A mis padres

Acknowledgements

Parece difícil resumir el trabajo de todos estos años en el laboratorio, pero más complicado resulta recoger en unas pocas páginas todos los recuerdos y emociones que lo han acompañado, y agradecer a todas las personas que lo han enriquecido y formado parte de esta experiencia. Por eso, estas páginas son para vosotros.

Arancha y Blanca, mis mentoras científicas. Si hoy estoy escribiendo esta Tesis es gracias a la oportunidad que me disteis de comenzar en la ciencia, a vuestra guía y profesionalidad. A veces, las circunstancias no os ponen las cosas fáciles, pero no por ello dejáis de trabajar y hacerlo de la mejor manera posible. Gracias por vuestra confianza, cariño y cercanía. En estos años he aprendido y crecido tanto científica como personalmente, y he superado retos que no hubiera podido imaginar. Gracias.

César, mi primer contacto con el grupo Hígado. Siempre recordaré la primera vez que entré en el despacho llena de nervios. Quien me iba a decir que años después seguiría entrando, ahora ya sí, sin tanta vergüenza y con muchas preguntas. Gracias por tu apoyo, consejos y tus palabras de ánimo. Gracias también Marga, por tu interés, cariño y fuerza.

Gracias a María, la transmisora de los cuidados de mis queridas TβT. Cuántas veces acudiste a mis llamadas de auxilio en mis comienzos. Gracias por tu ayuda, sinceridad, confianza y apoyo, por haber estado dentro del laboratorio, y más importante, seguir estando fuera de él. Gracias Annalisa, que junto con María fuisteis las primeras en recibirme y enseñarme como era la vida en laboratorio.

Gracias Nerea, mi vasca. Tu generosidad y compañerismo hacen fácil el trabajo en grupo. Tu entrada en el laboratorio fue una gran elección, y ahora parece mentira que haya pasado tanto tiempo desde entonces. Sería imposible contar aquí tantas experiencias y momentos que hemos pasado juntas (risas, muchas risas, pero también llantos, dramas, largos conciertos a cappella en el animalario, cotilleos...). No sé si podría haber tenido una compañera mejor. Gracias por estar ahí.

Gracias a todos los compañeros que por un corto o largo periodo de tiempo habéis formado parte del grupo Hígado. Todos habéis contribuido de una manera u otra a mi aprendizaje y muchos de vosotros formáis ahora parte de mi vida. Con especial cariño recuerdo a Ami, Chechu, Ceci, Esti, Sergio, Paulita...; Nerea Deleyto, sentí mucho cuando te fuiste del laboratorio, por suerte, sigo contando contigo como amiga. Sara Baak, we were lucky that you were part of the group, you are an excellent colleague and person. Diana, maravilloso, gracias

por tu tiempo y dedicación en la portada. Rebequiña, una pena no haber coincidido más tiempo en el laboratorio. Gracias por tu alegría, fuerza y cariño. Estoy segura de que podrás hacer todo aquello que te propongas.

Gracias Almudena Porras, por tu cercanía y afecto. Y gracias a tu grupo, indispensable apoyo en estos años. Gracias María Arechederra y Neibla por vuestra ayuda y cariño en mis primeras etapas en el laboratorio; y también, gracias Dani, que aun estando en Barcelona has seguido presente en el laboratorio. Ha sido una suerte el haber podido encontrarnos a lo largo de estos años. Como no, gracias Nerea Palao, Cristina, Celia, Sara, Noelia. Inolvidables van a ser vuestros consejos de sabias para apoyo profesional y/o personal y las reuniones higaporritos para tratar los distintos temas que iban aconteciendo. Vuestra alegría hace el día a día mucho más fácil en el laboratorio. Celia, han sido muchos años puerta con puerta, gracias por tu ayuda aquí, y por tus indicaciones a mi llegada a Marsella. Nerea y Cris, mil gracias también por vuestros abrazos, apoyo y preocupación en estos últimos meses.

Gracias a las nuevas y no tan nuevas incorporaciones: Paloma, Beatriz y Álvaro. Gracias por vuestras palabras de ánimo, por dar un punto de vista diferente y por ofrecer vuestra ayuda para lo que sea necesario. Estáis siendo un apoyo para mí.

Gracias a todos los que formáis parte de esta pequeña familia que es el Departamento y por haber formado también parte de mi etapa en él.

Gracias Oscar, Almudena Gómez, Mariola, Tamara, Elisa y Carlos, por vuestro interés y ayuda.

Gracias al grupo del Dr. José Carlos Segovia por su colaboración en este trabajo. Gracias María García Bravo, ha sido un placer trabajar contigo, tanto por tu profesionalidad como por el trato que me has dado.

Flavio. Many thanks for opening me the doors of your lab. It has been an excellent experience to be part of your group. Thanks for your energy, the enthusiasm for science that you transmit and your positive words. Thanks Fabienne and Rosanna for your advice and your help. Thank to rest of the members of the group Sylvie, Fahmida, Sehrish, Diane and the students Marta, Thomas and Alexia for your help and make me feel like part of the group. Gracias especiales Serena por tu tiempo, tu atención y por nuestras conversaciones en inglés/español latino.

No puedo olvidarme de mis francesas/españolas. Sin duda mi estancia en Marsella no habría sido lo mismo sin vosotras, y por supuesto, los momentos en el microscopio, hubieran sido insalvables. Irene, ojalá todo el mundo que tuviera que instalarse una nueva ciudad encontrase a una anfitriona como tú. Gracias por estar siempre pendiente de mí, por abrirme las puertas de tu casa y tu vida y por mostrarme rincones de la ciudad. Patricia, gracias por tu fuerza, ayuda y

comprensión. Voy a copiar las palabras que alguien te dijo una vez “buena científica y mejor persona”. Gracias a las dos por seguir estando presentes.

Sois muchos los familiares y amigos, viejos y nuevos, que fuera del laboratorio os habéis interesado por mí durante todos estos años. Gracias por vuestro cariño, interés y por vuestras palabras de ánimo que resultan mucho más alentadoras cuando se escuchan desde la distancia.

Gracias Noe, Sonia, María, Oli y Leyre por los buenos momentos de re-encuentro a lo largo de todos los años que llevo en Madrid. La vida nos ha puesto a kilómetros de distancia y hace que muchas veces nos sea fácil compartir momentos importantes como lo va a ser éste. De alguna manera, siempre estáis presentes, y espero que sigáis estándolo. Gracias Marta por comprenderme y entenderme tan bien, y por tu apoyo incondicional. Gracias por tenerme siempre presente. Y gracias, como no, por nuestros tan necesarios momentos de desconexión.

Gracias tía Petra por tu generosidad durante todos estos años, y por cuidarme y preocuparte por mi como si fueras una madre.

Gracias a los coautores ocultos de esta tesis, mis padres, Antonio y Leo. Sin duda todo lo que he conseguido es gracias a vosotros. Gracias por vuestra educación y por los valores que me habéis transmitido. Gracias por vuestros sacrificios, y por tanto amor.

1. Abstract

Crosstalk between HGF and TGF- β signaling pathways in adult liver progenitor cells and hepatocellular carcinoma cells

Introduction

Chronic liver diseases (CLDs) are associated with fibrosis, which eventually progress to cirrhosis and ultimately to hepatocellular carcinoma (HCC) development, constituting a major global health problem. In the context of chronic liver injury where the proliferative capacity of adult hepatic cells is impaired, the population of adult hepatic progenitor cells (HPCs), also known as oval cells in rodents, takes over the regenerative process. Upon activation, HPCs/oval cells expand, proliferate and migrate into liver parenchyma and due to their bipotential nature differentiate into hepatocytes and cholangiocytes compensating the cellular loss and maintaining liver functionality. However, some authors give HPCs/oval cells a pro-fibrotic role, establishing a direct relationship between the HPCs/oval cell expansion and the severity of the fibrosis. They could also be the cells of origin of a subset of HCC. It is therefore evident that the signals and mechanisms regulating HPC/oval cell biology and function need to be clarified not only because of their potential utility in regenerative medicine, but also because of their still uncertain role in the aforementioned diseases.

TGF- β signaling plays important roles in the sequence of events leading to fibrosis and HCC development. EMT induction is among the mechanisms through which TGF- β exerts its pro-fibrotic and pro-carcinogenic role. HPCs/oval cells can undergo EMT in response to TGF- β . However, it is unclear if TGF- β -induced EMT in HPCs/oval cells somehow affects their pro-regenerative or pro-fibrotic/pro-tumoral potential.

HGF/Met signaling axis is crucial for an efficient liver regenerative response, both hepatocyte- and HPCs/oval cell-mediated, but its aberrant activation is also involved in the development and progression of hepatocarcinogenesis. HGF/Met and TGF- β often trigger opposite activities during liver damage. In fact, experimental evidence indicates that HGF/Met opposes to TGF- β pro-fibrotic activity. Nevertheless, whether HGF/Met signaling could modulate oval cell response to TGF- β during liver damage is not known. Likewise, a potential crosstalk between these two pathways for the regulation of liver tumor cells has not yet been explored.

Aims

TGF- β and HGF/Met pathways are important mediators during liver regeneration, fibrosis and hepatocarcinogenesis and play roles on different liver cell populations. Taking this into consideration, the general objective of this work was to analyze the relevance of the crosstalk between TGF- β and HGF/Met pathways in oval cell biology and fate in a context of chronic liver injury as well as to explore if such crosstalk could play a role during hepatocarcinogenesis.

To achieve this general objective, we propose three specific objectives:

Objective 1: To characterize the TGF- β -induced EMT response in oval cells *in vitro* and to evaluate the effects on oval cell fate upon transplantation into a fibrotic liver.

Objective 2: To elucidate the HGF/Met signaling-mediated regulation on the EMT response induced by TGF- β and its contribution to oval cell properties.

Objective 3: To analyze the TGF- β pathway in liver tumor cells from Met-overexpressing livers and how affects tumor cell growth and survival properties.

Results

Our results show that oval cells suffer a partial EMT in response to chronic TGF- β treatment. After EMT, oval cells display profound changes in their phenotype and properties. Besides the loss of some epithelial markers and gain of mesenchymal markers, cells acquire proliferative, survival and invasive advantages. However, these changes are not associated with stemness but rather with induction of differentiation along the hepatic lineage. Importantly, these changes confer oval cells a greater *in vivo* regenerative capacity being able to attenuate liver damage when transplanted into mice submitted to CCl₄-induced liver fibrosis. Moreover, our results reveal that HGF/Met signaling pathway is essential to allow oval cell expansion after TGF- β -induced EMT. In the absence of Met tyrosine kinase activity oval cells enter into a senescence process concomitant with an exacerbated oxidative stress. In this respect, we have uncovered a novel role for Twist as a downstream mediator of HGF/Met antioxidant activity against TGF- β -induced oxidative stress in oval cells. Additionally, HGF/Met signaling pathway contributes to the phenotypic and functional properties of oval cells after EMT, counterbalancing the mesenchymal switch while promoting proliferation, survival and invasion.

On the other hand, we provide preliminary evidence on the activation of the TGF- β pathway in livers with moderate Met overexpression and in subsequently developed tumors. We also provide preliminary evidence on reciprocal regulatory interactions between HGF/Met and TGF- β signaling pathways in tumor cell lines derived from these livers. Thus, high levels of Met lead to constitutive Met activation and a decrease in TGF- β -triggered Smad activation,

whereas TGF- β decreases Met phosphorylation in Met-low overexpressing HCC cells. Notably, this signaling interplay affects tumor cell properties. In fact, our results suggest that Met kinase activity is critical for tumor cell survival and protection against TGF- β -induced apoptosis.

Conclusions

1. Chronic treatment of oval cells with TGF- β leads to a stable and partial EMT phenotype.
2. TGF- β -induced EMT in oval cells does not increase stemness but rather promotes differentiation along the hepatic lineage, while conferring proliferation, survival and invasion advantages *in vitro*.
3. Oval cells chronically treated with TGF- β attenuate CCl₄-induced liver damage and fibrosis upon transplantation.
4. HGF/Met signaling activation is required to overcome the oxidative stress-induced senescence and allow oval cell expansion after TGF- β -induced EMT.
5. Twist is a downstream target of HGF/Met in oval cells that mediates the antioxidant activity driven by HGF/Met signaling and prevents cell senescence.
6. HGF/Met signaling modulates TGF- β -induced EMT phenotype in oval cells contributing to cell proliferation, survival and invasive advantages while counterbalancing the mesenchymal phenotypic switching.
7. HCC cell lines derived from Alb-R26^{Met} mice show negative regulatory circuits between HGF and TGF- β signaling pathways. Thus, HCC cells with high levels of Met show an attenuation of TGF- β -triggered Smad signaling, whereas TGF- β is able to decrease Met phosphorylation but only in HCC cells with low overexpression of levels of Met.
8. HCC cell lines derived from Alb-R26^{Met} mice show dependence on Met signaling for cell survival and protection against TGF- β .

2. Resumen

Interacción entre las vías de HGF y TGF- β en células progenitoras adultas hepáticas y células de hepatocarcinoma

Introducción

Las enfermedades hepáticas crónicas (CLD) están asociadas con fibrosis, que eventualmente progresa a cirrosis, y en último término al desarrollo de un carcinoma hepatocelular (HCC), y constituyen un importante problema de salud global. En este contexto de daño hepático crónico en el que la capacidad regenerativa de las células maduras hepáticas se ve comprometida, es la población de células progenitoras adultas (HPCs), también conocidas como células ovales en modelos murinos, la que va a tomar las riendas del proceso de regeneración hepática. Tras su activación, las HPCs/células ovales se expanden, proliferan y migran en el parénquima hepático y gracias a su naturaleza bipotencial se diferencian a hepatocitos y colangiocitos, compensando así la pérdida de masa hepática y manteniendo la funcionalidad hepática. Sin embargo, algunos autores dotan a las HPCs/células ovales de un papel pro-fibrótico, estableciendo una relación directa entre su expansión y la severidad de la fibrosis. Estas células también pueden ser el origen celular de algunos subtipos de HCC. Resulta por tanto evidente la necesidad de estudiar las señales y mecanismos que regulan la biología y la función de estas células, no solo por su potencial utilidad en medicina regenerativa sino también por su papel aún no claro en las ya mencionadas enfermedades hepáticas.

La vía de señalización del TGF- β es clave en los distintos eventos que conducen a un proceso fibrótico y al desarrollo del HCC. La inducción de EMT es uno de los mecanismos a través de los cuales el TGF- β lleva a cabo su papel pro-fibrótico y pro-tumoral. Las HPCs/células ovales pueden sufrir EMT en respuesta al TGF- β . Sin embargo, no está claro si esta respuesta influye en su potencial pro-regenerativo o pro-fibrótico/pro-tumoral.

La vía de señalización de HGF/Met es fundamental para una regeneración hepática eficiente, tanto la llevada a cabo por las células maduras como la mediada por las HPCs/células ovales, aunque una activación aberrante de esta vía también está implicada en el desarrollo y la progresión de la carcinogénesis hepática. HGF/Met y TGF- β a menudo tienen papeles opuestos en el daño hepático crónico. De hecho, las evidencias experimentales indican que HGF/Met se opone a los efectos pro-fibróticos de TGF- β . Sin embargo, no se sabe si el HGF podría regular la respuesta de las HPCs/células ovales al TGF- β durante el daño hepático. Asimismo, tampoco se ha explorado una posible interacción entre estas dos vías de señalización en la regulación de las células tumorales hepáticas.

Objetivos

El objetivo general de este trabajo ha sido analizar la relevancia de la interacción cruzada entre las vías de TGF- β y HGF/Met en la biología y el destino de la célula oval en el hígado dañado, así como estudiar si dicha interacción podría intervenir en procesos de hepatocarcinogenesis.

Para conseguir este objetivo proponemos tres objetivos específicos:

Objetivo 1: Caracterizar la respuesta de EMT inducida por TGF- β en las células ovas *in vitro* y evaluar sus efectos en el destino de la célula oval tras su trasplante en un hígado fibrótico.

Objetivo 2: Elucidar la regulación medida por la vía de HGF/Met sobre la respuesta de EMT inducida por TGF- β y su contribución a las propiedades de la célula oval.

Objetivo 3: Analizar la vía de TGF- β en células tumorales hepáticas procedentes de hígados con sobre-expresión de Met y cómo esta vía podría afectar al crecimiento y supervivencia de la célula tumoral.

Resultados

Nuestros resultados muestran que las células ovas sufren un proceso de EMT parcial en respuesta al tratamiento crónico con TGF- β . Este proceso provoca profundos cambios en el fenotipo y las propiedades de las células. Además de la pérdida de algunos marcadores epiteliales y la adquisición de marcadores mesenquimales, estas células adquieren ventajas proliferativas, de supervivencia e invasión. Sin embargo, estos cambios desencadenados por la EMT no están asociados con la adquisición de marcadores y propiedades de célula madre, sino con la inducción de diferenciación hacia el linaje del hepatocito. Es importante destacar que estos cambios confieren a las células ovas una mayor capacidad regenerativa *in vivo*, siendo capaces de atenuar el daño hepático cuando son trasplantadas en ratones con un proceso de fibrosis hepática inducida por CCl₄. Adicionalmente, nuestros resultados revelan que la vía de HGF/Met es esencial para permitir la expansión de la célula oval tras la inducción de EMT por TGF- β . En ausencia de la actividad tirosina quinasa de Met las células ovas entran en senescencia, proceso que es simultáneo a un estrés oxidativo exacerbado. En este sentido, hemos descubierto un nuevo papel para Twist como mediador de la actividad antioxidante de HGF/Met frente al estrés oxidativo inducido por TGF- β en células ovas. La vía de HGF/Met también contribuye a las características fenotípicas y funcionales de las células ovas adquiridas después de la EMT, contrarrestando la transición mesenquimal a la vez que promueve la proliferación, supervivencia e invasión.

Por otro lado, con este trabajo mostramos evidencias preliminares de la activación de la vía de señalización de TGF- β en hígados de ratón con sobreexpresión moderada de Met y en los tumores hepáticos que desarrollan, así como de la existencia de interacciones regulatorias recíprocas entre las vías

de HGF/Met y TGF- β en líneas de células tumorales derivadas de estos hígados. Así, niveles altos de Met conducen a su activación constitutiva y a una disminución en la activación de Smads por TGF- β , mientras que el TGF- β disminuye la fosforilación de Met en células tumorales con una baja sobreexpresión de Met. Esta interacción a nivel de señalización afecta a las propiedades de la célula tumoral. De hecho, nuestros resultados sugieren que la actividad quinasa de Met es crítica para la supervivencia y la protección de las células tumorales frente a la apoptosis inducida por TGF- β .

Conclusiones

1. El tratamiento crónico con TGF- β induce en las células ovals un fenotipo EMT parcial y estable.
2. La inducción de EMT por TGF- β en las células ovals no conlleva un incremento en los marcadores y propiedades de célula madre, sino que promueve la diferenciación hacia el linaje hepático, confirmando, además, ventajas proliferativas, de supervivencia e invasivas *in vitro*.
3. El trasplante de las células ovals crónicamente tratadas con TGF- β atenúan el daño hepático y la fibrosis inducidos por CCl₄.
4. La activación de la vía de HGF/Met es esencial para superar la senescencia producida por estrés oxidativo y permitir la expansión de la célula oval tras la inducción de EMT por TGF- β .
5. Twist es una diana de la vía de señalización de HGF/Met en las células ovals que media la actividad antioxidante ejercida por HGF/Met previniendo la senescencia celular.
6. La vía de señalización de HGF/Met modula el fenotipo EMT inducido por TGF- β en las células ovals contribuyendo así a las ventajas proliferativas, de supervivencia e invasivas a la vez que contrarresta el cambio fenotípico mesenquimal.
7. Las células de hepatocarcinoma obtenidas de los ratones Alb-R26^{Met} muestran un circuito de regulación negativa entre las vías de señalización de HGF y TGF- β . Así, las células de hepatocarcinoma con altos niveles de Met muestran una atenuación de la señalización desencadenada por TGF- β a través de las Smad, mientras que TGF- β es capaz de reducir la fosforilación de Met, pero solo en las células de hepatocarcinoma con una baja sobreexpresión de Met.
8. La supervivencia y la protección frente al TGF- β de las células de hepatocarcinoma obtenidas de los ratones Alb-R26^{Met} es dependiente de la señalización de Met.

IGF-I	Insulin-like Growth Factor I
IL	Interleukin
IP	Immunoprecipitation
IPT	Immunoglobulin-like domains shared by Plexins and Transcriptional factors
I-SMAD	Inhibitory SMAD
JNK	c-Jun N-terminal kinase
KC	Kupffer Cells
LAP	Latency-Associated Peptide
MAPK	Mitogen-Activated Protein Kinase
MET	Mesenchymal to Epithelial Transition
MFB	Myofibroblasts
miRNA	microRNA
MIS	Müllerian Inhibiting Substance
MMP	Matrix Metalloproteinase
MOI	Multiplicity of Infection
mTOR	mammalian Target of Rapamycin
NADPH	Nicotinamide Adenine Dinucleotide Phosphate
NAFLD	Non-Alcoholic Fatty Liver Disease
N-CAM	Neural Cell Adhesion Molecule
NF-KB	Factor kappa-Light-chain-enhancer of activated B cells
NT	Non-Targeting
OC	Oval Cell
OCR	Oxygen consumption rate
PAI1	Plasminogen Activator Inhibitor-1
PBS	Phosphate Buffered Saline
PCR	Polymerase Chain Reaction
PDGF	Platelet Derived Growth Factor
PFA	Paraformaldehyde
PI	Propidium Iodide
PI3K	Phosphatidylinositol 3-kinase
PLCγ	Phospholipase C gamma
PSI	Plexin-Semaphorin-Integrin
PTP1B	Protein Tyrosine Phosphatase 1B
RB	Retinoblastoma Protein
RNA	Ribonucleic Acid
ROS	Reactive Oxygen Species
R-SMAD	Receptor-associated SMAD
RTK	Receptor Tyrosine Kinase
RT-qPCR	quantitative Reverse Transcription-Polymerase Chain Reaction
S.D.	Standard Deviation
S.E.M.	Standard Error Of The Mean

SAHF	Senescence-Associated Heterochromatic Foci
SASP	Senescence-Associated Secretory Phenotype
SA-β-GAL	Senescence-Associated beta-Galactosidase
SDF1	Stromal cell-Derived Factor 1
SDS	Sodium Dodecyl Sulphate
SDS-PAGE	SDS Polyacrylamide Gel Electrophoresis
SF	Scatter Factor
SHC	SH2 domain-containing transforming protein
SHP2	Src Homology 2 domain-containing Phosphatase-2
siRNA	Small interference RNA
STAT	Signal Transducers and Activators of Transcription
TE buffer	Tris-EDTA buffer
TERT	Telomerase Reverse Transcriptase
THY-1	Thymocyte Differentiation Antigen 1
TIEG1	TGF- β -Inducible Early Response Gene 1
TIMP	Tissue Inhibitors of Metalloproteinase
TNF-α	Tumor Necrosis Factor alfa
TNF-β	Transforming Growth Factor beta
TPBS	Tween 20-PBS
TTBS	Tween 20-Tris-Buffered Saline
TU	Transducing Units
TWEAK	Tumor Necrosis factor-like weak inducer of apoptosis
TβR	TGF- β Receptor
TβT-OC	Oval Cells chronically treated with TGF- β
VEGF	Vascular Endothelial Growth Factor
ZEB	Zinc finger E-box-Binding homeobox
ZO-1	Zonula Occludens 1
α-SMA	alfa Smooth Muscle Actin

4. Introduction

1. Liver damage

The liver, composed of parenchymal cells (hepatocytes and cholangiocytes) and non-parenchymal cells (endothelial cells, Kupffer cells (KC), lymphocytes and hepatic stellate cells (HSCs)), is a vital organ with a unique capacity to regenerate in response to liver damage (Itoh and Miyajima, 2014).

The functional unit of the liver is the hepatic lobule. The lobules are demarcated by portal triads, which consist of a portal vein, a hepatic artery and a bile duct. Blood enters the liver from portal vein and hepatic artery and flows through liver sinusoids towards the central vein. Row of hepatocytes is delimited by endothelium forming the sinusoids, which facilitate interaction between the blood and hepatocyte cell surface. Bile secreted by hepatocytes is collected into bile canaliculus, which is finally connected with bile ducts formed by cholangiocytes (bile duct epithelial cells) via the canal of Hering (Duncan et al., 2009).

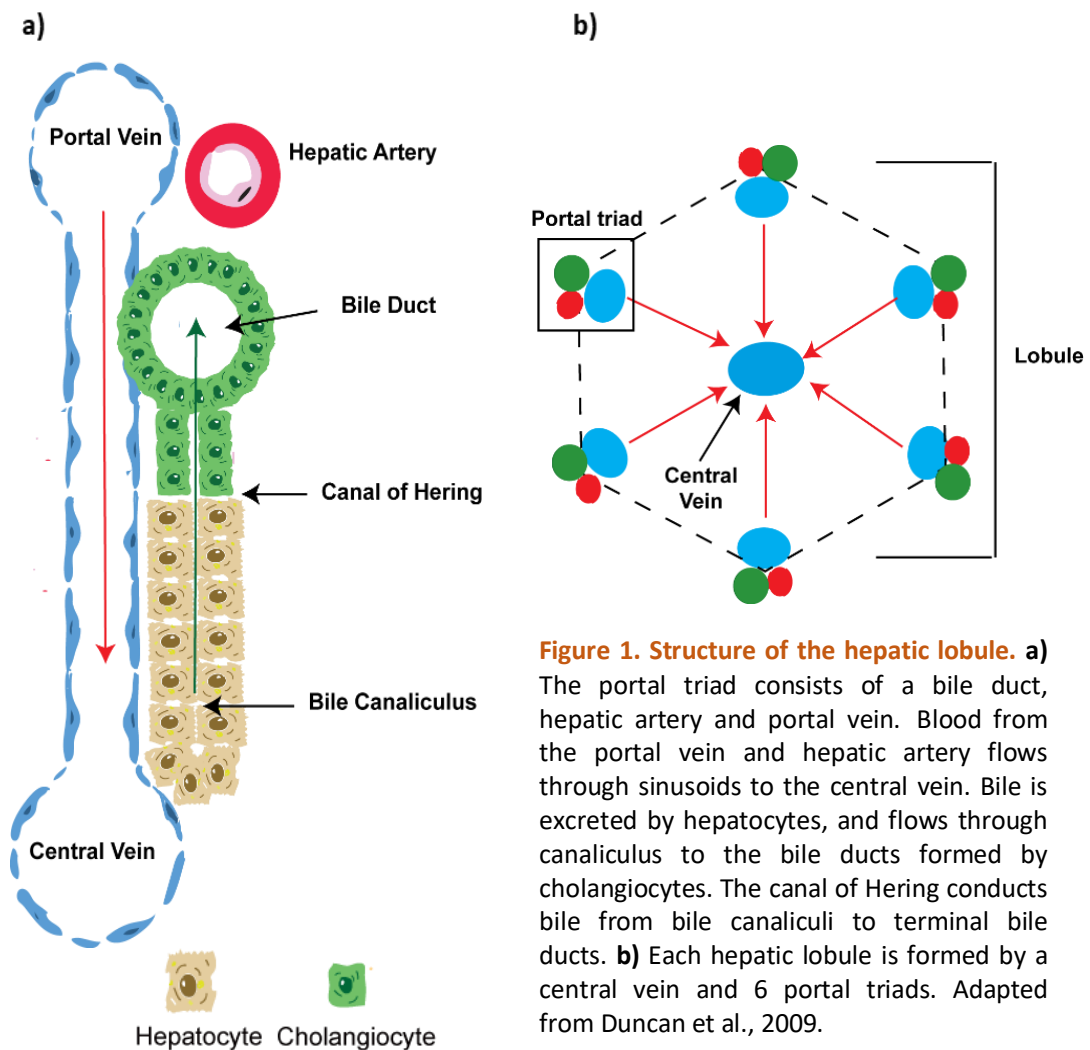

Figure 1. Structure of the hepatic lobule. a) The portal triad consists of a bile duct, hepatic artery and portal vein. Blood from the portal vein and hepatic artery flows through sinusoids to the central vein. Bile is excreted by hepatocytes, and flows through canaliculus to the bile ducts formed by cholangiocytes. The canal of Hering conducts bile from bile canaliculi to terminal bile ducts. **b)** Each hepatic lobule is formed by a central vein and 6 portal triads. Adapted from Duncan et al., 2009.

A number of insults, including viral activity (chronic hepatitis C virus and hepatitis B virus), chemical toxicity and metabolic overload, result in liver damage and hepatocyte and cholangiocyte death. Liver injury triggers a cascade of molecular and cellular reactions oriented towards damage limitation. Briefly,

the initial event of liver damage is liver epithelial cell stress, resulting in necrotic and/or apoptotic death. Death-mediated signals induce the activation of an inflammatory and wound healing response that might lead to tissue regeneration and repair in an acute damage. However, in chronic liver disease (CLD), the liver injury continues and the inflammation and wound healing become persistent. Finally, tissue remodeling goes awry, becomes inefficient, and results in fibrosis and cirrhosis, context in which hepatocellular carcinoma (HCC) could develop and deadly hepatic failure could occur. The number of patients with CLD is increasing, and CLD is becoming a common and difficult clinical challenge (Dooley and ten Dijke, 2012; Weiskirchen and Tacke, 2016).

1.1. Liver fibrosis and cirrhosis

Liver cirrhosis is the 13th most common cause of death in adults worldwide and the 4th among chronic diseases with 1,2 million deaths per year. Globally, the main causes of fibrosis and cirrhosis are, in this order, infection with hepatitis C virus, infection with hepatitis B virus and alcohol abuse (Rowe, 2017).

1.1.1. Pathophysiology

Liver fibrosis is a complex wound healing process characterized by an imbalance between extracellular matrix (ECM) synthesis and degradation in favor of deposition of ECM proteins. In the first stages of liver damage, liver fibrosis tries to encapsulate the injury in an attempt to limit its consequences and it is considered a reversible process. If injury is maintained, this process ultimately progresses to advanced fibrosis or cirrhosis, which might be irreversible, situation that occurs during a CLD (Ebrahimi et al., 2016). Cirrhosis is defined as an advanced stage of fibrosis characterized by regenerative nodules of liver parenchyma, which are encapsulated in fibrotic septa and associated with angioarchitectural changes (Pinzani, 2015). Together with chronic activation of the wound healing response, other different pro-fibrogenic mechanisms have been identified, including oxidative stress, disarrangement of epithelial-mesenchymal interactions, epithelial to mesenchymal transition (EMT) of parenchymal cells, hepatocyte loss and chronic inflammation (Czaja, 2014; Lee et al., 2014; Parola and Pinzani, 2019).

The principal source of ECM accumulation in the wound healing reaction is the activity of myofibroblasts (MFB). Different cell types have been proposed to be the origin of MFB, but undoubtedly, the major source of fibrogenic cells are portal fibroblasts and HSCs (Iwaisako et al., 2014).

HSCs are non-parenchymal liver cells that function as a major site of storage of vitamin A, constituting the largest reservoir of vitamin A in the body. In pathologic conditions, HSCs suffer a trans-differentiation process triggered by reactive oxygen species (ROS), pro-inflammatory and mitogenic cytokines and growth factors such as tumor necrosis factor alfa (TNF- α), transforming growth factor beta (TGF- β) or platelet derived growth factor (PDGF), changing from a quiescent phenotype to an activated myofibroblast state. MFB are characterized

by the expression of α -smooth muscle actin (α -SMA) protein, loss of lipid and retinoid storages, increased proliferation, survival, migration and contraction capacities, and secretion of pro-inflammatory cytokines and chemokines (Ebrahimi et al., 2016; Mallat and Lotersztajn, 2013). Furthermore, MFB contribute to the fibrous scar present in CLD by synthesizing large amounts of ECM proteins, specifically type I and type III collagen, and regulating ECM degradation. MFB express combinations of matrix metalloproteinases (MMPs) and tissue inhibitors of metalloproteinases (TIMPs) that degrade normal liver matrix, while inhibiting degradation of the accumulated fibrillary collagen in liver fibrosis. Although MMPs and TIMPs expression in MFB are thought to play central roles in the development of CLD, it has been suggested that hepatocyte-derived MMPs are also important mediators of the ECM turnover (Benyon and Arthur, 2001; Duarte et al., 2015; Mallat and Lotersztajn, 2013).

In addition to HSCs and fibroblasts, other cell types can suffer a myofibroblastic differentiation and therefore contribute to ECM accumulation (Weiskirchen et al., 2018; Wells, 2008). Thus, bone marrow fibrocytes (small subset of mononuclear bone marrow cells, that transmigrate to liver through the blood stream in response to injury), vascular smooth muscle cells, endothelial cells, pericytes and epithelial cells may undergo EMT (Rowe et al., 2011; Rygiel et al., 2008; Zeisberg et al., 2007), although the epithelial origin of MFB is still under debate.

