Shannon diversity ($H' = -\sum p_i \ln p_i$) where p_i is the proportion of individuals of each species, equitability ($E = H'/\ln S$), and Simpson's index of diversity ($D = 1 - \sum p_i^2$). H' is the common entropy measure of diversity that combines both species richness and the evenness of individuals distributed among the organisms in the sample. Equitability ranges from 0 to 1 and measures how evenly individuals are distributed among the S species present. Simpson's index of diversity for large samples approximates the probability that two individuals randomly sampled belong to different species. Abundance expressed as the number of individuals per square meter was also calculated, but this metric is not presented in detail, since abundance per sample was preferred. A geodatabase of the data and GIS maps displaying selected data were created in ArcGIS version 10.7.1 (ESRI, Redlands CA). All data were imported into the GIS directly from the Excel spreadsheets.

Multivariate Analysis

Data were analyzed by principal components analysis (PCA) and redundancy analysis (RDA). PCA is an ordination method that utilizes only the faunal data. RDA is a multivariate direct gradient technique that explicitly incorporates regression with environmental variables in the analysis of the faunal data. RDA, first suggested by Rao (1964), is a technique that combines ordination of sample sites based on species abundance data with regression on the environmental data in order to examine the relationship between community structure and environmental variables (Jongman *et al.*, 1995). By examining the environmental and biological data simultaneously, this analysis depicts the trends in the species data that are related to the selected environmental data. PCA and RDA are based on Euclidean distance, which is not the most appropriate resemblance measure for species data, since it incorrectly interprets shared species absences between samples as similarities. In order to circumvent this shortcoming, abundance data were Hellinger transformed by taking the square root of relative abundances of each species in a sample (Legendre and Gallagher, 2001). This transformation focuses the analysis on compositional differences, reduces the influence of the most abundant species, and combined with Euclidean distance, has been shown to produce good representations of ecological data (Legendre and Gallagher, 2001).

Within the RDA analysis, environmental variables that explained community variation were identified by sequentially adding variables in a forward selection process (Jongman *et al.*, 1995). Candidate variables included water depth, grab penetration depth, percent gravel, percent sand, and percent mud (i.e., silt-clay). At each step in the process, the environmental variable explaining the largest amount of faunal variability is selected, and its effect is removed before the next best fitting variable is considered. Variables identified by forward selection were checked for inclusion using the AICc stopping criterion (Burnham and Anderson 2002). AICc is the small sample, bias adjusted version of the Akaike Information Criterion (AIC). The use of AICc applies an information-theoretic approach to statistical modeling that overcomes problems associated with multiple significance testing (Burnham and Anderson 2014). Although a not entirely correct interpretation (see Burnham and Anderson 2002), AIC is often considered as measure that assesses the tradeoff between fit and complexity among models. In application, the model with the smallest AIC or AICc is chosen over the complete set of models considered (Hastie *et al.* 2009). PCA and RDA was carried out using Canoco 4.5 (ter Braak and Smilauer 2002).

RESULTS

Long Island Sound

General Description of the Environmental and Faunal Characteristics of the Reef Areas

Sediments within the Long Island Sound reef areas differed among the sites but were most often characterized by low percent gravel contents (Appendix 1). Of the 49 samples, only 11 had percent gravel contents greater than 1%, and none of these exceeded 6.2%. It should be noted that gravel included not just mineral grains but also bits of shell and other material that did not pass through the 2mm sieve. The predominant (i.e., > 50% by weight) grain size in 26 samples was sand, while 23 samples were dominated by mud (> 50%). Water depths at sampling stations

ranged from 9.0 to 29.0 m. The modified van Veen grab penetrated to its maximum depth of 10 cm for 33 of the 49 samples, and mean penetration depth was 9.3 cm.

A total of 3,783 animals representing 88 taxa were collected in the 49 samples. Average abundance in the 49 samples was 77.2 individuals per sample (1,930 per m²). Of the 88 taxa, 64% were polychaetes, 26% were molluscs, 5% were crustaceans, and the remainder (5%) was distributed among five other groups (Nematoda, Nemertinea, Oligochaeta, Echinodermata, and Chordata) (Table 1). Numerical dominants included the polychaete Maldanidae spp juveniles (538 individuals) that could not be identified to species level, the bivalve *Macoploma* (fr. *Macoma*) *tenta* (400 individuals), the polychaetes *Levinsenia gracilis* (388 individuals), *Cirritulidae* spp (*Kirkegaardia baptistae* + *Tharyx acutus*) (376 individuals), *Nephtys incisa* (167 individuals), the infaunal deposit feeding bivalve *Yoldia limatula* (167 individuals), Nematoda spp (151 individuals), the polychaete *Sigambra tentaculata* (147 individuals), the surface deposit feeding bivalve *Ameritella* (fr. *Tellina*) *agilis* (144 individuals), the archiannelid polychaete *Polygordius jouinae* (118 individuals), the polychaete *Prionospio* (= *Minusprio*) sp (108 individuals), the gastropod *Ilyanassa trivittata* (75 individuals), the polychaetes *Capitellidae* spp (*Heteromastus* + *Notomastus*) (68 individuals), the polychaete *Sabaco elongates* (59 individuals), the amphipod *Unciola irrorata* (58 individuals), the gastropod *Acteocina canaliculata* (51 individuals), the amphipods *Ampelisca* spp (*macrocephala* + *verrilli*) (48 individuals), and the bivalve *Pitar morrhuanus* (47 individuals). These 18 taxa represented about 83% of the total number of individuals collected, and no other taxon had an average abundance greater than 1 per sample (i.e., >49 individuals). Faunal data listed by sample are tabulated in Appendix 2.

a) Huntington – Oyster Bay

Fourteen samples were collected at this reef site. Sampling stations at this site had a mean water depth of 14.9 m \pm 0.4 m sd. The van Veen grab penetrated to its maximum depth of 10 cm at all stations. On average, sediments were an approximately even mixture of sand (mean \pm sd = 46.3% \pm 15.8) and mud (52.4% \pm 16.0 sd) (Figure 3). The gravel fraction (1.3% \pm 1.7) of the sediments consisted of mineral grains, shell hash, and other bits of organic detritus (e.g., wood).

Faunal abundances ranged from 31 to 94 individuals per sample and species richness varied from 9 to 17 species per sample. Mean abundance was 64.1 \pm 16.0 (sd) individuals per sample, and mean species richness was 14.4 \pm 2.4 (sd) species per sample (Figure 4). A total of 37 taxa and 897 individuals were collected. The most abundant taxon was the bivalve *Macoploma* (fr. *Macona*) *tenta* (Table 2). This taxon had an average abundance of 26 individuals per sample and represented 40.4% of the total number of individuals in the samples from this site. Other abundant taxa included *Prionospio* (= *Minusprio*) sp (mean = 4.7 per sample), juveniles of the polychaete Maldanidae spp (4.1) that could not be identified to species level, the polychaete *Nephtys incisa* (3.3), the amphipod *Unciola irrorata* (3.1), the polychaetes *Cirritulidae* spp (*Kirkegaardia baptistae* + *Tharyx acutus*) (3.0), the Maldanid polychaete *Sabaco elongates* (2.9), the polychaetes *Capitellidae* spp (*Heteromastus* + *Notomastus*) (2.9), the infaunal deposit feeding bivalve *Yoldia limatula* (2.6), the amphipod *Leptocheirus pinguis* (2.4), the cone shaped tube building polychaete *Pectinaria gouldii* (1.6), and the polychaete *Melinna cristata* (1.1). All other taxa had an average abundance less than 1.0 individual per sample. Mean Shannon diversity was 2.01 \pm 0.37 (sd), and mean equitability was 0.76 \pm 0.11 (sd) (Figure 4).

b) Smithtown

Seven samples were collected at this site, since it was an existing reef. Water depths averaged $11.3 \text{ m} \pm 1.5 \text{ sd}$. Five of the seven grab samples penetrated to their maximum depth of 10 cm, and average penetration depth was $9.6 \text{ cm} \pm 0.9 \text{ sd}$. There was a large variation in the amount of sand and mud present, with the sand fraction varying from 27-97% and the mud fraction ranging from 3-73%. Average sand and mud contents were $76.0\% \pm 24.2 \text{ sd}$ and $23.2\% \pm 24.4 \text{ sd}$, respectively (Figure 3). Sediment samples had small amounts of gravel ($0.8\% \pm 0.7 \text{ sd}$).

The Smithtown site had the largest total number of individuals and taxa of the Long Island Sound sites, despite the fact that only seven samples were collected compared to fourteen at the other Long Island Sound sites. A total of 1,426 individuals and 61 taxa were collected. Faunal abundances varied from 72 to 309 individuals per sample. Species richness ranged from 10 to 35 species per sample. Mean abundance was $203.7 \pm 96.8 \text{ (sd)}$ individuals per sample and mean species richness was $23.3 \pm 9.6 \text{ (sd)}$ species per sample (Figure 4). These values exceeded all of the other Long Island Sound reef sites. In contrast mean Shannon diversity and equitability at the Smithtown reef was lower than at the other Long Island Sound sites. Mean Shannon diversity was $1.86 + 0.25 \text{ (sd)}$, and mean equitability was $0.62 + 0.08 \text{ (sd)}$ (Figure 4). Twenty-three taxa had average abundances exceeding one individual per sample (Table 2). These included juveniles of the polychaete Maldanidae spp (mean = 63.4 per sample), the polychaetes Cirritulidae spp (*Kirkegaardia baptistae* + *Tharyx acutus*) (44.4), Nematoda spp (20.0), the polychaetes *Polygordius jouinae* (16.3), *Aricidea catherinae* (5.7), the surface deposit feeding bivalve *Ameritella* (fr. *Tellina*) *agilis* (5.1), the polychaete *Glycinde multidens* (= *G. solitaria*) (4.0), the polychaete *Prionospio* (= *Minusprio*) sp (3.9), the barrel-bubble gastropod *Acteocina canaliculata* (3.3), the polychaete *Levinsenia gracilis* (3.0), the polychaetes Capitellidae spp (*Heteromastus* + *Notomastus*) (2.9), the Maldanid polychaete *Sabaco elongatus* (2.4), the bivalve *Macoploma* (fr. *Macoma*) *tenta* (2.1), the mudsnail *Ilyanassa trivittata* (2.0), the infaunal deposit feeding bivalve *Yoldia limatula* (1.9), the polychaetes *Scoletoma fragilis* (1.7), *Sigambra tentaculata* (1.4), Spionidae spp juveniles (*Dipolydora* + *Polydora*) (1.4), the false quahog *Pitar morrhuanus* (1.3), the glassy and semitransparent bivalve *Lyonsia* spp (*arenosa* + *hyalina*) (1.1), the razor clam *Ensis leei* (fr. *E. directus*) (1.0), the Maldanid polychaete *Clymenella zonalis* (1.0), and the amphipod *Leptocheirus pinguis* (1.0).

c) Port Jefferson – Mt. Sinai

This potential reef site was the deepest and muddiest of the four Long Island Sound sites. Fourteen samples were collected at this site. Water depths ranged from 27-29 m, with an average of $28.1 \text{ m} \pm 0.7 \text{ sd}$. All grab samples penetrated to the maximum depth of 10 cm. Sediments were variable, but mud content exceeded 50% at all fourteen samples. Grain size ranges were 0-4.9% gravel, 12.1-45.7% sand, and 53.4-88.0% mud. Average gravel (with shell), sand, and mud contents were $0.8\% \pm 1.5 \text{ (sd)}$, $29.9\% \pm 10.9$, and $69.3\% \pm 11.3$, respectively (Figure 3).

