similar to the PRG. Finally, the PRG is well positioned to contribute as active partners in shaping the future priorities and focuses of the PMC.

In conclusion, the PRG offers an innovative, tested, and comprehensive model to appropriately integrate stakeholder and patient perspectives into healthcare research. By including a framework that supports all four facets (researchers, patients, clinicians/clinical leaders, community/stakeholders) of health research throughout the research lifecycle, studies obtain legitimacy and resource support that is not easily found elsewhere. The PRG offers inclusive engagement, external buy-in, and a community-connected perspective that is sure to provide a *Voice for the Voiceless*.

Authors' Contributions

The authors are appreciative of additional input in the development and finalization of this manuscript from Cynthia Brandt, MD, MPH, and Peter Peduzzi, PhD, directors of the Pain Management Collaboratory Coordinating Center.

Since the first spinal cord electrode implantation in 1967 by Shealy et al., spinal cord stimulation (SCS) has gained an established role in standard pain practice [1]. In SCS, epidural electrodes are used to electrically modulate the circuitry in the spinal cord, thereby altering the functional connectivity between peripheral or central pain generators and pain perception networks. Little has been reported on side effects caused by disrupting the functional connectivity of nonpathological non-pain pathways. In the present commentary article, we report on 11 patients with a normal (nonpathological) spinal cord presenting with stimulationrelated autonomic side effects during SCS. We discuss the clinical and pathophysiological aspects and propose diagnostic and therapeutic guidance for clinicians encountering autonomic side effects in patients receiving SCS. In theory, loss of normal bladder function can be attributed to an electrical stimulation-induced alteration of functional connectivity, which induces reversible neurogenic bladder symptoms.

Of 386 patients treated with SCS at the University Hospitals Leuven between 2005 and 2021, three patients (0.8%) with SCS presented with new stimulation-related micturition side effects. Table 1 summarizes patientspecific details and stimulation-relatedness.

A 47-year-old male with complex regional pain syndrome after a crush injury of the right hand received an epidural quadripolar electrode (Pisces Quad Medtronic, Minneapolis, MN, USA) at C6-C7 in 2000, which resulted in significant pain relief. Nine years after the initial implantation, he developed abdominal paresthesia and new-onset urge incontinence (a strong urge to micturate during stimulation ON). Switching the stimulator off could completely and immediately resolve symptoms. The patient had no other medical history or preexisting urinary problems, no recent changes in medication or in SCS use, and no triggering factor that could be withheld. Urodynamic studies in ON-OFF mode revealed a bladder capacity of 140 mL with normal compliance and normal miction phase without residue in the OFF mode. In the ON mode, bladder capacity was limited to 17 mL, and immediate loss of urine occurred because of detrusor overactivity, i.e., an abnormal overactive contraction (Figure 1). Electromyography (including the pelvic floor) revealed bilateral changes in the motor unit potentials of lumbosacral levels L4-S4 in the ON mode (light polyphasic motor unit potentials with irregular firing). Radiography showed no displacement of the electrode, and urinalysis was normal. After multiple unsuccessful reprogramming attempts (abdominal paresthesia disappeared, and urinary incontinence ameliorated somewhat but persisted), a revision with an octopolar electrode (Medtronic, Minneapolis, MN, USA) positioned at a higher cervical level (C4-C7) resulted in good pain control without urinary side effects. Urinary incontinence, however, reappeared after 3 weeks and remained stimulation dependent at follow-up, for which reason the patient still wears urinary pads. Botulinum toxin bladder injections were refused by the patient because of reimbursement issues. Seven years later, turning the stimulation off still completely abolishes incontinence, and during impedance measurement, the patient involuntarily loses urine.

A 68-year-old male with failed back surgery syndrome after right-sided L4-L5 discectomy had been treated with SCS since 2000 for bilateral neuropathic pain in the lower limbs. In his history, only mild obstructive urinary symptoms (which required no further treatment) were relevant. There were no recent changes in medication use. Since placement of a new octopolar electrode (Medtronic, Minneapolis, MN, USA) at the T10-T11 vertebral level in 2020, the patient reported a sudden exacerbation of obstructive urinary symptoms (increased hesitancy with impossible miction in the first minute and increased intermittency), as well as difficulties in defecation. Symptoms were relieved by turning the stimulator off. During a 3-day OFF trial, all symptoms improved and returned to baseline. Electrode radiography, magnetic resonance imaging, and urinalysis were normal (Figure 2). Reprogramming of stimulation parameters $(2+3-4-5+, 4.15 \text{ V}, 330 \text{ } \mu\text{s}, 60 \text{ } \text{Hz})$ by decreasing the amplitude to 3.2 V led to improvement of the exacerbated symptoms while maintaining a good effect on neuropathic pain (the preoperatively known mild obstructive symptoms persisted).