Apart from the wound healing response, other processes take place during CLD. For example, oxidative stress with formation and degradation of ROS is a crucial part of fibrosis development and persistence. Intracellular sources of ROS include the mitochondrial electron transport chain and extra-mitochondrial ROS generating enzymes (Richter and Kietzmann, 2016). Among these, the NOX family of nicotinamide adenine dinucleotide phosphate oxidases (NADPH oxidases) appears to have a key role during liver fibrosis, being NOX4 the isoform with a more critical role in ROS production under pro-fibrogenic conditions (Crosas-Molist et al., 2015; De Minicis et al., 2010; Paik et al., 2014). ROS production contributes to the fibrotic process directly or indirectly by sustaining inflammation and/or increasing the production of chemokines or growth factors. At this respect, it is worth mentioning that ROS can activate latent TGF- β , which further promotes ROS production and oxidative stress. All these mechanisms can in turn increase fibrosis. More specifically, ROS contribute to transdifferentiate HSC to MFB. Additionally, ROS may activate proliferation, migration and differentiation of fibroblasts, and ROS can induce EMT and are responsible for apoptosis of epithelial cells and/or ECM deposition (Richter and Kietzmann, 2016).

Among the cytokines involved in CLD, TGF- β has a major pro-fibrotic role and acts as the main orchestrator of the injury. Because of its importance, roles of TGF- β during CLD will be discussed in 3.3 section.

Inflammation is also a central pathogenic mechanism of liver disease. A number of signaling molecules and executor cells are involved in this process (Dooley and ten Dijke, 2012). Activation of KC, HSCs and MFB, and dying cells,

like hepatocytes, produce cytokines (TNF- α , interleukin (IL)-1 α/β , IL-6, IL-12, IL-18) and trigger the infiltration of macrophages, lymphocytes and eosinophils cells, which are responsible for a persistent inflammatory response (Weiskirchen and Tacke, 2016; Zhou et al., 2014). It is worthy to note that KC play a key role in the initiation and maintenance of the inflammatory response that sustains the fibrotic process. After activation, KC express chemokine receptors and secret various cytokines contributing to activate HSCs (Ebrahimi et al., 2016).

Figure 2. Pathogenesis of hepatic fibrosis. Prolonged liver injury results in fibrosis/cirrhosis where HSCs are key mediators. HSCs transdifferentiate to MFB by soluble mediators (chemokines/cytokines, ROS, growth factors) released by immune cells (KC, leukocytes) and other cell types including damaged hepatocytes and cholangiocytes. The pool of MFB is further increased by different cells (resident fibroblasts, hepatocytes, cholangiocytes, bone marrow fibrocytes, pericytes and endothelial cells) that acquire pro-fibrotic activities and become ECM producers. MFB, positive for α -SMA, display an increased proliferation, survival, migration and contraction capacities, and are the predominant source of collagen deposition. Moreover, ECM homeostasis is disturbed during fibrotic process through the increase of expression of TIMPs, decrease of matrix MMPs or the expression of pro-fibrotic MMPs. Adapted from Ralf Weiskirchen et al., 2018.

1.1.2. Diagnosis and therapy

Defining the disease state is essential in deciding the therapeutic choices and predicting prognosis. Liver biopsy is considered the gold standard method for assessing liver fibrosis but it has limitations such as invasiveness and sampling errors. Liver fibrosis is a heterogeneous process, often the obtained tissue does not represent the whole liver pathology and its analysis is subjected to observer variability. That is why other non-invasive methods have been developed. Imaging diagnostic modalities, including ultrasound-based or magnetic resonance imaging, and laboratory tests based on the detection of biochemical and hematological serum markers are other alternatives (Cheng and Wong, 2017; Ebrahimi et al., 2016).

Concerning the treatment, patients with fibrosis and cirrhosis caused by hepatitis virus infection show regression of liver fibrosis upon anti-viral therapy. In the case of non-alcoholic fatty liver disease (NAFLD), controlling metabolic risk factors is the option to improve liver fibrosis. Advances in the knowledge of the disease mechanisms are allowing the development of new treatments focused on HSCs regulation, collagen synthesis inhibition, blocking TGF- β action and inflammatory response control. Unfortunately, although some of these strategies work well in pre-clinical models, none of them has been translated into effective therapies in human so far (Cheng and Wong, 2017; Koyama et al., 2016).

1.2. Hepatocellular carcinoma (HCC)

Faery liver cancer association estimates that liver cancer is the second largest cause of cancer-related deaths (600,000 deaths each year) worldwide. HCC is the most common primary malignancy of the liver (80%-90% of all primary liver cancers) and the fourth most common cancer worldwide. Due to the asymptomatic nature in the early stages of the disease, the majority of HCC cases are detected in advanced stages, leading to incurable disease states (<https://www.bluefaery.org/statistics>).

Although HCC has a multitude of etiological risk factors, the development of HCC is closely related to the presence of CLD. In fact, around 80%-90% of HCC cases occur in the setting of underlying cirrhosis secondary to viral hepatitis (specifically hepatitis B virus or hepatitis C virus) or other non-viral CLD (Forner et al., 2012; Ghouri et al., 2017).

1.2.1. Pathophysiology

HCC is the result of a long-term process that begins with a pre-malignant stage that progresses to a dysplastic stage and ends in a malignant one. Hepatocarcinogenesis involves dysregulation of a number of molecular pathways as well as genetic alterations that ultimately lead to malignant transformation and HCC disease progression (Liu et al., 2014). It can originate from various cell types, including mature hepatocytes and stem or progenitor cells (Llovet et al., 2016). HCC hallmarks, as for other types of tumours, are

sustained cell proliferation, ability to evade growth suppression, resistance to cell death, invasion, metastasis, angiogenesis and deregulated energy metabolism (Liu et al., 2014).

HCC is a complex and heterogeneous disease both clinically and histopathologically, with a wide array of genetic and epigenetic changes that regulate cell proliferation, growth, survival, apoptosis, adhesion and metabolism (Liu et al., 2014). Recurrent somatic mutations in specific genes are well recognized as potential drivers of carcinogenesis. The most frequent mutations found affect telomerase reverse transcriptase (TERT) promoter, p53 (tumor suppressor) and Wnt/ β -catenin pathways. Additional mutations in HCC have been described, such as those affecting members of SWI/SNF chromatin remodeling complex and JAK/ signal transducers and activators of transcription (STAT) pathways; genes related to oxidative stress, RAS/mitogen-activated protein kinase (MAPK) signaling and genes that encode members of the ubiquitination process such as ubiquitin ligases (Dhanasekaran et al., 2016; Ding et al., 2017; Inokawa et al., 2016; Liu et al., 2014; Llovet et al., 2016).

In addition to genetic modifications, epigenetic alterations (changes in the methylation, hydroxymethylation, acetylation of histone proteins or dysregulation of the deoxyribonucleic acid (DNA) methylation) and changes in micro ribonucleic acid (miRNA) expression result in an altered expression of key proteins involved in HCC, contributing to carcinogenesis by influencing gene transcription, chromosomal stability and cell differentiation (Dhanasekaran et al., 2016; Inokawa et al., 2016; Llovet et al., 2016).

Apart from genetic and epigenetic alterations, several specific pathways are dysregulated in HCC that include: receptor tyrosine kinases (RTK) signaling pathways regulated by insulin-like growth factor (IGF); epidermal growth factor (EGF); PDGF and hepatocyte growth factor (HGF). It has also been reported alterations in pathways related to cell differentiation (Wnt, Notch, Hedgehog). Due to the fact that HCC is a highly vascularized tumor and the angiogenic process is a dominant feature, it is not surprising to find changes in angiogenic pathways and its ligands, such as vascular endothelial growth factor (VEGF) and fibroblast growth factor (FGF). Moreover, the main signaling mediators RAS/RAF/MEK/extracellular signal-regulated kinases (ERK) and phosphatidylinositol 3-kinase/AK strain transforming/ mammalian target of rapamycin (PI3K/AKT/mTOR) cascades are likewise important to liver carcinogenesis. Another pathway that has not been mentioned so far is the one triggered by TGF- β , which plays a critical role in cancer and will be subject of discuss in section 3.3 (Dhanasekaran et al., 2016; Tahmasebi Birgani and Carloni, 2017; Whittaker et al., 2010).

It is known that tumor microenvironment is critical for the initiation, growth and metastasis of tumor. Fibroblasts, myofibroblast, endothelial cells, pericytes, adipose cells, ECM and infiltrating immune cells form the typical tumor microenvironment. Tumor microenvironment is enriched with diffusible cytokines, chemokines or enzymes that are secreted from cancerous or non-cancerous cells (Tahmasebi Birgani and Carloni, 2017). All of these signals

determine tumor growth, angiogenesis and immune response, and jointly, tumor progression (Liu et al., 2014).

Figure 3. Pathogenesis of hepatocellular carcinoma. Chronic exposure of the liver to injury causes repeated hepatocyte damage and sets up a vicious cycle of cell death and regeneration which eventually results in cirrhosis. The resultant genomic instability leads to initiation of HCC. Accumulation of somatic mutations, epigenetic changes and molecular pathway alterations eventually lead to tumor progression and metastasis. Adapted from Dhanasekaran et al., 2016.

1.2.2. Diagnosis and therapy

HCC, as described previously, is genetically diverse and heterogeneous and is often diagnosed in a late phase because the symptoms appear at an advanced stage. These characteristics minimize the possibility to find and develop effective treatments against the disease at diagnosis and death is ensured after a few months. However, it is worth emphasizing that HCC has a prolonged subclinical course, which provides the opportunity for an early detection and treatment. Early-stage HCC lesions are small and frequently curable usually by minimally invasive methods (Dimitroulis et al., 2017; Llovet et al., 2016).

Within the different algorithms that have been developed to HCC detection, the principal methods for the diagnosis are the imaging studies and laboratory tests. For the imaging studies, ultrasonography, computed tomography, scanning and magnetic resonance imaging are used. As to laboratory tests, alpha-fetoprotein (AFP) is the most widely used serum marker. A part from these non-invasive diagnostic methods, liver biopsy is often a critical component in establishing the diagnosis of many forms of liver disease (Dimitroulis et al., 2017; Rockey et al., 2009).

In 2018, guidelines have been proposed to allow physicians to select the correct treatment for each patient. Complete HCC resection, either HCC lesion resection or a major hepatectomy is the treatment of choice when possible, mostly in patients without cirrhosis. Liver transplantation is the perfect

treatment for HCC with an underlying CLD because it eliminates liver disease. For early HCC, patients can undergo local ablative therapy (radiofrequency ablation, microwave ablation or laser-induced interstitial thermotherapy). An alternative to these options is the transarterial chemoembolization (Dimitroulis et al., 2017). Despite the existence of these clinical possibilities to deal with the tumor, chemotherapy is the most important treatment for advanced HCC even though results are still unsatisfactory mainly due to HCC high molecular heterogeneity and its resistance to conventional chemotherapy. This may be the reason why prognosis of HCC patients is poor. Sorafenib is the first-line therapy for patients with advanced HCC. Since its discovery, only one of the numerous studied agents, lenvatinib, has shown survival benefit and non-inferiority to sorafenib. Recently, immuno-oncologic treatment and other new agents are under development or in clinical trials. Individual therapies based on genome sequencing might be the solution to improve the treatment in patients with advanced HCC (Ikeda et al., 2018; Llovet et al., 2016).

2. Hepatic progenitor cell/oval cell regeneration

2.1. Liver regenerative response

The liver has a unique capacity to regenerate in response to liver damage. Following partial removal of the tissue, the remaining population of parenchymal cells starts proliferating to meet replacement demands of cellular loss. This process is better defined as a compensatory hyperplasia since the expanding liver does not regain its original anatomical structure (Mao et al., 2014).

Different animal models have been used to study this phenomenon but the most widely studied model is partial hepatectomy in rodents (Higgins et al 1931). 2/3 of liver mass are surgically removed and the regenerative response is complete within 5-7 days after surgery, both in rats and mice. The remaining mitotically quiescent hepatocytes undergo cell division entering into S phase and consequently, binuclear hepatocytes give rise to two mononuclear cells. After two or three cell cycles, remaining liver has enlarged to a mass equivalent to the original organ (Mao et al., 2014; Michalopoulos, 2007, 2010, 2014).

Nevertheless, if the liver injury is persistent or severe and the proliferation capacity and function of hepatocytes is impaired or exhausted, such as during submassive necrosis, chronic viral hepatitis and NAFLD, the normal renewal from mature epithelial cells is overwhelmed. In this context, adult hepatic stem/progenitor cells, called hepatic progenitor cells (HPCs) in humans and oval cells in rodents, act as a second line of defense against liver failure (Chen et al., 2017; Duncan et al., 2009).

2.2. HPC/oval cell generalities

HPCs have been described in many pathophysiological processes of human liver diseases (chronic hepatitis B and C, cirrhosis, alcoholic and nonalcoholic liver disease among others) (Bria et al., 2017; Chen et al., 2017; Lowes et al., 1999).

In rodents, oval cells were first described by E. Farber in 1956 as hepatobiliary reactive cells with approximately 10 µm of diameter, large nuclear-cytoplasm ratio and oval-shape nucleus (hence their name). The term hepatobiliary refers to their bipotential differentiation capacity towards both hepatocytes and cholangiocytes (Fausto and Campbell, 2003).

The oval cell-mediated regenerative process is referred to as “oval cell response” or “ductular reaction” because oval cells organize into ductular structures or ductules (Bria et al., 2017). However, ductular reaction is associated not only with HPCs/oval cells expansion, but also with other liver cells, such as stromal cells, inflammatory cells and infiltrated cells, including bone marrow-derived macrophages, and therefore, other liver processes such as ECM modifications, inflammatory infiltration and angiogenesis (Roskams et al., 2004; Sato et al., 2019).

Different liver injury protocols have been developed for activation and expansion of oval cells in rodents, but one of the most extensively used in mice is the administration of a diet containing 0.1% of 3,5-diethoxycarbonyl-1,4-dihydro-collidine (DDC), a porphyrinogenic hepatotoxin (Preisegger et al., 1999). DDC diet causes the inhibition of mitochondrial enzyme ferrochelatase leading to accumulation of protoporphyrin. This pigment accumulates in the cytoplasm of parenchymal cells and in KC. Due to its hydrophobic nature, the pigment only exits the liver through biliary secretion, precipitating and forming crystals in bile canaliculi and bile ducts that obstruct the biliary tree. Therefore, the tissue responds with a ductular reaction, peri-cholangitis, periductal fibrosis, and portal-portal fibrosis after 4–8 weeks that resembles the human cholestatic disease primary sclerosing cholangitis (Delire et al., 2015).

2.3. HPC/oval cell markers

HPCs/oval cells represent a heterogeneous population of cells that include different states of differentiation reflected by dynamic phenotype changes. Despite this, a number of surface antigens and intracellular proteins characteristic of the HPC/oval cell population have been described. Because of its bipotential and immature nature, these cells express a diverse set of markers that include hepatocyte markers as albumin (ALB), cytokeratins 8 and 18 (CK8, CK18) and MET; immature hepatocyte markers as AFP; biliary epithelial markers as CK19, A6, OV6 and epithelial cell adhesion molecule (EPCAM); markers associated with hematopoietic lineages as thymocyte differentiation antigen (THY-1) (CD90) and c-KIT; neuroendocrine markers as neural cell adhesion molecule (N-CAM); and stem cell markers as CD133, CD44 and nestin (Bria et al., 2017; Chen et al., 2017).

2.4. HPC/oval cell origin

The cellular origin and location of HPCs/oval cells is still controversial and different theories keep emerging. The classical theory supports that HPCs/oval cells derive from quiescent stem cells located in the Canal of Hering, which is a structure connecting bile canaliculi formed by hepatocyte with bile ducts lined by cholangiocytes in the portal triad (Fausto, 2004; Fausto and Campbell, 2003; Itoh and Miyajima, 2014). This is still considered the most likely origin of HPCs/oval cells. Nevertheless, recent studies have demonstrated the existence of other stem cell origins apart from canal of Hering including intralobular bile ducts, periductal cells and peribiliary hepatocytes (Kuwahara et al., 2008).

In contrast with this view, it has been proposed that a liver stem cell hierarchy exists with different stages of HPC/oval cell maturation where the most mature HPC/oval cell is the one with the bipotential capacity. An additional model proposes that there are different precursor cells for hepatocytes and cholangiocytes instead of a bipotential progenitor population (Duncan et al., 2009). An extrahepatic origin of oval cells, particularly bone marrow, has also been proposed. Additional theories hold that HPCs/oval cells may come from hepatic stellate cells (Kordes et al., 2014), or from hepatocytes or bile epithelial cells (Tarlow et al., 2014), after a dedifferentiation process in response to liver damage (Bria et al., 2017; Tarlow et al., 2014).

2.5. HPC/oval cell response

Following the classical theory, upon activation of HPC/oval cell precursors at periportal niches, HPCs/oval cells expansion occurs, proliferating, migrating into liver parenchyma and differentiating into hepatocytes and cholangiocytes. In fact, activation, proliferation, migration and differentiation are considered the four phases of the HPC/oval cell response (Tanaka et al., 2011).

These phases, together with HPC/oval cell survival, self-renewal and/or maintenance of stemness in HPCs/oval cells, are regulated by the microenvironment, which is referred to as HPC/oval cell niche, and is composed of different cell types, ECM scaffold, growth factors and cytokines and other signals and molecules released by the niche cells.

The different cell types in the niche can interact and cross-talk with HPCs/oval cells influencing its response. Parenchymal cells, hepatocytes and cholangiocytes, which are damaged during liver injury can direct/determine the activation and the fate of HPCs/oval cells. Moreover, cooperation with HSCs and myofibroblasts plays a critical role in HPC/oval cell expansion and differentiation through the release of growth factors and production of ECM. It has been also suggested that inflammatory cells stimulate and initiate regenerative responses in experimental models and can also remodel the ECM through the production of MMPs. ECM and ECM remodeling are essential for survival, activation, expansion and differentiation of HPCs/oval cells by binding, and presenting growth factors and signals to HPCs/oval cells (Bria et al., 2017; Chen et al., 2017; Van Hul et al., 2009; Vestentoft et al., 2013).

Figure 4. Classic model of HPC/oval cell origin. Quiescent stem cells are the precursors of HPCs/oval cells. The canal of Hering can provide a niche for these precursors of HPCs/oval cells. The niche is defined as the microenvironment which regulates HPC/oval cell behavior. Different cell types, ECM scaffold, growth factors and cytokines and other signals and molecules released by the niche cells form part of the HPC/oval cell niche. Adapted from Chen et al., 2017.

Important signals take part in HPC/oval cell response. Among these signals, which can act directly on HPCs/oval cells or indirectly via non-parenchymal cells that in turn regulate HPCs/oval cells, are growth factors such as HGF, TGF- β , FGF, connective tissue growth factor (CTGF); hormones (insulin, somatostatin); adipokines (leptin); chemokines (SDF1, stromal cell-derived factor 1); and neurotransmitters (serotonin, epinephrine or norepinephrine). Besides this signaling network, inflammatory response (immune cells and inflammatory cytokines, such as interferon alfa (IFN α), TNF α , tumor necrosis factor-like weak inducer of apoptosis (TWEAK), IL-6, STAT3, etc) is critical for HPC/oval cell regenerative process (Best et al., 2013; Bird et al., 2008; Lukacs-Kornek and Lammert, 2017). Additionally, morphogens such as Wnt, Notch and Hedgehog are key regulators of HPC/oval cell response (Apte et al., 2008; Chen et al., 2017; Darwiche et al., 2011; Yang et al., 2008).

Due to the large number of signals and molecules that regulate HPCs/oval cells, a better understanding of their specific role and relevance in HPC/oval cell biology is necessary.

Figure 5. HPC/oval cell response. With minor injury, restoration of hepatocyte mass and function is mediated by the replication of remaining healthy hepatocytes (and cholangiocytes). During major liver insult, this mechanism is overwhelmed and HPCs/oval cells compartment is activated in an attempt to restore epithelial cell mass, architecture and function. The bipotential HPCs/oval cells upon activation are able to infiltrate along the liver parenchyma from the Canals of Hering, proliferate and differentiate into hepatocytes and cholangiocytes. This regenerative process is triggered and regulated by a plethora of signals. Adapted from Best et al., 2013.

2.6. HPC/oval cell in therapy

The bipotential nature of HPCs/oval cells and their ability to restore the damaged liver make the scientific community think in this population as an interesting target to develop new strategies against CLD. Thus cell transplantation alone or combined with drugs to enhance native regeneration could be alternative options to liver transplantation, the only effective therapy nowadays for patients with end-stage liver disease.

Regeneration by liver repopulation with transplanted hepatocytes has been explored for patients with liver-based inborn errors of metabolism or acute liver failure. Clinical trials have proved that liver hepatocyte transplantation is safe and effective but it only partially corrects metabolic disorders and it only does it in the short-term. Additionally, working with hepatocytes presents a number of difficulties, including difficulty in obtaining an easy and reproducible hepatocyte source; poor survival of primary hepatocytes in hypothermic storage conditions and number variation, scarce availability of good quality hepatocyte; and poor traceability of cells post-transplantation (Gilgenkrantz and Collin de l'Hortet, 2018).

All of these problems together with the limitations in treatment of CLD and HCC make the use of HPCs in therapy more attractive. However, understanding the molecular and signaling regulation of HPCs/oval cells is critical not only because it will help determine their true regenerative potential and utility in clinical strategies, but also because evidences show a role of HPCs/oval cells in liver fibrosis and HCC (Huebert and Rakela, 2014). Today, it is still not clear if HPCs/oval cells are a friend or foe in chronic injury.

2.7. Oval cell in liver fibrosis and HCC

We have already mentioned that HPCs/oval cells are present not only in rodent models of liver injury but in different human liver pathologies. Studies performed in humans and rodents have established a direct relationship between the degree of hepatic injury, the HPCs/oval cells expansion and the severity of fibrosis (Knight et al., 2007; Williams et al., 2014). So, opposed to the viewpoint of HPCs/oval cells as pro-regenerative cells, another current of opinion sees them as pro-fibrotic/pro-tumorigenic cells.

A study published by Chobert et al. (2012) showed that expanded HPCs/oval cells, after strong fibrosis induction in mice, express TGF- β , contributing in this way to the accumulation of α -SMA-positive MFB and consequently, to the disease progression. Kuramitsu et al. (2013) studies also support the profibrotic role of HPCs/oval cells. In this work, failure of hepatocyte-mediated regeneration in fibrotic mouse livers triggers activation of HPCs/oval cells and a severe fibrotic response. In this setting, inhibition of HPC/oval cell response results in prevention of fibrotic process and in an improvement in liver regeneration. The work of Clouston et al. (2005) also demonstrates a correlation between the increase in hepatic fibrosis during chronic hepatitis C virus infection and a periportal ductular reaction. These evidences attribute HPCs/oval cells a role in the progression of fibrosis. The controversy about the precise role of HPCs/oval cells as pro-fibrogenic or anti-fibrogenic makes necessary further studies to clarify this point. It is worthy to understand that these two opposing ideas are not mutually exclusive, and this paradox can be resolved by recognizing heterogeneity in the ductular reaction activation and evolution in the specific context of the different models used.

One of the theories proposed to explain the origin of HCC states that HCC derives from stem cells whose differentiation is blocked. Stem cells that are committed to form a certain tissue divide into two daughter cells, during normal cell renewal. One daughter cell remains as a stem cell and the other cell expresses a more differentiated state. These differentiating cells are capable of proliferating and lead to terminally differentiated cells. However, mutations can occur during the differentiation process and the mitotically active cells acquire a malignant phenotype due to an abnormal differentiation state with self-renewal ability, multi-directional differentiation, unlimited proliferation and high tumorigenic ability. In this line, HPCs/oval cells have been proposed to behave as a cancer stem cell in certain contexts (Sell, 1993; Wu and Chen, 2006). Different evidences support this theory. 1) Cells phenotypically similar to

HPCs/oval cells are observed in many hepatic tumors and several studies based on immunohistochemical analysis of HCCs have concluded that about 28–50% of HCCs express markers of progenitor cells (such as CK19, AFP and OV6) (Roskams, 2006; Yang et al., 2012). Interestingly, these tumors carry a significantly poorer prognosis and higher recurrence after surgical resection and liver transplantation (Kohn-Gaone et al., 2016; Lee et al., 2006). 2) Microarray analysis have revealed that many of the disrupted pathways in HCC are involved in stem cell maintenance and self-renewal such as Wnt/ β -catenin, TGF- β , HGF/Met, Hedgehog (Marquardt and Thorgeirsson, 2010). 3) Both transfection of activated oncogenes or silencing of tumor suppressor genes in HPCs/oval cells can give rise to HCC (Braun et al., 1987; Dumble et al., 2002; Lidaka et al., 2005).

3. Transforming growth factor β (TGF- β)

3.1. Signaling pathway

Mammalian genome encodes 33 members of the TGF- β superfamily that includes isoforms of TGF- β , BMP (Bone Morphogenetic Proteins), nodal, activin, inhibin, GDPs (Growth Differentiation Factors), MIS/AMH (Müllerian Inhibiting Substance/Anti-Müllerian Hormone) and Lefty (Massague, 2012; Morikawa et al., 2016).

Focusing on TGF- β sub-family, the mammalian genome encodes 3 different isoforms: TGF- β 1, β 2 and β 3. TGF- β 1 is ubiquitously expressed and is the most abundant isoform. The ligands of the TGF- β are synthesized as polypeptide precursors formed by 3 segments: an amino-terminal signal peptide, a large precursor segment or pro-segment (LAPs, latency-associated peptides) and the carboxy-terminal polypeptide. TGF- β precursor segment must be eliminated before binding to its receptor, process accomplished by proteolytic cleavage mediated by furin enzymes in the trans-Golgi. The still inactive TGF- β form is released into the ECM, where the final activation by integrins and proteases like plasmin or gelatinases takes place. To become active, TGF- β must form dimers stabilized by a disulphide bridge and hydrophobic interactions (Massague, 2012; Morikawa et al., 2016).

Upon activation, TGF- β binds to a tetrameric complex consisting of two type I and two type II serine-threonine kinase receptors. There are 7 type I receptors (activin receptor-like kinase, ALK1-7) (T β RI) and 5 type II receptors (T β RII), but TGF- β preferentially signals through ALK5 (T β RI) and the type II receptor, T β RII. Thus, active TGF- β binds to T β RII that leads to recruitment and transphosphorylation of T β RI in a glycine and serine-rich domain (GS domain). This phosphorylation switches the GS region in T β RI from a site that binds the 12kDa FK506-binding protein (FKBP12), a protein that silences the kinase activity, into a site that binds R-Smad (receptor-associated Smad) proteins for their phosphorylation. Among the 5 different R-Smads, TGF- β 1 specifically activates Smad2 and Smad3. Then, they form a trimeric complex with the Co-Smad4 (common mediator Smad4) and subsequently, this complex translocates

to the nucleus where it cooperates with other transcription factors, coactivators and corepressors to regulate the expression of specific target genes. Apart from R-Smad and Co-Smad, Smad family includes other members named I-Smads (inhibitory Smads), I-Smad 6 and 7, which regulate negatively TGF- β signaling pathway. Smad7 binds to and inhibits essentially all type I receptors in the TGF- β family whereas Smad6 exhibits higher specificity on BMP mediated signaling. Smad family members consist in two domains (MH1 and MH2) coupled by an unstructured linker. The amino-terminal MH1 domain has a hairpin structure with DNA-binding ability. MH2 is the carboxy-terminal domain with hydrophobic segments that are able to interact with adaptor proteins, active TGF- β receptors and DNA coactivators and repressors. Apart from regulating genes expression, Smad also regulate miRNA expression and maturation, epigenetic changes, RNA splicing and RNA methylation (Derynck and Budi, 2019; Heldin and Moustakas, 2016; Huse et al., 2001; Itoh and ten Dijke, 2007; Massague, 2012; Shi and Massagué, 2003).

Besides the Smad signaling pathway, known as “canonical pathway”, TGF- β can activate other pathways that are referred to as “non-canonical” or “non-Smad” pathway. These pathways are activated through the interaction between the members of the canonical response with other signaling pathways and through the ability to TGF- β receptors to activate other signaling molecules. Non-canonical pathways include among others, various branches of MAPK pathways (ERK, c-Jun N-terminal kinase (JNK) and p38 kinase pathways); Rho-like GTPase, nuclear factor kappa-light-chain-enhancer of activated B cells (NF κ B), JAK/STAT and PI3K/AKT signaling pathways. These signaling pathways act alone or in conjunction with Smads to control TGF- β activities (Derynck and Budi, 2019; Derynck and Zhang, 2003; Heldin and Moustakas, 2016; Massague, 2012; Zhang, 2009).

TGF- β signaling pathway is subjected to regulation (positive, negative, spacio-temporal) at different levels such as ligand activation, receptor complex formation, R-Smad activation and translocation, and transcriptional activity.

I-Smad 6 and 7 negatively regulate TGF- β pathway by different mechanisms. These include: binding to activated type I receptor inhibiting R-Smad phosphorylation; interactions with Smad4 preventing R-Smad–Smad4 complex formation, degradation of T β RI through the proteasome pathway and recruitment of transcriptional Smad co-repressors (Itoh and ten Dijke, 2007; Yan et al., 2009). In addition to the regulation of the signaling pathway through I-Smads, numerous points of control exist in TGF- β pathway, some of them are mentioned below. TGF- β receptor expression, activity and stability can be controlled by different means, including phosphorylation, ubiquitination, sumoylation and neddylation (Budi et al., 2017; Heldin and Moustakas, 2016). In the same manner, Smad proteins are also regulated by phosphorylation, ubiquitination, sumoylation and acetylation (Massague et al., 2005). TGF- β receptor signaling intensity, duration, specificity and diversity are modulated by cell surface co-receptors such as betaglycan/T β RIII, endoglin or Neuropilin-1 and other cell-surface proteins such as integrins or occludin. Moreover, signaling via TGF- β receptors is modulated by interactions with cytoplasmic proteins and

with nuclear shuttling proteins (Heldin and Moustakas, 2016; Nickel et al., 2018). Another point of control is the regulation of the receptor by endocytosis (Zhao and Chen, 2014)

Figure 6. Canonical and non-canonical TGF-β signaling pathways. TGF-β dimer binds to the receptor complex and consequently activates the canonical Smad pathway, through Smad2/3 and Smad4, and non-canonical signaling pathways. Adapted from Budi et al., 2017.

3.2. TGF-β responses

In most cell types, in particular in normal epithelial cells, TGF-β family members regulate a large number of cellular responses including proliferation, differentiation, migration and apoptosis among others. Dysregulation of these signals is implicated in various human diseases including cancer, fibrosis, autoimmune diseases and vascular disorders (Akhurst and Hata, 2012; Heldin and Moustakas, 2016; Massague, 2008).

3.2.1. TGF-β and growth inhibition

TGF-β has a high growth inhibitory capacity in epithelial cells and many non-epithelial cell types, which is irreversible if cytokine is eliminated. The inhibitory action is based on the induction of cyclin dependent kinase inhibitors (CKI

inhibitors) and/or the inhibition of proliferative drivers. The specific mechanisms depend on the cell type and context (Morikawa et al., 2016).

In epithelial cells, TGF- β orchestrates the cytostatic effect primarily during G1 phase of the cell cycle through inhibition of CDKs, which leads to dephosphorylation of retinoblastoma protein (RB). Different studies show that TGF- β induces expression of p21 (Cdkn1a) and p57 (Cdkn1c), members of the Cip/Kip CKI family, which inhibit CDKs involved in the G1/S transition, and p15 (Cdkn2b), member of INK4 family, which inhibits Cyclin D-cdk4/6 complexes. p27 (Cdk1b) is another member of Cip/Kip family involved in the mechanism of growth arrest. p27 when bound to Cyclin D-Cdk4/6 complex is in an inactive state and upon induction of p15 by TGF- β , p15 displaces p27 from Cyclin D-Cdk4/6 and p27 moves on to inhibit Cdk2. At the same time, TGF- β induces c-Myc downregulation, a transcription factor that promotes cellular growth and proliferation, and the inhibition of ID1, 2 and 3 expression, transcription factors that oppose cellular differentiation (Massague and Gomis, 2006; Siegel and Massague, 2003). Although the majority of these effects are Smad-dependent, TGF- β is also able to induce cell cycle arrest through non-Smad pathways (Petritsch et al., 2000).

3.2.2. TGF- β and apoptosis

TGF- β -regulated apoptosis is highly dependent on the cell type. In fact, there is not a clear TGF- β apoptotic program and various components link TGF- β signaling pathway with the machinery of programmed cell death (Zhang et al., 2017). Different SMAD dependent and independent mechanisms have been described in the control of apoptosis in different cell types.

TGF- β cooperates in several systems with the death receptor apoptotic pathways: Fas ligand (FasL) or apoptosis antigen-1 ligand and TNF- α , enhancing or inhibiting the apoptotic responses. Intracellularly, several apoptotic target genes, the TGF- β -inducible early response gene 1 (TIEG1) and the death-associated protein kinase (DAP-kinase) among others, are regulated by Smad transcriptional complexes. But, at the same time, TGF- β activates pro-survival signals such as ERK MAPK, NF- κ B and PI3K-AKT, and the pro-apoptotic JNK and p38 MAPKs. This intricate and complex response leads us to think that the balance between pro- and anti-apoptotic signaling pathways is essential to determine whether or not cells will undergo apoptosis in response to TGF- β (Sanchez-Capelo, 2005; Schuster and Kriegelstein, 2002; Zhang et al., 2017).