Faunal summary characteristics at this site were fairly similar to that of the Huntington – Oyster Bay site (Figure 4). A total of 962 individuals and 36 taxa were collected. Mean abundance was 68.7 ± 13.8 (sd) individuals per sample and mean species richness was 13.0 ± 2.1 (sd) species per sample. Abundances ranged from 53 to 105 individuals per sample, and species richness varied from 9 to 17 species per sample. Mean Shannon diversity was 1.96 ± 0.32 (sd), and mean equitability was 0.76 ± 0.11 (sd). The most abundant taxa were the polychaetes *Levinsenia gracilis* (mean = 25.5 per sample), *Sigambra tentaculata* (8.8), the infaunal deposit feeding bivalve *Yoldia limatula* (8.4), the polychaete *Nephtys incisa* (6.6), the infaunal deposit feeding bivalve *Nucula proxima* (2.2), the false quahog *Pitar morrhuanus* (2.1), the barrel-bubble *Acteocina canaliculata* (2.0), the polychaete *Scolelepis bousfieldi* (1.7), the bivalve *Macoploma* (fr. *Macoma*) *tenta* (1.6), juvenile polychaetes of Maldanidae spp (1.6), the mudsnail *Ilyanassa trivittata* (1.1), the polychaetes Cirritulidae spp (*Kirkegaardia baptistae* + *Tharyx acutus*) (1.1), the polychaete *Melinna cristata* (1.0) (Table 2). All of the remaining taxa had an average abundance less than 1.0 individual per sample at this site.

d) Mattituck

This potential reef was the sandiest of the four Long Island Sound sites. Fourteen samples were collected. Water depths averaged $25.3 \text{ m} \pm 2.5$ sd. Grab samples penetrated to a depth of 7.9 cm ± 1.0 (sd), the lowest average penetration depth of the four Long Island Sound reef sites (Figure 3). Samples were primarily sand (mean = $92.2\% \pm 2.3$ sd) with a small amount of mud ($7.8\% \pm 2.3$), and virtually no gravel ($0.0\% \pm 0.1$). The sand fraction varied from 89-96% and the mud fraction ranged from 4-13%. Gravel never exceeded 0.3% in any sample.

The Mattituck site had the lowest abundance and the greatest Shannon diversity and equitability of the four Long Island Sound sites (Figure 4). Species richness was moderate and comparable to Huntington–Oyster Bay and Port Jefferson-Mt. Sinai. Faunal abundances varied from 3 to 50 individuals per sample, and species richness ranged from 2 to 19 species per sample. Mean abundance was 35.6 ± 13.1 (sd) individuals per sample, and mean species richness was 15.0 ± 4.5 (sd) species per sample. Mean Shannon diversity was 2.27 ± 0.52 (sd), and mean equitability was 0.87 ± 0.05 (sd). A total of 498 individuals and 48 taxa were collected in the fourteen samples. The most abundant taxon was the surface deposit feeding bivalve *Ameritella* (fr. *Tellina*) *agilis* (mean = 7.7 per sample) (Table 2). Other abundant taxa included the amphipod *Ampelisca* spp (*macrocephala* + *verrilli*) (3.4), the polychaete *Nephtys incisa* (3.2), the mudsnail *Ilyanassa trivittata* (2.9), the polychaetes *Spiophanes bombyx* (2.1), *Scoloplos rubra* (1.8), *Nephtys bucera* (1.4), *Spiochaetopterus oculatus* (1.1), and the commensal pea crab *Rathbunixa* (fr. *Pinnixa*) *sayana* (1.1) which lives in association with a tube-building polychaete, and juveniles of the polychaete Maldanidae spp (1.0) which could not be identified to genus. No other taxa had an average abundance greater than 1.0 individual per sample.

Multivariate Analysis

Forward selection RDA resulted in identifying and retaining 3 environmental variables based on the AICc stopping criterion: % sand, water depth, and grab penetration depth (Figure 5). These environmental variables explained 42.6% of the total variability in community structure. The separation of the reef sites in this ordination is almost complete and indicated that community

structure differed considerably among the sites. Within site variation was considerably less, as reflected in the tight grouping of sampling stations, especially at Port Jefferson – Mt. Sinai and Mattituck. A total of 96% of the explained species-environment relationship was contained in the first two ordination axes, so there was no need to plot additional axes.

Differences among sites with respect to environmental variables is straightforward using this diagram. Mattituck is distinguished as having the highest % sand and lowest penetration depth as indicated by its position along the first ordination axis. Water depths are deepest at the Port Jefferson – Mt. Sinai site and shallowest at Huntington - Oyster Bay and Smithtown, along the second ordination axis. Distinct difference in taxon abundances are also evident. For example, focusing just on several bivalve species, it is clear that *Ameritella agilis* (Amag) was more abundant at Mattituck than other sites, *Nucula proxima* (Nupr), *Pitar morrhuanus* (Pimo), and *Yoldia limatula* (Yoli) were most abundant at Port Jefferson – Mt. Sinai, and *Macoploma tenta* (Mate) was highly abundant at Huntington – Oyster Bay and absent at Mattituck. Comparable differences can be identified for other taxonomic groups. It should be noted that for clarity only 20 of the 88 taxa are plotted in this diagram. The remaining taxa would all be crowded around the origin, and the cluttered plot would have been very difficult to examine.

South Shore

General Description of the Environmental and Faunal Characteristics of the Reef Areas

Sediments within the South Shore reef areas were mostly sandy with a few exceptions (Appendix 3). Of the 105 samples, 97 had percent sand contents greater than 50%. Only five samples had gravel contents greater than 50% and only two samples had greater than 50% mud. It should be noted that gravel included not just mineral grains but also bits of shell and other material that did not pass through the 2mm sieve. Water depths ranged from 2.4 to 43.3 meters at the sampling stations. The modified van Veen grab penetrated to its maximum depth of 10 cm in only 8 of the 105 samples, reflecting the high sand content at most stations. Mean penetration depth was 6.6 cm.

A total of 24,970 animals representing 186 taxa were collected in the 105 samples. Average abundance in the 105 samples was 237.8 individuals per sample (5945 per m²). Of the 186 taxa, 51% were polychaetes, 11% were molluscs, 32% were crustaceans, and the remainder (6%) was distributed among ten other groups (Table 3). Numerical dominants included the polychaete *Polygordius jouinae* (5,433 individuals), Nematoda spp (4,293 individuals), the amphipod *Pseudunciola obliquua* (2,890), the polychaetes *Cirritulidae* spp (*Kirkegaardia baptistae* + *Tharyx acutus*) (2,855 individuals), the polychaetes *Microphthalmus sczelkowii* (2,021) and *M. aberrans* (997), Oligochaeta spp (826), the amphipods *Ampelisca* spp (*macrocephala* + *verrilli*) (331 individuals), the polychaetes *Caullerella venefica* (246), *Neanthes arenaceodentata* (238), *Goniadella gracilis* (230), and *Nephtys picta* (191), the amphipods *Rhepoxynius epistomus* (158), *Unciola irrorata* (158), and *Ampelisca* spp (*abrita* + *vadurum*) (152), the polychaetes *Streptosyllis arenae* (146) and *Protohaustorius wigleyi* (143), the slipper snail *Crepidula fornicate* (138), the polychaete *Paradoneis lyra* (138), the surf clam *Spisula solidissima* (133), the polychaetes *Prionospio pygmaeus* (131), *Spiophanes bombyx* (130), and *Aricidea catherinae* (120), the surface deposit feeding bivalve *Ameritella* (fr. *Tellina*) *agilis* (109), and the polychaete

Aricidea wassi(109). These 25 taxa represented about 89% of the total number of individuals collected, and no other taxon had an average abundance greater than 1 per sample (i.e., >105 individuals). Faunal data listed by sample are tabulated in Appendix 4.

a) Rockaway

Seven samples were collected at this site, since it was an existing reef. Water depths averaged $11.8 \text{ m} \pm 0.6 \text{ sd}$. Grab samples penetrated to a depth of $4.4 \text{ cm} \pm 1.0 \text{ (sd)}$, the lowest average penetration depth of the eleven South Shore reef sites (Figure 6). All samples exceeded 91% sand with small amounts of gravel (0-7%) and mud (1-2%) present. Average sand content was $96.6\% \pm 2.4 \text{ sd}$. Average gravel and mud contents were $2.0\% \pm 2.3 \text{ sd}$ and $1.3\% \pm 0.4 \text{ sd}$, respectively (Figure 6).

The Rockaway site had the lowest total number of individuals and taxa of the South Shore sites. A total of 342 individuals and 37 taxa were collected. Faunal abundances varied from 9 to 88 individuals per sample. Species richness ranged from 8 to 19 taxa per sample. Mean abundance was $48.9 \pm 31.2 \text{ (sd)}$ individuals per sample and mean species richness was $13.3 \pm 4.4 \text{ (sd)}$ species per sample (Figure 7). These values were lower than all sites except Moriches. In contrast, mean equitability at the Rockaway reef was greater than at the other South Shore sites. Mean Shannon diversity was $2.07 \pm 0.36 \text{ (sd)}$, and mean equitability was $0.83 \pm 0.15 \text{ (sd)}$ (Figure 7). Eleven taxa had average abundances exceeding one individual per sample (Table 4). These included the amphipods *Ampelisca* spp (*macrocephala* + *verrilli*) (mean = 18.7 per sample) and *Protohaustorius wigleyi* (4.6), the surf clam *Spisula solidissima* (3.1), the polychaetes *Nephtys picta* (3.0), *Spiochaetopterus oculatus* (2.3), *Caulieriella venefica* (2.1), and *Aricidea catherinae* (2.0), the surface deposit feeding bivalve *Ameritella* (fr. *Tellina*) *agilis* (1.4), the polychaete *Spiophanes bombyx* (1.1), Oligochaeta spp (1.0), and the polychaete *Polygordius jouinae* (1.0). No other taxa had an average abundance greater than 1.0 individual per sample.

b) Atlantic Beach

Seven samples were collected at the existing Atlantic Beach reef site. Water depths averaged $18.5 \text{ m} \pm 0.4 \text{ sd}$ (Figure 6). Grab samples penetrated to a depth of $6.1 \text{ cm} \pm 1.5 \text{ (sd)}$. Two sampling stations (AT-04, AT-06) had substantial amounts of gravel, while the other five locations were all $> 97\%$ sand. This grain size variability created large standard deviations in the average gravel and sand contents. Average gravel and sand contents were $15.4\% \pm 31.2 \text{ sd}$ and $81.8\% \pm 34.8 \text{ sd}$, respectively. Average mud content was $2.8\% \pm 3.7 \text{ sd}$. The two high gravel content stations were located along northwest to southeast trending high backscatter regions that appear to be sand waves.

Faunal abundances ranged from 13 to 325 individuals per sample and species richness varied from 10 to 32 species per sample. One of the gravel rich stations (AT-04 with 84% gravel) had the lowest abundance (13 individuals per sample), species richness (10 species), and the highest equitability (0.95) of the Atlantic Beach locations. Mean abundance was $174.1 \pm 97.8 \text{ (sd)}$ individuals per sample, and mean species richness was $21.9 \pm 8.7 \text{ (sd)}$ species per sample. A total of 69 species were collected. Mean Shannon diversity was $2.01 \pm 0.61 \text{ (sd)}$, and mean equitability was $0.67 \pm 0.19 \text{ (sd)}$. Twenty-three taxa had average abundances greater than or

equal to one individual per sample (Table 4). These included the polychaete *Polygordius jouinae* (mean = 37.4 per sample), the amphipod *Pseudunciola obliquua* (37.3), Nematoda spp (19.6), the tube building amphipods *Ampelisca* spp (*macrocephala* + *verrilli*) (12.3), the polychaete *Aricidea wassi* (6.6), Oligochaeta spp (5.3), the surf clam *Spisula solidissima* (4.1), the polychaetes Cirritulidae spp (*Kirkegaardia baptistae* + *Tharyx acutus*) (3.9) and *Aricidea catherinae* (3.7), the amphipod *Protohaustorius wigleyi* (3.6), the polychaetes *Scoletoma tenuis* (3.4) and *Goniadella gracilis* (3.3), the amphipod *Unciola irrorata* (2.7), the tanaid crustacean *Tanaissus psammophilus* (2.4), the polychaetes *Caulieriella benefica* (2.4) and *Nepthys picta* (2.1), the amphipod *Rhepoxynius epistomus* (1.9), the polyshaetes Capitellidae spp (+ *Notomastus*) (1.7), the surface deposit feeding bivalve *Ameritella* (fr. *Tellina*) *agilis* (1.6), the polychaetes *Parapionosyllis longicirrata* (1.6) and *Polydora cornuta* (1.4), the cumacean *Pseudoleptocuma minus* (1.4), and the isopod *Edotia triloba* (1.1).

c) McAllister

The McAllister reef site stations, like Atlantic Beach, had highly variable grain size values. These were associated with large variations in backscatter and potential sand waves. Fourteen stations were sampled. Water depths ranged from 15.2 to 16.5 m (mean = 15.9 m \pm 0.4 sd), and the grab penetration depth was consistently between 4 and 6 cm (mean = 5.2 cm \pm 0.8 sd). Sediment grain size was highly variable, ranging from 0.0 - 84.0% gravel and shell, 14.2 - 98.5% sand, and 0.5 - 60.3% silt-clay. Average gravel (with shell), sand, and mud contents were 17.5% \pm 28.5 (sd), 75.6% \pm 30.4, and 6.9% \pm 15.5, respectively. High gravel contents were found at stations MC-02, MC-03, MC-05, MC-12, and MC-14. Station MC-07 had a very high mud content. The remaining stations were largely sand in composition (MC-01, MC-04, MC-06, MC-08, MC-09, MC-10, MC-11, and MC-13).