In a 41-year-old woman with a newly implanted epidural electrode with the lower tip at the T11–T12 level for failed back surgery syndrome (after left-sided L5-S1 microdiscectomy) with unilateral neuropathic pain, two unprecedented episodes of significant and sudden urinary incontinence occurred in the first 3 months after SCS implantation. Between episodes, she had no urinary symptoms. The electrode was initially inserted at the T9-T10 level, but postoperative radiography revealed accidental displacement of the electrode (T11-12) as compared with intraoperative images. This displacement was accepted, as there was excellent pain relief. There was no relevant history or change in medication use. A direct causal role between SCS and the patient's urinary problems was less clear than in the two previously described patients, as urodynamic studies performed in ON mode were completely normal. The patient is currently in follow-up, and reprogramming will be considered in case of new urinary incontinence.

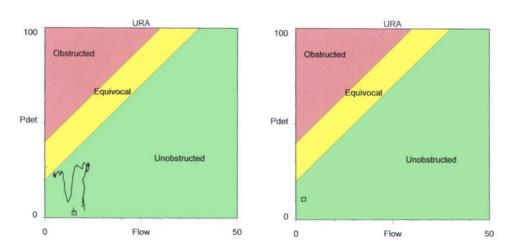

To compare our findings with international databases, we performed a search in the ongoing international PSR/ ISPR database (Medtronic, Minneapolis, MN, USA; Product Surveillance Registry [PSR], 2012-2021 and ongoing; Implantable Systems Performance Registry [ISPR], 2003-2016). This search resulted in eight additional patients with urinary side effects associated with SCS, out of a total of 2,259 patients (0.35%). Five patients presented with irritative urinary symptoms (urgency, frequency, or incontinence), and three presented with obstructive autonomic symptoms. More detailed information on the complaints, the stimulation-

Table 1. continued

Figure 2. Patient 2—electrode radiography and MRI. Patient 2 had stimulation-related obstructive autonomic symptoms during SCS for failed back surgery syndrome. After placement of a new octopolar electrode in 2020, stimulation-related obstructive urinary and fecal symptoms developed. Radiography revealed correct position of the electrode epidurally at the T10–T11 vertebral level. MRI confirmed correct position of the electrode and ruled out damage to the conus or spinal cord after surgery (MRI-compatible system). MRI= magnetic resonance imaging.

relatedness (by turning the stimulation ON and OFF), and reprogramming effects is presented in Table 1.

The present report aims to increase awareness about possible autonomic side effects of SCS. Two previous case studies discussed micturition inhibition during thoracolumbar SCS in patients with previous spinal cord injury [2, 3]. Urinary adverse effects were categorized as "very rare" in a recent review, based on these reports [4]. According to our report, autonomic bladder dysfunction could occur in an estimated 0.3–0.8% of patients receiving SCS.

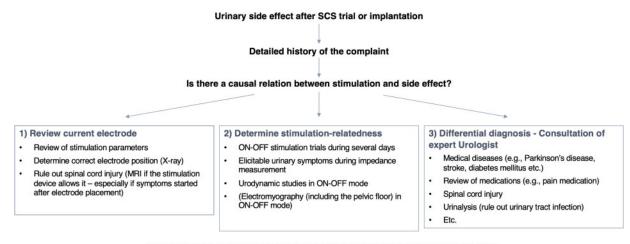

Urinary side effects were seen in both cervical and thoracic electrode locations and can encompass the spectrum of both obstructive and irritative bladder and bowel symptoms (obstructive bladder symptoms in 4/11, irritative bladder in 7/11, obstructive bowel in 3/11, and irritative bowel in 1/11 subjects). Furthermore, a direct causal link between neurostimulation and reversible bladder symptoms is suggested by 1) a urodynamic study in ON-OFF mode in one patient, 2) involuntary urine loss during routine electrode impedance measurement at a clinical visit in two patients, and 3) resolution of symptoms by turning the stimulation OFF in eight patients (not reported in three). Reprogramming of the stimulation parameters resulted in resolution of symptoms in three of five patients (i.e., the five out of eleven subjects that underwent reprogramming. A watchful waiting strategy was deployed in one out of eleven and no information on management in the remaining five out of eleven subjects), one of five showed partial resolution (resolution of the exacerbated symptoms, though baseline prostatism complaints remained), and one of five showed improvement without complete resolution, for which a surgical revision brought partial relief.