TGF- β also induces apoptosis via mitochondrial apoptotic pathway through cytochrome c release mediated by B-cell lymphoma 2 (BCL-2) family members. TGF- β modulate the expression, localization and activation of pro- and anti-apoptotic BCL-2 proteins. In fact, TGF- β has been shown to induce ROS and oxidative stress by different means, by regulating ROS producing systems (as NADPH) or by down regulating antioxidant genes (Carmona-Cuenca et al., 2008; Herrera et al., 2001; Martinez-Palacian et al., 2013; Sanchez-Capelo, 2005; Sanchez et al., 1996; Schuster and Kriegelstein, 2002; Zhang et al., 2017).

3.2.3. TGF- β and epithelial to mesenchymal transition (EMT)

Definition of EMT

Classically, EMT has been described as a biological process that allows an epithelial cell to undergo multiple biochemical changes that enable it to acquire a mesenchymal phenotype which includes enhanced migratory capacity, invasiveness, elevated resistance to apoptosis, and increased production of ECM components. Numerous biochemical changes take place during this phenotype transition: loss of junctions and apical-basal polarity, reorganization of cytoskeleton, and changes in signaling programs that altogether define cell shape and reprogramming of gene expression (Lamouille et al., 2014; Nieto et al., 2016).

However, nowadays, EMT is not only described as a shift between two alternative states, full mesenchymal or full epithelial. Cells can transition through a spectrum of intermediary states that could be understood as partial EMT, states in which cells present a hybrid epithelial and mesenchymal phenotype. Many studies define the hybrid state as the co-expression of epithelial and mesenchymal markers, but cells do not need to gain mesenchymal proteins in a partial EMT, it is enough to repress epithelial properties. Likewise, induction of mesenchymal markers while maintaining E-cadherin is considered a partial EMT. It is unknown whether this hybrid status reflects an intermediate phase during a mesenchymal transition or represents its own end state. Mechanisms driving partial EMT remain to be clarified (Aiello et al., 2018; Kai et al., 2018; Nieto et al., 2016).

EMT transcription factors and inducers

EMT process is orchestrated by specific transcription factors (EMT-TF): Zinc-finger binding transcription factors Snail1 and Snail2 and several helix-loop-helix factors such as zinc finger E-box-binding homeobox 1 (Zeb1), Zeb2 and Twist (Twist 1 and 2). Expression of these transcription factors and their precise contribution to EMT regulation depend on the cell or the tissue in which EMT takes place and on the signaling pathway that initiates the process. EMT-TF often regulate each other and act coordinately to repress epithelial genes and induce mesenchymal genes. Additionally, epigenetic modifications, differential splicing of RNA and miRNA have been described as modulators of the EMT process (Lamouille et al., 2014; Nieto et al., 2016; Skrypek et al., 2017).

Although different signals induce EMT process, TGF- β is one of the best known and studied. TGF- β triggers EMT through Smad proteins, regulating the transcriptional program that involves the EMT-TF. Besides the canonical pathway, non-canonical TGF- β effectors can mediate TGF- β ability to induce the transition between epithelial to mesenchymal features in cells. ERK/MAPK, p38/MAPK Rho GTPases, PI3K/AKT, NF-KB, JNK are some of the pathways associated with TGF- β -induced EMT (Gonzalez and Medici, 2014; Wendt et al., 2009; Xie et al., 2004; Xu et al., 2009).

EMT-related phenotypic and functional changes

Cell to cell contact is maintained through tight junctions, adherent junctions, desmosomes and gap junctions. After EMT induction, these cell junctions are deconstructed and the junction proteins are relocalized and/or degraded. Loss of tight junctions is characterized by decreased claudin and occludin expression and intracellular relocalization of zonula occludens 1 (ZO-1). Adherent junctions suffer a “cadherin switch”, that is, E-cadherin is down-regulated, cleaved at the plasma membrane and degraded whereas N-cadherin expression is upregulated. EMT is also accompanied by desmosomes and gap disruption, being the later accompanied by a decrease in connexins levels (Lamouille et al., 2014).

Another important event during EMT process is the re-organization of the actin cytoskeleton. This process enables cells to change their shape, and favors the formation of membrane projections that facilitate cell movement and invasion. Progressive alterations in cell morphology are accompanied by reorganization of actin filaments from thin cortical bundles in epithelial cells to thick and contractile bundles, actin stress fibers, that facilitate contractility in mesenchymal cells (Haynes et al., 2011; Lamouille et al., 2014; Yilmaz and Christofori, 2009).

The intermediate filament composition also changes during the EMT process with a repression of cytokeratin and an activation of vimentin (Lamouille et al., 2014).

In addition to these alterations, an increase in the expression of MMPs takes places. MMPs collaborate in ECM degradation, facilitating the invasion process. MMPs contribute to the loss of adherent junctions, targeting some transmembrane proteins, and more strikingly, some of them can induce the EMT program by inducing signaling molecules like the GTPase RAC1 that in turn leads to Snail activation (Lamouille et al., 2014).

As previously mentioned, cells that have undergone EMT acquire resistance to senescence and apoptosis, which will be relevant to tumor progression (Brabletz et al., 2018). Different studies have associated resistance to TGF- β -induced cell death with an EMT induction (Gal et al., 2008; Valdes et al., 2002) and others have demonstrated that some EMT-TF confer resistance to cell death (Snail and Twist) (Vega et al., 2004). EMT and cellular senescence are two processes that seem to cross paths, sharing transcription factors. In fact, some EMT-TFs prevent cells to undergo cellular senescence (Ansieau et al., 2008; Puisieux et al., 2014; Smit and Peeper, 2010).

Figure 7. General features of epithelial to mesenchymal transition. The transition of epithelial cells towards a mesenchymal phenotype, induced by several factors such as TGF- β , is characterized by the loss of junctions and apical-basal polarity and reorganization of cytoskeleton. These changes disrupt the epithelial architecture and mesenchymal cells acquire migratory and invasive competences. EMT is orchestrated by specific transcription factors (Snail1/2, Zeb1/2, Twist1/2) that modulate well-known markers such as E-cadherin, claudins or cytokeratin. The acquisition of mesenchymal markers sustains and stabilizes the newly acquired phenotype. Adapted from Morandi et al., 2017.

3.3. Physiological and pathological activities of TGF- β in the liver

In general, TGF- β regulates cell proliferation, migration and differentiation during embryonic development and has an essential role in maintaining tissue homeostasis. In the liver, TGF- β dosage and spatiotemporal activity is involved in different aspects of hepatogenesis, controlling gene expression and determining the differentiation of hepatoblasts to hepatocytes or cholangiocytes. Moreover, TGF- β regulates liver architecture and biliary morphogenesis (Karkampouna et al., 2012). Contrary to these beneficial activities, TGF- β is one of the main orchestrators of liver fibrogenesis and hepatocarcinogenesis processes upon liver injury.

3.3.1. TGF- β in liver fibrosis

After liver damage, active TGF- β levels increase, being the non-parenchymal liver cells, principally macrophages and HSCs, the main sources of TGF- β .

Moreover, hepatocytes appear to acquire and store latent TGF- β in the cytoplasm, that could be activated and released upon damage, providing a source of active cytokine. Active TGF- β plays important roles on different hepatic cell populations, therefore contributing to critical events from the initial liver injury to the final stages of CLD (Dooley and ten Dijke, 2012).

Among the hepatic cell population, HSCs are the main target for TGF- β action during CLD; TGF- β induces the trans-differentiation of HSCs into MFB while promoting their proliferation. MFB play a key role in hepatic fibrosis since they are the principal cell type responsible for production of an excess of ECM proteins (Dewidar et al., 2015; Dooley and ten Dijke, 2012).

TGF- β induces growth arrest and apoptosis in hepatocytes, events considered critical for hepatic fibrosis. It is important to mention that cytostatic properties of TGF- β are key during hepatocyte liver regeneration since they mark the end of the regenerative process (Karkampouna et al., 2012). In relation to this, our group has shown that low doses of TGF- β inhibit fetal hepatocyte growth whereas higher doses result in an apoptotic cell death (Sanchez et al., 1995). TGF- β -induced apoptosis is associated with an induction of ROS that results in loss of mitochondrial transmembrane potential that leads to the release of cytochrome c, and subsequently, the activation of caspase-3. Upregulation of NOX4 by TGF- β is required for ROS induction and therefore, for its pro-apoptotic activity in fetal hepatocytes (Carmona-Cuenca et al., 2008; Herrera et al., 2001; Sanchez et al., 1996). It has also been suggested that oxidative stress mediates the progression of fibrosis, ROS acting as mediators of molecular and cellular events implicated in liver fibrosis. In fact, there are evidences sustaining critical roles for members of the NOX family, upon activation by TGF- β , both in hepatocyte apoptosis (NOX4) and HSC activation and proliferation (NOX1,4) during the fibrotic process (Crosas-Molist and Fabregat, 2015; Sanchez-Valle et al., 2012).

Controversy exists regarding hepatocyte EMT as a source of MFB (Dooley et al., 2008; Herbst et al., 1997; Nitta et al., 2008; Wells, 2008; Zeisberg et al., 2007). Our group has demonstrated that fetal hepatocytes undergo an EMT in response to TGF- β . After EMT, hepatocytes acquire progenitor markers and properties and become resistant to apoptosis (del Castillo et al., 2008a; Del Castillo et al., 2006; Pagan et al., 1999). However, if adult hepatocytes suffer an EMT process in response to TGF- β is still not clear, with some *in vitro* studies in favor of this hypothesis (Meyer et al., 2013) and others against it (Caja et al., 2007). Despite these discrepancies, EMT seems to be key in the development of liver fibrosis.

Additional potential targets of TGF- β in liver fibrosis are HPCs/oval cells. It has been reported that TGF- β induces apoptosis and inhibits proliferation of HPCs/oval cells in mouse models of liver damage (Park and Suh, 1999; Thenappan et al., 2010). Additionally, *in vitro* studies of our group reveal that TGF- β induces cell growth arrest and apoptosis in HPCs/oval cells by a mitochondrial apoptotic program associated with induction of oxidative stress. Similar to what was observed in hepatocytes, TGF- β induces disruption of

mitochondrial transmembrane potential and increases the expression of pro-apoptotic BCL-2 proteins, such as BCL-2 modifying factor (BMF) and BCL-2-like-11 (BIM). These events are related to an oxidative stress process, which also involves increase in NOX4 expression and decrease in antioxidant enzymes protein levels (del Castillo et al., 2008b; Martinez-Palacian et al., 2013). Interestingly, it has been described that hepatocytes are more sensitive to TGF- β -induced apoptosis than HPCs/oval cells, fact that allows this population to proliferate and repair the liver damage in a situation in which hepatocyte proliferation is blocked (Karkampouna et al., 2012; Nguyen et al., 2007). Besides the apoptotic effect of TGF- β in HPCs/oval cells, some authors have reported an induction of ECM genes and HSC markers in HPCs/oval cells in culture upon TGF- β treatment, suggesting these cells might be an origin of HSC via EMT, becoming another source of MFB and so contributing to liver fibrosis (Wang et al., 2009).

Figure 8. TGF- β effects on different hepatic cells population during liver fibrosis/cirrhosis. TGF- β plays important roles during CLD by acting on different hepatic cell populations. TGF- β induces the transdifferentiation process of HSC to MFB, the main cell responsible for fibrosis. Additionally, TGF- β induces growth arrest and apoptosis in hepatocytes, critical for hepatic fibrosis. More controversial is that hepatocyte EMT could be another source of MFB. TGF- β could also participate in liver fibrosis targeting HPCs/oval cells. TGF- β induces apoptosis and inhibits proliferation of HPCs/oval cells. HPCs/oval cells could suffer EMT in response to TGF- β becoming MFB.

Based on the key roles played by TGF- β in the pathogenesis of liver fibrosis and cirrhosis, different therapeutic strategies targeting TGF- β signaling have been proposed to treat these diseases, including anti-sense oligonucleotides, blocking antibodies, soluble receptors that bind the ligand and block ligand-receptor binding or overexpression of I-SMADs (Smad7) among others. Anti TGF- β therapies have successful results in experimental models. However,

unfortunately these results have not been translated to humans, which might be a consequence of the multiple and cell- and context-dependent TGF- β functions (Cheng and Wong, 2017; Dooley and ten Dijke, 2012). Clearly, a better understanding of the TGF- β participation in CLDs is needed in order to develop efficient treatments in humans.

3.3.2. TGF- β in HCC

It is widely recognized that TGF- β has critical roles in tumor initiation, development and metastasis in several cancer types. Strikingly, TGF- β switches from a potent cytostatic and pro-apoptotic effect in normal epithelial cells to a tumor promoter activity at the late stages of the disease, phenomenon that is known as the “TGF- β paradox” (Seoane and Gomis, 2017; Siegel and Massague, 2003).

Accumulating mutations in components of the TGF- β pathway or selective impairment of the growth inhibitory response are some of the strategies developed in tumor cells to bypass the TGF- β suppressor activities (Seoane and Gomis, 2017). In HCC, mutations or alterations in Smad proteins or TGF- β receptors are not very frequent. However, TGF- β upregulation is found in a large number of HCC patients, and in contexts where the canonical pathway is blocked, TGF- β can still signal via non-canonical pathways (Fabregat et al., 2016b). Alternative mechanisms to escape from TGF- β suppressor effects in HCC cells are: i) expression of specific miRNAs that allow them to escape from TGF- β -induced apoptosis (Huang and He, 2011); ii) epigenetic silencing in genes encoding TGF- β pathway components (Seoane and Gomis, 2017); iii) over-activation of growth factors that trigger survival signaling pathways (MAPK/ERKs, PI3K/AKT or NF-KB) (Colak and Ten Dijke, 2017; Fabregat et al., 2016b; Huang et al., 2018).

It has been also demonstrated that tumor cells that overcome TGF- β -induced growth arrest/apoptosis undergo EMT in response to TGF- β . Acquisition of mesenchymal properties confers stemness, invasiveness and motility to tumor cells, properties that strongly influence their metastatic capacity. Therefore, tumor cells invade the surrounding environment being able to colonize distant sites and disseminate the disease (Seoane and Gomis, 2017).

TGF- β pathway also exerts its pro-tumorigenic effects by remodeling tumor microenvironment. Accumulating evidence has demonstrated that immune microenvironment plays crucial roles in the development of HCC and that TGF- β generate a favorable microenvironment for tumor growth and metastasis. TGF- β has immunosuppressive effects on innate and adaptive immune cells and also affects cytokine production by tumor cells (Colak and Ten Dijke, 2017; Shen et al., 2015; Yang et al., 2010). Another important aspect of the HCC microenvironment is its strong angiogenic activity, which seems to be induced by TGF- β (Colak and Ten Dijke, 2017; Mazzocca et al., 2009). TGF- β is also able to differentiate stromal mesenchymal cells into MFB that secrete ECM proteins and fibrotic growth factors to support tumor growth. Besides, TGF- β induces an

endothelial to mesenchymal transition towards tumor-facilitating fibroblast-like cells in endothelial cells (Colak and Ten Dijke, 2017).

Just like in the case of liver fibrosis, the pivotal role played by TGF- β during HCC development make it a promising target to develop new therapies. Similar strategies to those mentioned before have been develop to inhibit TGF- β pathway in cancer: antisense oligonucleotide, blocking antibodies and ligand traps, T β RII and/or ALK5 inhibitors, in addition to immune response-based strategies and other inhibitors of the TGF- β pathway (Fabregat et al., 2014). As an example, ongoing clinical trials evaluating galunisertib, a T β RI kinase inhibitor factor, has shown promising results in HCC patients. Nevertheless, further advances in HCC therapies targeting TGF- β signaling require a better understanding of the disease, and more particularly, the diverse functions of TGF- β in the hepatic cell populations (Giannelli et al., 2016; Neuzillet et al., 2015).

Figure 9. Regulation of non-cancerous cells and tumor microenvironment cells by TGF- β . TGF- β is expressed by tumor cells and stromal cells, including cancer-associated fibroblasts. TGF- β in normal cells induces cell-cycle arrest and/or apoptosis. However, tumor cells escape from these effects and undergo EMT in response to TGF- β . EMT is thought to foster tumor cell migration and invasion and plays an important role in conferring therapy resistance. TGF- β can also contribute to tumor progression by stimulating immune evasion and promoting angiogenesis. Adapted from Colak and Ten Dijke, 2017.

4. Hepatocyte growth factor (HGF)/Met

4.1. Signaling pathway

HGF was discovered as a strong mitogen for hepatocytes (Miyazawa et al., 1989; Nakamura, 1989). It is also known as Scatter Factor (SF), since a fibroblast-derived cell motility factor for epithelial cells that was identified independently (Stoker et al., 1987) was later found to be the same factor as HGF (Naldini et al., 1991).

HGF is produced and secreted primarily by stromal and mesenchymal cells (fibroblasts, macrophages, smooth muscle cells, among others) but acts mainly on epithelial cells, where its receptor Met is expressed, therefore acting in a paracrine fashion (Zarnegar, 1995). Some cells show an autocrine HGF/Met signaling, at least in certain contexts, expressing both the ligand and its receptor, as it is the case in HPCs/oval cells (del Castillo et al., 2008b). Additionally, Met is not only expressed in epithelial cells, but also in other cell types including vascular endothelial cells, lymphatic endothelial cells, neural cells, hematopoietic cells and pericytes (You and McDonald, 2008).

HGF is secreted as an inactive single-chain peptide that is cleaved by proteases to generate an active heterodimer with two chains, α - and β -chains, held together by a disulphide bond. The α -chain is formed by an amino-terminal hairpin loop (HL) and four kringle domains (K1-K4, amino acid double-looped structures formed by three internal disulphide bridges). β -chain is a serine protease homology domain without proteolytic activity (Nakamura and Mizuno, 2010; Trusolino et al., 2010).

HGF triggers its signaling pathway by binding to its tyrosine kinase receptor Met. Met receptor is a heterodimer, consisting of an extracellular α -subunit and a transmembrane β -subunit, disulphide-linked. The entire α -subunit forms a semaphorin domain and is associated with the extracellular region of the β -subunit, which is formed by a semaphorin domain (SEMA), a plexin-semaphorin-integrin (PSI) cysteine-rich domain (also present in semaphorins and plexins), and four immunoglobulin-like domains shared by plexins and transcriptional factors (IPT). The intracellular part of the β -subunit is composed by a juxtamembrane region, an intracellular tyrosine kinase domain (catalytic region) and a C-terminal tail (Kato, 2017; Trusolino et al., 2010).

Figure 10. Domain structures of Met and HGF. **a)** HGF is an α - and β -chain heterodimer. HGF consists of six domains: an amino-terminal hairpin loop (HL), four Kringle domains (K1-k4, amino acid double-looped structures formed by three internal disulphide bridges) and a serine protease homology (SPH) domain. **b)** MET receptor is a disulphide-linked heterodimer formed by an extracellular α -subunit and a transmembrane β -subunit. The extracellular region of Met is composed of three domains: the Sema domain that includes the entire α -chain and part of the β -chain; the PSI domain and four IPT domains. The intracellular region is formed by a juxtamembrane sequence, a catalytic region and a carboxy-terminal multifunctional docking site. This portion of Met contains the catalytic tyrosines (Tyr1234 and Tyr1235) and the Tyr1003 that negatively regulates Met. The Tyr1349 and Tyr1356 recruit several transducers and adaptors after Met activation. Adapted from Trusolino et al., 2010.

When HGF binds to the SEMA domain of Met receptor, two molecules of the receptor homodimerize and the intracellular tyrosine kinase domains of the two β -subunits trans-phosphorylate each other at tyrosine residues (Tyr1234 and Tyr1235) in the catalytic loops. Subsequently, tyrosines 1349 and 1356 in the carboxy-terminal tail become phosphorylated. These two tyrosines form a tandem SH2 recognition motif (multifunctional docking site) that acts recruiting signaling molecules (Organ and Tsao, 2011; Trusolino et al., 2010).

Upon ligand binding, numerous signaling adaptors and signaling effectors are recruited to activated Met receptor. Among adaptors proteins we find growth factor receptor bound protein 2 (**GRB2**), the non-receptor tyrosine kinase (**Src**), v-crk sarcoma virus CT10 oncogene homolog (**CRK**), and the SH2 domain-containing transforming protein (**SHC**). Moreover, Met biological activity is principally due to the recruitment and phosphorylation of the scaffold protein GRB2-associated binding protein 1 (**GAB1**) to activated Met receptor, providing binding sites for additional downstream adaptors or signaling molecules. Interestingly, GAB1 binds to Met directly or indirectly through GRB2 (Gherardi et al., 2012; Organ and Tsao, 2011).

Different signaling pathways mediate the downstream response to Met activation. The two major pathways downstream of Met are the **ERK/MAPK** and **PI3K/Akt**. Activation of ERK/MAPK occurs through the SHC/GRB2/SOS/RAS/RAF pathway or via GAB1/Src homology 2 domain-containing phosphatase (SHP2). MAPK pathway activation results in the regulation of transcription factors that control the expression of genes related to cell proliferation and cell cycle progression and/or cell motility. Regarding **PI3K/Akt** pathway, the p85 subunit of PI3K binds to Met directly or indirectly through GAB1. This signaling pathway is responsible for Met-driven cell survival response. Other signaling pathways are: i) **STAT3**. STAT3 binds directly to Met, becomes phosphorylated, dimerizes and translocates to the nucleus. This signaling pathway has been implicated in tubulogenesis and invasion, although contradictory data has been reported in this respect. ii) **JNK** and **p38**. These pathways are stimulated by RAC GTPase, which is switched on by PI3K/RAS. JNK and p38 control differentiation, transformation, proliferation and apoptosis. iii) Focal adhesion kinase (**FAK**). FAK is activated through Src and has been related to cellular migration and anchorage-independent growth. iv) **NF-κB**. Met activation leads to the release of NF-κB through PI3K/Akt- and Src- dependent pathways. Once in the nucleus, stimulates the transcription of genes related with mitogenic and anti-apoptotic functions. v) Phospholipase Cγ (**PLCγ**). PLCγ binds directly to Met or indirectly through GAB1 and participates in the morphogenesis activity of Met (Gherardi et al., 2012; Kim and Salgia, 2009; Organ and Tsao, 2011; Trusolino et al., 2010).

Figure 11. HGF/Met signaling pathway. Binding HGF to Met initiates receptor activation, dimerization and trans-phosphorylation of the Tyr1234 and Tyr1235. This results in the phosphorylation of the tyrosines in the multifunctional docking site (Tyr1349 and Tyr1356). They recruit signaling effectors and adaptor proteins that lead to the activation of signaling pathways including ERK/MAPK, PI3K, JNK, p38, NF-κB, STAT3, PLCγ and FAK pathways, which mediate HGF/Met biological effects. Adapted from Organ and Tsao, 2011.

HGF/Met signaling pathway is regulated at different levels. Thus, Met downstream signaling can be modulated, potentiated or inhibited through cross-talk with different membrane receptors such as plexins, integrins ($\alpha6\beta4$), semaphorins, CD44 family members, intercellular adhesion molecule 1 (ICAM1), mucins, death receptors (Fas), and other tyrosine kinase receptors (EGFR, Her2) (Giordano and Columbano, 2014; Trusolino et al., 2010; Viticchie and Muller, 2015), thus creating complex interacting networks that can operate in different ways.

Additionally, Met is rapidly internalized by endocytosis and recycled back to the plasma membrane or degraded by lysosomal pathway. Phosphorylation of Tyr1003 at the juxtamembrane domain facilitates the recruitment of the E3 ubiquitin ligase casitas B-lineage lymphoma (c-CBL) after internalization, therefore leading to Met ubiquitination and degradation (Parikh and Ghatge, 2018). However, Met continues signaling from endosomal compartments. Thus, the compartmentalization of the receptor in endocytic vesicles is required for the full activation of signals such as GAB1, ERK, STAT3 and RAC1 (Barrow-McGee and Kermorgant, 2014; Kermorgant and Parker, 2005). Phosphorylation of Ser985 in the juxtamembrane domain also inhibits the phosphorylation and activation of Met. Besides, tyrosine phosphatases such as protein-tyrosine phosphatase 1B (PTP1B) can attenuate Met signaling (Parikh and Ghatge, 2018).

4.2. Physiological and pathological activities of HGF/Met in the liver

HGF/Met is essential for liver development. Homozygous null mice for both Met and HGF fail to complete the developmental process and die in utero due to impaired organogenesis of the placenta, the skeletal muscles of the limb and diaphragm, and the liver (Bladt et al., 1995; Schmidt et al., 1995; Uehara et al., 1995). HGF/Met plays important roles in the migration of myogenic precursor cells and in epithelial morphogenesis through its mitogenic, motogenic, morphogenic and anti-apoptotic activities. The impaired development of the embryonic liver in Met or HGF knockout mice is known to be due to the submassive apoptosis of hepatoblasts (Fausto et al., 1995; Nakamura et al., 2011; Stoker et al., 1987).

4.2.1. HGF/Met in liver regeneration

Despite the key roles exerted by HGF in developmental liver, selective ablation of Met in adult mouse livers seems not to be detrimental to hepatocyte function under physiological conditions. However, these conditional knockout models have demonstrated that the lack of Met dramatically affects the reparative responses of the liver against injury (Huh et al., 2004).

Hepatocytes lacking a functional Met receptor display an augmented sensitivity to Fas-induced apoptosis which might be explained by the defects in the redox regulation and the lack of survival signaling pathway triggered by HGF/Met (Gomez-Quiroz et al., 2008; Huh et al., 2004). Liver specific Met knockout mice show delayed liver regeneration after partial hepatectomy. In this context, a decrease in mitotic hepatocytes due to a lack of ERK1/2

activation is observed in association with a persistent inflammatory reaction (Borowiak et al., 2004; Factor et al., 2010).

However, HGF/Met is not only important during hepatocyte-mediated regeneration, it is also essential for liver regeneration associated with HPC/oval cell-expansion. Thus, in liver-specific Met knockout mice, HPC/oval cell-mediated regenerative response after liver injury is abolished, which is associated with alteration in HPC/oval cell proliferation, survival, differentiation, migration and stemness capacities (Ishikawa et al., 2012). Moreover, other *in vivo* studies show that the increase in the expression of HGF accelerates proliferation of HPCs/oval cells in a damaged liver (Shiota et al., 2000). Our group and others have analyzed the effects of HGF/Met on HPCs/oval cells *in vitro*. We have demonstrated that HGF has a mitogenic activity while promotes invasion and migration and a morphogenic response in HPCs/oval cells (del Castillo et al., 2008b; Okano et al., 2003; Suarez-Causado et al., 2015; Yao et al., 2004). Furthermore, HGF/Met protects HPCs/oval cells from TGF- β -induced apoptotic death (Martinez-Palacian et al., 2013). These results indicate a unique role for HGF/Met in regulation of HPCs/oval cells biology that is critical for their function during liver regeneration.

Furthermore, liver specific Met knockout mice are more susceptible to chronic inflammation and liver fibrosis (Giebeler et al., 2009; Marquardt et al., 2012). HGF/Met exerts its hepatoprotective effect against fibrosis by different mechanisms. On the one hand, HGF/Met opposes to TGF- β pro-fibrotic activity at different levels. It reduces the expression of TGF- β , impairs TGF- β -mediated hepatocyte apoptosis and TGF- β -dependent transcriptional activity (Inagaki et al., 2008; Ueki et al., 1999), induces MMPs expression, which is believed to contribute to the resolution of liver fibrosis (Kanemura et al., 2008), and blocks TGF- β -induced EMT on biliary epithelial cells, one of the process that might contribute to MFB generation (Xia et al., 2006). HGF anti-fibrotic activity also relies on the induction of collagenase expression (Matsuda et al., 1997; Ozaki et al., 2002) and a strong cytostatic effect on activated HSCs (Kim et al., 2005; Li et al., 2008).

All of these findings set the basis to propose HGF/Met as a therapeutic target for the development of new anti-fibrotic and pro-regenerative liver treatments.

4.2.2. HGF/Met in HCC

As mentioned previously, HCC is a heterogeneous disease and the pathogenic mechanisms are still not clear. Dysregulation of HGF/Met signaling pathway has been associated with tumor onset but mainly tumor progression since this pathway can promote tumor growth, invasion, metastasis and angiogenesis (Giordano and Columbano, 2014). Contrarily, some works describe HGF/Met signaling as a tumor suppressor (Takami et al., 2007), highlighting the need to clarify the importance of HGF/Met in this context.

Met aberrations occur in approximately 50% of patients with HCC and can arise through gene mutation (4%), gene amplification (24%), increased mRNA expression (50%) and receptor overexpression (28%). Constitutively activating mutations in the kinase domain are rare in HCC. It is more frequent to find Met overexpression driving independent dimerization and activation. In other setting, abnormal high HGF levels also resulted in aberrant Met activity (Bouattour et al., 2018). In terms of the status and role of Met and HGF in liver cancer there are controversial results. While most of the studies show a decrease in HGF expression, there are disagreements on the percentage of liver tumor showing Met overexpression, and not only that, some works reveal opposite results, that is, a downregulation of Met in HCC (Giordano and Columbano, 2014). The prognostic utility of Met and HGF overexpression is also uncertain. While some works have not found any correlation between Met overexpression and tumor size, proliferation or invasive behavior (Boix et al., 1994; Okano et al., 1999), others have related Met overexpression with poorly differentiated HCC, increased metastasis and angiogenesis, early tumor recurrence and shorter survival (Daveau et al., 2003; Kim et al., 2017b; Ueki et al., 1997; Xie et al., 2001). The discrepancies could be consequence of the different techniques used to determine the levels of Met, the size and diversity of the group of patients included in the study with different tumor origins, or lack of data on Met activation. Indeed, the analysis of Met activation is important to classify the cluster of patients that would be sensitive to therapy with Met inhibitors (Giordano and Columbano, 2014; Venepalli and Goff, 2013).

In order to clarify the role of HGF/Met in HCC a number of *in vitro* and *in vivo* analyses have been performed, but unfortunately, findings are not conclusive. Thus, some early works described that HGF inhibits growth in most of HCC cell lines while exerts a pro-invasive action (Shiota et al., 1992; Tajima et al., 1991). Noticeably, the intracellular mechanisms triggered by HGF to impair HCC cell growth are not known. In later studies, inhibition or downregulation of Met interferes with both cell growth and invasion. Numerous studies show that Met overexpression promote HCC cell invasion and relate it to the ability of HGF/Met to induce EMT (Salvi et al., 2007; Xie et al., 2010). Thus, HCC cells lines with high Met levels display a mesenchymal phenotype and markers (Ogunwobi and Liu, 2011; You et al., 2011).

Unfortunately, *in vivo* studies are not much more clarifying. A number of laboratories have analyzed the effects of inactivating or overexpressing Met and/or HGF on HCC, but the results are discordant. Both stimulatory and inhibitory effects on liver tumor formation have been described after exogenous administration of HGF on rat models of carcinogen-induced HCC (Liu et al., 1995; Ogasawara et al., 1998). Likewise, results from HGF transgenic mice showed either a pro-tumorigenic role of HGF or an inability to form HCC (Sakata et al., 1996; Santoni-Rugiu et al., 1996). The same variability is observed with Met receptor. Loss of Met in hepatocytes led to bigger tumors with shorter latency compared to controls in an experimental model of HCC. On the contrary, transgenic mouse models of MET overexpression in liver spontaneously generate liver tumors (Fan et al., 2017; Wang et al., 2001). The scenario is

complex and suggest that a fine balance of HGF/Met signaling is necessary for liver homeostasis.

Despite the controversy, based on evidence supporting a pro-tumorigenic role of HGF/Met in liver, HGF/Met axis has emerged as a therapeutic target in HCC. Nevertheless, the uncertain results indicate the necessity of further studies in order to select those patients with HGF/Met-dependent tumors for whom developing therapies could be effective. Indeed, inhibitors of Met/HGF signaling have demonstrated signs of efficacy against Met-positive HCCs. HGF neutralizing antibodies, HGF antagonists and Met tyrosine kinase inhibitors are utilized to inhibit Met in the clinic. Recently, the HGF/Met inhibitor cabozantinib has been approved for patients with HCC previously treated with sorafenib; and to date, other five HGF/Met inhibitors have been investigated in clinical trials in HCC. Tivantinib is in phase III studies and others such as capmatinib are being investigated in phase II (Bouattour et al., 2018; Zhang et al., 2018).

5. Senescence

Cellular senescence is defined as a long-term cell cycle arrest despite continued viability and metabolic activity (Kuilman et al., 2010). Senescence plays both beneficial and detrimental roles in the organism. Excessive accumulation of senescent cells and the inability to eliminate them can affect regenerative capacity and create a pro-inflammatory environment that favors the progression of some diseases, including cancer (Hernandez-Segura et al., 2018). On the contrary, transient induction of this program followed by tissue remodeling contribute to eliminate damaged cells, and due to the cell cycle arrest works as a barrier against cancer progression (Munoz-Espin and Serrano, 2014).