Mean Shannon diversity (2.19 ± 0.44) was higher at this reef site compared to other sites along the South Shore. Mean abundance and species richness was 115.5 ± 160.3 (sd) individuals per sample and mean species richness was 18.2 ± 6.6 (sd) species per sample. Mean equitability was 0.79 ± 0.17 (sd). Abundances ranged from 18 to 604 individuals per sample, accounting for the high standard deviation, and species richness ranged from 7 to 31 species per sample. A total of 76 taxa were collected. Twenty-on taxa exceeded a mean abundance ≥ 1 individual per sample. The most abundant taxon was the amphipod *Pseudunciola obliquua* (mean = 37.6 individuals per sample). Other abundant taxa included Oligochaeta spp (10.1), Nematoda spp (8.6), the amphipods *Ampelisca* spp (*macrocephala* + *verrilli*) (6.4), the polychaetes *Paradoneis lyra* (6.1), *Polygordius jouinae* (5.1), and *Prionospio pygmaeus* (5.0), the surface deposit feeding bivalve *Ameritella* (fr. *Tellina*) *agilis* (2.4), the amphipod *Protohaustorius wigleyi* (2.4), the polychaetes *Nepthys picta* (2.4) and *Spiophanes bombyx* (1.9), the amphipods *Ampelisca* spp (*abdita* + *vadurum*) (1.9), and *Rhepoxynius epistomus* (1.8), the polychaetes *Polydora cornuta* (1.8), *Polycirrus eximius* (1.7), Cirritulidae spp (*Kirkegaardia baptistae* + *Tharyx acutus*) (1.4), *Caulieriella benefica* (1.2), Capitellidae spp (*Heteromastus* + *Notomastus*) (1.2), and *Parapionosyllis longicirrata* (1.1), the cumacean *Pseudoleptocuma minus* (1.1), and the polychaete *Streptosyllis arenae* (1.1).

d) Hempstead

Seven samples were collected at this existing reef site. With the exception of HE-01 and HE-06, samples consisted of > 98% sand. Water depths averaged 18.2 ± 1.4 (sd) meters and ranged from 15.8 to 20.1 m (Figure 6). The van Veen grab penetrated to an average of 7.0 ± 0.6 cm, ranging from 6-8 cm. Average gravel (and shell) content was $6.1\% \pm 9.7$ (sd). Mean sand and mud contents were $91.5\% \pm 12.3$ and $2.3\% \pm 4.3$, respectively. Station HE-01 and HE-06 had 23.0 and 17.2% gravel, respectively.

Average abundance was 162.6 ± 150.5 individuals per sample (Figure 7), and average species richness was 20.1 ± 3.0 species per sample. Faunal abundances varied from 47 to 492 individuals per sample. Species richness ranged from 17 to 26 species per sample. A total of 63 species were collected. Mean Shannon diversity was 2.11 ± 0.48 (sd), and mean equitability was 0.71 ± 0.17 (sd).

Like McAllister and Atlantic Beach, the polychaete *Polygordius jouinae* (mean = 58.9 per sample) and the amphipod *Pseudunciola obliquua* (31.7) were abundant at the Hempstead reef site. Twenty-five other taxa were found at abundances > 1 per sample at Hempstead. These included Nematoda spp (9.9), the polychaete *Prionospio pygmaeus* (7.6), the amphipod *Unciola irrorata* (5.7), Oligochaeta spp (3.9), the polychaete *Scoletoma tenuis* (3.6), the amphipod *Rhepoxygnus epistomus* (3.3), the polychaetes *Nephtys picta* (2.3), *Spiophanes bombyx* (2.1), and *Caulieriella venefica* (2.1), the amphipods *Liljeborgia* sp (2.0) and *Phoxocephalus holboelli* (1.7), the polychaete Cirritulidae spp (*Kirkegaardia baptistae* + *Tharyx acutus*) (1.7), the amphipods *Ampelisca* spp (*macrocephala* + *verrilli*) (1.6), the polychaete *Aricidea catherinae* (1.6), the amphipod *Corophium* sp (1.6), the tanaid *Tanaissus psammophilus* (1.4), the polychaete *Polycirrus eximius* (1.4), the surf clam *Spisula solidissima* (1.4), the polychaete *Harmothoe extenuate* (1.4), the surface deposit feeding bivalve *Ameritella* (fr. *Tellina*) *agilis* (1.3), the amphipods *Protohaustorius wigleyi* (1.1) and *Ampelisca* spp (*abdita* + *vadurum*) (1.0), the polychaetes *Goniadella gracilis* (1.0) and *Aricidea wassi* (1.0), and the sand dollar *Echinarachnius parma* (1.0).

e) Sixteen Fathoms

Fourteen samples were collected at this potential reef site. The van Veen grab penetrated an average of 6.6 ± 1.3 cm, and water depths ranged from 26.8 to 31.1 m, averaging 29.1 ± 1.5 m (Figure 6). Sediments were primarily sandy (sand mean = $90.9\% \pm 14.4$ sd). The one exception was at station SF-13 which consisted of both gravel (47.2%) and sand (44.2%). The gravel fraction (mean = $5.3\% \pm 13.0$ sd) and mud fraction ($3.8\% \pm 3.9$ sd) were both minor parts of the sediments at most sampling sites.

Faunal abundances ranged from 42 to 761 individuals per sample and species richness varied from 16 to 34 species per sample. Mean abundance was 297.7 ± 275.3 (sd) individuals per sample (Figure 7), and mean species richness was 24.9 ± 6.6 (sd) species per sample. A total of 98 taxa were collected, the highest total of any site along the South Shore. Mean Shannon diversity was 1.85 ± 0.68 (sd), and mean equitability was 0.59 ± 0.23 (sd). Twenty-five taxa exceed an average abundance of 1 per sample (Table 4). The most abundant taxon was again the polychaete *Polygordius jouinae* (mean = 167.8 individuals per sample), followed by Cirritulidae spp (*Kirkegaardia baptistae* + *Tharyx acutus*) (28.4), Nematoda spp (26.8), Oligochaeta spp

(7.8), the amphipods *Ampelisca* spp (*abdicta* + *vadurum*) (7.2), the polychaetes *Caulieriella venefica* (5.5) and *Nephtys picta* (3.4), the amphipod *Unciola irrorata* (2.8), the polychaete *Goniadella gracilis* (2.6), the amphipods *Leptocheirus pinguis* (2.5) and *Byblis serrata* (2.4), the sand dollar *Echinarachnius parma* (2.3), the polychaete *Scoletoma fragilis* (2.3), the infaunal deposit feeding bivalve *Nucula tenuis* (2.3), the polychaete *Exogone dispar* (1.9), the amphipod *Rhepoxygnus epistomus* (1.9), the surf clam *Spisula solidissima* (1.9), the polychaetes *Aricidea catherinae* (1.6), *Aricidea wassi* (1.6) and *Scalibregma inflatum* (1.6), the isopod *Politolana polita* (1.5), the polychaetes *Streptosyllis arenae* (1.4) and *Harmothoe extenuate* (1.3), the amphipods *Phoxocephalus holbolli* (1.1) and *Pseudunciola obliquua* (1.1).

f) Fisherman

Seven samples were collected at the Fisherman (Yellowbar) reef site. Water depths ranged from 9.1 to 11.6 meters, averaging 10.4 ± 0.8 (sd) meters. Five of the seven grab samples penetrated to the maximum of 10 cm, and the average penetration depth was $9.4 \text{ cm} \pm 1.1$ (sd). This was the highest mean grab penetration depth of the South Shore reef sites (Figure 6). The samples were primarily sand but sometimes mixed with a small amount of gravel and shell (Figure 6). Sand content averaged $94.6\% \pm 5.7\%$ (sd), and ranged from 84 to 99%. Gravel content ranged from 0.1% to 15.2% and averaged $4.6\% \pm 5.5$ (sd). The mud fraction was a very minor part of the sediment in the samples (mean = $0.8\% \pm 0.3$ sd).

One station (FS-01) was quite different in faunal characteristics than the remaining sampling locations at this reef site. FS-01 had the highest abundance (2,497 individuals per sample) and lowest species richness (10 species), Shannon diversity (0.66), and equitability (0.29) of samples at this site, primarily because of the large number of individuals (2,012) of the polychaete *Microphthalmus sczelkowii* collected in the grab. The remaining six samples at this reef location had high abundances of a related species *M. aberrans*.

In part because of the high abundances of these two polychaete taxa (*M. sczelkowii* and *M. aberrans*), the Fisherman reef site had the highest average abundance and lowest average Shannon diversity and equitability of the South Shore sites (Figure 7). Abundances ranged from 182 to 2,497 individuals per sample and species richness varied from 10 to 30 species per sample. Average abundances were 814.6 ± 780.4 (sd) individuals per sample, and average species richness was 18.0 ± 7.0 (sd) species per sample. A total of 54 species were collected. Mean Shannon diversity was 1.22 ± 0.40 (sd), and mean equitability was 0.43 ± 0.12 (sd). The most abundant taxon was the polychaete *Microphthalmus sczelkowii* (mean = 287.4 individuals per sample), but as mentioned previously it was found in only one sample. Other abundant taxa were from 17 other groups and included Nematoda spp (mean = 200.6 individuals per sample), the polychaetes *Microphthalmus aberrans* (142.0), Cirritulidae spp (*Kirkegaardia baptistae* + *Tharyx acutus*) (103.7), *Polygordius jouinae* (14.6), *Neanthes arenaceodentata* (12.9), *Streptosyllis arenae* (9.0), Oligochaeta spp (6.9), the polychaete *Brania wellfleetensis* (6.4), the isopod *Chiridotea coeca* (5.7), the polychaete *Parapionosyllis longicirrata* (2.9), the amphipods *Eobrolgus spinosus* (2.9) and *Lysianopsis alba* (1.6), the polychaete *Polycirrus eximius* (1.3), Nemertinea spp (including juvenile *C. lacteus*) (1.0), the surface deposit feeding bivalve *Ameritella* (fr. *Tellina*) *agilis* (1.0), the surf clam *Spisula solidissima* (1.0), and the polychaete

Caulieriella venefica (1.0). No other taxa exceed an average abundance of 1 per sample at this site (Table 4).

g) Kismet

Like the Fisherman reef site, Kismet was within Great South Bay, and this was the shallowest of the South Shore reefs, averaging $2.8 \text{ m} \pm 0.6$ (sd), and ranging from 2.4 to 4.0 m (Figure 6). Grab penetration depths averaged $7.1 \text{ cm} \pm 1.9$ (sd) and varied from 4.5 to 10 cm. Sediments samples were all greater than 50% sand, but several (KI-02, KI-06) had substantial amounts of gravel (44.9%, 15.7%, respectively). Mean gravel content was $10.4\% \pm 16.2$ (sd), and average sand content was $87.0\% \pm 16.0$ (sd). Mud formed a minor fraction of the sediment (mean = $2.5\% \pm 2.5$ sd). Gravel, sand, and mud contents ranged from 0.1 to 44.9%, 54.2 to 99.0, and 0.9 to 7.5%, respectively (Figure 6).

Faunal abundances varied widely from 19 to 1,132 individuals per sample. This variation was mainly due to variable abundances of the polychaetes Cirritulidae spp (*Kirkegaardia baptistae* + *Tharyx acutus*) in the samples. This polychaete group varied between 2 and 808 individuals per sample. Species richness ranged from 11 to 47 species per sample, producing the highest average species richness (mean = 27.1 ± 14.9 species) of the South Shore reef sites (Figure 7). A total of 79 species were collected. Average abundances were 411.6 ± 445.1 (sd) individuals per sample. Average Shannon diversity and equitability were 2.03 ± 0.35 (sd) and 0.68 ± 0.22 (sd), respectively. Reflecting the high species richness at this site, a total of 34 taxa exceeded 1 individual per sample. These abundant taxa included Cirritulidae spp (*Kirkegaardia baptistae* + *Tharyx acutus*) (mean = 231.4 individuals per sample), Nematoda spp (48.0), the polychaete *Neanthes arenaceodentata* (21.0), the amphipod *Lysianopsis alba* (7.7), the isopod *Ianiropsis* sp (7.0), the amphipod *Batea catharinensis* (6.3), the polychaete *Brania wellfleetensis* (6.1), the subsurface deposit feeding bivalve *Nucula proxima* (6.1), the cumacean *Oxyurostylis smithi* (5.1), the amphipods *Elasmopus levius* (5.0), *Rhepoxynius epistomus* (4.9), *Eobrolgus spinosus* (4.9), the polychaetes *Polygordius jouinae* (4.0) and *Caulieriella venefica* (3.0), the amphipod *Unciola irrorata* (2.7), the polychaete *Dipolydora socialis* (2.6), the bivalve *Solemya velum* (2.4), the polychaetes Capitellidae spp (*Heteromastus* + *Notomastus*) (2.3), Oligochaeta spp (2.3), the polychaetes *Prionospio heterobranchia* (2.1), *Capitella* spp (2.0), *Scolelepis bousfieldi* (2.0), the amphipods *Ampelisca* spp (*macrocephala* + *verrilli*) (2.0), the amphipod *Rudilemboides naglei* (2.0), the polychaetes *Aricidea catherinae* (1.9) and *Exogone dispar* (1.7), the amphipods *Ampelisca* spp (*abdicta* + *vadurum*) (1.4), the surface deposit feeding bivalve *Ameritella* (fr. *Tellina*) *agilis* (1.4), the polychaete *Parapionosyllis longicirrata* (1.3), the amphipod *Idunella barnardi* (1.3), the polychaetes *Streptosyllis arenae* (1.1) and *Glycinde solitaria* (1.1), and the amphipods *Stenothoe minuta* (1.1) and *Microdeutopus anomalus* (1.0). Other taxa at this reef site did not exceed an average abundance of 1 per sample (Table 4).

h) Fire Island

Seven samples were collected at this existing reef site. Water depths ranged from 19.2 to 21.0 m, averaging $20.1 \text{ m} \pm 0.6$ (sd). Grab penetration depths were above 7 cm and averaged $7.9 \text{ cm} \pm 1.1$ (sd). Samples were largely sand (Figure 6), with sand contents ranging from 92.0 to 99.5%.

Average sand by weight was $97.9\% \pm 2.7$ (sd). Gravel ranged from 0 to 7.2% in samples and averaged $1.5\% \pm 2.6$ (sd). Mud content was always less than 1% (mean = $0.6\% \pm 0.2$ sd).

Faunal abundances ranged from 104 to 600 individuals per sample. Average abundance was 393.7 ± 169.5 (sd) individuals per sample. Average species richness was 22.1 ± 3.9 (sd) species per sample, and samples contained 15 to 27 species. Average Shannon diversity was 1.52 ± 0.47 (sd). Average equitability was 0.49 ± 0.15 (sd) (Figure 7). A total of 55 taxa were collected at this site. Much like McAllister, Atlantic Beach, and Hempstead, the amphipod *Pseudunciola obliquua* (mean = 228.9 individuals per sample) and the polychaete *Polygordius jouinae* (mean = 58.9 per sample) were abundant at the Fire Island reef site (Table 4). Sixteen other taxa had abundances greater than 1 per sample. These included Nematoda spp (mean = 37.1 per sample), Oligochaeta spp (27.3), the polychaetes *Streptosyllis arenae* (4.9), *Caulieriella benefica* (4.1), and *Syllides longocirratus* (3.0), the amphipod *Rhepoxygnus epistomus* (2.6), the polychaetes *Parougia caeca* (2.6), *Exogone dispar* (2.4), *Spiophanes bombyx* (2.1), *Goniadella gracilis* (1.6), Cirritulidae spp (*Kirkegaardia baptisteae* + *Tharyx acutus*) (1.3), the surf clam *Spisula solidissima* (1.3), the amphipod *Protohaustorius wigleyi* (1.3), the polychaetes *Nephtys picta* (1.1) and *Aricidea wassi* (1.0), and the tanaid *Tanaissus psammophilus* (1.0).

i) Moriches

With one exception (MO-09), all of the fourteen samples at this potential reef site were sandy with little gravel or mud. MO-09 had 41.6% sand and 58.4% mud. This station MO-09 had the lowest species richness (5), Shannon diversity (0.64), and equitability (0.40) of the samples at this site.

Sand contents averaged $95.0\% \pm 15.4$ (sd), and without MO-09 ranged from 95.2% to 100%. Average gravel content was $0.1\% \pm 0.3$ (sd), and average mud content was $4.9\% \pm 15.4$ (sd). Without station MO-09, mud content ranged from 0.1% to 4.3%. Water depths were $22.9 \text{ m} \pm 0.8$ (sd) on average and varied from 21.6 to 24.1 m. Grab penetration depths ranged from 2 to 10 cm, and the average was $5.2 \text{ cm} \pm 2.0$ (sd) (Figure 6).

A total of 51 taxa and 599 individuals were collected at this site in the fourteen samples. Average abundance was 42.8 ± 40.1 (sd) individuals per sample, the lowest average of the South Shore sites (Figure 7). Average species richness was 10.2 ± 4.8 (sd) species per sample, also the lowest average for the South Shore sites. Abundances ranged from 11 to 148 individuals per sample. Species richness varied from 5 to 21 taxa per sample. Average Shannon diversity was 1.74 ± 0.50 (sd), and mean equitability was 0.78 ± 0.19 (sd). Reflecting the low number of animals collected, only eight taxa had average abundances exceeding 1 individual per sample. These were the polychaete *Polygordius jouinae* (mean = 13.7 individuals per sample), Nematoda spp (7.2), the amphipod *Pseudunciola obliquua* (4.6), Oligochaeta spp (3.0), the polychaetes *Spiophanes bombyx* (1.9) and *Nephtys picta* (1.6), the sand dollar *Echinarachnius parma* (1.6), and the amphipod *Protohaustorius wigleyi* (1.4). Note that the two most abundant species at Moriches, the polychaete *Polygordius jouinae* and the amphipod *Pseudunciola obliquua*, were also the most abundant taxa at McAllister, Atlantic Beach, and Hempstead, and Fire Island.

j) Twelve Mile

Seven samples were collected at the Twelve Mile reef site. Water depths ranged from 38.4 to 43.3 meters and averaged $41.6 \text{ m} \pm 1.6$ (sd), the deepest of the South Shore sites (Figure 6). Grab penetration depths ranged from 6.0 to 8.0 cm. Average penetration depth was $6.9 \text{ cm} \pm 0.7$ (sd). Gravel was generally 1% or less (mean = $0.4\% \pm 0.4$ sd). Sediments were primarily sandy ranging from 89.0% to 99.2% (mean = $97.3\% \pm 3.7$ sd). One station (TW-01) had 11.0% mud, but all other sites had low mud content, ranging from 0.6% to 1.2%. Mean mud content was $2.3\% \pm 3.8$ (sd).

A total of 60 taxa and 1,117 individuals were collected in the seven samples at this site. Abundances varied from 19 to 339 individuals per sample, and species richness ranged from 13 to 24 species per sample. Average abundance was 159.6 ± 112.8 (sd) individuals per sample. Average species richness was 19.7 ± 4.1 (sd) species per sample (Figure 7). Mean Shannon diversity was 1.99 ± 0.58 (sd), and mean equitability was 0.67 ± 0.20 (sd) (Figure 7). Seventeen taxa exceeded an average of 1 individual per sample (Table 4). These included the polychaete *Polygordius jouinae* (mean = 77.0 individuals per sample), Nematoda spp (32.6), the polychaete *Goniadella gracilis* (5.7), the amphipod *Byblis serrata* (5.0), the polychaetes Cirritulidae spp (*Kirkegaardia baptistae + Tharyx acutus*) (3.6) and *Exogone dispar* (3.3), Oligochaeta spp (2.7), the polychaetes *Scoletoma fragilis* (2.4), *Scalibregma inflatum* (2.3), *Caulieriella venefica* (2.1), and *Spiophanes bombyx* (1.9), the sand dollar *Echinarachnius parma* (1.6), the amphipod *Unciola spp (dissimillis + serrata)* (1.3), the polychaetes *Glycinde solitaria* (1.3), *Nephtys picta* (1.1), *Aglaophamus circinata* (1.0), and *Potamilla neglecta* (1.0).

k) Shinnecock

Fourteen samples were collected at the Shinnecock potential reef site. Water depths ranged from 23.8 to 25.3 m. Average depths were $24.6 \text{ m} \pm 0.4$ (sd). Grab penetration depths were 6.0 to 9.0 cm and the average penetration depth was $7.9 \text{ cm} \pm 0.8$ (sd). Sand was the dominant sediment fraction (Figure 6), but several stations (SH-04, SH-09, SH-03) had substantial amounts of gravel (62.0, 52.3, and 19.1%, respectively). Mean gravel content was $11.3\% \pm 20.2$ (sd), and mean sand content was $87.9\% \pm 20.4$ (sd). Mud was generally less than 1.8% by weight (mean = $0.8\% \pm 0.4$ sd).

Faunal abundances ranged from 56 to 545 individuals per sample. Average abundance was 244.9 ± 125.6 (sd) individuals per sample. Average species richness was 19.1 ± 3.5 (sd) species per sample, and samples contained 13 to 24 species. Average Shannon diversity was 1.60 ± 0.36 (sd). Average equitability was 0.54 ± 0.11 (sd). A total of 74 taxa and 3,428 individuals were collected at this site. Fifteen taxa had average abundances greater than or equal to 1 per sample (Table 4). These included Nematoda spp (mean = 90.1 individuals per sample), the polychaete *Polygordius jouinae* (75.6) commonly found at all of the South Shore sites, Oligochaeta spp (13.5), the amphipod *Pseudunciola obliquua* (13.5), the slipper snail *Crepidula fornicata* (9.5), the polychaetes *Goniadella gracilis* (6.9), *Spio filicornis* (5.2), *Paradoneis lyra* (3.4), and *Pseudomystides* sp (1.8), the tanaid *Tanaissus psammophilus* (1.6), the polychaetes *Caulieriella venefica* (1.6), *Aricidea catherinae* (1.2), Cirritulidae spp (*Kirkegaardia baptistae + Tharyx acutus*) (1.1), and *Scoletoma fragilis* (1.1), and the surf clam *Spisula solidissima* (1.1).

Multivariate Analysis

Forward selection RDA resulted in identifying and retaining all of the environmental variables based on the AICc stopping criterion: water depth, grab penetration depth, % gravel, % sand, and % mud (Figure 8). Since the sediment grain size variables always add to 100%, only two are independent. These environmental variables explained only 17.0% of the total variability in community structure. The large variation (i.e., large envelopes around the samples) in community structure for some reef sites like Atlantic Beach, McAllister, Hempstead, Moriches, and Shinnecock is also reflected in the high contrast in bottom type (high backscatter variation) and distinctly different grain size among stations within these sites. For example, two Shinnecock stations (SH-04 and SH-09) plot well away from other Shinnecock samples and also have higher backscatter and gravel content than other locations within this site. Reef sites with relatively small envelopes (e.g., Rockaway, Fisherman, Kismet, Twelve Mile, and Fire Island) tended to have more homogeneous backscatter patterns and grain size. Additionally, the two Great South Bay sites (Fisherman and Kismet) are separated from the remaining South Shore sites along the second ordination axis, suggesting clear differences in faunal composition.

DISCUSSION

General Description of the Sediments and Faunal Characteristics

Both sediment and faunal characteristics varied within and among the areas sampled. It is tempting to compare the Long Island Sounds areas to those along the South Shore; however, this would be problematic for several reasons. Samples for the South Shore and Long Island Sound areas were collected in different years and almost in different seasons (August 2020 vs. June 2021, respectively). Nearshore benthic communities are dynamic and capable of changing rapidly in response to physical (e.g., low DO) and biotic events (e.g., recruitment success or failure). Twice as many samples were collected along the South Shore compared to Long Island Sound, so comparisons of the total number of animals collected and the number of taxa are not valid. In addition, the two regions experience very different environmental regimes, i.e., coastal ocean vs. estuarine, and the salinity, temperature, primary productivity, stratification, and other drivers differ considerably.