In vitro cell senescence can be induced by different stimuli such as progressive shortening of telomeres (replicative senescence) but it can be also activated in the absence of detectable telomere loss or dysfunction by different conditions such as DNA-damage, oncogene signals, oxidative stress, mitochondrial dysfunction and epigenetic changes, among others. If these “types of senescence” occur *in vivo* is not clear (Hernandez-Segura et al., 2018; Kuilman et al., 2010; Munoz-Espin and Serrano, 2014).

Mechanisms that ultimately lead to senescence depend on the cell type, conditions and stimuli. In general, many of the intracellular pathways driving senescence modulate p53, CKI such as p16 (cdkn2a), p15 (cdkn2b), p19 (ARF, cdkn2d)/p14 in humans, p21 (cdkn1a) and p27 (cdkn1b). Subsequently, hypophosphorylated RB accumulates, a crucial event in senescence, that in turn results in proliferative growth arrest (Munoz-Espin and Serrano, 2014). In human cells, p53 can induce senescence through a pathway independent of the RB family (Smogorzewska and de Lange, 2002).

5.1. Biomarkers

The identification of senescent cells is not an easy work. Many of the senescence-associated molecular and morphological features are present in other cellular states and the process is quite heterogeneous and dynamic (Hernandez-Segura et al., 2018). In spite of the complexity of the program, a panel of markers and hallmarks is often used to detect senescence in cultured cells and in tissue samples (Hernandez-Segura et al., 2018; Kuilman et al., 2010; Munoz-Espin and Serrano, 2014).

- *In vitro* senescent cells usually undergo evident morphological changes. Cells become large, flat, vacuolized and sometimes, multinuclear. Contrarily, senescent cells *in vivo* maintain their normal morphology.
- Histochemical detection of β -galactosidase activity at pH 6.0, commonly referred to as senescence-associated β -galactosidase (SA- β -GAL). Its increased activity in senescent cells derives from lysosomal β -D-galactosidase and is due to an expansion of the lysosomal compartment giving rise to an increase in β -galactosidase activity that can be measured at suboptimal pH 6.0.
- Lack of proliferative markers (Ki67, 5-bromodeoxyuridine incorporation) and presence of common mediators of senescence: p16, p19, p53, p21, p15, p27 and hypo-phosphorylated RB.
- Senescence-associated heterochromatic foci (SAHF). Cellular senescence can be associated with an altered chromatin structure, at least *in vitro*. Senescent cells show different heterochromatin patterns, but DNA SAHFs are enriched in repressive epigenetic markers.
- Senescence-associated secretory phenotype (SASP). Senescent cells secrete numerous factors that include TGF- β , IGF-I, inflammatory cytokines and chemokines that can reinforce and propagate senescence in an autocrine and paracrine manner.

Figure 12. Overview of senescence biomarkers. Senescence program can be activated by different stress stimuli such as oxidative stress, oncogenic signaling, ionizing radiation and replicative stress (due to deficiencies in the DNA replication machinery or maintenance of cell cycle checkpoints). Hallmarks of senescent cells include an irreversible cell cycle arrest, secretion of growth factors, cytokines among others (SASPs factors), expansion of the lysosomal compartment and SA- β -GAL expression, and rearrangement of the chromatin landscape (SAHFs). Adapted from Gonzalez-Meljem et al., 2018.

5.2. Physiological and pathological senescence

Generally, senescence process has been related to cellular damage or stress. However, cells with senescence features are found in embryonic structures where might play a role in organogenesis. Although these cells express SA- β -GAL, they do not present other characteristics found in stress-induced senescence. Thus, there is no relation with DNA damage; p53 and p16 are not usually found in these cells and SASP is not present. Evidences suggest that this type of senescence process relies on p21. In addition to embryonic development, senescence also takes part in maturation programs in adult cells (He and Sharpless, 2017).

In liver diseases, senescence may occur in different cell populations as part of the pathogenic mechanism.

Senescence in activated HSCs during liver fibrosis can block their proliferation, inhibit their activation, reduce ECM secretion and enhance immune surveillance (Guo, 2017; Krizhanovsky et al., 2008). Some growth factor and cytokines induce senescence in this hepatic cell population during liver

fibrosis/cirrhosis: IL-22, through the activation of STAT3; cysteine-rich angiogenic inducer 61, a non-structural protein of the extracellular matrix whose expression is induced upon injury; GATA6 and IGF-I. Mechanism of HSC senescence may involve upregulation of p53, p16, p21 and p27 (Guo, 2017; Kong et al., 2012; Krizhanovsky et al., 2008; Panebianco et al., 2017). In this way, induction of HSC senescence could constitute a therapeutic approach against liver fibrosis.

Immune cells also suffer the senescence process in patients with CLD. Accelerated telomere shortening in peripheral lymphocytes has been demonstrated in chronic viral hepatitis and cirrhosis (Guo, 2017).

Senescence in parenchymal cells, hepatocytes and cholangiocytes, has been observed in chronic human liver disorders and has been demonstrated in animal models of liver disease (Wiemann et al., 2002; Yang et al., 2004). The mechanism driving senescence in these cells during liver disease remains undefined. Replicative senescence or telomeric and non-telomeric DNA damage by oxidative stress have been proposed as origin of these senescent cells, although a combination of mechanisms is more likely (Aravinthan and Alexander, 2016). The accumulation of senescent cells influence disease progression through an impact on the microenvironment and tissue homeostasis. Hepatocyte senescence is a way of limiting tissue injury during normal wound healing process. The recruitment of immune cells for clearance of cell debris and senescent cells also contributes to successful wound healing outcome. However, sustained liver insult, which continuously generate senescent cells, together with immune cell senescence found in patients with CLD, which avoids the clearance of senescent cells, contribute to senescent cells accumulation. Additionally, animal models reveal that the accumulation of senescent hepatocytes leads to continuous activation of HSC and fibrosis progression. Although increased senescent cholangiocytes during CLD has also been demonstrated, it is not clear whether senescent cholangiocytes induce HSC activation or rather cholangiocyte senescence and HSC activation are parallel consequences of biliary injury. On the other hand, senescent hepatocytes undergo major metabolic changes such as alterations in the transport of bilirubin and acquisition of insulin resistance that lead to a decline in hepatocellular function (Aravinthan and Alexander, 2016).

Interestingly, SASP factors have both beneficial and detrimental effects. SASP factors reinforce the senescent state in an autocrine manner and induce senescence in neighboring normal hepatocytes, a phenomenon known as senescence-induced-senescence. Additionally, these factors promote inflammation, which aids in clearance of senescent cells and cell debris, thus favoring tissue repair and remodeling (Aravinthan and Alexander, 2016).

SASP factors may also promote tumorigenesis in neighboring cells. Accumulation of senescent cells during CLD results in a SASP-rich microenvironment, which promotes tumorigenesis in DNA-damaged, pre-senescent hepatocytes (Aravinthan and Alexander, 2016; Coppe et al., 2010;

Davalos et al., 2010). Related with this, escape of hepatocytes from senescent process is consider a primary mechanism involved in HCC development, as demonstrated by gene expression analysis of cirrhosis and HCC. Therefore, a potential therapeutic strategy could be induction of senescence in HCC cells, regulating the influence of SASP on the tumor microenvironment (Aravinthan and Alexander, 2016; Yildiz et al., 2013).

5. Background

HPC/oval cell response takes place during CLD in order to restore liver function (Duncan et al., 2009; Tanaka et al., 2011). However, the HPC/oval cell-associated regenerative response sometimes fails and HPCs/oval cells have been involved in the progression of liver fibrosis (Kuramitsu et al., 2013; Williams et al., 2014). Thus, the HPCs/oval cells fate and the mechanisms that regulate their function during the regenerative process accompanying CLDs are not fully understood. Dr. Sánchez's laboratory research is focused on deciphering signals and mechanisms that regulate the biology and function of oval cells. Specifically, over the past few years, major efforts have been put into characterizing the relevance of the interaction between TGF- β ligands (TGF- β and BMP9) and two tyrosine kinase receptors, Met and EGFR, on oval cells regulation.

For that purpose, oval cell lines expressing a functional (Met^{flx/flx}) or non-functional (Met^{-/-}) Met receptor that lacks tyrosine kinase activity, were established from a Met knock-out mouse model generated in Dr. S.S.Thorgeirsson's lab (Huh et al., 2004). These cell lines have become a key tool for the study of HGF/Met axis in oval cell control. A detailed characterization of this *in vitro* model showed that Met^{-/-} oval cells are more sensitive to both serum withdrawal- and TGF- β -induced apoptosis than Met^{flx/flx} cells (del Castillo et al., 2008b) (**Figure 13a and b**).

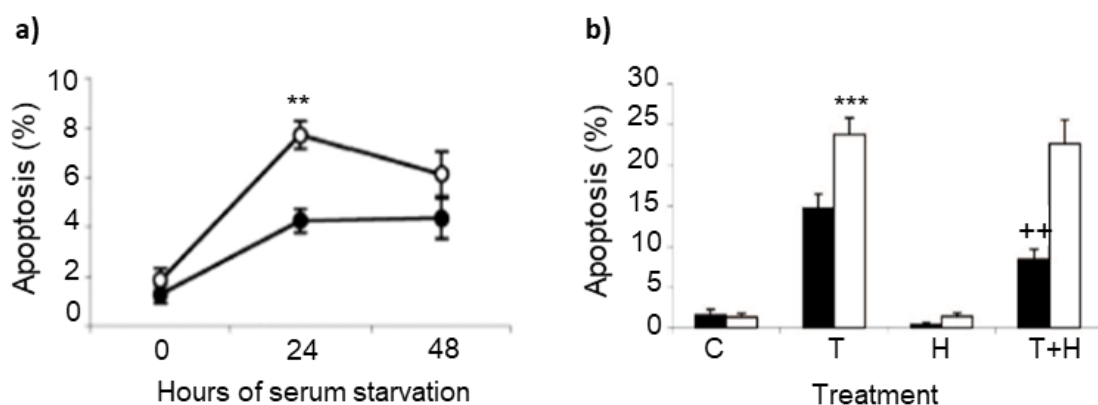

Figure 13. Met^{-/-} oval cells are more sensitive to serum withdrawal and TGF- β -induced apoptosis than Met^{flx/flx} oval cells. **a)** Apoptotic index at different time points after serum withdrawal. A total of 1000 to 2000 cells were counted per dish after propidium iodide (PI) staining under a fluorescence microscope in a blinded manner. **Solid circles**, Met^{flx/flx} oval cells. **Open circles**, Met^{-/-} oval cells. Data are mean \pm S.E.M. of at least eight experiments. ** $p < 0.01$. **b)** Apoptotic index in oval cells treated with TGF- β (T; 1 ng/ml) for 48 hours in the absence or presence of HGF (H; 20 ng/ml). Apoptotic cells were determined as in a). **Black bars**, Met^{flx/flx} oval cells. **White bars**, Met^{-/-} oval cells. Data are mean \pm S.E.M. of three experiments. *** $p < 0.001$ (versus T, Met^{flx/flx}), ++ $p < 0.01$ (versus T, Met^{flx/flx}) (del Castillo et al., 2008b).

The differential behavior of these two cell lines in response to apoptotic signals evidenced the key pro-survival activity of HGF/Met signaling pathway on oval cells. This anti-apoptotic effect occurs through a paracrine (**Figure 13b**) and autocrine signaling, since an active autocrine HGF/Met loop is present in oval cells (**Figure 14a and b**).

Figure 14. HGF/Met autocrine loop is active in $Met^{flx/flx}$ oval cells. **a)** HGF mRNA levels detected by RT-PCR analysis in untreated $Met^{flx/flx}$ and $Met^{-/-}$ oval cells. BI, Blank, no reverse transcription. β -actin was used for normalization. **b)** Kinetics of Met activation in $Met^{flx/flx}$ cells cultured in serum-free medium or conditioned serum-free medium (CM). Whole protein extracts were used for immunoprecipitation of Met protein. Phosphorylation was detected by immunoblotting with anti-P-tyrosine antibody using Met as a loading control (del Castillo et al., 2008b).

It was also shown that TGF- β apoptotic process is mediated by intracellular ROS production. The upregulation of Nox4 suggested both mitochondrial and extra-mitochondrial sources for ROS (Figure 15a and b). Consistent with an increased sensitivity to apoptosis, intracellular ROS content and Nox4 expression were increased in TGF- β -treated $Met^{-/-}$ (Figure 15a and b) respect to $Met^{flx/flx}$ oval cells.

Figure 15. Intracellular oxidative stress induced by TGF- β in oval cells is amplified in cells lacking a functional Met receptor. $Met^{flx/flx}$ and $Met^{-/-}$ oval cell lines were serum starved and incubated in the absence (C) or presence of 1 ng/ml TGF- β (T β) for different periods of time. **a)** After 30 minutes incubation with DFCH-DA (5 μ M) fluorescence intensity was measured in a FACScan flow cytometer. Data are expressed as fold induction over untreated cells and are mean \pm S.E.M. of three independent experiments run in duplicate. **b)** Nox4 mRNA levels were analyzed by RT-qPCR and normalized to the housekeeping gene Gusb. Data are expressed relative to untreated samples and are mean \pm S.E.M. of at least four independent experiments. * $p < 0.05$; ** $p < 0.01$; *** $p < 0.001$ (treated versus untreated); # $p < 0.05$ (treated $Met^{-/-}$ versus treated $Met^{flx/flx}$). **Black bars**, $Met^{flx/flx}$ oval cells. **White bars**, $Met^{-/-}$ oval cells (Martinez-Palacian et al., 2013).

Importantly, oxidative stress leads to Bmf upregulation and subsequent cell apoptosis. Indeed, pre-treatment of Met^{flx/flx} and Met^{-/-} oval cells with antioxidant agents abolishes ROS accumulation and Bmf expression induced by TGF- β (Figure 16a and b). Furthermore, pharmacological inhibition of PI3K impaired HGF-driven protection against TGF- β -induced cell death. Together, these results revealed that Met-driven PI3K activity exerts a pro-survival action against apoptosis and oxidative stress induced by TGF- β in oval cells.

Figure 16. Effect of antioxidant agents on intracellular ROS content and Bmf expression in oval cells. **a)** Met^{flx/flx} and Met^{-/-} oval cell lines were serum starved, pre-treated or not with radical scavengers (1 mM ascorbate + 50 μ M PDTC) for 1 hour prior to TGF- β (1 ng/ml) treatment for 24 hours. After 30 minutes incubation with DFCH-DA (5 μ M) fluorescence intensity was measured in a FACScan flow cytometer. Data are expressed as fold induction over untreated cells and are mean \pm S.E.M. of two independent experiments run in duplicate. **b)** Met^{flx/flx} oval cell lines were pre-treated or not with radical scavengers (1 mM ascorbate + 50 μ M PDTC) for 1 hour prior to TGF- β (1 ng/ml) treatment. After 5 hours, RNA was isolated and Bmf mRNA levels were analyzed by RT-qPCR and normalized to the housekeeping gene Gusb. Data are expressed as fold induction over untreated cells and are mean \pm S.D. from one representative experiment out of two. * $p < 0.05$; ** $p < 0.01$; *** $p < 0.001$ (treated versus untreated); # $P < 0.05$ (TGF- β treated versus TGF- β +antioxidant agents treated). **Black bars**, Met^{flx/flx} oval cells. **White bars**, Met^{-/-} oval cells (Martinez-Palacian et al., 2013).

Besides this pro-survival activity, HGF/Met axis controls other biological processes in oval cells. Indeed, our data showed that HGF is a proliferative factor (del Castillo et al., 2008b) and promotes migration and invasion in oval cells (Suarez-Causado et al., 2015). Thus, HGF increases the rate of DNA synthesis in a dose dependent fashion in Met^{flx/flx} oval cells (del Castillo et al., 2008b) (Figure 17a), effect that was not observed in Met^{-/-} oval cells. Furthermore, we demonstrated that HGF induces collective migration and invasion in oval cells, which requires a remodeling of cytoskeleton and cell-cell contacts but not an EMT process (Figure 17b and c). HGF pro-invasive activity is also triggered via PI3K activation (Figure 17d) and involves MMPs induction and activation (Suarez-Causado et al., 2015).

Figure 17. HGF acts as a proliferative, pro-migratory and pro-invasive factor in oval cells. a) [³H] Thymidine incorporation assay in Met^{flx/flx} and Met^{-/-} oval cells treated for 48 hours with HGF (10 and 40 ng/ml) and epidermal growth factor (20 ng/ml). Results are expressed as cpm/dish. Data are mean ± S.E.M. of triplicate experiments. **Black bars**, Met^{flx/flx} oval cells. **White bars**, Met^{-/-} oval cells (del Castillo et al., 2008b). **b)** Quantitative analysis of *in vitro* wound closure. Met^{flx/flx} and Met^{-/-} oval cells were cultured at confluency on plastic dishes. Next day a wound was done using a sterile tip and cells were cultured during 48 hours with or without HGF (40 ng/ml). Data are expressed as % of closure and are mean ± S.E.M. of four independent experiments. **c)** Met^{flx/flx} and Met^{-/-} oval cells were plated on the upper chamber of a 24-transwell plate coated with matrigel and incubated for 24 hours in the absence or presence of HGF (40 ng/ml). Cells that passed through matrigel-coated filters were fixed and stained with crystal violet and counted by phase contrast microscopy. Data are number of invaded cells and are mean ± S.E.M. of at least 5 experiments performed in duplicate. **d)** Effect of p85 silencing on HGF-induced oval cell invasion. 24 hours after transfection with non-targeting (NT) small interference RNA (siRNA) or p85 specific siRNAs (sip85) cells were trypsinized and seeded on transwell chambers coated with matrigel and cultured for 24 hours with or without HGF (40 ng/ml). Data are expressed as fold change with respect to control and are mean ± S.E.M. of 5 independent experiments run in triplicate. * *p* < 0.05; ***p* < 0.01; ****p* < 0.001 (treated *versus* untreated or as indicated) (Suarez-Causado et al., 2015).

Importantly, in regard to TGF-β-induced effects in oval cells, we observed that, not all the cells die in response to acute TGF-β treatment and there is a population of Met^{flx/flx} and Met^{-/-} oval cells that survive, as it occurs in fetal hepatocytes (Sanchez et al., 1999). Oval cells that survive to TGF-β-induced cell death undergo phenotypical changes that are consistent with an EMT process.

Both $Met^{flx/flx}$ and $Met^{-/-}$ oval cells upon acute TGF- β treatment showed an increased expression of mesenchymal markers (N-CADHERIN and VIMENTIN), decreased levels of epithelial markers (E-cadherin), and upregulation of EMT-inducing TF (Snail, Zeb1) (Figure 18a and b) therefore confirming that an EMT has taken place (Almale et al., 2019).

Figure 18. Acute TGF- β treatment induces EMT in $Met^{flx/flx}$ and $Met^{-/-}$ oval cells. **a)** Total RNA was isolated from $Met^{flx/flx}$ and $Met^{-/-}$ oval cells treated or not with 1 ng/ml TGF- β in 0% FBS medium for different periods of time. Cdh1, Snai1 and Zeb1 mRNA levels were determined by RT-qPCR and normalized to Gusb. Data are expressed relative to untreated cells and are mean \pm S.E.M. (n=2-4). **Black bars**, $Met^{flx/flx}$ oval cells. **White bars**, $Met^{-/-}$ oval cells. **b)** $Met^{flx/flx}$ and $Met^{-/-}$ oval cells were untreated or treated with 1 ng/ml TGF- β in 0% FBS medium for 48 hours, then fixed and stained with specific antibodies against VIMENTIN and N-CADHERIN for immunofluorescence analysis under a confocal microscopy. Nuclei were stained with DAPI. Representative images out of 2 experiments are shown. Scale bar=50 μ m (Almale et al., 2019).

To further study the EMT response triggered by TGF- β in oval cells we established oval cell lines with a stable EMT phenotype induced by chronic treatment with TGF- β (Almale et al., 2019). For the generation of these cell lines, we used a modified version of the protocol used previously in fetal hepatocytes and tumor hepatic cells (Bertran et al., 2009; Valdes et al., 2002) as illustrated in Figure 19. Briefly, oval cells are treated with TGF- β (1 ng/ml) for 48 hours in the absence of serum. Afterwards, the medium is changed to 10% FBS medium supplemented with 0.5 ng/ml of TGF- β (maintenance dose). From then on, cells are always maintained in presence of TGF- β . These cells are named as T β T-OC (TGF- β treated oval cells).

Figure 19. Scheme of the establishment of TβT-OC.

Once TβT-OC were established, functional properties of these cells were analyzed (Almale et al., 2019).

Figure 20. Chronic EMT induces functional changes in oval cells. **a)** Apoptotic index in oval cells and TβT-OC treated with TGF-β for 48 hours. A total of 1000 to 2000 cells were counted per dish after PI staining under a fluorescence microscope in a blinded manner. Data are mean ± S.E.M. of 4 experiments performed in triplicate. **b)** OCR and rate ECAR of oval cells, TβT-OC and Ras-oval cells were analyzed in 25 mM glucose medium. Ratios OCR/ECAR were calculated. Data are mean ± S.E.M. (n=8). **c)** Lactate production in oval cells, TβT-OC and Ras-oval cells in 25 mM glucose medium. Data are mean ± S.E.M. of 2 independent experiments performed in triplicate. **d)** Oval cells, TβT-OC and Ras-oval cells were plated in soft agar and the colonies were counted after 2 weeks. Data are mean ± S.E.M. (n=4). * $p < 0.05$; ** $p < 0.01$; *** $p < 0.005$ (versus oval cells or untreated group or as indicated). (Almale et al., 2019)

Firstly, cells chronically treated with TGF- β lost the apoptotic cell death response upon acute treatment with TGF- β , proving that EMT confers oval cells resistance against TGF- β -induced apoptosis (**Figure 20a**). Likewise, T β T-OC showed lower apoptosis under serum deprivation. Moreover, T β T-OC displayed a switch in their bio-energetic profile towards a more glycolytic phenotype, expressed as oxygen consumption rate/ extracellular acidification rate (OCR/ECAR) ratio, further confirmed by increased lactate production (**Figure 20b and c**).

These features (apoptotic resistance and switch of bio-energetic profile) found in T β T-OC are similar to those found in oval cells transformed with oncogenic v-Ha-Ras (Ras-OC), used as a control of tumorigenic cells (**Figure 20b and c**). However, despite these similarities with tumor cells, T β T-OC do not acquire anchorage independent growth capacity (**Figure 20d**) discarding a malignant transformation after EMT (Almale et al., 2019).

6. Aims

TGF- β and HGF/Met pathways are important mediators during liver regeneration, fibrosis and hepatocarcinogenesis and play roles on different liver cell populations. Taking this into consideration, the **general objective** of this work was **to analyze the relevance of the crosstalk between TGF- β and HGF/Met pathways in oval cell biology and fate in a context of chronic liver injury as well as to explore if such crosstalk could play a role during hepatocarcinogenesis.**

To achieve this general objective, we propose three specific objectives:

Objective 1: To characterize the TGF- β -induced EMT response in oval cells *in vitro* and to evaluate the effects on oval cell fate upon transplantation into a fibrotic liver.

Objective 2: To elucidate the HGF/Met signaling-mediated regulation on the EMT response induced by TGF- β and its contribution to oval cell properties.

Objective 3: To analyze the TGF- β pathway in liver tumor cells from Met-overexpressing livers and how affects tumor cell growth and survival properties.

7. Materials and methods

1. Cell culture

1.1. Cell models

$Met^{flx/flx}$ oval cell lines derive from Met conditional knockout mice (Huh et al., 2004) fed with 0.1% DDC-supplemented diet for 13 days to induce liver damage and oval cell expansion. In order to generate $Met^{-/-}$ oval cells, *in vitro* inactivation of Met was achieved by infecting the parental $Met^{flx/flx}$ oval cells with adenovirus expressing the Cre recombinase under the control of the cytomegalovirus promoter (Ad-CMV-Cre) (Vector Biolabs). Cre-mediated conditional gene targeting resulted in the deletion of exon 16 containing a critical ATP-binding site in the intracellular tyrosine kinase domain, essential for Met catalytic activity. Removal of this region leads to the expression of a Met receptor lacking its tyrosine kinase activity. Cells were phenotypically and functionally characterized and validated (del Castillo et al., 2008b). $Met^{flx/flx}$ and $Met^{-/-}$ oval cells were used only in early passages.

Figure 21. Representative phase contrast images of $Met^{flx/flx}$ and $Met^{-/-}$ oval cells lines in culture.

To generate T β T-OC (oval cells chronically treated with TGF- β), oval cells were treated for 2 days with TGF- β (1 ng/ml) in 0% foetal bovine serum (FBS) medium. Then, medium was replaced and remaining surviving cells were cultured in 10% FBS medium supplemented with TGF- β (0.5 ng/ml) until they reached confluency. Cells were sub-cultured in the same medium and after 4-5 subsequent passages a stable cell line of T β T-OC was established.

Figure 22. Representative phase contrast images of T β T-OC lines in culture.

Green fluorescence protein (GFP) expressing oval cells and T β T-OC were generated by lentiviral transduction with GFP. For the transduction we used the lentiviral vector pLVX-SFFV-zsGFP. 250,000 cells were seeded in 10% FBS medium in 6-well plates. Following day, medium was removed and viral particles were added in 1 ml of DMEM-10% FBS with a multiplicity of infection (MOI) of 5 (from a 1.10^9 transducing units (TU)/ml titer). After 24 hours, medium was replaced by normal growth medium. Cells were sub-cultured 2-3 times per week at 80%-90% confluency. GFP expressing cells were selected by cell sorting. These experiments were done at Dr. J.C. Segovia laboratory (CIEMAT).

Figure 23. Representative fluorescence microscopy images of OC-GFP and TβT-OC-GFP in culture.

Alb-R26^{Met} HCC cells derive from Alb-R26^{Met} mice, mice with increased Met levels in the liver generated in Dr. F. Maina laboratory. For the generation of these animals, R26^{stopMet} (international nomenclature Gt(ROSA)26Sor^{tm1(Actb-Met)Fmai}) mice were crossed with Albumin-Cre, that is, mice expressing Cre recombinase under the control of albumin promoter. Thus, in R26^{Met} mice, Met transgene is carried in the Rosa26 locus that is expressed in albumin positive cells. These mice spontaneously generate liver tumors (from 40 weeks of age). Several HCC cell lines from individual Alb-R26^{Met} tumors were generated (Alb-R26^{Met} HCC cells). In this work, we use two different HCC cells lines expressing different Met levels: HCC1, with high Met levels (named as HCC1^{HMet}) and HCC3, with low Met levels (named as HCC3^{LMet}).

Figure 24. Representative phase contrast images of HCC1^{HMet} and HCC3^{LMet} cells in culture .

1.2. Cell culture conditions

Cell lines were grown in the appropriated medium (**Table 1**) and were placed in a humidified incubator at 37°C and 5% CO₂. Cells were passaged at 80%-90% confluency using trypsin-ethylene diaminetetraacetic acid (EDTA) and medium was replaced every 3 days.

For cryopreservation, cells were harvested and centrifuged (5 minutes, 1,300 rpm). The cells pellet was resuspended in 10% (v/v) dimethyl sulfoxide (DMSO)-FBS and transferred to cryotubes. Cells were frozen slowly using the Mr. Frosty freezing container (Thermo Scientific) at -80°C and moved to the liquid nitrogen (-190°C) tank within a week.

Cells thawing was done quickly in a water bath at 37°C. Once thawed, cells were placed in a culture dish with growth medium. Upon attachment, medium was replaced with fresh medium to completely remove the DMSO.

Cell line	Medium	Supplements	
Met ^{fix/fix} Met ^{-/-} OC-GFP	DMEM Dulbecco's Modified Eagle Medium, 4.5 g/l glucose	10% FBS Hepes 20 mM (ph 7.4) Penicillin G 120 µg/ml Streptomycin 100 µg/ml	
TβT-OC TβT-OC-GFP		Amphotericin B 2.5 µg/ml	TGFβ* 0.5 ng/ml
HCC1 ^{HMet} HCC3 ^{LMet}	William's Medium E (-) L-Glutamine	10% FBS 1X Penicillin/Streptomycin 2 mM L-Glutamine 0.0025 g/l Glucose 0.7 mM Sodium Pyruvate 0.4 µg/ml Dexamethasone 10 µg/ml Insulin* 20 ng/ml EGF* 10 ng/ml HGF*	

(*) Supplements are added immediately before use

Table 1. Cell culture media used for the different cell lines.

1.3. Growth factors and inhibitors

Growth factors and inhibitors used in this work are listed in **Table 2**

Growth Factor/Inhibitor	Final concentration	Manufacturer
TGF-β	1 ng/ml or 2 ng/ml	Calbiochem
HGF	40 ng/ml	R&D systems/Peprtech
PHA665752	3 µM or 5 µM	Sigma Aldrich
SB431542	10 µM	Sigma Aldrich

Table 2. Growth Factors and inhibitors.

Oval cells were serum starved for 3-15 hours before treatment. For HCC cell lines, all treatments were performed in 10% FBS-medium to avoid cell death.

Inhibitors were added 1 hour before treatment with the growth factors. To inhibit Met activity in TβT-OC cell lines, cells were treated with the inhibitor

PHA665752 during 2 weeks prior to the experiment and during the course of the experiment.

2. DNA analysis

2.1. DNA isolation from cultured cells

DNA was extracted for genotyping Met^{flx/flx} and Met^{-/-} oval cells. First, cells were washed with cold phosphate buffered saline (PBS) and lysed overnight in lysis buffer (**Table 3**) at 58°C in a rotating oven (400 rpm). DNA was isolated using a phenol/chloroform extraction protocol. An equal volume of phenol was added to cell lysates and mixed for 10 minutes. They were centrifuged at 12,000 rpm for 3 minutes and the supernatant was transferred to a new tube. An equal volume of chloroform/isoamylalcohol (24:1) was added, mixed for 10 minutes, and centrifuged at 12,000 rpm for 3 minutes. Supernatant was transferred to a new tube and the extraction was repeated with chloroform alone. DNA was precipitated with 1/10 volume of 3M sodium acetate (pH 5.2) and 1 volume of isopropanol. Precipitated DNA was transferred into a tube with 70% ethanol and centrifuged at 9,000 rpm for 2 minutes. The pellet was resuspended in tris-EDTA (TE) buffer (**Table 4**) and incubated at 37°C to facilitate resuspension.

Component	Final concentration
Tris-HCl pH 8.5	100 mM
EDTA	5 mM
Sodium dodecyl sulphate (SDS)	0.2%
NaCl	200 mM
Proteinase K*	100 µg/ml

(*) Added immediately before use

Table 3. DNA isolation buffer.

Component	Final concentration
Tris-HCl pH 8	10 mM
EDTA	1 mM

Table 4. TE buffer

2.2. DNA isolation from liver tissue

DNA from liver tissue was isolated for the detection of floxed allele in the liver of transplanted mice (analysis of cell engraftment). For genomic DNA isolation, hepatic tissue was digested overnight in lysis buffer (**Table 3**), as explained before. Next day samples were centrifuged at 13,000 rpm for 10 minutes, supernatant was collected and genomic DNA was precipitated with cold isopropanol. DNA was diluted in TE buffer (**Table 4**) at 37°C.

2.3. Polymerase chain reaction (PCR)

1 µg of genomic DNA isolated from either liver tissue or cultured cells was incubated with a mix of 1 µM of specific primers (Table 5), 200 µM of dNTPs, 1.5 mM of MgCl₂ and 2 units of Taq polymerase. PCR conditions were:

- 95°C for 5 minutes.
- 39 cycles with 3 steps: 94°C for 1 minute (denaturation), 61°C for 30 seconds (primer annealing) and 72°C for 1 minute (extension).
- 72°C for 2 minutes.

The obtained PCR products were analyzed in 1.3% agarose gels containing Gel Red Nucleic Acid Stain. In each reaction, we included a negative control containing H₂O instead of cDNA (no-RT sample).

Gene (mouse)	Forward primer (5'-3')	Reverse primer (5'-3')	T (°C)	Cycles #
Flox Allele	TTAGGCAATGAGGTGTCCCAC	CCAGGTGGCTTCAAATTCTAACG	61	39
Deleted Allele	CAGCCGTCAGACAATTGGCAC	CCAGGTGGCTTCAAATTCTAAGG	63	30

Table 5. Sequences of primers used for PCR.

Figure 25. Illustrative PCR for genotyping of Met^{flx/flx} and Met^{-/-}. The PCR confirms the presence of the flowed allele (380bp) in Met^{flx/flx} together with the presence of deleted allele (600bp) in Met^{-/-} oval cells.

3. mRNA expression analysis

3.1. Total RNA extraction

Cells were washed with cold PBS and total RNA was extracted following manufacturer's instructions of GeneAll Ribospin™ Kit. DNase treatment was included to avoid possible genomic DNA contamination. RNA was eluted with ultrapure water. Concentration of RNA was spectrophotometrically measured (A_{260nm}), considering that 1 unit of absorbance at 260 nm corresponds to 40 µg/ml of RNA. Estimation of its purity was based on the ratio A₂₆₀/A₂₈₀. A ratio between 1.8-2 was accepted as pure RNA.

3.2. cDNA synthesis (reverse transcription, RT)

cDNA synthesis was performed using two alternative protocols:

For oval cells, we used 1 µg of total RNA. cDNA synthesis was performed in two consecutive reactions. In a first reaction, RNA was incubated with oligo dT (0.25 µg) and dNTPs (0.5 mM) at 65°C for 5 minutes to denature RNA. Then, this mix was incubated at 50°C for 1 hour in the presence of a cDNA synthesis mix (5X RT Buffer, 20 units of RNase inhibitor, 5 mM dithiothreitol (DTT), 200 units of SuperScript III) in a final volume of 20 µl. The enzyme was inactivated by heating samples at 70°C for 15 minutes.

For HCC cells, 600 ng of total RNA was used for complementary DNA synthesis by iScript™ Reverse Transcription Supermix (Bio-Rad) following the manufacturer's instructions.

In both cases, cDNA was diluted as required with nuclease free water and stored at -20°C until further use.

3.3. Quantitative reverse transcription PCR (RT-qPCR)

Real time PCR was performed using specific primers (Table 6) and SYBR Green to detect DNA in the 7900 Fast Real Time System (Life technologies)/ QFX 96 (BioRad). PCR reactions were done in triplicate. Gusb and Hprt were used as housekeeping genes.

During the exponential phase of real time PCR, a fluorescence signal threshold was determined, so that it was significantly greater than background fluorescence. The fractional number of PCR cycles required to reach this threshold is defined as the cycle threshold or Ct. Based on this, quantification of RNA levels was performed through calculation of RQ ($2^{-\Delta\Delta Ct}$). First, ΔCt value for each sample and gene is obtained by subtracting the Ct value for Gusb from the Ct value for the target gene under a particular experimental condition. Then, resulting ΔCt value is referred to control ΔCt value (sample ΔCt - control ΔCt = $\Delta\Delta Ct$) to calculate the RQ value.

Leupetin *	10 µg/ml
PMSF *	1 mM

Table 7. RIPA buffer composition.

EGTA	5 mM
EDTA	5 mM
NaPP*	1 mM
NaF *	10 mM
Na ₃ VO ₄ *	1 mM
β-glycero-phosphate*	10 mM
Leupeptin*	5 µg/ml
Pepstatin*	5 µg/ml
Aprotinin*	2 µg/ml
Benzamidin	5 mM
PMSF *	1 mM

Table 8. EBM buffer composition.

(*) Inhibitors are added immediately before use

Cells were detached from the plate by scraping in presence of lysis buffer and collected in an eppendorf tube. Cell lysates were incubated for 30 minutes at 4°C, vortexed every 5 minutes and centrifuged at 13,000 rpm for 10 minutes at 4°C. The supernatant was collected in a new eppendorf tube and stored at -80°C until use.

4.1.2. Protein quantification

Protein concentration was determined using the Bradford method. Absorbance at 595 nm was measured using a plate reader (Powerwave XS, Biotek). Different concentrations of bovine serum albumin (BSA) were used (0-10 µg) to generate a standard curve and calculate protein concentration of cell extracts.

4.1.3. Protein electrophoresis and blotting

Samples were prepared using Laemmli buffer 4X (**Table 9**) and were denatured at 95°C for 5 minutes. Then, samples were loaded into the gel together with a molecular weight standard (ThermoFisher).

Component	Laemmli buffer 4x Final concentration
SDS	8%
Tris-HCl pH 6.8	250 mM
Glycerol	40%
Bromophenol blue	0.002%
β-mercaptoethanol	5%

Table 9. Laemmli buffer composition.

Electrophoresis conditions are listed in the table below:

Electrophoresis conditions	
SDS-polyacrylamide gel electrophoresis (SDS-PAGE)	80-120 V 25 mM Tris-HCl (pH 8.3), 0.2 M Glycine and 0.1% SDS
Anderson gels	25-30 V/ gel 250 mM Tris-HCl, 2 M Glycine and 20% SDS

Table 10. Electrophoresis conditions.

4.1.4. Protein transfer

After electrophoresis, proteins were transferred onto a Nitrocellulose or Immobilon membrane using a wet transfer equipment. Protein transfer conditions are indicated in **Table 11**:

Transfer conditions	
SDS-PAGE	0.3 A, 90-110 min, room temperature (RT) 20% Methanol, 25mM Tris-HCl, 190 mM Glycine
Anderson gels	0.4 A, 4 h, 4°C 20% 2-propanol, 1X Carbonate buffer

Table 11. Transfer conditions.

After transfer, membranes were stained with Ponceau Red (0.5% in 1% acetic acid solution) to evaluate the efficiency of the protein transfer.

4.1.5. Immunodetection

Membranes were blocked for 1 hour at RT in Tween-tris-buffered saline (TTBS) or Tween-PBS (TPBS) 5% non-fat dry milk or BSA (depending on the primary antibody) (**Table 12**) to block unspecific binding. Then, membranes were incubated overnight at 4°C with the primary antibody diluted as indicated in **Table 13** in TTBS or TPBS supplemented with 0.5-5% milk or BSA. Next day, membranes were washed with TTBS or TPBS (3 times, 5 minutes each) and were incubated with the secondary antibody at 1:5000 dilution in TTBS or TPBS

supplemented with 0.5-1% milk or BSA for 1-2 hours at RT. After this period, membranes were washed 3 times (5 minutes each) and incubated with a chemiluminescent solution (Pierce ECL western blotting substrate).

SDS-PAGE	Anderson gels
TTBS	TPBS
20mM Tris-HCl (pH 7.6) 150mM NaCl 0.05% Tween-20	PBS 0.1% Tween 20

Table 13. Primary antibodies used for western blot.

4.2. Protein expression analysis by immunoprecipitation assay

Total cell extracts for Met immunoprecipitation were prepared using RIPA buffer (section 4.1.1.). 1,000 µg of protein were diluted in lysis buffer to 1 µg/µl and anti-Met antibody (SC-162) was added (7 µg/mg of protein). This mix was incubated overnight at 4°C under rotation in presence of protein A-agarose beads (Roche), previously washed and resuspended in lysis buffer.

Next day, immunoprecipitates were washed 3 times with lysis buffer and resuspended in Laemli buffer 4X (section 4.1.3.). Then, samples were heated at 95°C for 5 minutes and centrifuged to separate the protein A-agarose. In parallel, we prepared a mock IP control (lacking protein extract) and IP control (without antibody).

Samples were loaded into an 8% SDS-PAGE gel together with a molecular weight standard. Gel electrophoresis and wet transfer (2 hours, 100V) were performed as described before (section 4.1.3. and 4.1.4) to detect phosphorylated and total Met by western blot (section 4.1.5) using the antibodies listed in **Table 14** (del Castillo et al., 2008b).

Primary Antibody	Laboratory	Dilution	Secondary antibody
MET	Santa Cruz Biotechnology (162)	1:1000 TTBS-0.5% milk	Rabbit 1:5000 TTBS-0.5% milk
Anti-phospho-Tyr Kinase	Upstate Biotechnology (4G10)	1:1000 TTBS-3% milk	Mouse 1:3000 TTBS-0.5% milk

Table 14. Antibodies used for immunoprecipitation and western blot assays.

4.3. Protein expression analysis by flow cytometry

For protein expression analysis by flow cytometry, cells were detached with trypsin-EDTA and centrifuged at 1,200 rpm for 5 minutes at 4°C. Then, cells were washed and centrifuged again in the same conditions and resuspended in PBS. 1x10⁶ cells were collected for each condition and the following protocols were followed to analyze different proteins.

EPCAM analysis

A blocking step was performed by incubating cells in PBS-5% mouse serum for 15 minutes at 4°C. Cells were washed with PBS-3% BSA and centrifuged at 2,000 rpm for 5 minutes at 4°C. The cell pellet was resuspended in PBS-3% BSA and incubated with EPCAM-Phycoerythrin or with Isotype control mouse IgG1 (**Table 15**) or with PBS-3% BSA only, as a control, for 30 minutes at 4°C in darkness. Then, cells were washed with PBS and centrifuged at 2,000 rpm for 5 minutes at 4°C. The pellet was resuspended in PBS and transferred to cytometry tubes.

CD44 analysis

Cells were resuspended in PBS-0.1% BSA and incubated with CD44-Alexa 488 or with Isotype control Rat IgG (Table 15) or with PBS-0.1% BSA only, as a control, for 30 minutes at 4°C in darkness. Then, cells were washed with PBS and centrifuged at 2,000 rpm for 5 minutes at 4°C. The pellet was resuspended in PBS and transferred to cytometry tubes.

In both cases, 10,000 cells per condition were analysed by FACScalibur (Becton Dickinson; Flow Cytometry and Microscopy Core Facility at UCM

Antibody	Laboratory	Dilution
EPCAM-Phycoerythrin	Santa Cruz Biotechnology 66020	1:50
EPCAM isotype control Mouse IgG1	Santa Cruz Biotechnology 2866	1:50
CD44-Alexa 488	BioLegend 103016	1:50
CD44 Isotype control Rat IgG	BioLegend 400625	1:50

Table 15. Antibodies used for protein expression analysis by flow cytometry.

4.4. Protein expression analysis by immunocytochemistry

150,000 oval cells or 700,000 HCC cells were seeded on gelatin-coated glass coverslips in 12-wells plates or in 6 cm dishes, respectively. Next day, cells were washed with PBS and the following protocols were followed for detecting specific proteins (Suarez-Causado et al., 2015; Almale et al., 2019).

E-CADHERINE, N-CADHERIN and ALBUMIN analysis

Cells were fixed in cold methanol (-20°C) for 2 minutes at RT and then coverslips were washed twice with PBS and blocked in PBS-2% BSA for 1 hour at RT. Next, they were incubated with primary antibody (Table 16) in PBS-1% BSA, in a humidified chamber for 1 hour at 37°C. Coverslips were washed 3 times in PBS (5 minutes each) and incubated with secondary antibody in PBS-1% BSA for 1 hour at 37°C. Finally, cells were washed 3 times in PBS (5 minutes each) and mounted with Slowfade gold antifade reagent containing 4',6-diAmidino-2-phenylIndole (DAPI) (Invitrogen).

CK19

Cells were fixed in ethanol 95% for 10 minutes at 4°C. Then, coverslips were washed twice with TBS (Table 12), blocked and fixed in TBS-0.3% Triton X-100-5% goat serum for 2 hours at RT. After washing once with TBS cells were incubated with primary antibody (Table 16) in blocking solution, in a humidified chamber overnight at 4°C. Coverslips were washed 3 times in TBS (5 minutes each) and incubated with secondary antibody in PBS-0.1% BSA for 1 hour at 37°C. Finally, cells were washed and mounted as explained before.

ZO-1 analysis

Cells were fixed in 4% paraformaldehyde (PFA) for 20 minutes at RT and permeabilized with PBS-0.1% Triton X-100-0.1% BSA for 20 minutes. Then coverslips were washed twice with PBS and blocked in PBS-2% BSA for 1 hour at RT. Next, they were incubated with primary antibody (**Table 16**) in PBS-1% BSA, in a humidified chamber for 1 hour at 37°C. Coverslips were washed 3 times in PBS (5 minutes each) and incubated with secondary antibody in PBS-1% BSA for 1 hour at 37°C. Finally, cells were washed and mounted as explained before.

In all cases, cells were examined in a confocal microscope (Olympus FV1200, Flow Cytometry and Microscopy Core Facility at UCM).

Cleaved CASPASE-3 analysis

For detecting activated CASPASE-3, we used an antibody against the large fragment (17/19 kDa) resulting from cleavage of the pro-caspase (**Table 16**). Cells were fixed in 4% PFA for 10 minutes followed by two washes with PBS. The unmasking was done in PBS supplemented with 50 mM Lysine-50 mM NH₄Cl₂ for 15 minutes at RT. Then, cells were washed 3 times (5 minutes each), permeabilized with PBS-0.1% Triton X-100 for 15 minutes, washed 3 times (5 minutes each) with TPBS (**Table 12**) and blocked in TPBS-10% donkey serum for 1 hour. Incubation with primary antibody (**Table 16**) was done overnight at 4°C in blocking solution using a humidified chamber. Coverslips were washed 3 times (10 minutes each) with TPBS and incubated with the secondary antibody in blocking solution 1 hour at RT. Then, cells were washed with TPBS 3 times (10 minutes each) and once with PBS. For nuclear counterstaining cells were incubated in PBS-DAPI (1 µg/ml) for 15 minutes at RT. Finally, cells were washed with PBS and mounted in Prolong Gold antifade reagent (Thermofisher).

Primary Antibody	Laboratory	Dilution	Secondary Antibody	Dilution
E-CADHERIN	BD Transduction Laboratories (610181)	1:50	Mouse Alexa 488	1:200
ALBUMIN (RaRa/Alb/PO)	Nordic Immunology	1:50	Rabbit Alexa 594	1:200
CK19 (TROMAIII)	Hybridoma Bank	1:50	Rat Fitc	1:200
N-CADHERIN	BD Transduction Laboratories (610921)	1:50	Mouse Alexa 488	1:200
ZO-1	Thermo Fisher Scientific (617300)	1:50	Rabbit Alexa 594	1:200
Cleaved CASPASE-3	Cell Signaling Technology (Asp175) (9661)	1:500	Rabbit Alexa 488	1:500

Table 16. Antibodies used for immunofluorescence staining for confocal microscopy analysis.

Cells were visualized under a Zeiss Apotome Microscope with a 20X objective. The fluorescence intensity was measured in at least 6 fields per condition by Image J program.

4.5. Protein expression analysis by immunohistochemistry and immunofluorescence in hepatic tissues

4.5.1. pSMAD2 staining on liver sections: paraffin embedding and immunohistochemistry

For paraffin embedding, liver tissue was fixed in 4% PFA for 4 hours at 4°C, rinsed twice with PBS and dehydrated by immersion in increasing concentrations of alcohol. Dehydrated samples were then embedded in paraffin as indicated in **Table 17**. Following day, samples were allowed to solidify at RT.

Step	Time
Ethanol 50%	40 minutes
Ethanol 70%	40 minutes
Ethanol 95%	40 minutes
Ethanol 95% (4°C)	Overnight
Ethanol 100%	40 minutes
Ethanol 100%	40 minutes
Ethanol 100%	40 minutes
Acetone:Paraffin (1:1) (62°C)	30 minutes
Paraffin (62°C)	1 hour
Paraffin (62°C)	1 hour
Paraffin (62°C)	Overnight

Table 17. Steps for paraffin-embedding.

Paraffin-embedded samples were cut into 4 µm-thick sections using a microtome, placed in slides and left air-drying at 37°C. For pSMAD2 staining, paraffin was removed and tissue was rehydrated. For that, samples were placed at 50°C for 30 minutes and passed through alcohol solutions with decreasing concentrations as indicated in **Table 18**.

Step	Time
Xylene	10 minutes
Xylene	10 minutes
Xylene	10 minutes
Ethanol 100%	5 minutes
Ethanol 100%	5 minutes
Ethanol 100%	5 minutes
Ethanol 96%	5 minutes
Ethanol 96%	5 minutes
Ethanol 70%	5 minutes
Distilled water	5 minutes

Table 18. Hydration steps for immunohistochemistry.

Next, samples were immersed in 10 mM citric buffer (pH6) and boiled for 12 minutes. This step breaks the methylene bridges and exposes the antigenic sites to allow binding of antibodies. When temperature of the buffer reached 35-45°C, samples were washed with PBS for 5 minutes. Samples were then permeabilized in PBS-0.1% Triton X-100 for 5 minutes and washed in PBS for 5 minutes. Endogenous peroxidase was inactivated to reduce the background by incubating the tissue in methanol-3% H₂O₂ for 10 minutes at RT. Slides were rinsed with water and with TPBS (**Table 12**) (10 minutes). Blocking was performed in TPBS supplemented with-2% BSA and 20% FBS for 2 hours. Then slides were incubated overnight with pSMAD2 primary antibody (Cell Signaling, 3106, S465,467) diluted 1:100 in blocking solution in a humidified chamber at 4°C overnight. Samples were washed 3 times with TPBS (10 minutes each) and incubated for 1 hour with anti-rabbit peroxidase-conjugated secondary antibody diluted 1:500 in blocking solution in a humidified chamber at RT. Then, samples were washed 3 times with TPBS (10 minutes each). Peroxidase staining was revealed with D.A.B (SK-410 Vector Laboratories). Upon acquisition of an adequate signal, the reaction was stopped by soaking the samples into tap water for 5 minutes. Finally, samples were dehydrated as indicated in **Table 19** and slides were mounted with Eukitt quick-hardening mounting medium (Sigma).

Step	Time
Distilled water	5 minutes
Ethanol 70%	5 minutes
Ethanol 96%	5 minutes
Ethanol 96%	5 minutes
Ethanol 100%	5 minutes
Ethanol 100%	5 minutes
Ethanol 100%	5 minutes
Xylene	10 minutes
Xylene	10 minutes
Xylene	10 minutes

Table 19. Dehydration steps for immunohistochemistry.

Staining was observed with bright light under a Zeiss Apotome with a 20X objective. The intensity and the number of pSMAD2 positive nuclei were analysed using image J in at least 6 fields per sample.

4.5.2. Detection of GFP by confocal microscopy/immunofluorescence

For immunofluorescence staining of GFP on paraffin-embedded liver sections (performed Department of Pathological Anatomy of the Hospital Clínico San Carlos (HCSC)), firstly paraffin was removed by heating sections at 65°C for 15 minutes and then tissue was rehydrated by immersion in decreasing concentrations of alcohol as indicated in **Table 20**.

Step	Time
Xylene	20 minutes
Ethanol 100%	3 minutes
Ethanol 80%	3 minutes
Ethanol 60%	3 minutes
PBS	5 minutes

Table 20. Hydration steps of paraffin sections for GFP detection by immunofluorescence.

Next, samples were washed with PBS for 5 minutes and incubated with 0.3% pepsin-0.1N HCl solution for 5 minutes at 37°C to unmask the antigenic sites. Samples were washed in PBS for 5 minutes and blocking was performed in PBS-0.05% Tween 20-5% HyClone serum for 30 minutes at RT. Incubation with the primary antibody (Rabbit α GFP, A11122 ThermoFisher) was done in blocking solution for 1 hour at RT at 1:100 dilution. After 3 washes (5 minutes each) with PBS-0.05% Tween20 sections were incubated with the secondary antibody (Alexa 488 donkey antirabbit IgG A21206 ThermoFisher) diluted 1:1000 in the blocking solution. DAPI (1 ng/ μ l) was added for nuclei counterstaining. Finally, slides were washed with PBS 3 times (5 minutes each) and mounted in Mowiol.

Staining was visualized under a confocal microscope (Olympus FV1200, Flow Cytometry and Microscopy Core Facility at UCM).

5. Clonogenic assay

To measure colony-forming/self-renewal capacity, 200 and 500 oval cells were seeded in 6-well dishes. Medium was replaced every 3 days. After 8-10 days, medium was removed, dishes were washed with PBS and colonies were stained with a crystal violet solution (0.2% crystal violet in 2% ethanol) for 20 minutes.

Total number of colonies per condition was quantified using Image J program.

6. Spheres formation assay

5,000 cells were seeded into low-attachment 6-well plates in a defined medium (**Table 21**). Culture was maintained for 15 days adding fresh medium twice a week (Ocana et al., 2012).

Medium	Supplements	Final Concentration
DMEM 4,5 g/l glucose	Hepes (pH 7.4)	20 mM
	Penicilin G	120 µg/ml
	Streptomycin	100 µg/ml
	Amphotericin B	2.5 µg/ml
	Insulin*	5 µg/ml
	hEGF*	20 ng/ml
	Heparin*	4 µg/ml
	B27 (w/ vit A)*	2%
	Hydrocortisone*	0.5 µg/ml

(*) Supplements are added immediately before use

Table 21. Medium used for spheres formation assay.

For spheroid formation analysis, photographs of all spheroids in each well were taken under a phase contrast microscopy (Eclipse TE300, Nikon, connected to a camera Nikon digital Sight DS-U2) using a 20X objective. Both number of spheroid and spheroid diameter were measured using the Image J program. Spheroids were classified in three groups based upon size: [25-50 µm], (50-100 µm], > 100 µm.

7. Analysis of cell number

7.1. Analysis of cell number in the presence of serum

20,000 oval cells were seeded in 12-well plates in triplicates in DMEM-10% FBS. Media was replaced twice a week and cells were counted daily for 7 days using trypan blue staining and a Neubauer chamber.

7.2. Analysis of cell number in the absence of serum

57,000 oval cells or 25,000 HCC cells were seeded in 12-well plates in triplicate in 10% FBS media. The following day, serum (oval cells) or medium supplements (HCC cells) were removed prior to stimuli addition. Cells were counted at specific times as explained before (section 7.1).

8. Invasion assay

Analysis of cell invasive/migratory capacity was performed using transwell inserts (24-well plate inserts; 8 µm pore size; cell growth area 0.3 sq cm, BD Bioscience) coated with Matrigel (330 µg/ml) or type IV collagen (7.5 µg/ml) according to the manufacturer's recommendation. 50,000-67,000 oval cells were seeded in triplicate on the upper chamber and incubated in the presence of stimuli in DMEM-0% FBS. DMEM-0% FBS was added in the lower compartment.

After 24 hours in culture, cells in the upper chamber were carefully removed with a cotton swab and cells that had invaded the membrane were fixed with 4% PFA for 20 minutes and stained with 0.2% crystal violet for 20 minutes.

Quantification of cell invasion was done by counting stained invaded cells in at least 14 fields/insert using a phase-contrast microscopy (Eclipse TE300, Nikon) and a 10X objective.

9. Analysis of MMP2 and MMP9 activities by zymography

Zymography is an electrophoretic technique for the detection of matrix degrading catalytic activity. We assessed gelatinase (MMP9) by gelatin zymography.

Cells at 80% confluency were serum starved for 48 hours and the culture medium was collected. Samples were prepared using non-reducing conditions and a non-reducing loading buffer 4X (**Table 22**) to avoid protein denaturation and loss of MMP activity.

Component	Final concentration
Tris-HCl pH 6.8	250 mM
Glycerol	25 %
SDS	2.5 %
Bromophenol blue	1 mg/ml

Table 22. Loading buffer used for zymography.

Then, samples were loaded in an 8% SDS-PAGE, polymerized with 1% gelatin. Electrophoresis was carried out at a constant voltage of 80 V for 3-4 hours. Then, gels were incubated in 2.5% Triton X-100 to remove SDS from the gels and rinsed with substrate buffer (**Table 23**). Next, gels were incubated in substrate buffer for 15 hours at 37°C to allow protein renaturation and MMP activation. Following day, gels were stained with Coomassie Brilliant Blue (BioRad, 161-0400). Gelatin degradation was visualized as clear bands on the gel.

Component	Final concentration
NaCl	0.2 M
CaCl ₂	5 mM
Triton X-100	1 %
NaN ₃	0.02 %
Tris-HCl pH 7.5	50 mM

Table 23. Substrate buffer used for zymography.

10. Senescence associated β -galactosidase staining (SA- β -Gal)

To evaluate cell senescence, staining with SA- β -Gal was performed. After treatment, cells were washed with PBS and fixed with PBS-2% PFA and 0.2% glutaraldehyde for 5 minutes at RT. Then, cells were washed with PBS and incubated for 16 hours at 37°C with the staining solution (Table 24). Next day, cells were washed with PBS and then with methanol. Cells were air-dried at RT in the darkness (Debacq-Chainiaux et al., 2009).

Component	Final concentration
Citric acid/sodium phosphate (pH 6.0)	40 mM
Potassium ferrocyanide	5 mM
Potassium ferricyanide	5 mM
NaCl	150 mM
MgCl ₂	2 mM
5-bromo-4-chloro-3-indolyl- β D-galactopyranoside in methylformamide	1 mg/ml

Table 24. SA- β -Gal staining solution.

Photographs were taken under a phase contrast microscopy (Eclipse TE300, Nikon, connected to a camera Nikon Digital Sight DS-U2).

11. Analysis of apoptosis by propidium iodide (PI) staining

250,000 oval cells were seeded in triplicate in 35 cm dishes in DMEM-10% FBS. After treatment, plates were washed twice with cold PBS and fixed using a mixture of methanol and acetic acid (3:1) for 30 minutes at RT. Next, cells were washed twice with PBS and stained for 20 minutes at 37°C with a staining solution prepared in PBS (Table 25). Finally, dishes were washed with PBS and coverslipped with Mowiol mounting medium (del Castillo et al., 2008b).

Component	Final concentration
PI (Sigma P-417)	5 μ g/ml
TritonX-100	0.1 %
EDTA	0.1 M
RNAsa (Sigma)	25 U/ml

Table 25. PI staining solution.

Apoptotic cells were observed under an inverted fluorescence microscope (Eclipse TE300, Nikon) using a 60X objective, following standard morphological criteria. At least 15 fields were counted per plate in a blinded manner.

12. Measurement of intracellular ROS

For visualization and analysis of intracellular ROS the oxidation-sensitive probe DCFH-DA (2', 7'-Dichlorofluorescein diacetate, Molecular Probes) at 5 μ M was used. This compound diffuses into cells and turns into highly fluorescent 2',7'-dichlorofluorescein upon oxidation by reactive oxygen species, mainly hydrogen peroxide (Herrera et al., 2001).

12.1. Analysis by confocal microscopy

For confocal microscopy analysis, cells were seeded on gelatin-coated glass coverslips in 6 cm dishes in DMEM-10% FBS. After treatment with different factors cells were washed with PBS and loaded with DCFH-DA (5 μ M) for 30 minutes at 37°C. Cellular fluorescence intensity was visualized by using a confocal microscope and a 60X objective (Olympus FV1200, Flow Cytometry and Microscopy Core Facility at UCM).

12.2. Analysis by flow cytometry

To analyze the intracellular generation of ROS by flow cytometry cells were detached by trypsinization and centrifuged at 1,200 rpm for 5 minutes at 4°C. Then, cells were washed and resuspended in PBS, transferred to cytometry tubes and incubated with DCFH-DA for 30 minutes (37°C). The cellular fluorescence intensity was measured by FACScalibur (Becton Dickinson, Flow Cytometry and Microscopy Core Facility at UCM). 10,000 cells were recorded in each analysis.

13. Gene silencing by siRNA

Transient Twist1 knockdown was performed by transfection with a mouse Twist1 siRNA-SMART pool (Dharmacon, M-055047-01-0005). Non-targeting siControl (NT) (Dharmacon, D-001210-03-05) was used as a negative control. For siRNA transfection, we used TransITsiQuest reagent (Mirus) according to the manufacturer's recommendation and a final siRNA concentration of 100 nM. Cells were transfected twice to warrant down-regulation during the whole process. 24 hours after first transfection, cells were serum starved and treated with TGF- β for 48 hours. Then, medium was removed and we performed a second transfection. Medium was subsequently replaced with complete medium supplemented with TGF- β . Experiment was stopped at different time points.

14. Intrasplenic transplantation of oval cells

As recipients for cell transplantation we used mice submitted to CCl₄-induced liver injury. For that, five-nine week-old mice (C57/Bl6) received bi-

weekly intraperitoneal injections of 3 μ l CCl₄/g body weight (solution of 10% CCl₄ in mineral oil) for four weeks before transplantation. CCl₄ treatment continued post-transplantation until mice sacrifice.

At transplantation, mice were randomly assigned to 3 groups: PBS-group (animals injected with PBS); OC-GFP-group (animals transplanted with OC-GFP), and T β T-OC-GFP-group (animals transplanted with T β T-OC-GFP).

Surgery was performed as follows: once mouse was anesthetized (isoflurane inhalation anesthesia), an incision was made to allow access to the spleen. Either PBS or cells (2.5x10⁶cells/100 μ l PBS) were slowly infused into the spleen with a 29 gauge needle. Spleen was ligated with thread to avoid hemorrhage. Finally, the wound was closed with suture.

Animals were sacrificed 1 week or 8 weeks after transplantation and 72 hours after last injection to eliminate acute effects of CCl₄.

14.1. Sample collection

Under anesthesia (using inhalatory isoflurane), the thoracic cavity was opened to expose the heart. Blood was obtained by cardiac puncture using a 1 ml heparinized hypodermic syringe and a 25 gauge needle and placed in eppendorf tubes. Blood samples were allowed to clot at RT and centrifuged at 1,800 rpm for 10 min at RT for serum separation. Serum was immediately frozen and stored at -80°C until analysis.

The whole liver was removed. Part of the liver lobes were thinly sectioned and fixed in 10% formalin solution (Sigma) overnight. Then, they were washed 3 times with PBS and immersed in PBS-30% sucrose, PBS-20% sucrose and PBS-10% sucrose, consecutively. Next, the tissue was embedded in paraffin, sectioned (4 μ m) and stained with hematoxylin and eosin (H&E). Preparation of the tissue samples in paraffin and H&E was performed at the Department of Pathological Anatomy of the HCSC.

The remaining portions of the liver were immediately snap-frozen in liquid nitrogen and collected in RNase-free tubes for DNA extraction.

15. Analysis of serum parameters

L-aspartate aminotransferase (L-AST) and alanine aminotransferase (L-ALT) activities were measured in blood serum at the laboratory of “Centro de Análisis Sanitarios” (Madrid) using gold-standard methods.

16. Histopathological analysis of liver damage

H&E stained liver sections were analyzed by Dr. Julián Sanz (head of the Department of Pathological Anatomy, HCSC). He evaluated histopathological changes observed in the CCl₄ experimental model (Liedtke et al., 2013) such as central hepatocytes damage (ballooning) and necrosis with steatosis and a mixed inflammatory cells infiltrate, with variable intensity and extent (by confluent bridging) that were scored as follows:

- 0: Normal liver.
- 1: Minimal centrilobular steatosis and hepatocytic changes.
- 2: Centrilobular steatosis with occasional bridges.
- 3: Frequent centro-central and centro-portal bridges without complete lobulation.
- 4: Extense lobulation.

17. Statistical analysis

Means \pm standard error of the mean (S.E.M) were used to describe each of the variables analysed. When only one experiment was shown, data have been represented as the mean value \pm standard deviation (S.D.). An unpaired Student's t-test or one-way ANOVA followed by the Bonferroni post hoc test were used to compare different variables between two or more experimental groups, respectively. Longitudinal studies were performed using paired or unpaired Student's t-test as appropriate. For all analysis, p values below 0.05 were considered statistically significant and were indicated in each figure. All statistical analyses were performed using GraphPad Prism 8 software.

8. Results

1. TGF- β induces partial EMT in oval cells

TGF- β participates in different stages of chronic liver disease, having a critical role in the development of liver fibrosis. In this context, TGF- β -induced EMT is believed to be very important (Watsky et al., 2010; Zeisberg et al., 2007). On the other hand, HGF/Met signaling has been shown to be crucial for an efficient liver regenerative response, both hepatocyte and oval cell-mediated (Huh et al., 2004; Ishikawa et al., 2012). However, whether oval cells are an important target for TGF- β during liver fibrosis and whether HGF/Met signaling could modulate oval cell response to TGF- β in this context need to be clarified.

As indicated in background section, previous experiments performed in our laboratory (Almale et al., 2019) indicated that acute treatment with TGF- β induces EMT in oval cells and that loss of Met tyrosine kinase activity does not interfere with such response. Further studies also showed that under chronic treatment with TGF- β , oval cells with a functional Met receptor acquire a stable EMT phenotype and functional advantages, like apoptosis resistance and glycolytic shift. Taken all this into consideration, we decided to further characterize the effect of TGF- β -induced EMT on oval cell biology and function and to investigate the potential relevance of the crosstalk between TGF- β and HGF/Met pathways for oval cells in the context of an EMT.

1.1. TGF- β induces phenotypic changes in oval cells

First, we performed a detailed characterization of the phenotypic changes induced in oval cells in response to chronic TGF- β treatment. For this, oval cells were treated with 1 ng/ml TGF- β for 48 hours followed by continuous subculture in the presence of TGF- β 0.5 ng/ml. We used untreated oval cells as control and oval cells treated with 1 ng/ml TGF- β for 48 hours (acute treatment) as a reference for acute TGF- β treatment. Hereinafter, oval cells chronically treated with TGF- β will be referred to as TGF- β treated oval cells (T β T-OC) to distinguish them from untreated oval cells.