Sediments at all sites along the South Shore and two sites in Long Island Sound were primarily sandy, with an average of 75% or greater sand content by weight. Two sites in Long Island Sound, i.e., Port Jefferson – Mt. Sinai and Huntington – Oyster Bay were muddy, with 69.3% and 52.4% mud (silt-clay), respectively. These two potential reef sites had an interesting community structure worth noting. Work by Sanders (1956) in Long Island Sound and Sanders (1958, 1960) in Buzzards Bay, Massachusetts described a mud species assemblage termed the *Nucula/Nephtys/Yoldia* mud community. This community was named after two infaunal deposit feeding bivalves and the polychaete *Nephtys*, presumed by Sanders at the time to be an infaunal deposit feeder and which was later discovered to be a predator. Other researchers, especially Rhoads et al. (1978), described this assemblage as a late successional stage mud community, i.e., characteristic of an area that had been stable for a long enough period of time to allow species with relatively long life spans and low recruitment rates to become dominate. Late succession species tend to feed on buried organic material and have high rates of bioturbation, so they are

functionally important in recycling nutrients in soft sediment systems. In contrast, early successional species have very little impact on sub-surface sediment characteristics.

Cursory observations taken when the samples were collected suggested that the Port Jefferson – Mt. Sinai site has been stable longer than the Huntington – Oyster Bay site. *Yoldia limatula* were about 5 cm in shell length at the Port Jefferson – Mt. Sinai site. This is close to their maximum size of 6.25 cm reported in Abbott (1974). *Y. limatula* at the Huntington – Oyster Bay site were about half that size (~ 3 cm), suggesting younger individuals. *Nucula proxima* was absent from the Huntington – Oyster Bay site. Instead two small, fast growing, early colonizing species, *Macoploma (Macoma) tenta* and *Mulinia lateralis*, were present (Pearson and Rosenberg, 1978; Rhoads et al. 1978). Additionally, shell hash from the latter two species was a dominant part of the gravel fraction of the sediments at Huntington – Oyster Bay, also suggesting a disturbance at some point(s) in the past.

Multivariate analysis revealed that water depth, grab penetration depth, and grain size characteristics (% gravel sand, mud) explained about 17.0% of the community structure at the South Shore sites and 42.6% of the community structure at the Long Island Sound sites. The South Shore result is not unusually low. Flanagan et al. (2019) found that depth and grain size characteristics were weak to moderate predictors of benthic community structure. Additionally, given greater within site variability in bottom type, the South Shore sites were more under sampled relative to Long Island Sound sites which showed less contrast in bottom type. The lower within site variation within the Long Island Sound sites coupled with the high contrast in depth and grain size between sites accounts for the greater amount of explained community variation there. Further, Cerrato and Maher (2007) examining benthic samples in the Peconic Estuary system discovered that 10 samples or more within a single homogenous bottom type would be needed to adequately characterize benthic community structure. Thus, the sampling in the current study which averaged only two samples per bottom type was limited in its ability to fully characterize benthic community structure at these existing and potential reef areas.

Figure 1. Artificial reef locations in New York waters. From HDR Inc., et al (2020). All reef sites except Matinecock Reef in LIS were sampled.

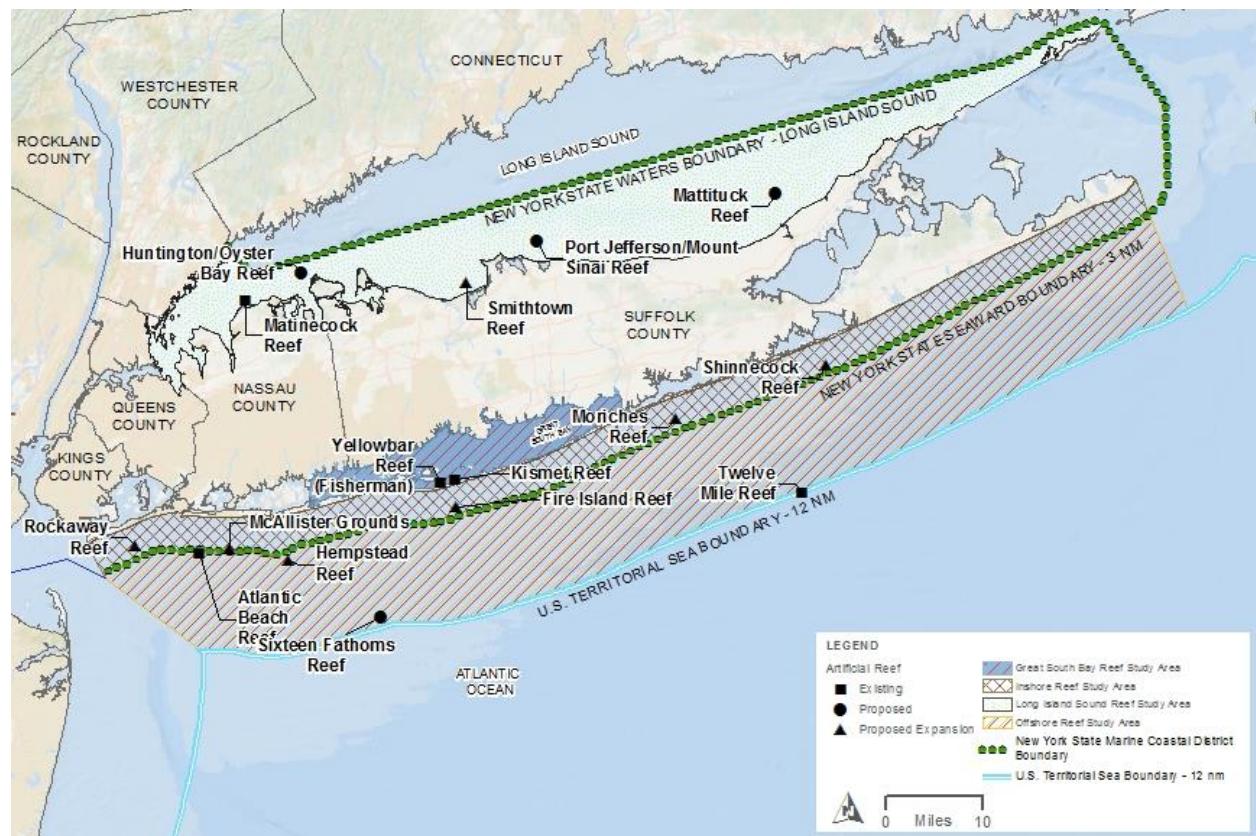

Figure 2. Sonar bottom type provinces and sampling locations. Sampling locations are green circles, the sample ID for the location is in red with a beige border, and the arbitrarily assigned bottom type province codes are in black. Stars are reef material.

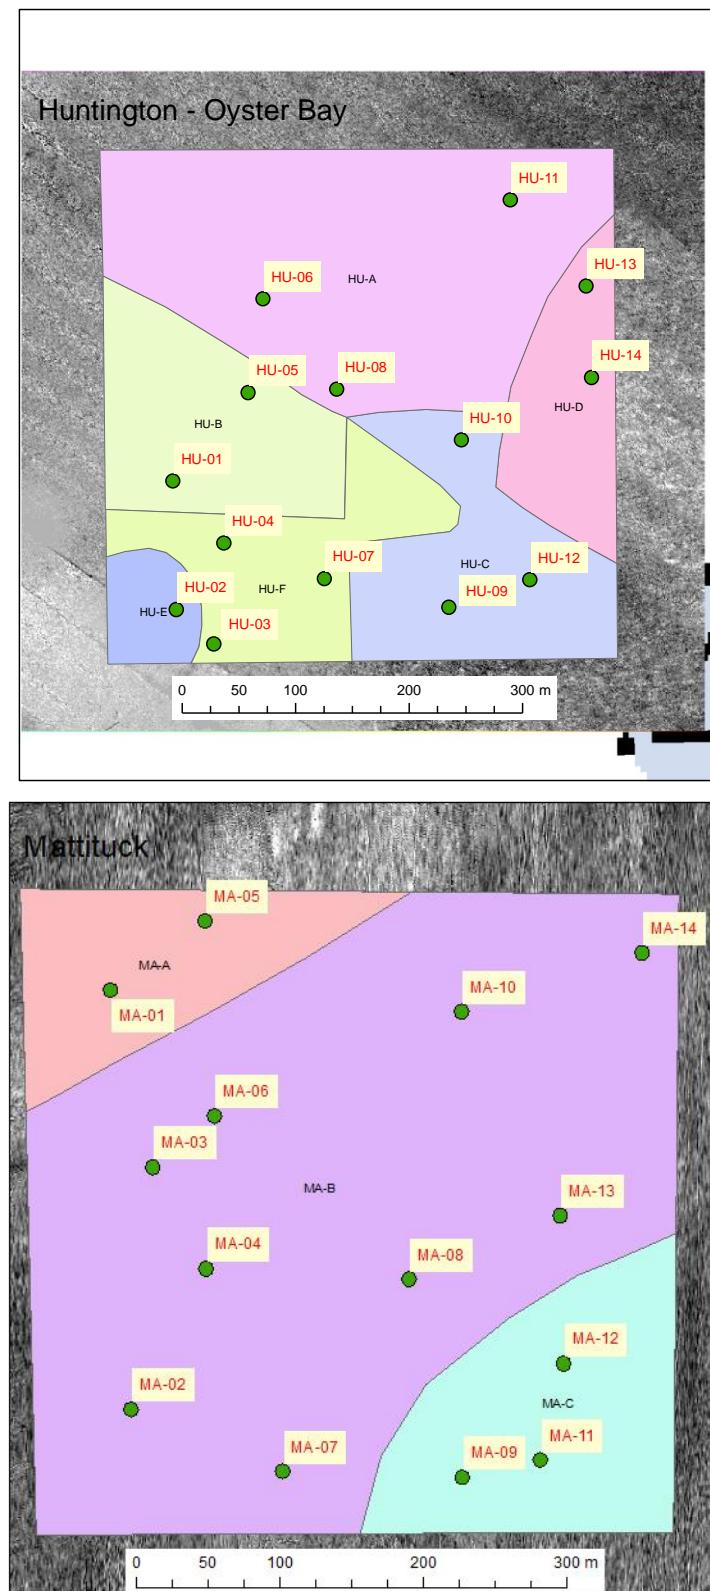

Figure 2. continued

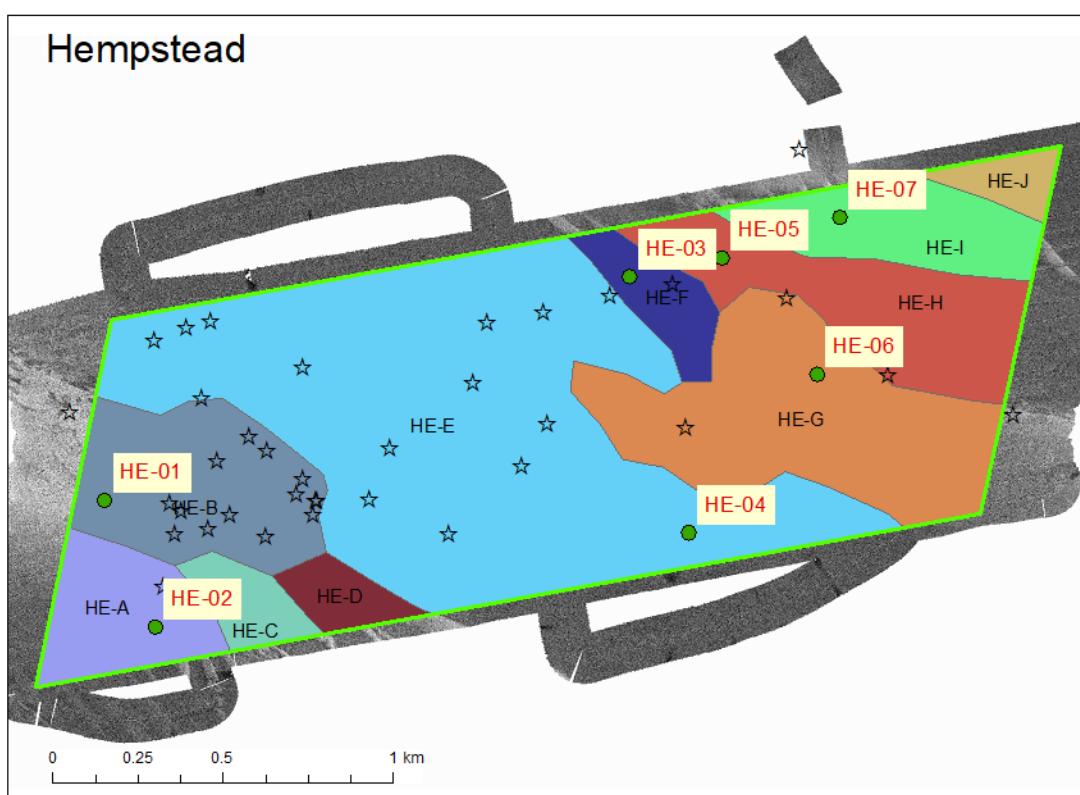

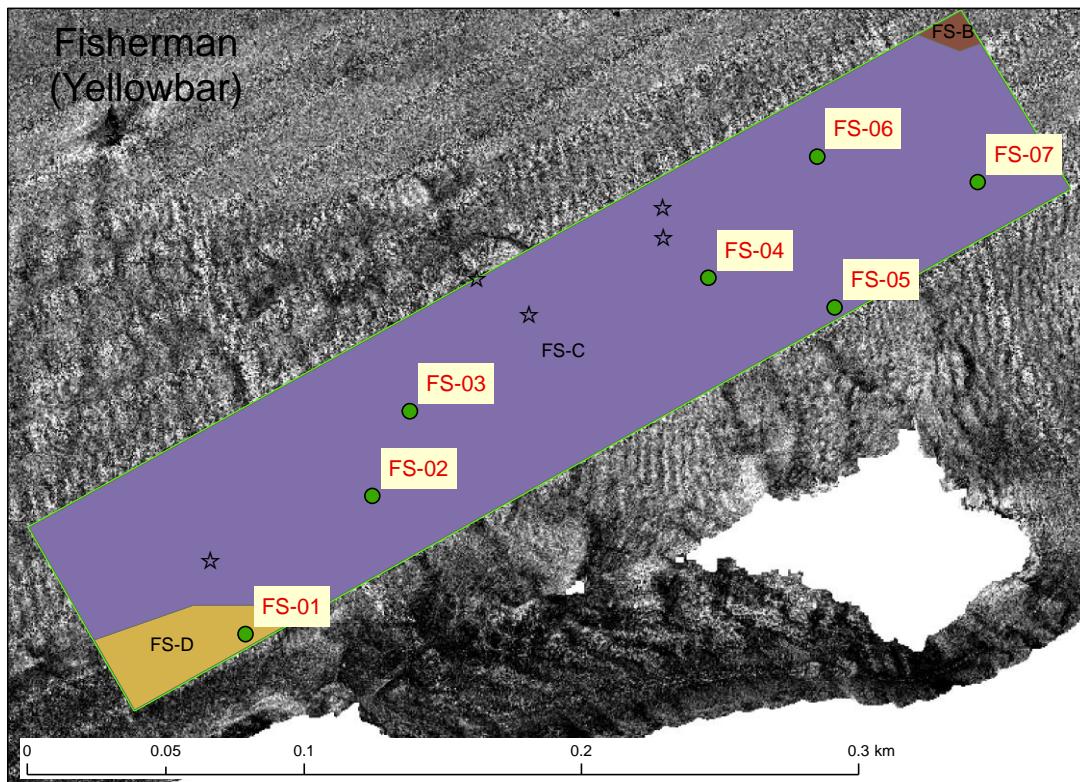

Figure 2. continued

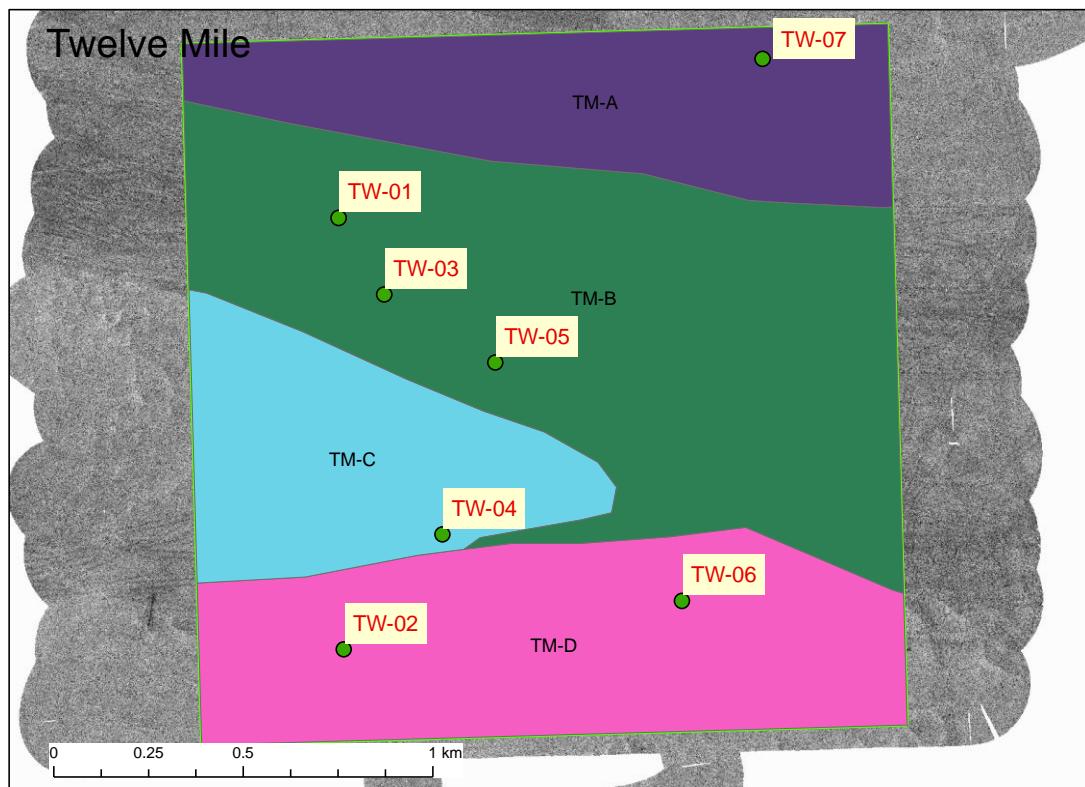

Figure 3. Mean water depth, grab penetration depth, and sediment grain-size characteristics at the LIS reef sites. Error bars are standard deviation.

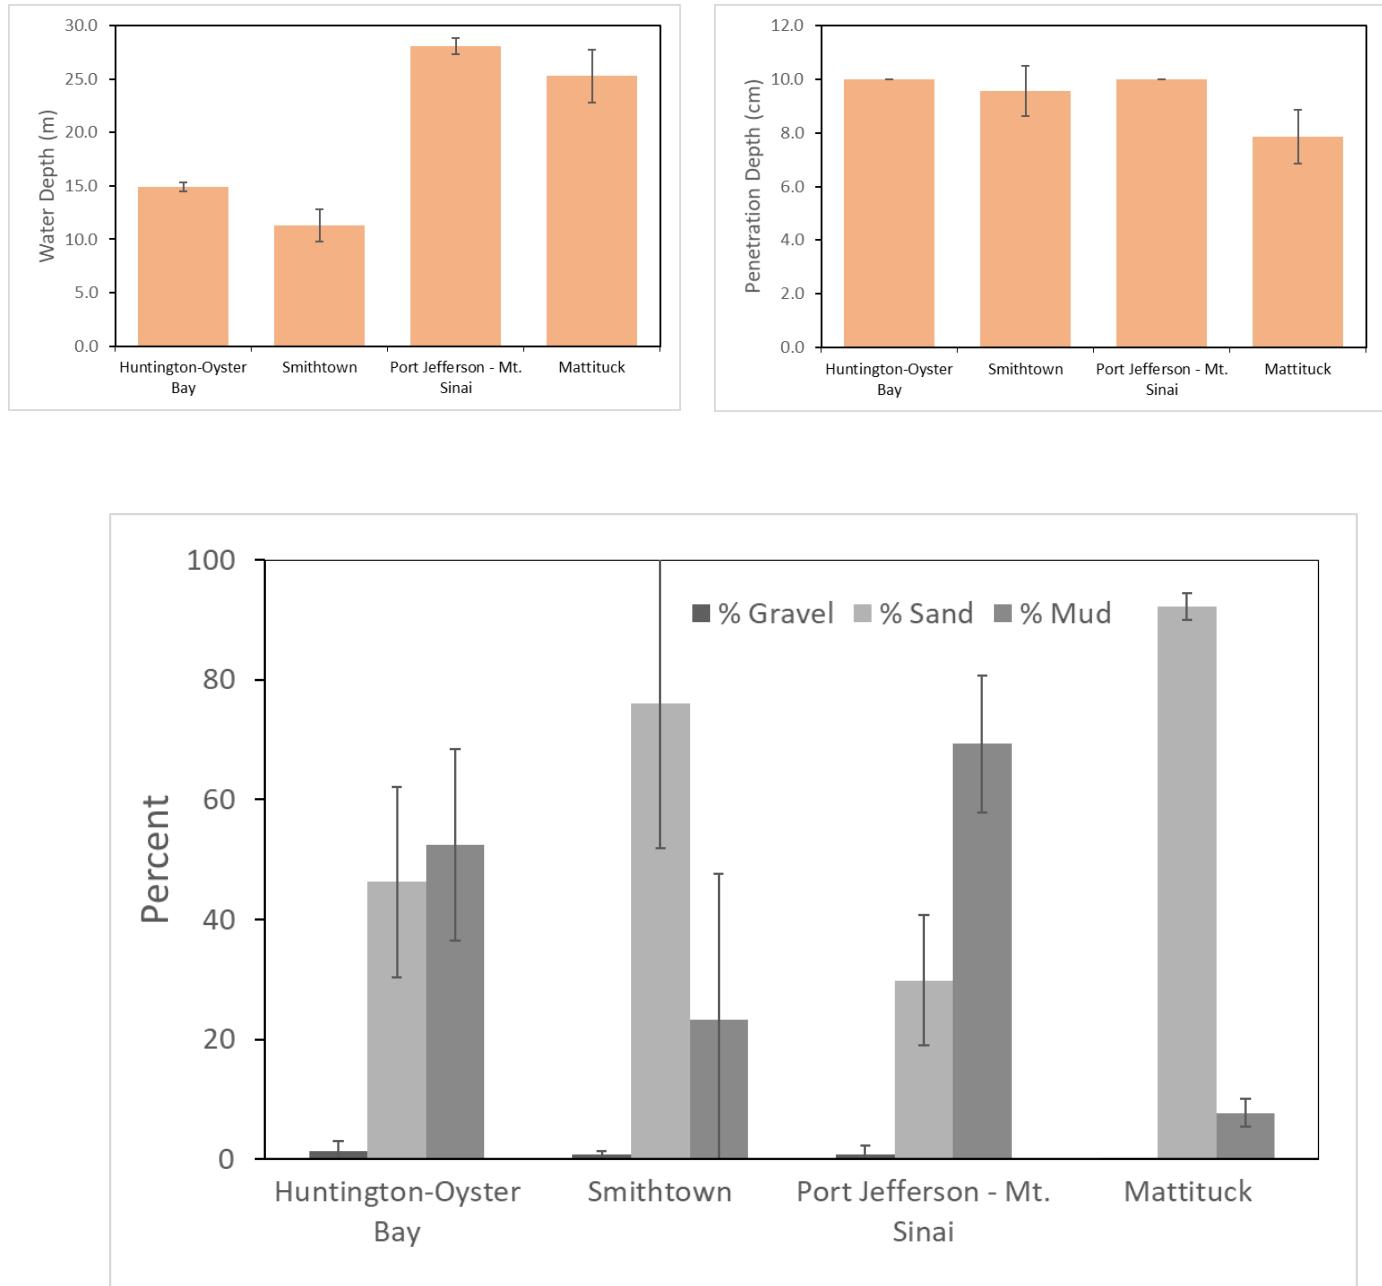

Figure 4. Mean abundance, species richness, Shannon diversity and Equitability at the LIS reef sites. Error bars are standard deviation.