RT-qPCR analysis of Snai1 (Snail) and its target Cdh1 (E-cadherin) was performed. Snai1 is one of the most relevant EMT-inducing TF and Cdh1 (E-cadherin) is a cell-to-cell contact protein of the cadherin family considered as an epithelial cell marker (Cano et al., 2000). Results showed an important induction of Snai1 together with a decrease in the expression of Cdh1 after acute treatment with TGF- β respect to untreated oval cells. Chronically treated cells maintained Snai1 induction although lower than acutely treated cells, however, Cdh1 expression was heterogeneous, being low in some cell lines while in others was even higher than in parental oval cells (**Figure 26**)

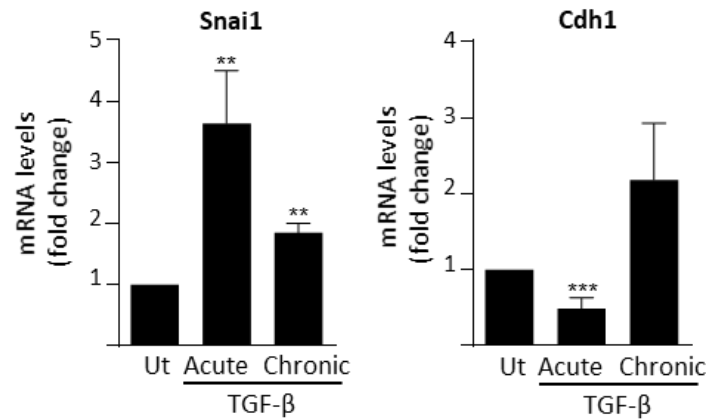

Figure 26. Analysis of the expression of Snai1 and Cdh1 in oval cells treated with TGF- β . Total RNA was isolated from oval cells untreated (Ut) or treated with TGF- β (1 ng/ml) in 0% FBS medium for 48 hours (Acute) or oval cells chronically treated with TGF- β (cultured in 0% FBS medium for 48 hours) (Chronic). Snai1 and Cdh1 mRNA levels were determined by RT-qPCR and normalized to Gusb. Data are expressed relative to the untreated group and are mean \pm S.E.M. of 11 independent experiments. ** = $p < 0.01$, *** = $p < 0.001$ versus untreated oval cells. Five different TGF- β chronically treated cell lines were used.

We next analyzed the protein levels of E-CADHERIN and other EMT markers by western blot and/or immunocytochemistry. Consistent with RT-qPCR data, we found a decrease in E-CADHERIN levels during acute treatment together with a heterogeneous profile in chronically treated cells with T β T-OC lines showing either low or high E-CADHERIN levels (Figure 27a, b and c). As additional epithelial markers we chose L-CADHERIN, another member of the cadherin superfamily of proteins whose expression is restricted to epithelial cells of the gastrointestinal system (Liu et al., 2009); and OCCLUDIN, a protein component of tight junctions. While L-CADHERIN showed a decrease after acute TGF- β treatment, OCCLUDIN did not show significant changes. However, both were downregulated in T β T-OC lines (Figure 27a and b). Contrarily, analysis of N-CADHERIN and VIMENTIN, two mesenchymal markers, showed an increased expression in T β T-OC lines (Figure 27a, b and c).

In parallel, we analyzed ZO-1 expression pattern by confocal microscopy as other component of the tight junctions. ZO-1 protein displayed a change from cell to cell contact sites to a diffuse intracellular distribution (Figure 27c), a phenomenon commonly observed during EMT (Polette et al., 2007).

Altogether, these results would indicate that chronic treatment with TGF- β induces an EMT in oval cells as it mediates the loss or reorganization of some epithelial markers and the gain of mesenchymal markers. The fact that the phenotypic change is not associated with E-cadherin loss suggests a partial rather than a full EMT response.

Figure 27. Epithelial and mesenchymal markers in oval cells treated with TGF- β . **a)** Total proteins were extracted from oval cells untreated (Ut) or treated with TGF- β (1 ng/ml) in 0% FBS medium for 48 hours (Acute) or oval cells chronically treated with TGF- β cultured in 0% FBS medium for 48 hours (Chronic). Western blot assay was performed for the analysis of the indicated proteins using β -ACTIN as loading control. A representative experiment using three different T β T-OC lines (designated #1, #2 and #3) is shown. **b)** Optical density values relative to loading control were calculated. Data are expressed relative to untreated (Ut) oval cells and are mean \pm S.E.M. of 3-5 independent experiments (n=3-18). * = $p < 0.05$, ** = $p < 0.01$ versus untreated oval cells. **c)** Untreated and TGF- β chronically treated oval cells maintained in 10% FBS medium were fixed and stained with specific primary antibodies for the indicated proteins and a fluorescent secondary antibody. Nuclei were counterstained with DAPI. Representative confocal microscopy images from 2-3 independent experiments are shown. Scale bar=20 μ m. At least three different T β T-OC lines were used in both analyses.

1.2. TGF- β -induced EMT in oval cells is associated with decreased stemness

Evidence in the literature supports the concept the EMT process induced by TGF- β in epithelial cells correlates with a less differentiated phenotype and acquisition of stem cell properties (Abell and Johnson, 2014; Jayachandran et

al., 2016). We therefore analyzed if TGF- β -induced EMT somehow affected oval cell stemness.

We first checked the mRNA levels of different stem cell markers, Epcam, Cd44 and Prom1 (CD133), in oval cells and T β T-OC. Our data revealed a downregulation of Epcam and Prom1 in T β T-OC, markers usually associated with epithelial cells (Malfettone et al., 2017), with no significant changes in Cd44 (Figure 28a). In parallel to the RT-qPCR analysis, we also studied EPCAM and CD44 protein levels by flow cytometry. EPCAM-positive oval cells, measured both as percentage of positive cells and mean of fluorescence intensity, decreased in T β T-OC (Figure 28b and c). However, CD44-positive cells did not change between OC and T β T-OC (Figure 28b and c). Therefore, flow cytometry analyses confirmed RT-qPCR results.

Figure 28. Analysis of stem cell markers in oval cells and T β T-OC. **a)** Oval cells and T β T-OC were maintained in 0% FBS medium for 48 hours, and total RNA was isolated. Epcam, Prom1 and Cd44 mRNA levels were determined by RT-qPCR and normalized to Gusb. Data are expressed relative to oval cells and are mean \pm S.E.M. of 4-6 independent experiments performed in triplicate. *** = $p < 0.001$ versus oval cells. **b-c)** Oval cells and T β T-OC maintained in 10% FBS medium were stained with specific antibodies for EPCAM and CD44 or with isotype controls, and analyzed by flow cytometry. **b)** Representative histograms are shown. **c)** Percentage of positive cells and fluorescence intensity (F.I.) values are mean \pm S.E.M. of 2 independent experiments ($n=2-6$). Three different T β T-OC lines were used in both analyses.

Additionally, we performed clonogenic and sphere formation assays under anchorage-independent conditions. This could help us to determine if there were any alterations in the clonogenic and self-renewal capacity, typical stem cells properties (Cao et al., 2011; Pastrana et al., 2011) that are observed in oval cells, in TβT-OC.

Figure 29. Analysis of stem cell properties in oval cells and TβT-OC. **a)** Oval cells and TβT-OC were seeded at low density and maintained in 10% FBS medium for up to 8-10 days and number of colonies were counted. Data are expressed relative to oval cells and are mean ± S.E.M. of 3 experiments performed in triplicate. ** = $p < 0.01$ versus oval cells. **b)** Representative images of the whole plate and phase contrast microscopy images of individual colonies (border areas) are shown. Scale bar=100 μm. **c)** Oval cells and TβT-OC were seeded in ultra-low-attachment plates in 0% FBS medium supplemented with factors for up to 15 days. Graph shows the number of spheroids per well, distributed according to their diameter. Data are mean ± S.E.M. of 2 independent experiments (n=2-5). **d)** Representative phase contrast microscopy images of formed spheroids are shown. Scale bar=50 μm. At least two different TβT-OC lines were used in both analyses.

Clonogenic assay revealed a decrease in the clonal growth capacity of TβT-OC in comparison to oval cells (Figure 29a). Interestingly, colonies formed by TβT-OC were bigger than oval cell colonies and morphologically different. Consistent with the acquisition of a mesenchymal and more migratory phenotype upon EMT, TβT-OC loosed cell adhesion, occupied a larger cell spreading area and grew in a more disorganized manner overall resulting in less tight colonies. This phenomenon was very clear at the colonies periphery where cells become very loose. This was opposed to what was seen with oval cells, which showed stronger cell-cell adhesions and formed tightly packed colonies

with more defined borders (**Figure 29b**). Concerning the spheroid formation assay, culture was maintained over time and once per week we took pictures of the spheres formed by each cell line. Number and diameter of spheres were measured to control the evolution of the spheres. The assay failed to reveal significant differences in the ability to form spheres between T β T-OC and oval cells, although T β T-OC showed a tendency to form bigger spheres (**Figure 29c and d**).

Collectively, these data suggest that EMT induced in oval cells by chronic treatment with TGF- β does not result in acquisition of stem cell properties.

1.3. TGF- β -induced EMT in oval cells is associated with alterations in hepatic lineage markers

Since Epcam is also a marker of hepatic progenitor cells (Chen et al., 2017; Itoh and Miyajima, 2014), and showed a decreased expression in T β T-OC, we further explored the effects of EMT on the intrinsic lineage features of oval cells.

We first analyzed the expression of CK19 and ALBUMIN, two commonly used markers of oval cells (Chen et al., 2017).

Figure 30. Analysis of oval cells markers in oval cells and T β T-OC. **a)** Oval cells and T β T-OC were maintained in 0% FBS medium for 48 hours, and total proteins were isolated. Western blot assay was performed for the indicated proteins using β -ACTIN as loading control. A representative experiment using three different T β T-OC lines (designated #1, #2 and #3) is shown. **b)** Optical density values relative to loading control were calculated. Data are expressed relative to oval cells and are mean \pm S.E.M. of 2 independent experiments (n=2-10). **c)** Oval cells and T β T-OC maintained in 10% FBS medium were fixed and stained with specific primary antibodies for the indicated proteins and a fluorescent secondary antibody. Nuclei were counterstained with DAPI. Representative confocal microscopy images out of 2-3 independent experiments are shown. Scale bar=20 μ m. At least two different T β T-OC lines were used in both analyses.

Western blot analysis showed no changes in CK19 expression levels in T β T-OC as compared to oval cells whereas ALBUMIN showed a slight increase (Figure 30a and b). Same results were obtained by confocal microscopy analysis (Figure 30c).

To characterize in more detail the phenotype of T β T-OC, we studied the expression of other hepatocyte and biliary epithelial cell lineage markers including members of the hepatocyte nuclear factors family (HNF) since oval cells are bipotential progenitor cells that can differentiate into both hepatocytes and cholangiocytes.

We found a sharp decrease in Hnf1b, Onecut1 (Hnf6) mRNA levels of T β T-OC when compared to oval cells (Figure 31). All of these genes are predominantly expressed in biliary epithelial cells and are required for the normal development of biliary tract (Clotman et al., 2002; Limaye et al., 2008; Nagy et al., 1994). Gamma-glutamyltransferase (Ggt), a biliary epithelial cell marker expressed in oval cell, was also downregulated in T β T-OC (Figure 31). On the other hand, Hnf4a, a transcription factor that is essential for the differentiation into hepatocytes (Watt et al., 2003), and alpha-fetoprotein (Afp), a marker of immature hepatocytes, were upregulated in T β T-OC (Figure 31).

Figure 31. Analysis of biliary epithelial and hepatocyte lineage markers in oval cells and T β T-OC. Oval cells and T β T-OC were maintained in 0% FBS medium for 48 hours, and total RNA was isolated. Hnf1b, Onecut1, Ggt, Hnf4a and Afp mRNA levels were determined by RT-qPCR and normalized to Gusb. Data are expressed relative to oval cells and are mean \pm S.E.M. of 3-7 independent experiments. * = $p < 0.05$, *** = $p < 0.001$ versus oval cells. At least two T β T-OC lines were used.

Based on these results, we could state that chronic treatment of oval cells with TGF- β results in a decrease of biliary epithelial cell markers and increase in hepatocyte markers. These data suggest that EMT could be associated with a step forward in the hepatocyte lineage differentiation of oval cells.

1.4. TGF- β -induced EMT in oval cells is associated with alterations in the autocrine signaling

EMT is able to induce changes in the secretory phenotype of cells, increasing the expression of some ligands (Reka et al., 2014). Concretely, our group has demonstrated that EMT in fetal hepatocytes induces an autocrine loop of TGF- β 1, which increases EGFR ligands production (Del Castillo et al., 2006).

Taking these results into account, we wanted to determine possible changes in the T β T-OC autocrine signaling, thus we checked the expression of TGF- β 1, TGF- α , as an EGFR ligand, and other growth factors related to EMT.

Our RT-qPCR analysis showed that oval cells secrete Tgfb1, Tgfa or Ctgf, an extracellular matrix-associated protein of the CCN family, but no changes in the expression of these ligands were observed in T β T-OC (**Figure 32**). However, we found differences in the expression levels of some isoforms of PDGF family ligands. PDGF ligands through binding to tyrosine-kinase receptors stimulate proliferation, growth differentiation, secretion of growth factors and, in some circumstances, contribute to regulate EMT (Andrae et al., 2008; Gotzmann et al., 2006). Among the different Pdgf isoforms analyzed, Pdgfb expression was not altered in T β T-OC, but Pdgfa and c were upregulated in T β T-OC respect to oval cells (although data did not reach statistical significance) and Pdgfd was significantly down-regulated in T β T-OC (**Figure 32**). These data suggest TGF- β chronic treatment of oval cells modifies gene expression profile of some growth factors, which could be relevant for cell phenotype and behavior.

Figure 32. Analysis of ligands in oval cells and T β T-OC. Oval cells and T β T-OC were maintained in 0% FBS medium for 48 hours, and total RNA was isolated. Tgfb1, Tgfa, Ctgf, Pdgfa, b, c, and d mRNA levels were determined by RT-qPCR and normalized to Gusb. Data are expressed relative to oval cells and are mean \pm S.E.M. of 3-6 independent experiments. *** = $p < 0.001$ versus oval cells. At least three T β T-OC lines were used.

1.5. TGF- β -induced EMT in oval cells confers functional advantages

It is widely established that cells that have undergone an EMT acquire growth, survival, migratory and invasive advantages (Brabletz et al., 2018; Kim et al., 2017a). We therefore investigated if T β T-OC have gained any of these functional changes.

First, we analyzed cell growth capacity in response to the mitogenic signals present in the serum. In these conditions, we found that T β T-OC showed identical cell growth rate than parental cells (Figure 33a). When we performed this assay in the absence of serum, oval cells displayed a significant decrease in cell number, because of the apoptotic response elicited by serum withdrawal (del Castillo et al., 2008b). However, T β T-OC showed an increase in cell number (Figure 33b), indicating that T β T-OC have acquired an intrinsic growth capacity.

Figure 33. Analysis of cell growth in oval cells and T β T-OC. a) Oval cells and T β T-OC were maintained in 10% FBS medium for different periods of time up to 7 days and were counted. Data are expressed respect to zero time and are mean \pm S.E.M. of 2-7 independent experiments performed in triplicate. b) Oval cells and T β T-OC were maintained in 0% FBS medium for 48 hours and were counted. Data are expressed respect to zero time and are mean \pm S.E.M. of 14 independent experiments performed in triplicate. *** = $p < 0.001$ versus zero time or as indicated. At least three different T β T-OC lines were used in both analyses.

We next examined the invasive capacity of T β T-OC in comparison with oval cells. To address this question, we plated cells on matrigel-coated transwells. Due to their invasive cell capacity, cells passed through the matrigel to the other side of the membrane in the absence of exogenous stimuli. Quantitative analysis of cell invasion assays showed that T β T-OC have acquired invasive advantages as compared to oval cells (Figure 34a and b).

Figure 34. Analysis of the invasive capacity in oval cells and TβT-OC. a) Oval cells and TβT-OC were plated in 0% FBS medium in the upper 24-transwell units coated with matrigel. Cells were allowed to pass through matrigel-coated filters for 24 hours and then were fixed in PFA and stained with crystal violet and counted by phase contrast microscope (14 random fields). Data are expressed relative to oval cells and are mean \pm S.E.M. of 9 independent experiments performed in triplicate. *** = $p < 0.001$ versus oval cells. b) Representative phase contrast microscopy images of invading cells are shown. Scale bar=100 μ m. Five different TβT-OC lines were used.

The role of MMPs in the extracellular matrix degradation during cell migration/invasion is well recognized (Kessenbrock et al., 2010). Particularly, results of our group have demonstrated the involvement of some MMPs in the pro-invasive activity triggered by HGF/Met in oval cells (Suarez-Causado et al., 2015). This prompted us to analyze a potential implication of MMPs in the TβT-OC invasive phenotype.

Hence, we analyzed in oval cells and TβT-OC the mRNA levels of Mmp2, 9, 10 and 13 and Timp1 and 3. As shown in **figure 35a**, Mmp2, 10 and 13 were significantly increased in TβT-OC. However, chronic EMT in oval cells did not modify the Mmp9 mRNA expression. With respect to TIMPs, while Timp1 was downregulated, Timp3 mRNA levels were higher in TβT-OC (**Figure 35a**).

Additionally, we measured the gelatinase activity by performing gelatin zymography, and found that MMP9, whose expression hardly changes in TβT-OC, showed an increased activity in TβT-OC, as compared to oval cells (**Figure 35b**), suggesting post-transcriptional regulation of MMP9. Besides, despite the increase in Timp3 expression in TβT-OC, zymography assays demonstrated MMPs activity in TβT-OC.

These results show that chronic EMT induces changes in MMPs and TIMPs expression in oval cells, which likely participate in the TβT-OC invasive capacity. A specific role for MMP9 is suggested.

Figure 35. Analysis of MMPs and TIMPs in oval cells and TβT-OC. **a)** Oval cells and TβT-OC were maintained in 0% FBS medium for 48 hours, and total RNA was isolated. Mmp2, 9, 10, 13, Timp1 and Timp3 mRNA levels were determined by RT-qPCR and normalized to Gusb. Data are expressed relative to oval cells and are mean \pm S.E.M. of 3-7 independent experiments. **b)** Pro-MMP9 activities were analyzed by zymography. The bar graph shows the quantitative analysis of zymography. Optical density values are expressed relative to oval cells and are mean \pm S.E.M. of 3 independent experiments. * = $p < 0.05$ versus oval cells. Two different TβT-OC lines were used in both analyses.

Putting it all together, the acquisition of intrinsic growth capacity and a higher invasive capacity of TβT-OC, added to previous results of the group (see background section) such as an apoptosis-resistant phenotype and a switch in their bio-energetic profile towards a more glycolytic phenotype, indicate that EMT confers key functional advantages to oval cells.

1.6. EMT enhances oval cells repopulation capacity in a damaged liver

Since the *in vitro* approaches taken so far show that TβT-OC had acquired functional advantages, our next goal was to analyze whether these changes conferred growth/survival advantages to TβT-OC *in vivo*, in an injured liver.

To this end, we used an animal model of hepatic fibrosis induced by CCl₄ injections. Wild type mice were subjected to 4 weeks of CCl₄ treatment (intraperitoneal injections of 3 μ l CCl₄/g of body weight twice a week), and then

we performed intrasplenic injection of parental oval cells and TβT-OC, previously transduced with GFP (OC-GFP, TβT-OC-GFP), and PBS as control. CCl₄ treatment was maintained after transplantation and mice were sacrificed 1 week or 8 weeks after transplantation as depicted in **figure 36**.

Figure 36. Scheme of CCl₄-induced liver fibrosis model and cell transplantation assay.

First, we analyzed the engraftment of oval cells and TβT-OC in the liver of transplanted mice by two different approaches.

Figure 37. Detection of transplanted cells in host livers. a) Immunofluorescence staining was performed using a specific anti-GFP antibody in liver sections 1 week after transplantation. Nuclei were stained with DAPI. Representative confocal microscopy images of one mouse and two mice transplanted with OC-GFP and TβT-OC-GFP, respectively are shown. Arrowheads indicate GFP-positive cells corresponding to engrafted OC-GFP and TβT-OC-GFP. **b)** Genomic DNA was isolated from livers of mice injected with PBS, OC-GFP and TβT-OC-GFP 1 and 8 weeks after transplantation. DNA was used for PCR analysis of the floxed allele. DNA from cultured oval cells and water were used as a positive (Pos.) and negative (Neg.) control, respectively.

On the one hand, we performed immunofluorescence staining with anti-GFP antibody on liver sections to visualize GFP-positive cells engrafted in the liver parenchyma after 1 week of transplantation (**Figure 37a**). Interestingly, GFP-positive cells are more abundant and form larger cell clusters in livers from mice transplanted with T β T-OC when compared to those transplanted with oval cells, suggesting a better engraftment or enhanced cell survival and/or proliferation upon engraftment. Unfortunately, we were not able to detect GFP-positive cells 8 weeks after transplantation using this approach, so we decided to run a PCR for detection of the floxed allele carried by oval cells and T β T-OC to confirm the presence of transplanted cells in the liver, obtaining positive results at both time points (**Figure 37b**).

Once we had confirmed that oval cells and T β T-OC were integrated in host livers, we evaluated the impact of transplanted cells on damaged liver. We measured liver function parameters in serum, in particular aspartate aminotransferase (AST) (**Figure 38a**) and alanine aminotransferase (ALT) (**Figure 38b**), which are elevated during liver damage. T β T-OC-transplanted animals showed a reduction in the increase of AST and ALT provoked by CCl₄ treatment, in comparison to mice that received PBS only or those transplanted with oval cells. In the case of AST, differences were statistically significant.

Figure 38. Analysis of liver function parameters in mice transplanted with oval cells and T β T-OC. a-b) Analysis of AST and ALT serum levels in untreated mice, CCl₄-treated mice and mice transplanted with OC-GFP, T β T-OC-GFP and PBS 8 weeks after transplantation. Data are expressed respect to untreated mice and are mean \pm S.E.M. of 4-9 animals per group. * = $p < 0.05$, ** = $p < 0.01$ versus untreated group or as indicated.

To reinforce these data we analyzed the collagen deposition by Sirius red staining as a way to measure the grade of fibrosis. As expected, 1 week after transplantation (e.g. after 5 weeks of treatment with CCl₄) PBS-injected livers presented a high-degree of fibrosis, compared with untreated mice, which was not altered in livers of mice transplanted with oval cells and T β T-OC (**Figure 39a**). However, results corresponding to 8 weeks after transplantation support those obtained from liver function test, being the livers from T β T-OC-transplanted mice the ones that display the lowest fibrosis degree. Interestingly, oval cell transplanted animals also showed a trend to present a decreased liver fibrosis (**Figure 39b and c**).

Figure 39. Analysis of liver fibrotic area in mice transplanted with oval cells and TβT-OC. **a-b)** Fibrotic area (Sirius red-stained area) was measured in liver sections from untreated mice, CCl₄-treated mice and mice transplanted with OC-GFP, TβT-OC-GFP and PBS 1 and 8 weeks after transplantation. 4-6 animals per experimental group were used. Data are expressed as % mean of fibrotic area. * = $p < 0.05$, *** = $p < 0.005$ versus untreated group or as indicated. **c)** Representative phase contrast images of Sirius red staining in liver tissue sections (8 weeks after transplantation). Scale bar=500 μm (upper panels) and 100 μm (lower panels).

These data were confirmed by a histopathological assessment of the grade of liver damage performed by a single pathologist. Common histopathological changes caused by CCl₄ treatment (Liedtke et al., 2013) were detected in H&E-stained liver sections from all mice groups (Figure 40a). However, differences in the intensity and the extension of the damage were observed between groups. A scoring system was established (see material and methods for details), which comprised values between 0, normal liver, to 4, severe damage. Thus, while the majority of the mice from PBS and OC-transplanted groups were assigned scores 2-4, TβT-OC-transplanted mice got lower scores (1 and 2) (Figure 40b). It is noteworthy that no hepatocarcinoma nodules were identified in any case.

Figure 40. Histopathological assessment of liver damage in mice transplanted with oval cells and TβT-OC. a-b) H&E staining of liver sections from untreated mice, CCl₄-treated mice and mice transplanted with OC-GFP, TβT-OC-GFP and PBS 8 weeks after transplantation were evaluated. **a)** Representative phase contrast images. Scale bar=100 μm. **b)** Number of mice with a particular score in each experimental condition (n=4-6) is indicated.

These results, all together, provide evidence supporting that transplanted TβT-OC improve liver function in CCl₄-damaged livers, therefore, treatment with TGF-β confers unique properties to oval cells that improve their regenerative potential, ultimately resulting in a reduction of liver damage.

In order to understand the molecular mechanisms that could explain how TβT-OC could attenuate liver fibrosis, we analyzed mRNA levels of Hgf, a well-known anti-fibrotic and pro-regenerative factor. Livers 8 weeks post-transplantation showed higher expression levels of Hgf in mice transplanted with OC and TβT-OC when compared to PBS infusion, reaching the highest levels with TβT-OC, although differences are not significant (**Figure 41**). Additionally, based on the results showing a step forward in the hepatocyte lineage in oval cells after EMT (**Figure 31**), we checked Cytochrome P450 7a1 (Cyp7a1) expression, as a marker of liver maturation. Cyp7a1 showed the same pattern observed for Hgf expression, with the highest levels in livers from TβT-OC-transplanted mice (**Figure 41**).

These results serve as evidence of a regeneration process taking place in transplanted livers and suggest a role of HGF in this process.

Figure 41. Analysis of the expression of Hgf and Cyp7a1 in hepatic tissue from mice transplanted with oval cells and TβT-OC. Total RNA was isolated from CCl₄-treated mice and mice transplanted with OC-GFP, TβT-OC-GFP and PBS 8 weeks after transplantation. Hgf and Cyp7a1 mRNA levels were determined by RT-qPCR and normalized to Gusb. Data are expressed respect to PBS group and are mean ± S.E.M. of 4-6 animals per group. * = $p < 0.05$, ** = $p < 0.01$ versus PBS group.

2. Relevance of HGF/Met pathway in TGF-β-induced-EMT in oval cells

As described in background section, previous results of our group using oval cells expressing a mutant Met receptor lacking tyrosine kinase activity ($Met^{-/-}$) showed that $Met^{-/-}$ oval cells undergo an acute EMT by TGF-β treatment in a similar manner to their normal counterparts, $Met^{flx/flx}$ oval cells (Almale et al., 2019). These data indicate that absence of Met kinase activity does not interfere with acute induction of EMT by TGF-β in oval cells. However, whether Met signaling could somehow be involved in the chronic EMT response triggered by TGF-β was not clear. So, we decided to explore this question.

2.1. Lack of Met tyrosine kinase activity induces replicative senescence and impedes oval cell expansion after chronic EMT

Following the same experimental protocol used to generate TβT-OC $Met^{flx/flx}$ lines, we tried to generate TβT-OC from $Met^{-/-}$ oval cells (**Figure 42a and b**).

As expected, the behavior of the two cell lines, $Met^{flx/flx}$ and $Met^{-/-}$, was similar during the acute treatment with TGF-β except for the higher apoptosis rate of $Met^{-/-}$ oval cells compared to $Met^{flx/flx}$. However, after the first passage differences between cell lines emerged. $Met^{flx/flx}$ oval cells maintained a typical mesenchymal phenotype and after a brief interval of time they acquired a growth rate similar to that of untreated cells (prior to TGF-β treatment). Thus, subsequent passages lead to establishment of a stable TβT- $Met^{flx/flx}$ oval cell line. However, $Met^{-/-}$ oval cells acquired senescent cell-like appearance after the first passage. They became large flat cells with a big cytoplasm, which were not able to progress in culture (**Figure 42b**). Phenotypical appearance of $Met^{-/-}$ oval

cells suggested that these cells were undergoing a senescence process in response to chronic TGF- β treatment.

Figure 42. Generation of T β T-Met^{flx/flx} and T β T-Met^{-/-} oval cells.

a) Scheme of the protocol followed for the generation of T β T-Met^{flx/flx} and T β T-Met^{-/-} oval cells. **b)** Representative phase contrast microscopy images corresponding to Met^{flx/flx} and Met^{-/-} oval cells at specific phases during the T β T-OC generation process: prior to TGF- β treatment, acute and chronic treatment with TGF- β .

To confirm this hypothesis, we analyzed some of the common markers used for identifying senescent cells. First, we performed a SA- β -Gal staining to detect the β -galactosidase activity, a hydrolase enzyme that catalyzes the hydrolysis of β -galactosides into monosaccharides only in senescent cells (Debacq-Chainiaux et al., 2009). The assay showed a positive staining for SA- β -Gal in T β T-Met^{-/-} cells already at passage 1, while T β T-Met^{flx/flx} cells were negative for this staining (**Figure 43a**).

Additionally, we studied the expression of CKIs, cell cycle inhibitors considered as senescence markers, due to the strong link between cell cycle arrest and senescence (Hernandez-Segura et al., 2018; Kulman et al., 2010). Particularly, we checked the expression of two members of INK4 family, Cdkn2b (p15) and Cdkn2a (p19) and two members of Cip/Kip family, Cdkn1a (p21) and Cdkn1b (p27).

The expression of these CKIs was analyzed during the course of establishment of T β T-OC lines. Thus, we collected samples from T β T-Met^{flx/flx} and T β T-Met^{-/-} oval cells at different passages (p1/2 and p5). However, samples of passages after p1 could only be collected in the case of T β T-Met^{flx/flx} cells, because T β T-Met^{-/-} oval cells did not progress in culture after the first subculture. As reference, samples were also collected from Met^{flx/flx} and Met^{-/-}

oval cells untreated and acutely treated with TGF- β . In agreement with the SA- β -Gal staining results (Figure 43a), T β T-Met^{-/-} cells at p1/2 showed a significantly higher expression of Cdkn2b (p15), Cdkn2a (p19), Cdkn1a (p21) and Cdkn1b (p27) than T β T-Met^{flx/flx} (Figure 43b), further demonstrating the senescent phenotype.

Figure 43. Analysis of senescence markers after chronic treatment of oval cells with TGF- β . **a)** SA- β -Gal staining in T β T-Met^{flx/flx} and T β T-Met^{-/-} oval cells. Bright-field microscopy images are shown. Scale bar=50 μ m. **b)** Total RNA was isolated from Met^{flx/flx} and Met^{-/-} oval cells treated or not (Ut) with TGF- β (1 ng/ml) in 0% FBS medium for 48 hours. Met^{flx/flx} and Met^{-/-} oval cells were chronically treated with TGF- β in 10% FBS medium and total RNA was isolated at different passage number (p1/p2 and p5). mRNA levels of the CKIs p15, p19, p21 and p27 were determined by RT-qPCR and normalized to Gusb. Data are expressed relative to untreated Met^{flx/flx} oval cells and are mean \pm S.E.M. (n=2-8). * = $p < 0.05$, ** = $p < 0.01$, *** = $p < 0.001$ versus untreated oval cells or as indicated.

Next, we wanted to confirm that the senescence response of $\text{Met}^{-/-}$ oval cells to chronic TGF- β treatment was a direct consequence of the lack of Met tyrosine kinase activity. Thus, we used the Met inhibitor PHA665752, an ATP competitive inhibitor of the tyrosine kinase activity, to chemically mimic the behavior of $\text{Met}^{-/-}$ oval cells. First, we confirmed PHA665752 activity in $\text{Met}^{\text{flx/flx}}$ oval cells as it completely abolished HGF-induced activation of its downstream target ERKs (**Figure 44a**). Then, we proceed to generate T β T-OC from $\text{Met}^{\text{flx/flx}}$ oval cells in the presence of PHA665752. Interestingly, the treatment with Met inhibitor phenocopied $\text{Met}^{-/-}$ oval cells. Thus, cells displayed the same senescent-like phenotype observed in $\text{Met}^{-/-}$ cells upon subculture with TGF- β and stopped dividing (**Figure 44b**). This served to prove that the senescence response in oval cells was a consequence of the absence of a functional Met receptor.

Figure 44. Generation of T β T- $\text{Met}^{\text{flx/flx}}$ oval cells in the presence of PHA665752. a) $\text{Met}^{\text{flx/flx}}$ oval cells were serum starved and treated or not with HGF (40 ng/ml) for 10 minutes in the absence or presence of the Met inhibitor PHA665752 (5 μM , 1 hour-pretreatment), and total proteins were isolated. Western blot assay was performed for the indicated proteins. A representative experiment is shown. **b)** Representative phase contrast microscopy images of $\text{Met}^{\text{flx/flx}}$ and T β T- $\text{Met}^{\text{flx/flx}}$ oval cells during the T β T-OC generation process in the presence of PHA665752 (5 μM) are shown.

Altogether, these data evidence that $\text{Met}^{-/-}$ oval cells undergo cellular senescence after chronic treatment with TGF- β while highlighting that Met kinase catalytic activity is critical to allow oval cell expansion after TGF- β -induced EMT.

2.2. Met tyrosine kinase activity is essential for oval cell expansion and contributes to T β T-OC properties

To further explore the role of Met in oval cell expansion after an EMT process, we focused our efforts on the study of the role of Met tyrosine kinase activity on the functional and phenotypic properties of T β T-OC.