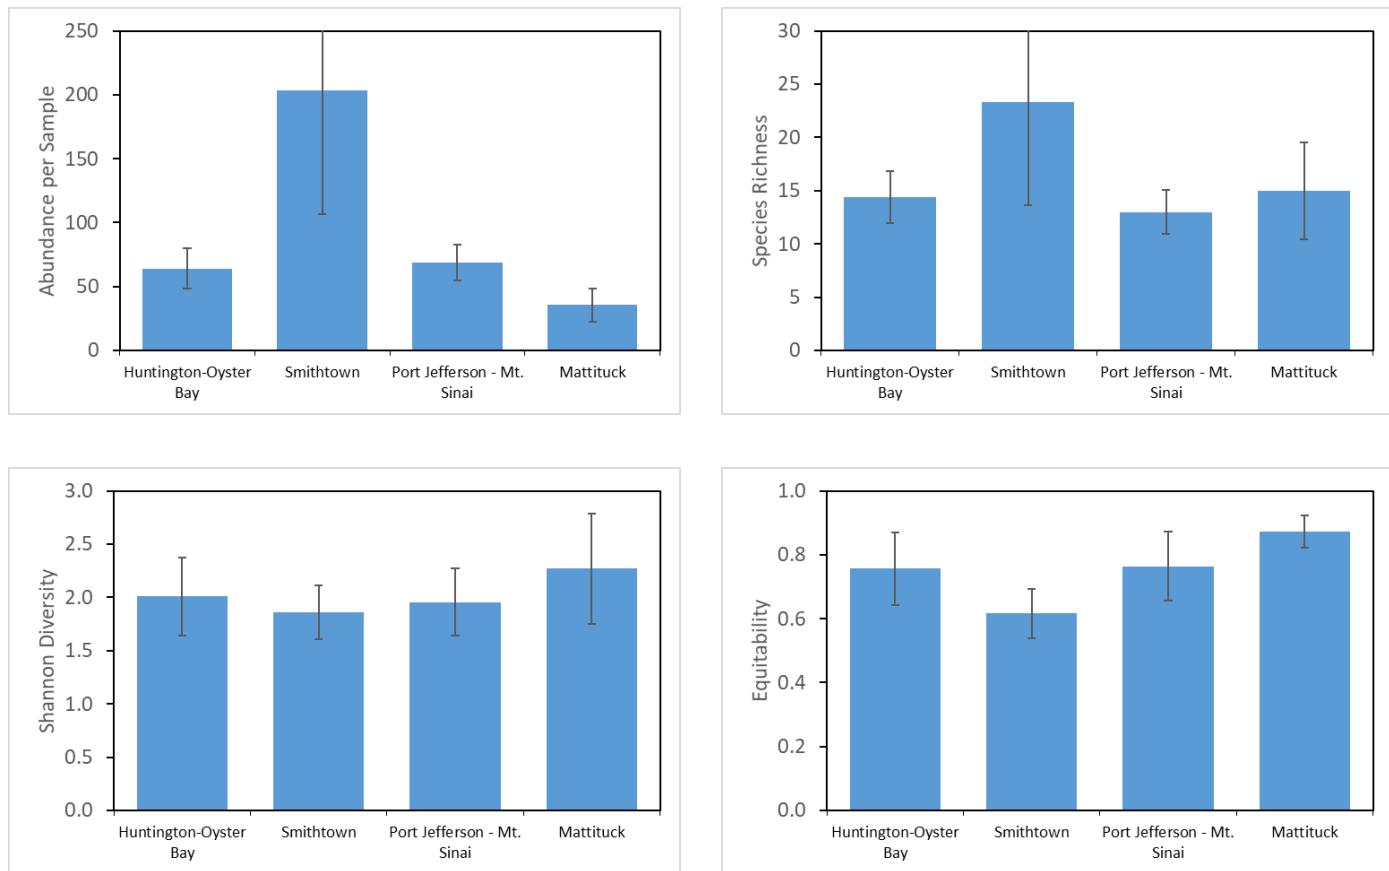

Figure 5. RDA ordination triplot results for axes 1 & 2 of the Long Island Sound data. Eigenvalues for these axes are 0.232 and 0.165, respectively. The third axis eigenvalue (not shown) was 0.030. Samples are plotted as points, and they are colored and enclosed in envelopes based on membership in each reef site. Sample points close to one another tend to have similar faunal structure than those further apart. Continuous explanatory variables and individual taxa are plotted as vectors. The arrowhead represents high, the origin average, and the tail (when extended through the origin) low values. Projections of sample points onto an individual taxa vector approximate the Hellinger transformed abundances for that taxon. For clarity, only the species with the highest amounts of explained variance (those with > 25%) are plotted. See Table 2 for species abbreviation codes.

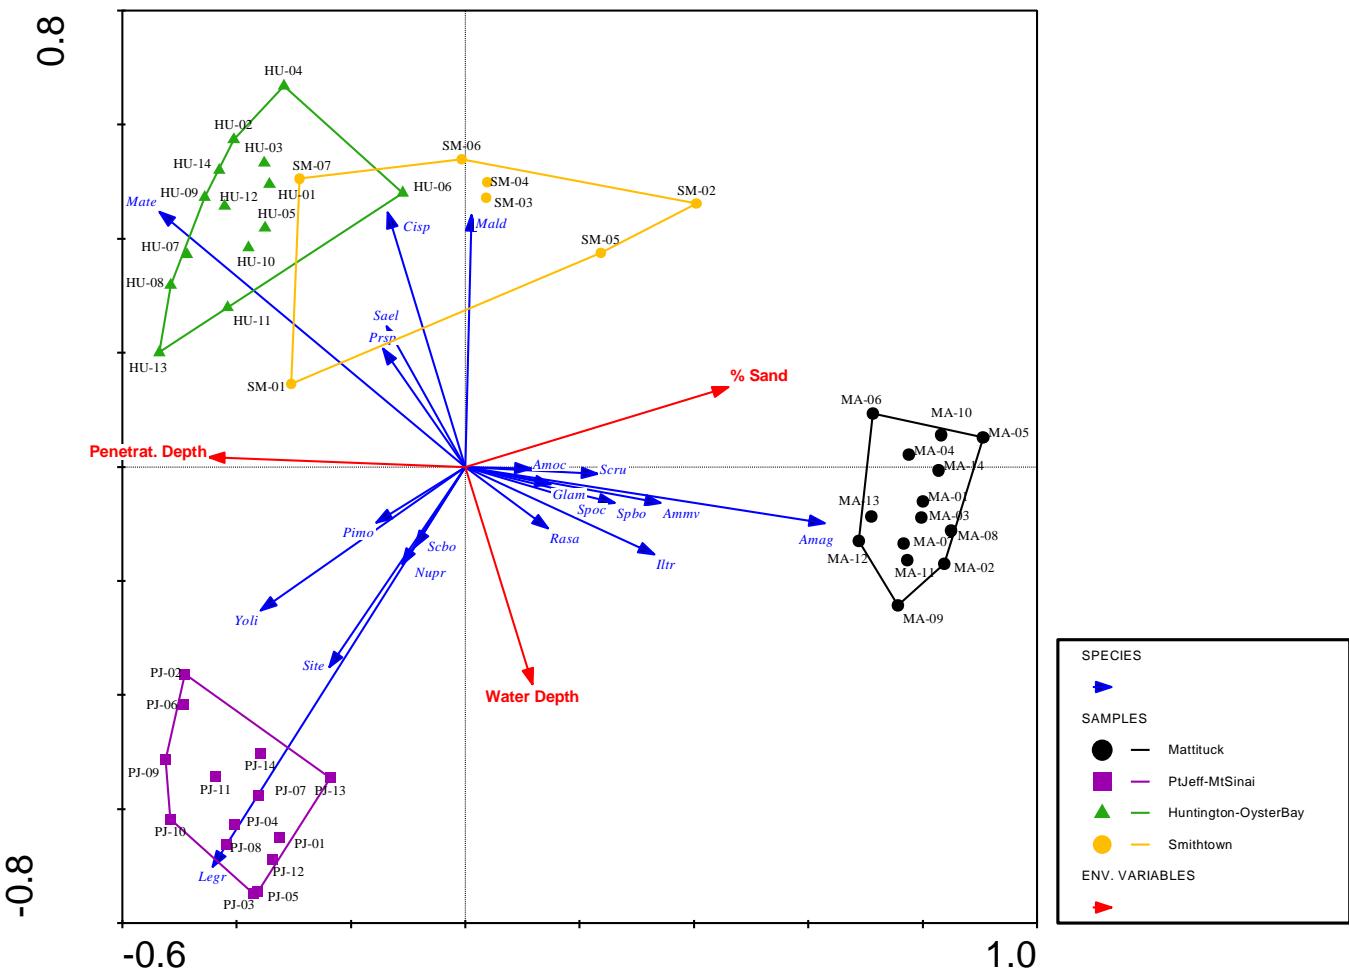

Figure 6. Mean water depth, grab penetration depth, and sediment grain-size characteristics at the SS reef sites. Error bars are standard deviation.