Since we had previously identified an autocrine HGF/Met loop in oval cells (del Castillo et al., 2008b), as previously mentioned, we wondered if this signaling loop was still operative in T β T-OC. We performed an analysis of the expression of Hgf by RT-qPCR and we observed that T β T-OC expressed higher levels of Hgf than oval cells in basal conditions, i.e. in the absence of exogenous stimulation (**Figure 45a**). To provide additional evidence of the HGF/Met autocrine signaling loop, we studied MET tyrosine phosphorylation by running immunoprecipitation assays in oval cells and T β T-OC in basal conditions. Our results confirmed MET phosphorylation, that is MET activation, in both cell lines (**Figure 45b**), proving that an autocrine HGF/Met signaling remains operative in oval cells after EMT.

Figure 45. Analysis of autocrine HGF/Met signaling in oval cells and T β T-OC. **a)** Oval cells and T β T-OC were maintained in 0% FBS medium for 48 hours, and total RNA was isolated. Hgf mRNA levels were determined by RT-qPCR and normalized to Gusb. Data are expressed relative to oval cells and are mean \pm S.D. of one representative experiment using three different T β T-OC lines. **b)** Oval cells and T β T-OC (designated #1, #2 and #3) were maintained in 0% FBS medium for 16 hours, and total proteins were isolated. Protein extracts were used for MET immunoprecipitation (IP). Phosphorylation was detected by immunoblotting (IB) with anti P-tyrosine antibody. Western blot assay for MET was used as a loading control. Control IP (without antibody) and Mock IP (without proteins) were used as controls. A representative experiment out of 4 is shown.

To further clarify the role of Met signaling in oval cell expansion and properties post-EMT, we used PHA665752 Met inhibitor. T β T-OC were pre-treated with the inhibitor for 2 weeks prior to the experiments and during the course of experiment in order to mimic Met^{-/-} oval cell conditions (**Figure 42**). PHA665752 inhibitory activity in T β T-OC was confirmed at the same dose used in oval cell. Indeed, pretreatment for 2 weeks with PHA665752 completely abolished HGF-induced MET phosphorylation and activation of its downstream target AKT (**Figure 46a**).

Importantly, long-term exposure of T β T-OC to PHA665752 inhibitor resulted in a reduced cell growth capacity. In other words, pharmacological inhibition of Met signaling inhibited the intrinsic T β T-OC growth capacity (**Figure 46b**). This, together with the cell cycle arrest observed in Met^{-/-} oval cells after chronic treatment with TGF- β (**Figure 43**) support the existence of an autocrine loop

through HGF/Met, which sustains TβT-OC growth and it is essential to allow oval cells expansion after EMT.

Figure 46. Analysis of Met tyrosine kinase inhibition in functional TβT-OC properties. a-d) TβT-OC were treated with Met inhibitor PHA665752 (5 μM) for 2 weeks. **a)** PHA665752 treated TβT-OC were serum starved and treated with HGF (40 ng/ml) for 10 minutes, and total proteins were isolated. Western blot assay was performed for the analysis of the indicated proteins using β-ACTIN as loading control. A representative experiment is shown. **b)** TβT-OC and PHA665752 treated TβT-OC were maintained in 0% FBS medium for 48 hours and counted. Data are expressed respect to zero time and are mean ± S.E.M. of 9 independent experiments performed in triplicate. **c)** TβT-OC and PHA665752 treated TβT-OC were maintained in 0% FBS medium for 24 hours and number of apoptotic nuclei after PI staining were counted under a fluorescence microscope (15 random fields). Data are expressed relative to untreated TβT-OC and are mean ± S.E.M. of 6 independent experiments performed in triplicate. **d)** TβT-OC and PHA665752 treated TβT-OC were plated in 0% FBS medium in the upper 24-transwell units coated with collagen. Cells were allowed to pass through collagen-coated filters for 24 hours and stained with crystal violet and counted by phase contrast microscope (14 random fields). Data are expressed relative to untreated TβT-OC and are mean ± S.E.M. of 5 independent experiments performed in triplicate. * = $p < 0.05$; ***, = $p < 0.001$ versus untreated TβT-OC. At least three TβT-OC lines were used in all analyses.

Besides, our data clearly showed that under PHA665752 treatment, TβT-OC cell number decreased below baseline (i.e. number of TβT-OC after 48 hours culture in the absence of serum was lower than number of cells at zero time) (Figure 46b). These data evidence that PHA665752 sensitizes TβT-OC to serum deprivation. This hypothesis was further confirmed with the analysis of apoptotic cell death. Indeed, results in Figure 46c show that treatment with PHA665752 increased TβT-OC apoptotic index under serum withdrawal.

In addition to this, T β T-OC treated with PHA665752 underwent a moderate but significant decrease in their invasive capacity, as demonstrated by the decrease in the number of cells that pass through collagen-coated transwells (Figure 46d).

Interestingly, besides the differences in cell functional capabilities, in the presence of Met inhibitor T β T-OC showed changes in the expression of epithelial (E-CADHERIN) and mesenchymal (VIMENTIN) markers consistent with acquisition of a more mesenchymal phenotype (Figure 47a and b).

Figure 47. Analysis of Met tyrosine kinase inhibition in T β T-OC phenotype. **a)** T β T-OC were treated with Met inhibitor PHA665752 (5 μ M) for 2 weeks. T β T-OC and PHA665752 treated T β T-OC were maintained in 0% FBS medium for 48 hours, and total proteins were isolated. Western blot assay was performed for the indicated protein using TUBULIN as loading control. A representative experiment using three different T β T-OC lines (designated #1, #2 and #3) is shown. **b)** Optical density values relative to loading control were calculated. Data are expressed relative to untreated T β T-OC and are mean \pm S.E.M. of 2-4 independent experiments (n=6-9). *** = $p < 0.001$ versus untreated T β T-OC.

All together, results indicate that HGF/Met autocrine loop critically regulates the phenotypic and functional properties acquired by oval cells after TGF- β -induced EMT.

On the other hand, it is worth highlighting a change in cell response to HGF after EMT. We and others have previously demonstrated that HGF is a mitogenic factor for oval cells (del Castillo et al., 2008b). However, treatment of T β T-OC with HGF did not increase their proliferation over the intrinsic cell growth capacity (Figure 48a).

A similar trend is observed in *in vitro* invasion assays. Our previous data showed that HGF increased the invasive capacity of oval cells (Suarez-Causado et al., 2015). In contrast, HGF failed to increase T β T-OC invasive capacity, which once again was higher than that observed in parental oval cells (Figure 48b).

Figure 48. Analysis of the response triggered by exogenous HGF in oval cells and TβT-OC. a) Oval cells and TβT-OC were treated or not with HGF (40 ng/ml) in 0% FBS medium for 48 hours and counted. Data are expressed respect to zero time and are mean \pm S.E.M. of 10 independent experiments performed in triplicate. **b)** Oval cells and TβT-OC were plated in 0% FBS medium in the upper chamber units coated with matrigel and were treated or not with HGF (40 ng/ml). Cells were allowed to pass through matrigel-coated filters for 24 hours and stained with crystal violet and counted by phase contrast microscope (14 random fields). Data are expressed relative to untreated cells and are mean \pm S.E.M. of 9 independent experiments performed in triplicate. **c)** Oval cells and TβT-OC were serum starved and treated with HGF (40 ng/ml) for different periods of time, and total proteins were isolated. Western blot assay was performed for the indicated proteins using β -ACTIN as a loading control. A representative experiment is shown. **d)** Optical density values relative to loading control were calculated. Data are expressed relative to untreated oval cells and are mean \pm S.E.M. of 3-4 independent experiments. * = $p < 0.05$ ***, = $p < 0.001$ versus untreated oval cells or TβT-OC or as indicated. At least three TβT-OC lines were used in all analyses.

Since TβT-OC did not response to exogenously added HGF in terms of proliferation and invasion, we next study whether these cells presented alterations in the signaling pathway triggered by HGF. For that, we analyzed phosphorylation of AKT and ERKs, two downstream targets of HGF, by western blot. We detected activation of AKT and ERKs after 10 minutes of HGF treatment, in both oval cells and TβT-OC, and was maintained along the treatment. Although differences did not reach statistically relevance, data suggest that levels of activated ERKs were higher in parental cells than TβT-OC,

and a similar trend, although less pronounced, was also observed in AKT activation (**Figure 48c and d**). These data could suggest that EMT results in a decreased activation of the HGF/Met pathway, which might explain the absence of proliferative and invasive response in T β T-OC upon HGF stimulus.

2.3. EMT-induced senescence in Met deficient oval cells is associated with oxidative stress and decreased Twist expression

Cumulative evidence support the concept that there is a strong association between cellular senescence, oxidative stress and ROS production (Chandrasekaran et al., 2017; Hernandez-Segura et al., 2018).

Previous results of our group indicated that TGF- β induces oxidative stress in oval cells, which is impaired by antioxidant signals triggered by the HGF/Met signaling axis (Martinez-Palacian et al., 2013). Therefore, we hypothesized that oxidative stress might be the driving force of the senescence response observed in Met^{-/-} oval cells undergoing EMT.

To analyze this possibility, we first analyzed intracellular levels of ROS at the early stages of chronic TGF- β treatment in Met^{flx/flx} and Met^{-/-} respect to untreated oval cells. For that, we employed DCFH-DA, a fluorescent probe used for the detection of intracellular peroxide content, and analyzed fluorescence intensity by flow cytometry and confocal microscopy. Both approaches revealed an exacerbated oxidative stress in Met^{-/-} oval cells in comparison with Met^{flx/flx} oval cells after chronic treatment with TGF- β (**Figure 49a and b**).

Additionally, given that Nox4, a member of the Nox family of NADPH oxidases, is involved in TGF- β -induced ROS production (Carmona-Cuenca et al., 2008; Martinez-Palacian et al., 2013), we studied Nox4 expression. We found higher basal mRNA levels as well as a stronger upregulation of Nox4 during acute and chronic TGF- β treatment in Met^{-/-} than in Met^{flx/flx}, in parallel with the increase in ROS intracellular levels (**Figure 49c**).

These data suggest that an exacerbated oxidative stress in Met^{-/-} oval cells after chronic treatment with TGF- β could be the cause of the senescence and growth arrest.

Figure 49. Analysis of oxidative stress in *Met^{flx/flx}* and *Met^{-/-}* oval cells chronically treated with TGF-β. **a-b)** *Met^{flx/flx}* and *Met^{-/-}* oval cells (Ut) were cultured in 0% FBS medium for 48 hours. *Met^{flx/flx}* and *Met^{-/-}*-TβT-OC were maintained in 10% FBS medium and analysed at different passages (p1 and p2) during chronic treatment. Cells were incubated for 30 minutes with DCFH-DA (5 μM) and cellular fluorescence intensity was analysed. **a)** Confocal microscopy images from one experiment out of 2 are shown. Scale bar=20 μM. **b)** DCFH-DA fluorescence intensity measured by flow cytometry. Data are expressed relative to untreated oval cells and are mean ± S.D. (n=3) from one representative experiment. **c)** Total RNA was isolated from *Met^{flx/flx}* and *Met^{-/-}* oval cells treated or not (Ut) with TGF-β (1 ng/ml) in 0% FBS medium for 48 hours or from *Met^{flx/flx}* and *Met^{-/-}* oval cells chronically treated with TGF-β in 10% FBS medium (TβT-OC) at different passages (p1/p2 and p5). Nox4 mRNA levels were determined by RT-qPCR and normalized to Gusb. Data are expressed relative to untreated *Met^{flx/flx}* oval cells and are mean ± S.E.M. (n=3-6). * = $p < 0.05$, ** = $p < 0.01$, *** = $p < 0.001$ versus untreated cells or as indicated.

One of the proteins that have been linked to abrogation of cellular senescence programs is Twist (Zhao et al., 2017). Twist has been also described as an antioxidant factor (Floc'h et al., 2013). Thus, as we aimed to further characterize the mechanisms underneath the senescence process that occurs in our cellular model, we decide to analyze Twist levels in cells chronically treated with TGF-β. Western blot analysis revealed higher levels of TWIST in TβT-OC cells than in their normal counterparts (Figure 50a and b). Moreover, Twist was downregulated in *Met^{-/-}* compared to *Met^{flx/flx}* oval cells, both at the mRNA and protein levels (Figure 50c, d and e).

Figure 50. Analysis of Twist expression in Met^{flx/flx} and Met^{-/-} oval cells and TβT-OC. **a)** Oval cells and TβT-OC were cultured in 0% FBS or 10% FBS medium for 24 hours, and total proteins were isolated. Western blot assay was performed for the analysis of TWIST using β-ACTIN as loading control. A representative experiment using two different TβT-OC lines (designated #1 and #2) is shown. **b)** Optical density values relative to loading control were calculated. Data are expressed relative to oval cells and are mean ± S.E.M. of 2 independent experiments (n=2-7). Three different TβT-OC lines were used. **c)** Met^{flx/flx} and Met^{-/-} oval cells were cultured in 0% FBS medium for 24 hours, and total proteins were isolated. Western blot assay was performed for the analysis of TWIST using β-ACTIN as loading control. A representative experiment is shown. **d)** Optical density values relative to loading control were calculated. Data are expressed relative to Met^{flx/flx} oval cells and are mean ± S.E.M. of 2 independent experiments (n=6). **e)** Met^{flx/flx} and Met^{-/-} oval cells were cultured in 0% FBS medium for 48 hours, and total RNA was isolated. Twist1, 2 mRNA levels were determined by RT-qPCR and normalized to Gusb. Data are expressed relative to Met^{flx/flx} oval cells and are mean ± S.E.M. of (n=3-5). * = $p < 0.05$, ** = $p < 0.01$, *** = $p < 0.001$ versus Met^{flx/flx}.

Next, we tested whether HGF/Met was responsible for the upregulation of Twist levels as previously published in other cell types (Wang et al., 2015a; Yoshida et al., 2014). We demonstrated that HGF treatment increases Twist1 mRNA levels in Met^{flx/flx} oval cells at different time points. To confirm that this effect was specifically dependent on the signaling triggered by HGF/Met, we submitted Met^{flx/flx} oval cells to Met inhibitor (PHA65752). In the presence of PHA65752, Met^{flx/flx} oval cells showed a decrease in basal Twist1 mRNA levels. Furthermore, combined treatment of PHA665752 and HGF abolished the expression of Twist1 induced by HGF (Figure 51a). We also studied Twist2 mRNA levels. Results showed the same tendency, although they were less

robust (Figure 51a). Parallel analyses by western blot confirmed the results showed in Figure 51a, thus TWIST protein levels were upregulated in response to HGF, effect that was abolished by chemical inhibition of Met (Figure 51b and c). These data demonstrate that HGF regulates Twist expression in oval cells.

Figure 51. Analysis of Twist induction in response to HGF in oval cells. **a)** Met^{flx/flx} oval cells were treated or not with HGF (40 ng/ml) ± PHA665752 (5 μM) in 0% FBS medium for different periods of time, and total RNA was isolated. Twist1, 2 mRNA levels were determined by RT-qPCR and normalized to Gusb. Data are expressed relative to untreated Met^{flx/flx} oval cells and are mean ± S.E.M. of 6 different experiments performed in triplicate. Data were compared as follows: untreated vs HGF, * = $p < 0.05$, ** = $p < 0.01$, *** = $p < 0.005$; untreated vs PHA665752, # = $p < 0.05$; untreated vs PHA665752+HGF, && = $p < 0.01$. **b)** Met^{flx/flx} oval cells were treated or not with HGF (40 ng/ml) ± PHA665752 (5 μM) in 0% FBS medium for 48 hours, and total proteins were isolated. Western blot assay was performed for the analysis of TWIST using β-ACTIN as a loading control. A representative experiment is shown. **c)** Optical density values relative to loading control were calculated. Data are expressed relative to untreated Met^{flx/flx} oval cells and are mean ± S.E.M. of 3 independent experiments (n=8-9).

Based on these results, we decided to perform a silencing-based approach to further confirm the involvement of Twist in cell response to chronic TGF-β treatment. We transiently knocked-down Twist, using a Twist1-targeted siRNA, in Met^{flx/flx} oval cells. Then, we treated cells with TGF-β following the protocol shown in results section 2.1. We checked Twist1 levels by RT-qPCR analysis and data showed that a 70% reduction of Twist1 levels was achieved (Figure 52a). When we analyzed the expression levels of cell cycle inhibitors, we observed a strong upregulation of cdkn2b (p15) and cdkn2a (p19) suggesting that Twist silencing results in activation of a senescence process. Furthermore, Twist1 transient knockdown led to an upregulation of Nox4 levels after treatment with TGF-β (Figure 52b).

Figure 52. Analysis of the effects of Twist1 silencing on *Met^{flx/flx}* oval cells. a-b) Oval cells were transiently transfected with targeting negative control siRNA (NT) or Twist1 targeting siRNA (siTwist1). **a)** Twist1 mRNA levels were determined by RT-qPCR. Data are expressed respect to NT. **b)** NT and siTwist1 oval cells were maintained in 0% FBS medium for 48 hours. NT and siTwist1 were chronically treated with TGF- β in 10% FBS medium and were analyzed at passage 1 (p1 T β T-OC) of chronic treatment. Total RNA was isolated and Cdkn2b, Cdkn2a and Nox4 mRNA levels were determined by RT-qPCR and normalized to Gusb. Data are expressed relative to NT oval cells and are mean \pm S.E.M. of 2 different experiments performed in duplicated. * = $p < 0.05$, ** = $p < 0.01$ as indicated.

Collectively, these data support that HGF is able to induce Twist expression in oval cells and that Twist silencing promotes a senescence program in oval cell through the upregulation of Nox4

3. Relevance of the crosstalk between HGF/Met and TGF- β in hepatocellular carcinoma

Both Met and TGF- β pathways are known to play a critical role in HCC. Although there are some evidences of crosstalk between these pathways in liver cells, e.g. results included in this thesis and published work from our laboratory and others (del Castillo et al., 2008b; Martinez-Palacian et al., 2013), there is hardly any information about the potential relevance of a functional interaction between Met and TGF- β in HCC (Amicone et al., 2002; Liang et al., 2018). For this reason, we thought it would be interesting to study this crosstalk in a context of liver cancer.

To this aim, we used the following *in vivo* and *in vitro* approaches, generated and available at Dr. Maina's laboratory (Fan et al., 2017) : i) a conditional mouse model of overexpression of Met in the liver (Alb-R26^{Met}), which has been shown to lead to spontaneous development of liver tumors with a progenitor-like phenotype, and ii) HCC cell lines isolated from these tumors, with different levels of expression of Met (low and high).

3.1. TGF- β signaling pathway is activated prior to tumor appearance and during tumor development in Alb-R26^{Met} mice

First, we analyzed the activation of TGF- β -triggered signaling pathway in WT and Alb-R26^{Met} liver sections (pre-neoplastic stage, before 40 weeks old Alb-R26^{Met}), and in HCC samples (neoplastic stage, from 40 to 67 weeks old Alb-R26^{Met} mice which have developed tumors), by detecting the phosphorylated form of SMAD2, the TGF- β canonical signaling mediator, by immunohistochemistry. A quantitative analysis of the immunohistochemistry assay showed enhanced nuclear staining of pSMAD2 in Alb-R26^{Met} mice, which is higher in HCC samples (**Figure 53a and b**).

These results evidence an interesting over-activation of the TGF- β pathway in livers with Met overexpression, both in pre-neoplastic and neoplastic stages. This suggests a role for TGF- β signaling during HCC development and in the regulation of the properties of these tumors.

Figure 53. Analysis of TGF- β /Smad signaling activation in WT and Alb-R26^{Met} mice. a-b) Immunohistochemistry staining was performed using a specific anti-pSMAD2 antibody on liver section of WT, Alb-R26^{Met} mice and HCC samples. **a)** Representative bright-field images of WT, Alb-R26^{Met} mice and HCC sample are shown. Magnification=20X. **b)** Intensity of nuclear staining per area in WT, Alb-R26^{Met} and HCC was measured in at least 8 areas per mice. Data are expressed relative to WT group and are mean \pm S.E.M. of 4 animals per group. * = $p < 0.05$, ** = $p < 0.01$ versus WT group.

3.2. Activation of TGF- β signaling pathway inversely correlates with Met expression levels in HCC lines derived from Alb-R26^{Met} mice

Considering these results, we decided to take *in vitro* approaches that allowed us to study more in detail the interplay TGF- β /Met and how it could affect HCC properties in a context of liver cancer driven by overexpression of Met.

We selected two HCC lines with different expression levels of Met, established from liver tumors developed in Alb-R26^{Met} mice: HCC1 and HCC3 cell lines. As shown in **Figure 54a and b**, HCC1 cells, displayed about two fold higher levels of MET (HCC1^{HMet}) than HCC3 (HCC3^{LMet}), levels that were not modified neither in presence of exogenous TGF- β nor HGF in both cell lines. In terms of activation of MET, analyzed by the detection of its phosphorylated form (pMET) (**Figure 54a and b**), the receptor was constitutively phosphorylated in HCC1^{HMet} and remained unaltered regardless of HGF and/or TGF- β treatment. However, activation of MET in HCC3^{LMet} was only observed upon HGF stimulus. Interestingly, TGF- β prevented HGF-induced MET activation in HCC3^{LMet}, which could indicate that TGF- β interferes with HGF/Met pathway.

Figure 54. Analysis of canonical and non-canonical TGF- β and HGF/Met pathways in HCC1^{HMet} and HCC3^{LMet} cells. a) HCC1^{HMet} and HCC3^{LMet} cells were treated or not with TGF- β (2 ng/ml) \pm HGF (40 ng/ml) in 10% FBS medium for 30 minutes and total proteins were isolated. Western blot assay was performed for the analysis of the indicated protein using β -ACTIN as a loading control. A representative experiment out of 2 is shown. **b)** Optical density values were calculated. Data are expressed relative to untreated HCC1^{HMet} cells or as total protein levels and are mean \pm S.E.M. of 2 independent experiments.

Additionally, we analyzed the activation of HGF/Met pathway through the phosphorylation levels of GAB1 (pGAB1), a Met's adaptor protein that mediates many of the Met-initiated signals (Organ and Tsao, 2011; Trusolino et al., 2010) (Figure 54a and b). Similar to MET, GAB1 was constitutively activated in HCC1^{HMet}, but in this case, pGAB1 levels were further increased in the presence of HGF, regardless of the presence or absence of TGF- β . These results suggest that basal activation of MET only triggers a partial activation of its major adaptor. In HCC3^{LMet} cells, we only detected pGAB1 in response to exogenous addition of HGF. TGF- β had no effect on HGF activation of GAB1.

Once we had done a basic characterization of MET expression and activation in HCC1^{HMet} and HCC3^{LMet} cells, we wondered if differential expression/activation of MET could affect to TGF- β signaling activation in HCC

cells. Interestingly, although differences did not reach statistical significance, western blot analysis revealed a stronger activation of SMAD2 triggered by TGF- β treatment in cells with low Met levels, HCC3^{LMet}, than in HCC1^{HMet}. The presence of exogenous HGF did not significantly affect the activation of the TGF- β pathway (**Figure 54a and b**). Both the increased activation of SMAD2 in HCC3^{LMet} cells and the decreased activation of Met in HCC3^{LMet} cells in the presence of TGF- β suggest a negative functional crosstalk between TGF- β and HGF/Met pathways in HCC Alb-R26^{Met} lines.

In an attempt to further characterize this interaction, we next analyzed an additional downstream signaling pathway, ERK-MAPKs, activated by both TGF- β and HGF. ERK-MAPKs is one of the signaling pathways that mediates the downstream response to Met activation and is considered a non-canonical pathway for TGF- β (Massague, 2012; Trusolino et al., 2010). Active ERKs (pErks) were only detected after HGF treatment, both in HCC1^{HMet} and HCC3^{LMet}, but levels tended to be higher in HCC3^{LMet} cells, particularly under TGF- β and HGF combined treatment (**Figure 54a and b**). These results suggest that different levels of Met in HCC cells could affect MAPKs activation induced by HGF or TGF- β .

3.3. TGF- β -dependent transcriptional activity is enhanced in HCC cells with low levels of Met

Signaling studies performed evidenced that lower levels of Met expression and activation in mouse HCC cells correlate with a higher activation of TGF- β canonical pathway. Next, we ought to determine if differential SMAD activation results in changes in the expression of well-known Smad transcriptional targets. Specifically, we analyzed the expression of Tgfb1, Tgfbr1, Smad6, Smad7 and plasminogen activator inhibitor 1 (Pai1). As a way to prove the specificity of the effects induced by TGF- β and HGF/Met, we treated cells with some specific inhibitors of Met and TGF- β receptor, PHA665752 and SB431542, respectively.

Upregulation of Tgfb1 mRNA levels was observed by RT-qPCR only under TGF- β treatment in both HCC1^{HMet} and HCC3^{LMet} with no obvious differences between the two cell lines. Neither combined treatment with HGF or with Met inhibitor had a significant effect on Tgfb1-mediated induction. Likewise, treatment with Met inhibitor alone did not affect baseline levels of Tgfb1 expression. In other words, activation of HGF/Met pathway, in mouse HCC cell lines, either basal or by stimulation with HGF, did not affect Tgfb1 expression (**Figure 55**).

Interestingly, a strong upregulation of the mRNA levels of Tgfbr1, Smad6, Smad7 and Pai1 were observed in response to TGF- β treatment in HCC3^{LMet}, whereas in HCC1^{HMet} was either null or very mild. Among all these genes, Pai1 was the one showing significant changes between HCC3^{LMet} and HCC1^{HMet}. Again, neither co-treatment with HGF or with Met inhibitor altered TGF- β -mediated induction with the exception of Smad6 and 7 where Met inhibitor seemed to increase the basal expression in HCC1^{HMet} (**Figure 55**).

Figure 55. Analysis of TGF- β -dependent transcriptional activity in HCC1^{HMet} and HCC3^{LMet} cells. HCC1^{HMet} and HCC3^{LMet} cells were treated or not with TGF- β (2 ng/ml) \pm HGF (40 ng/ml) in the presence or absence of PHA665752 (3 μ M) or SB431542 (10 μ M) in 10% FBS medium for 24 hours and total RNA was isolated. Tgfb1, Tgfr1, Smad6, 7 and Pai1 mRNA levels were determined by RT-qPCR and normalized to Hprt. Data are expressed relative to untreated cells and are mean \pm S.E.M. of 2 independent experiments. * = $p < 0.05$, ** = $p < 0.01$, *** = $p < 0.001$ versus untreated cells or as indicated.

All these data suggest that lower levels of Met in mouse HCC lines lead to a stronger TGF- β /Smad-dependent transcriptional activity. But, further activation or inhibition of HGF/Met pathway does not seem to affect TGF- β -mediated transcriptional response.

3.4. HCC lines with low levels of Met are more sensitive to anti-proliferative and apoptotic effects of TGF- β

TGF- β plays a dual role in tumorigenesis. Thus, TGF- β can promote cell cycle arrest and apoptosis or on the contrary, induce cell motility, invasion, EMT and cell stemness (Seoane and Gomis, 2017). Since we found that HCC cells with low levels of Met, HCC3^{LMet} cells, show stronger activation of TGF- β signaling pathway than HCC1^{HMet}, we next explored whether this differential response to TGF- β led to differences in terms of cell growth and death.

Analysis of cell growth capacity revealed that HCC1^{HMet} present a higher growth rate than HCC3^{LMet}. HCC1^{HMet} did not show difference in the cell number when treated with TGF- β . However, HCC3^{LMet} displayed a slight decrease in cell number in response to TGF- β (Figure 56).

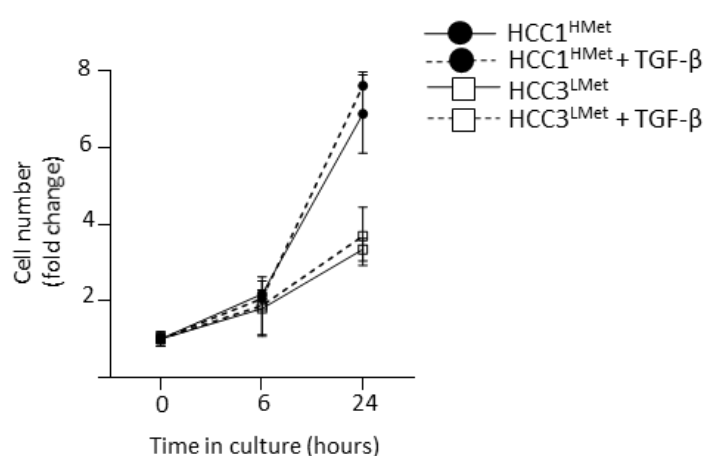

Figure 56. Analysis of cell growth capacity in HCC1^{HMet} and HCC3^{LMet} cells. HCC cells were treated or not with TGF- β (2 ng/ml) in 10% FBS medium for 6 and 24 hours and then counted. Data are expressed respect to zero time and are mean \pm S.D. (n=3) from one representative experiment performed in triplicate.

In parallel, we performed an immunofluorescence assay to detect active caspase-3, a crucial mediator of programmed cell death, as a way to specifically analyze if the HCC cell lines displayed an apoptotic response to TGF- β . HCC1^{HMet} cells showed an increase in the levels of active caspase-3 after TGF- β treatment. In HCC3^{LMet} cells we did not observe response at 6 hours, however, a strong peak of caspase-3 activation was seen at 16 hours, notably higher than that seen in HCC1^{HMet} at the same time point (Figure 57a and b).

Figure 57. Analysis of active caspase-3 in HCC1^{HMet} and HCC3^{LMet} in response to TGF-β. **a-b)** HCC1^{HMet} and HCC3^{LMet} cells were treated or not with TGF-β (2 ng/ml) in 10% FBS medium for 6 and 16 hours and then fixed and stained with a specific primary antibody for caspase-3 and a fluorescent secondary antibody. Nuclei were counterstained with DAPI. **a)** Fluorescence intensity was measured in at least 6 fields per condition. Data are expressed relative to untreated cells and are mean ± S.E.M. of 2 independent experiments. **b)** Representative apoptosis microscopy images from 2 independent experiments are shown. Magnification=10X.

To further test if the differential expression and activation of Met could account for the differential cell response seen in terms of cell number and apoptosis, we run similar experiments but in the absence or presence of HGF and/or the Met inhibitor PHA665752. We focused on the 16 hours-time point since it seemed to be the more appropriate timing to detect the peak of apoptosis and the differences between cell lines. HCC1^{HMet} cells treated with TGF-β showed a moderate increase in caspase-3 activity however in combination with PHA665752, TGF-β induced a sharp drop in cell number together with a strong increase in caspase-3 activity as compared to TGF-β alone (**Figure 58a and b**). It is noteworthy that PHA665752 alone was able to trigger apoptosis in HCC1^{HMet} cells, although at a lesser extent than in combination with TGF-β (**Figure 58b**). Exogenous HGF had no apparent effect neither in cell number nor in caspase-3 activity (**Figure 58a and b**). These results suggest that HCC1^{HMet} are dependent on autocrine Met signaling for protection against TGF-β induced apoptosis.

Parallel experiments were run in HCC3^{LMet} cells. These cells responded to TGF-β with a slight decrease in cell number and activation of caspase-3. Interestingly, despite not showing a basal activation of Met, combined treatment with TGF-β and PHA665752 resulted in an amplified response to TGF-β, both in terms of decrease in cell number and activation of caspase-3 (**Figure 58c and d**). It is worth noting that the levels of active caspase-3 in HCC3^{LMet} cells are much higher than those reached in HCC1^{HMet}, which is consistent with a higher sensitivity to apoptosis (**Figure 58d**). In contrast to HCC1^{HMet}, HCC3^{LMet} cells showed no apoptotic response when treated with PHA665752 alone. Similarly to HCC1^{HMet}, exogenous HGF had no effect on cell number but reduced active caspase-3 levels (**Figure 58c and d**).

Figure 58. Analysis of cell growth capacity and active caspase-3 levels in HCC1^{HMet} and HCC3^{LMet} cells. **a and c)** HCC1^{HMet} and HCC3^{LMet} were treated or not with TGF- β (2 ng/ml) \pm HGF (40 ng/ml) in the absence or presence of PHA665752 (3 μ M) in 10% FBS medium for 24 hours and then counted. Data are expressed relative to untreated cells. A representative experiment performed in triplicate is shown. **b and d)** HCC1^{HMet} and HCC3^{LMet} were treated or not with TGF- β (2 ng/ml) \pm HGF (40 ng/ml) in the absence or presence of PHA665752 (3 μ M) in 10% FBS medium for 16 hours. Then, cells were fixed and stained with a specific primary antibody for caspase-3 and a fluorescent secondary antibody. Fluorescence intensity was measured in at least 6 fields per condition. Data are expressed relative to untreated cells and are mean \pm S.E.M. of 2 independent experiments.

Collectively, all these results evidence a pro-survival activity of Met in HCC cells. HCC cells with high levels of Met and endogenous activation of Met become dependent of Met catalytic activity for survival. But, Met activity protects HCC cells against TGF- β independently of Met levels since inactivation of Met sensitizes both HCC1^{HMet} and HCC3^{LMet} cells to TGF β -induced apoptosis.

9. Discussion

1. HGF/Met signaling is essential to allow oval cells expansion after TGF- β -induced EMT

The purpose of this study was to characterize the TGF- β -induced EMT in oval cells, how it could affect cell function and fate *in vivo*, and the potential relevance of a TGF- β -HGF crosstalk in this context.

It is recognized that HPCs/oval cells a bipotential hepatic progenitors population participate in the regenerative process accompanying chronic liver injury. It has been established that these cells can either contribute to re-establish liver function (Riehle et al., 2011) or contribute to the progression of liver fibrosis (Kuramitsu et al., 2013; Williams et al., 2014) and even become tumor-initiating cells (Kohn-Gaone et al., 2016). These opposite effects show us the plasticity of HPCs/oval cells and the importance of understanding the mechanisms controlling their behavior. This would allow us to modulate or favor their pro-regenerative activity, providing new therapeutic approaches for the treatment of CLDs. TGF- β and HGF are among the key signals involved in liver fibrosis and regeneration and are components of HPC/oval cell niche that regulate HPC/oval cell biology (Giannelli et al., 2016; Nakamura et al., 2011), what makes them interesting signals in the study of HPC/oval cell fate in CLD.

Several groups have reported that TGF- β induces EMT in rat HPCs/oval cells *in vitro* and increases expression of HSC or myofibroblast markers, being able to contribute to the progression of liver fibrosis and cirrhosis (Chen et al., 2015; Deng et al., 2011; Wang et al., 2009) or to convert them into tumor-initiating cells (Wu et al., 2018). Co-expression of epithelial and mesenchymal proteins has been found in HPCs/oval cells isolated from a rat model of liver disease (Yovchev et al., 2008). Interestingly, other authors suggest that active HSCs could undergo mesenchymal to epithelial transition (MET) and originate HPCs/oval cells (Deng et al., 2011) supported by the fact that markers of active HSCs and HPCs/oval cells were observed simultaneously in HPCs/oval cells (Tennakoon et al., 2015). These findings might indicate a role for EMT-MET in regulation of HPC/oval cell biology although its precise contribution and mechanisms involved need to be clarified. According to these previous evidences of EMT in HPCs/oval cells, our results show that chronic treatment with TGF- β in oval cells induces an EMT process that is maintained over time. Thus, TGF- β represses the expression of some epithelial markers (L-CADHERIN, OCCLUDIN), increases the expression of mesenchymal markers (N-CADHERIN, VIMENTIN) and promotes a change in the subcellular localization of ZO-1 (**Figure 27**). However, the co-expression of E-Cadherin with mesenchymal markers, led us to think that TGF- β treatment induces a partial rather than a full EMT in oval cells (**Figure 26 and 27**). These results might be not surprising, considering that EMT is seen nowadays as a broad spectrum of transitional states with multiple and dynamic intermediary phases (Nieto et al., 2016). In support of the hypothesis of a partial EMT induction in oval cells chronically treated with TGF- β

(T β T-OC), we found coexistence of ALBUMIN and CK19, markers of liver epithelial cells (hepatocyte and cholangiocyte, respectively) (**Figure 30**), and Cd44 (**Figure 28**), considered as a critical regulator of TGF- β -mediated EMT in HCC cells (Fernando et al., 2015; Gao et al., 2015; Malfettone et al., 2017; Mima et al., 2012). Our data are also in line with the finding of partial EMT states HPCs/oval cells derived cell lines LE/6 and WB-F344, states that were at least partly maintained by autocrine TGF- β and activin A/Smad signaling (Wu et al., 2018). CD44, CD133 and EPCAM are all stem cell markers. However, unlike Cd44, Cd133 (prom1) and Epcam show a decreased expression in T β T-OC (**Figure 28**). It is widely accepted that EMT induces the expression of stem cell markers and enhances stem cell properties in epithelial cells (Fabregat et al., 2016a). Indeed, it has been demonstrated that TGF- β treatment in rat and human hepatocytes, induces a less differentiated and a more mesenchymal phenotype with loss of expression of hepatic genes and acquisition of specific stem cell markers (Caja et al., 2011; Sanchez et al., 1999). However, our results do not fit this model. Partial EMT in oval cells does not result in an increase of stem cell markers (**Figure 28**) nor increases the clonogenic capacity or the sphere formation capacity of the cells (**Figure 29**). EMT in oval cells instead of favoring a stem cell phenotype, lean cells forward along the hepatic lineage, as deduced from the increase in some hepatocyte markers (Hnf4a and Afp) and the decrease in biliary epithelial markers (Hnf1b, Onecut1, Ggt) in T β T-OC (**Figure 31**). In this sense, our group has previously demonstrated that TGF- β besides inducing EMT also promotes a more differentiated phenotype in hepatocytes, particularly in the presence of HGF or EGF, resulting in a mixed phenotype in which hepatocytes co-express liver specific genes and epithelial and mesenchymal marker genes (Pagan et al., 1997; Pagan et al., 1999; Sanchez et al., 1995; Sanchez et al., 1998). Therefore, EMT and a differentiated phenotype are not mutually exclusive. Likewise, HPCs/oval cells from human fetal liver display a phenotype consistent with mesenchymal-epithelial transitional cells (Dan et al., 2006). Furthermore, recent findings show that a sequential EMT-MET process drives differentiation of human embryonic stem cells toward hepatocytes, and that TGF- β and SNAI1 induction plays a key role not only in EMT but also in definitive endoderm induction (Li et al., 2017).

Among other phenotypic changes, EMT results in changes in the secretory phenotype of cells, increasing the expression of growth factors and cytokines (Reka et al., 2014) that could be critical for phenotype acquisition or maintenance, thus controlling the mesenchymal state and properties (Del Castillo et al., 2006; Jahn et al., 2012; Scheel et al., 2011). An increase in the mRNA levels of Ctgf together with changes in the mRNA of specific members of the Pdgf family, specifically upregulation of Pdgfa and c and downregulation of Pdgfd, are seen in T β T-OC (**Figure 32**). Interestingly, CTGF, protein is upregulated in many fibrotic disorders and promotes fibrogenesis, and it has been described to directly bind TGF- β in the extracellular space and enhance receptor binding and signaling (Abreu et al., 2002). Regarding the modulation of PDGF family members, it is important to highlight that PDGF family ligands have an important role in EMT having been correlated with cell survival and invasiveness in human mammary carcinomas and chemoresistance in HCC

(Jechlinger et al., 2006; Wang et al., 2015b). Upregulation of PDGFA and PDGF receptors in p19 null hepatocytes after TGF- β -induced EMT provides *in vitro* adhesive and migratory properties and proliferative stimuli during tumor formation (Fischer et al., 2007). On the contrary, a reduction in the expression of PDGFD in lung fibrosis correlates with the production of TGF- β , so that downregulation of PDGFD by TGF- β might serve as a negative feedback regulation of cytokines that control fibrosis (Charni Chaabane et al., 2014). These observations support the idea of a role for these factors in cell phenotype regulation. Nevertheless, if these signals are somehow involved in the chronic EMT triggered by TGF- β in our cellular model needs to be further investigated.

Further in this regard, our results show that T β T-OC autocrinely produce HGF. Our group has already shown that oval cells have an HGF autocrine loop that exerts antioxidant and anti-apoptotic actions (del Castillo et al., 2008b; Martinez-Palacian et al., 2013). Now, we demonstrate that HGF autocrine loop remains operative in T β T-OC (Figure 45). Strikingly, although T β T-OC express higher Hgf levels, they do not display higher Met activation. Further studies are needed to clarify this result, but one possible explanation is that the amount of ligand is greater than that of Met receptor due to either limiting expression or enhanced degradation of the receptor, so that it is not able to bind the available ligand. In any event, HGF autocrine loop counterbalances the TGF- β -induced EMT maintaining and/or promoting their epithelial properties (Figure 47). Evidences in the literature suggest the capacity of HGF to induce EMT. Indeed, HCC cells secrete HGF which contribute to maintain a mesenchymal phenotype, favoring invasion, proliferation and metastasis *in vivo* (Ding et al., 2010). Likewise, HGF induces down-regulation of cell junctions in HCC cells through Snail induction via MAPK/early growth response factor-1 activation, which have critical roles in HGF-induced cell scattering, migration and invasion (Grotegut et al., 2006). Contrarily, we had reported that HGF/Met does not induce EMT in oval cells despite enhancing oval cell migration/invasion capacities (Suarez-Causado et al., 2015), and results presented here go in the same direction. Recapitulating, our results provide further evidence of the HPC/oval cell plasticity and the importance of dynamic phenotypic transitional states of liver cells during liver injury, while pointing to an important functional cooperation between the TGF- β and HGF signaling pathways in its regulation.

Partial EMT in oval cells not only has consequences on phenotypic properties, but additionally confer cells some advantages in terms of invasion capacity *in vitro* (Figure 34). These results are in agreement with other studies performed in epithelial cells in which EMT enhance invasiveness (Brabletz et al., 2018; Thiery et al., 2009; Zhang and Weinberg, 2018). The increase in the invasive capacity after EMT in oval cells correlated with an increase in the expression of some MMPs (Mmp2, Mmp10 and Mmp13) (Figure 35). Although non-parenchymal cells are the main source of MMPs in the liver, they are also produced by hepatocytes and cholangiocytes; and we have shown expression of some MMPs in oval cells as well (Suarez-Causado et al., 2015). This is not surprising since these proteinases are crucial not only for fibrosis development but also for healing, and play an active role in modulation of stem cell niches

(Hemmann et al., 2007; Roderfeld, 2018). In fact, it is well known that HPC/oval cell-mediated regenerative response involves ECM degradation and deposition, processes in which MMPs participate (Williams et al., 2014). Interestingly, upregulation of MMP2 and MMP13 has been associated with resolution of liver fibrosis (Fallowfield et al., 2007; Radbill et al., 2011). Although Mmp9 expression is not altered in T β T-OC, these cells show higher MMP9 activity than untreated oval cells (**Figure 35**). This lack of relationship between MMP9 expression and activity should be investigated in detail but the existence of a wide range of MMPs regulatory mechanisms at different levels including transcriptional, epigenetic and post-transcriptional levels may help explain it (Chernov and Strongin, 2011; Chicoine et al., 2002; Hadler-Olsen et al., 2011; Piedagnel et al., 1999). We also observe changes in Timps expression upon TGF- β -induced EMT, specifically an increase in Timp3 and a decrease in Timp1 (**Figure 35**). MMP activity is controlled by TIMPs under physiological conditions having this regulation an important role in normal degradation of ECM to maintain liver homeostasis. However, alterations in MMPs-TIMPs balance have been linked to chronic liver pathologies, where MMPs and TIMPs play anti- and/or pro-fibrotic roles. MMP9 has been involved in the early stage of liver fibrosis, specifically promoting TGF- β release; but on the other hand, MMP9 can promote HSCs apoptosis in the presence of low TIMP1 levels (Duarte et al., 2015). Evidence endow TIMPs overexpression a pro-fibrotic action. Concretely, an enhancement in CCl₄-induced hepatic fibrosis was demonstrated by TIMP1 overexpression (Yoshiji et al., 2000). So, the changes in the expression of Mmps and Timps in T β T-OC after EMT might be a reflection of what occurs in a context of liver injury and fibrosis and might indicate an anti-fibrotic profile whose relevance in a regenerative process remains open for further investigation.

Interestingly, our group has demonstrated that HGF/Met through PI3K and p38MAPK activation induces a complex and specific migratory response in oval cells that involves MMPs (Suarez-Causado et al., 2015). Based on these results, and on the reduction of the invasive capacity of T β T-OC by inhibiting Met (**Figure 46**); we hypothesize that the autocrine HGF/Met loop operating in T β T-OC could be in part responsible for Mmps induction and therefore, for the invasive phenotype. Nonetheless, additional experiments are required to establish a direct relationship between Mmps induction and HGF/Met axis in T β T-OC.

In terms of cell growth, although EMT does no result in an increased growth capacity in the presence of serum, it enhances oval cell proliferation and resistance to pro-apoptotic stimuli in the absence of serum (**Figure 33**). A link between EMT and apoptosis resistance has been previously proposed by other authors (Robson et al., 2006; Valdes et al., 2002). We prove here that autocrine HGF/Met significantly contributes to T β T-OC growth and survival properties, as it does to cell invasive capacity (**Figure 46**). But, it is worth mentioning that HGF/Met autocrine signaling might not be the only autocrine pathway active in T β T-OC, since we have shown upregulation of other signaling ligands (**Figure 32**).

Interestingly, although HGF autocrine signaling plays a relevant role in T β T-OC properties, exogenous HGF has lost its ability to increase proliferation and invasion over cell intrinsic capacities (**Figure 48**), as it does in oval cells (del Castillo et al., 2008b; Suarez-Causado et al., 2015). Additionally, we see a weaker activation of some key downstream targets under HGF stimulation (**Figure 48**). One possible explanation could be that the autocrine HGF/Met signaling leads to maximum proliferative and invasive capacities. This is in line with the observation that a higher HGF expression in T β T-OC does not result in a higher activation of Met receptor.

So far, this study has allowed us to elucidate the biological consequences of a partial EMT induction by TGF- β in oval cells *in vitro*. Next step is to clarify the consequences for oval cell fate *in vivo*, in a context of liver damage. Although some authors defend EMT could be responsible for the pro-fibrotic action of HPCs/oval cells (Wang et al., 2009), we found that transplantation of T β T-OC reduce liver fibrosis grade and improve liver function in CCl₄-treated mice more efficiently than oval cells which have not underwent EMT process (**Figure 38, 39 and 40**). In other words, our work support that EMT-induced traits improve and/or accelerate the regenerative potential of oval cells, thus facilitating the restoration of liver function upon injury. It is worth emphasizing that in our experimental model, oval cells, independently of the EMT, did not enhance liver fibrosis either, but rather contributed to ameliorate it, although differences did not reach significance, perhaps due to sample size limitations. This would be in agreement with different works published in the literature supporting a pro-regenerative role for HPCs/oval cells (Awan et al., 2017; Espanol-Suner et al., 2012; Lu et al., 2015).

We have not yet provided a mechanism for the pro-regenerative/anti-fibrotic effect of T β T-OC. However, based on results from GFP immunohistochemistry at 1 week after transplantation, we hypothesize that an improved engraftment or enhanced cell survival and/or proliferation could certainly make a difference and enhance the effects of the transplanted cells on the injured liver (**Figure 37**). Based on our *in vitro* findings it is feasible to hypothesize that the improved regenerating capacity is the result of a combination of cell advantageous traits. Thus, increased Mmps expression and greater invasive capacity could contribute to enhance oval cell regenerative activity, since MMPs are known to be important for such activity (Van Hul et al., 2009; Vestentoft et al., 2013). Additionally, data pointing to a switch to a more mature hepatic phenotype in T β T-OC (**Figure 30 and 31**) may suggest that T β T-OC have an enhanced hepatocyte differentiating capacity *in vivo*, which would result in an enhanced capacity to restore liver functionality. Although further research is needed to demonstrate this hypothesis, we have preliminary data that indirectly support it. Cyp7a1, a known transcriptional target of HNF4 α and a common marker of hepatocyte maturation and functionality (Asahina et al., 2004; Cai et al., 2007), shows the highest levels in livers from T β T-OC-transplanted mice (**Figure 41**). Certainly, Cyp7a1 expression could come from endogenous hepatocytes or from newly-formed OC- and T β T-OC-derived hepatocytes. In any event, data are overall consistent with an improved liver

function and decreased damage in livers from TβT-OC-transplanted mice. Finally, the highest levels of HGF in TβT-OC transplanted mice suggest a participation of this growth factor in this process (**Figure 41**). This finding is in line with a higher HGF expression in TβT-OC (**Figure 45**) *in vitro*. Thus, upon transplantation, TβT-OC could release HGF in the liver driving autocrine and paracrine actions on oval cells and other liver cell populations, respectively. The pro-regenerative and anti-fibrotic effects of HGF in the liver are well-known. Among others, HGF could promote survival and maturation in transplanted HPCs/oval cells and hepatocytes and inhibit the growth of activated HSCs (del Castillo et al., 2008b; Huh et al., 2004; Ishikawa et al., 2012; Kim et al., 2005; Li et al., 2008).

Our work points to a fundamental activity of HGF/Met to allow oval cell expansion after EMT. In the absence of Met activity (Met^{-/-} oval cells or pharmacological inhibition of Met), oval cells submitted to chronic treatment with TGF-β enter into senescence, as demonstrated by phenotypical changes, the presence of β-Gal activity and an increase in the expression of cell cycle inhibitors (**Figure 42, 43 and 44**). In other words, HGF/Met signaling pathway is essential to bypass senescence and to allow oval cell survival and expansion during TGF-β-induced EMT.

It has already been reported that senescence and EMT, two processes initially considered independent, could be mechanistically linked. Indeed, there are numerous examples in the literature that show how Twist and Zeb1, two EMT-TF, impact on cell cycle machinery and suppress cellular senescence. For example, mouse embryonic fibroblasts from Zeb1-null mice show diminished replicative capacity in culture and undergo replicative senescence associated with Cdkn2b (p15) and Cdkn1 (p21) (Liu et al., 2008). Twist is responsible for the sustained proliferation of immortalized prostate epithelial cells through p14ARF down-regulation, which consequently suppresses cellular senescence caused by genomic damage (Kwok et al., 2007). Likewise, silencing of Twist in oncogene-driven tumors results in growth inhibition and activation of oncogene-induced senescence program and in some cases apoptosis (Burns et al., 2013; Tran et al., 2012). Twist 1 and 2 block the suppressor proteins pRB and p53, cooperating with oncoproteins such as H-Ras to induce a full EMT and cell invasion (Ansieau et al., 2008). Our data is in line with these findings and support the concept that overcoming senescence is a critical step for cell expansion upon EMT induction, highlighting a role for HGF/Met in this process.

But what are the mechanisms underlying the senescence process in our cell model? TGF-β induces senescence in tumor cells and other cell types (Lyu et al., 2018; Wu et al., 2009). TGF-β also induces ROS production in different cells (Krstic et al., 2015), including oval cells. The source of ROS in oval cells involves the NADPH oxidase, Nox4 although we can not discard the mitochondria as an additional source of ROS (Almale et al., 2019; Martinez-Palacian et al., 2013). Oxidative stress drives senescence and interestingly, TGF-β is able to induce senescence via increase of ROS in bone marrow mesenchymal cells and HCC cells (Senturk et al., 2010; Wu et al., 2014). In agreement with these findings,

here we show that during the establishment of T β T-OC very high levels of Nox4 mRNA and intracellular ROS are observed in oval cells lacking Met tyrosine kinase activity (**Figure 49**). Awaiting further experiments mechanistically connecting the oxidative stress with the induction of senescence, these results suggest that TGF- β induces senescence in oval cells by an oxidative stress-dependent way.

In an effort to understand how the HGF/Met axis exerts its anti-senescent role in oval cells, we found that oval cells lacking Met tyrosine kinase activity have lower levels of Twist (**Figure 50**). Indeed, HGF upregulates Twist in oval cells (**Figure 51**). It has been already demonstrated that HGF/Met can induce Twist expression. Thus, HGF-driven Twist upregulation results in cell motility in canine mammary cell line and HGF triggers EMT in melanoma cells by inducing Twist (Koefinger et al., 2011; Yoshida et al., 2014). However, our results appear to contradict the established idea of Twist as an EMT-inducing TF since HGF/Met signaling in T β T-OC help maintain epithelial properties while upregulating Twist (**Figure 47**). In this regard, studies in bone metastatic and parental breast carcinoma cells revealed that induction of a MET process by HGF involves E-cadherin upregulation via activation of a Twist program. Notably, a coordinated action of HGF and TGF- β is also reported in this context (Bendinelli P, 2015). So, the scenario is far more complex than initially thought. The fact that Twist knockdown in T β T-OC leads to increase in Nox4 and cell cycle inhibitors expression (**Figure 52**) supports the hypothesis that HGF/Met through upregulation of Twist would contain TGF- β -induced oxidative stress, which would in turn overcome cell senescence and allow cell survival and expansion. In this regard, it is well established that Met exerts a powerful antioxidant activity in hepatocytes and oval cells (Gomez-Quiroz et al., 2008; Martinez-Palacian et al., 2013). Less is known about Twist antioxidant activity, which is mainly linked to its anti-apoptotic effects (Floc'h et al., 2013). It is worth noting that we provide here the first evidence of a role for Twist in HGF/Met-driven antioxidant activity. In conclusion, our data provide evidence that the balance between HGF and TGF- β signaling pathways might be critical for oval cell fate and outcome of liver regeneration. We propose a scenario where HGF/Met signaling restrains TGF- β effects. This allows maintaining a controlled oxidative stress and apoptotic response thereby promoting the expansion of oval cells and overall improving the regenerative potential of oval cells.

2. Interaction between HGF and TGF- β in HCC. A pro-survival role for the HGF/Met axis

In the second part of this thesis, we run a small preliminary study on the relevance of the crosstalk between HGF/Met and TGF- β in hepatocellular carcinoma.

Through a collaboration with Dr. Maina we had access to a mouse model recently generated in his laboratory that demonstrate that a subtle increase in wild type Met expression is sufficient to drive liver carcinogenesis. Using this model we aimed to answer the question of whether TGF- β could have any role in the development and/or progression of Met overexpression-driven HCC.

Although there are not many studies in the literature that relate TGF- β and HGF/Met pathways during tumor development and more specifically HCC, we have found some direct or indirect evidence of this interaction. TGF- β suppresses tumor emergence in certain epithelial tissues by inhibiting fibroblast-mediated production of growth factors involved in the regulation of cell survival, proliferation and motility, such as HGF (Massague, 2008). β -catenin in hepatocytes aggravates HCC development driven by an oncogenic β -catenin in combination with Met due to, among others events, an upregulation of pro-tumorigenic cytokines such as TGF- β (Liang et al., 2018) Co-expression of transgenic Met and c-Myc leads to the emergence of HCC. In this scenario, T β RII expression was down-regulated in tumors indicating that an impairment of TGF- β 1-induced growth inhibition is required for an acceleration of hepatocarcinogenesis (Amicone et al., 2002). In our work, we provide preliminary results of the activation of TGF- β canonical signaling pathway in HCC from Alb-R26^{Met} mice (**Figure 53**). This result goes in opposite direction to that of Amicone et al, although the consequences of Smad activation in Alb-R26^{Met} HCCs are not yet clear. Several opposing hypotheses can be drawn. Activation of TGF- β signaling could cooperate with HGF/Met signaling for tumor development, or alternatively, could be trying to restrain or inhibit HGF/Met pro-tumorigenic action. Indeed, our results show that HCC cells are able to respond to TGF- β , as demonstrated by phosphorylation of SMAD, but interestingly, the response is different depending on Met levels (**Figure 54**). High levels of Met and its constitutive activation (demonstrated by phosphorylation of MET and its signaling adaptor GAB1) in HCC cells attenuates TGF- β signal, that is, decreases the levels of phosphorylated SMAD2 (**Figure 54**) and Smad-dependent transcriptional activity (**Figure 55**). This is not the first evidence of the ability of HGF to block TGF- β -induced biological responses at the transcriptional level. In fact, TGF- β -induced EMT in kidney epithelial cells and TGF- β profibrotic action in mesangial cells were inhibited by HGF through upregulation or stabilization of Smad transcriptional co-repressors SnoN or TGIF, respectively (Dai, 2004; Yang et al., 2005). However, it should be pointed out

that chemical inhibition of Met is not able to modulate significantly the transcriptional response elicited by TGF- β (**Figure 55**). There are several potential explanations that include (i) a non-optimal experimental design, (ii) differences are not Met-dependent, (iii) HCC cells have turned on additional pathways and eventually became independent on the upstream driver, in this case Met activity, a known phenomenon in carcinogenesis (Qi et al., 2011; Singh et al., 2017). In the same direction, combined treatment with HGF and TGF- β do not seem to affect in a significant manner the TGF- β -triggered transcriptional response (**Figure 55**). So, somehow, cells are not responsive to modulation of the HGF/Met pathway, at least in terms of Smad-mediated transcriptional activity. This is an interesting finding that should be further analyzed.

From the other side, TGF- β is able to decrease or inhibit MET phosphorylation only in HCC cells with lower levels of Met (**Figure 54**), an additional evidence of the dose-dependent counteracting effect of Met on TGF- β . However, the activation of the GAB1 adaptor protein is not modified by TGF- β suggesting that in this case, the TGF- β action occurs at a different time point or that the interaction between TGF- β and HGF is independent of GAB1. Negative control of the HGF/Met pathway by TGF- β has been described in glioblastoma cells where TGF- β inhibits Met phosphorylation and as a result, inhibits stemness (Papa et al., 2017). Additionally, authors propose ERK1/2 pathway as the major mediator of the crosstalk between TGF- β and HGF. Remarkably, we observe a stronger activation of ERKs under combined treatment with HGF and TGF- β in both cell lines, although this phenomenon seems more robust in cells with lower levels of Met (**Figure 54**). Results do not reach statistical significance probably due to the limited number of experiments performed, but for now, results provide a potentially interesting candidate for the mechanism mediating the functional crosstalk between TGF- β and HGF in this model of Met-driven HCC that should be further evaluated.

Could the interplay TGF- β /HGF contribute somehow to tumor cell properties? The expression and/or activation of survival signaling pathways in HCC have been described to confer resistance to apoptosis. That is the case for EGFR signaling (Sancho et al., 2009) and Met signaling. Regarding the latest, it was shown that HGF through the activation of PI3K/AKT suppresses Fas-induced cell death in HCC cells (Suzuki et al., 2000). In the same line, our results evidence a proliferative and survival role for Met that counteracts the TGF- β growth inhibitory and pro-apoptotic activity. Thus, HCC cells with higher levels of Met show enhanced proliferative capacity and decreased sensitivity to TGF- β -induced apoptosis (**Figures 56 and 57**). We demonstrate Met dependence of cell proliferative and survival properties as Met inhibition results in sharp decrease in cell number and a strong increase in caspase-3 activity in both cell lines (**Figure 58**). Furthermore, in low-Met, but not high-Met HCC cells, co-treatment with HGF decreases the apoptotic response triggered by TGF- β (**Figure 58**) evidencing that the former cells are still able to respond to paracrine HGF. Besides, the lack of effect of HGF on cell number (**Figure 58**), suggests that HGF/Met signaling mainly drives survival. Nonetheless, if HGF/Met is able to block TGF- β -induced growth inhibition in this model of Met-driven HCC needs to

be clarified. Literature in this respect is also not fully clarifying since early works showed that HGF does not induce but rather inhibits proliferation in HCC (Tajima, 1991). Inhibitory effect on HCC development was also seen in HGF/TGF- α double transgenic mice with respect to TGF- α transgenic mice (Shiota et al., 1992). However, more recent findings demonstrate that treatment of HCC cell lines with PHA665752 Met inhibitor inhibits cell proliferation and induces apoptosis (You et al., 2011). Likewise, suppressing the Met/Ras/Raf/ERK signaling pathway (Cheng et al., 2018).

In summary, preliminary results presented here provide evidence that TGF- β signaling pathway is able to interfere with HGF/Met and viceversa. More in detail, Met exerts a negative regulation on TGF- β signaling, that leads to blockage of its apoptotic activity. TGF- β is also able to decrease Met activation, but this regulatory activity is lost when Met is constitutively active. This opens the door to future studies to analyze the implications of these and other potential effects in tumor development and progression.

3. General discussion

There are numerous studies about the key roles of HGF and TGF- β signaling pathways in liver pathophysiology, liver regeneration and hepatocarcinogenesis. However, much less is known about how these two signaling axes could interfere or interact with each other to control oval cell behavior during a regenerative process and its relevance in the development and progression of liver tumors.

On the one hand, in the present study, we deeply characterize the TGF- β -induced EMT in oval cells, process that leads to the acquisition of *in vitro* invasion, survival and proliferation advantages, but rather than promoting stemness it induces a more mature hepatic phenotype. The consequence of all these changes is an enhancement in oval cell regenerative capacity *in vivo*. Interestingly, HGF/Met signaling pathway has an essential role during EMT induction, counteracting TGF- β oxidative activity and allowing oval cells to overcome the senescence process activated during chronic treatment with TGF- β , and therefore, promoting oval cell expansion. Moreover, we reveal a role for Twist as a downstream mediator of Met-mediated antioxidant activity. HGF/Met signaling pathway also contributes to the induction and/or maintenance of the phenotypic and functional properties of oval cells after EMT.

On the other hand, we show preliminary results of an activation of the TGF- β pathway in livers with moderate Met overexpression and in subsequently developed tumors, which suggest a role of TGF- β in the development of the disease as well as a potential interaction between HGF and TGF- β signaling pathways in this context. Indeed, studies in HCC lines derived from these tumors show negative feedback loops of reciprocal regulation between HGF/Met and TGF- β . Although analysis of the functional relevance of such cross-regulation *in*

in vivo is still pending, we provide evidence that Met activity in HCC cells is critical for cell survival and protection against TGF- β -induced apoptosis.

This work contributes to improve our understanding of the mechanisms that regulate oval cell biology and fate in a liver regeneration process, which could be useful for the development of new therapies for CLDs. Besides, it opens new paths in the study of liver cancer pathogenic mechanisms.

10. Conclusions

1. Chronic treatment of oval cells with TGF- β leads to a stable and partial EMT phenotype.
2. TGF- β -induced EMT in oval cells does not increase stemness but rather promotes differentiation along the hepatic lineage, while conferring proliferation, survival and invasion advantages *in vitro*.
3. Oval cells chronically treated with TGF- β attenuate CCl₄-induced liver damage and fibrosis upon transplantation.
4. HGF/Met signaling activation is required to overcome the oxidative stress-induced senescence and allow oval cell expansion after TGF- β -induced EMT.
5. Twist is a downstream target of HGF/Met in oval cells that mediates the antioxidant activity driven by HGF/Met signaling and prevents cell senescence.
6. HGF/Met signaling modulates TGF- β -induced EMT phenotype in oval cells contributing to cell proliferation, survival and invasive advantages while counterbalancing the mesenchymal phenotypic switching.
7. HCC cell lines derived from Alb-R26^{Met} mice show negative regulatory circuits between HGF and TGF- β signaling pathways. Thus, HCC cells with high levels of Met show an attenuation of TGF- β -triggered Smad signaling, whereas TGF- β is able to decrease Met phosphorylation but only in HCC cells with low levels of Met.
8. HCC cell lines derived from Alb-R26^{Met} mice show dependence on Met signaling for cell survival and protection against TGF- β .

Key Words. HGF/c-Met • Oval cell • TGF- β • EMT

ABSTRACT

Adult hepatic progenitor cells (HPCs)/oval cells are bipotential progenitors that participate in liver repair responses upon chronic injury. Recent findings highlight HPCs plasticity and importance of the HPCs niche signals to determine their fate during the regenerative process, favoring either fibrogenesis or damage resolution. Transforming growth factor- β (TGF- β) and hepatocyte growth factor (HGF) are among the key signals involved in liver regeneration and as component of HPCs niche regulates HPCs biology. Here, we characterize the TGF- β -triggered epithelial–mesenchymal transition (EMT) response in oval cells, its effects on cell fate *in vivo*, and the regulatory effect of the HGF/c-Met signaling. Our data show that chronic treatment with TGF- β triggers a partial EMT in oval cells based on coexpression of epithelial and mesenchymal markers. The phenotypic and functional profiling indicates that TGF- β -induced EMT is not associated with stemness but rather represents a step forward along hepatic lineage. This phenotypic transition confers advantageous traits to HPCs including survival, migratory/invasive and metabolic benefit, overall enhancing the regenerative potential of oval cells upon transplantation into a carbon tetrachloride-damaged liver. We further uncover a key contribution of the HGF/c-Met pathway to modulate the TGF- β -mediated EMT response. It allows oval cells expansion after EMT by controlling oxidative stress and apoptosis, likely via Twist regulation, and it counterbalances EMT by maintaining epithelial properties. Our work provides evidence that a coordinated and balanced action of TGF- β and HGF are critical for achievement of the optimal regenerative potential of HPCs, opening new therapeutic perspectives. *STEM CELLS* 2019;00:1–11

SIGNIFICANCE STATEMENT

The findings from this study support that a balanced action of transforming growth factor- β and hepatocyte growth factor could determine liver progenitor's fate and the outcome of liver regeneration, and open possibilities for targeted therapies oriented at improving the regenerative capacity of these cells in chronic liver diseases.

INTRODUCTION

Adult hepatic progenitor cells (HPCs), known in rodent as oval cells, expand in situations of chronic liver damage or diseases in which hepatocyte proliferation and function are impaired and thus becoming a critical asset to orchestrate liver repair response [1, 2]. The progenitor-associated liver regeneration and supporting signals are still not well characterized. A good understanding of the regulation of HPCs is crucial not only because their regenerative potential makes them interesting

therapeutic targets in liver pathologies, but also because increasing evidence points to a role of oval cells in progression of liver fibrosis [3, 4], leaving the question on the role of oval cells in the context of chronic liver disease (CLD) open.

Transforming growth factor- β (TGF- β) is a central regulator in CLD contributing to seemingly all stages of disease [5, 6]. Once TGF- β is activated upon damage, it triggers crucial cellular events that drive disease progression. Thus, it promotes hepatic stellate cell (HSC) trans-differentiation into myofibroblast, the main