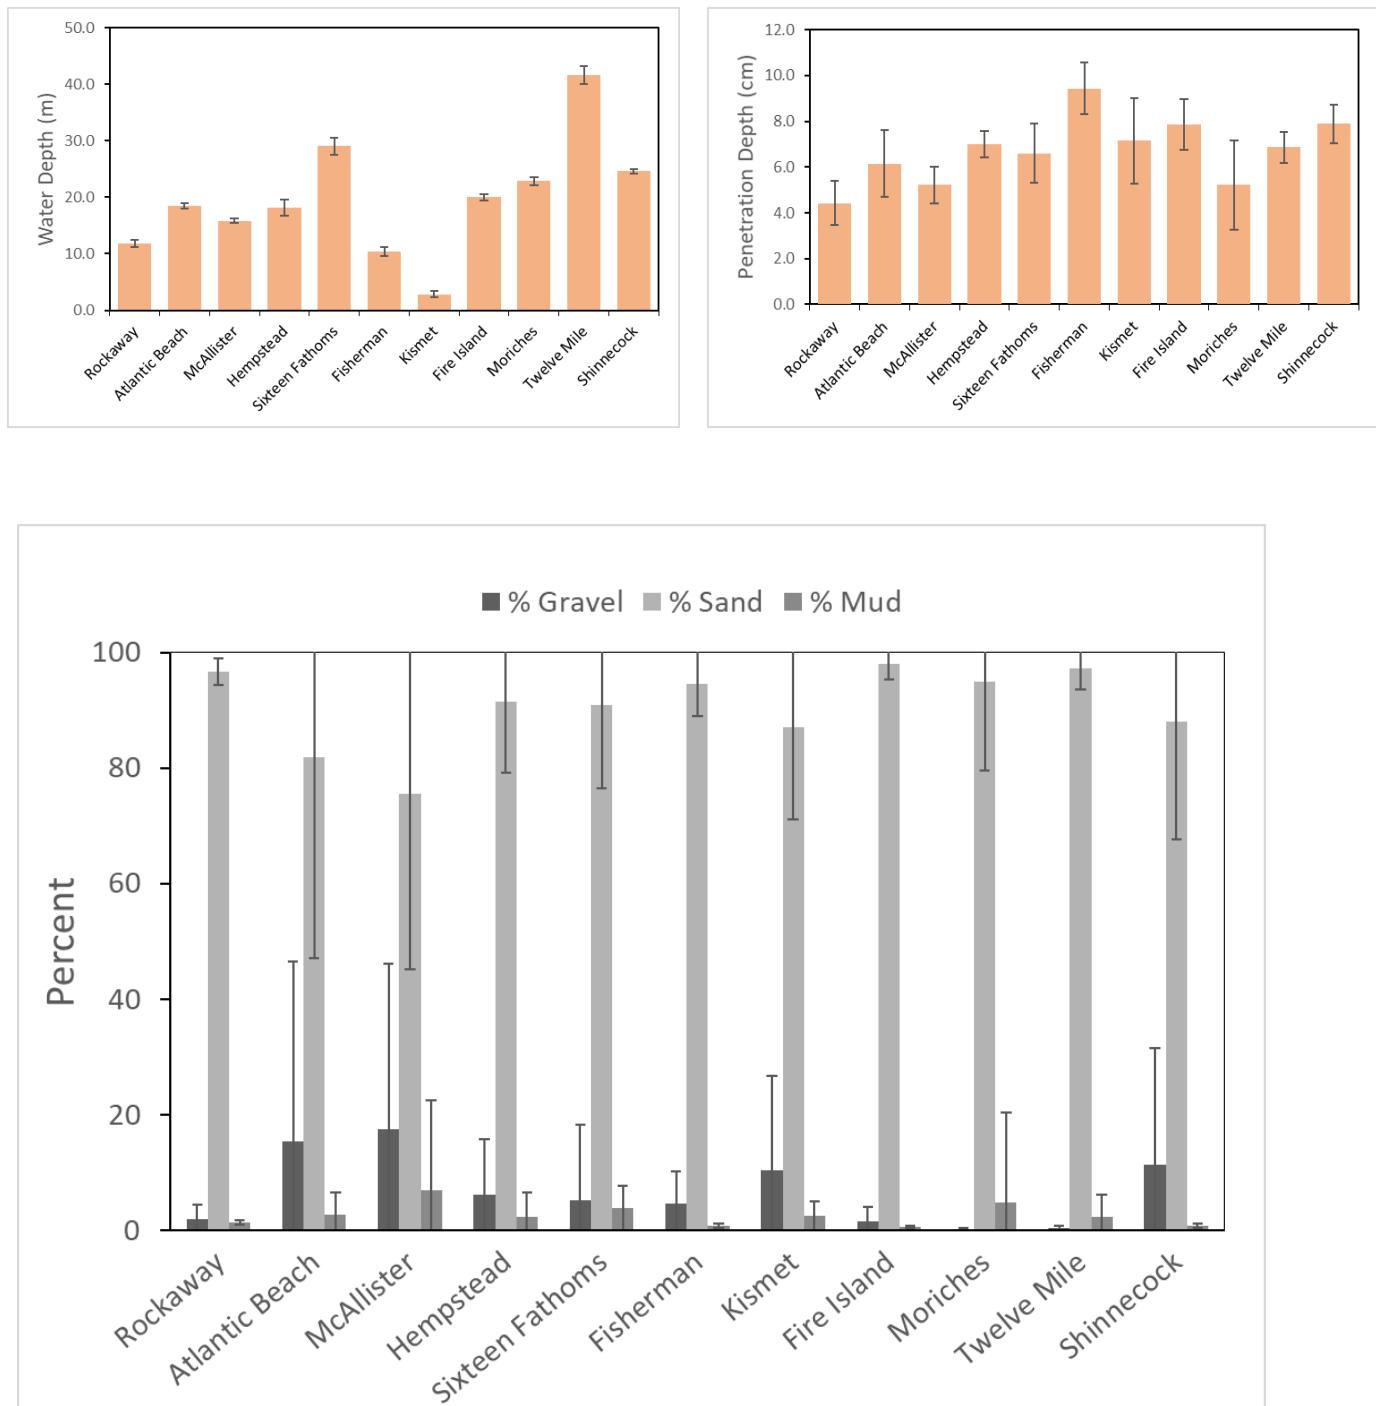

Figure 7. Mean abundance, species richness, Shannon diversity and Equitability at the SS reef sites. Error bars are standard deviation.

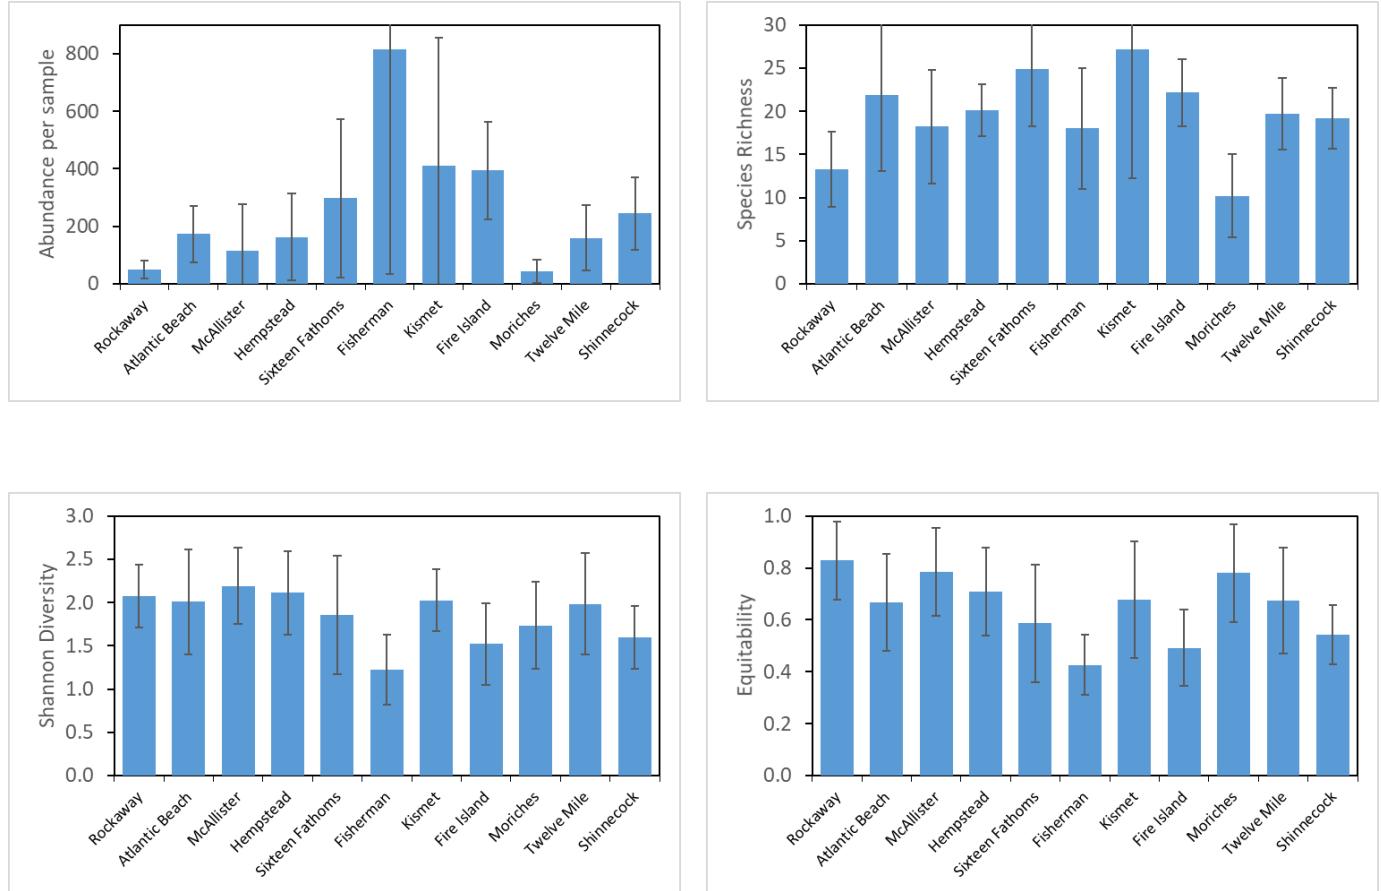

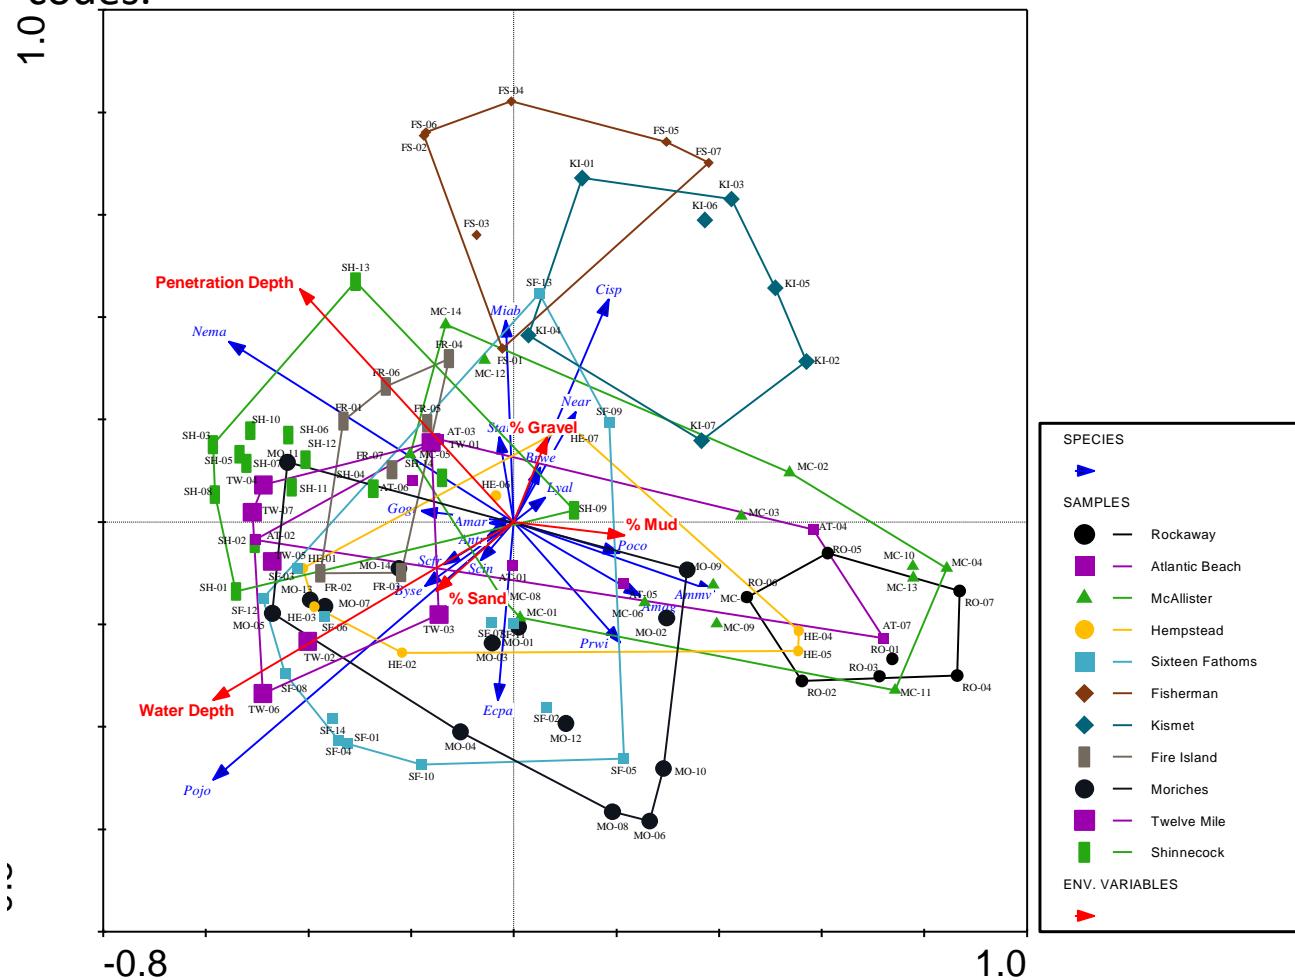

Figure 8. RDA ordination triplot for axes 1 & 2 of the South Shore data. Eigenvalues for these axes are 0.085 and 0.055, respectively. The third and fourth axis eigenvalue (not shown) were 0.021 and 0.010. Samples are plotted as points, and they are colored and enclosed in envelopes based on membership in each reef site. Sample points close to one another tend to have similar faunal structure than those further apart. Continuous explanatory variables and individual taxa are plotted as vectors. The arrowhead represents high, the origin average, and the tail (when extended through the origin) low values. Projections of sample points onto an individual taxa vector approximate the Hellinger transformed abundances for that taxon. For clarity, only the species with the highest amounts of explained variance (those with > 20%) are plotted. See Table 4 for species abbreviation codes.

4606 cells in main matrix
 Percent of cells empty = 83.565
 Matrix total = 3783

Abund. = total abundance per sample
 S = Richness = number of non-zero elements in sample
 E = Evenness = $H' / \ln(\text{Richness})$
 H' = Diversity = $-\sum(P_i * \ln(P_i))$ = Shannon's diversity index
 D = Simpson's diversity index for infinite population = $1 - \sum(P_i * P_i)$
 where P_i = proportion of individuals in the sample belonging to species i

19530 cells in main matrix
Percent of cells empty = 89.708
Matrix total = 24970

Abund. = total abundance per sample
S = Richness = number of non-zero elements in row
E = Evenness = H' / ln (Richness)
H' = Diversity = - sum (Pi*ln(Pi)) = Shannon's diversity index
D = Simpson's diversity index for infinite population = 1 - sum (Pi*Pi)
where Pi = proportion of individuals in the sample belonging to species i