Conversely, SCS has been experimentally used to treat urinary dysfunction [5]. A case report described a patient with preexisting urinary incontinence, for which she received sacral nerve stimulation [6]. She concomitantly suffered from failed back surgery syndrome after lumbar surgery, for which an SCS device was implanted (T8–T10). This resulted in excellent pain relief and an unforeseen relief of urinary incontinence, which allowed the sacral neurostimulator to be discontinued [6]. Another article reported on high-frequency SCS in treating neurogenic bladder incontinence in spinal cord injury or neurological disease [7].

We offer a diagnostic and therapeutic guide for clinicians encountering autonomic side effects in SCS in daily practice. As a first step, one should determine a probable

causality between stimulation and the side effect: A detailed history of the complaint, ON-OFF stimulation trials (and provoking symptoms during impedance measurement), and urodynamic studies in ON and OFF mode can objectify the impact of stimulation on voiding. Electromyography (including the pelvic floor) might reveal a functional impact on normal motor function. Second, there exists a complex interplay between the neural control of micturition and (chronic and acute) disease, medications, and spinal cord injury. To differentiate, ruling out spinal cord (or conus) damage with magnetic resonance imaging (if the stimulation device allows, and especially if symptoms started after electrode insertion), assessing correct epidural position with electrode radiography, ruling out infection with urinalysis, and reviewing medications (e.g., opioids) and concurrent medical diseases affecting micturition (e.g., benign prostatic hyperplasia, diabetes mellitus, stroke, Parkinson's disease, etc.) are necessary. Consultation with an expert urologist can be useful (Figure 3).

We propose reprogramming stimulation parameters as a first step in an attempt to resolve side effects. If this fails, surgical repositioning of the electrode might alleviate symptoms. Decreasing the amplitude of stimulation will decrease the volume of activated tissue, whereby, hypothetically, the tracts related to micturition will be less affected by SCS. A replacement in a different position can theoretically benefit the patient, as the target tissue activated by stimulation will differ. One could speculate that such stimulation will still result in positive effects on pain while at the same time avoiding the

Probable, possible or uncertain causal relation between stimulation and side effect

Management options

- 1) Reprogramming of stimulation parameters
- 2) Surgical repositioning of the electrode
- Symptomatic treatment Consult expert
- Urologist (e.g., Botulinum toxin injections for overactive bladder symptoms)

Figure 3. Diagnostic flowchart. Suggested diagnostic measures to guide clinicians in determining a probable, possible, or uncertain causal relation between stimulation and urinary side effects after SCS trial or implantation. X-ray = radiography; MRI = magnetic resonance imaging.

Insula Hypothalamus (caudal and preoptic)	Visceral sensation (desire to void) Likely role in permitting voiding when enviro PMC)	nment is deemed "safe" (through direct control of

During bladder filling, a local interneural spinal reflex known as the "guarding reflex" promotes continence. Afferent vesical input (pelvic nerves) stimulates spinal sympathetic output, which leads to contraction of the bladder neck and urethra (hypogastric nerve), inhibits detrusor muscle contraction, and stimulates pudendal output to the external sphincter (contraction). A pontine storage center might also contribute to external urethral sphincter contraction. The spinobulbospinal reflex facilitates voiding. Afferent ascending input passes via the PAG to the PMC, which stimulates parasympathetic output to the detrusor muscle (contraction) and internal sphincter (relaxation) and inhibits sympathetic and pudendal output. Higher cerebral regions are responsible for conscious sensation, integration of the social environment, and the switch between storage and voiding.^{8, 9} CNS = central nervous system; T = thoracic; L = lumbar; S = sacral; PAG = periaqueductal gray; PMC = pontine micturition center.

adverse effects due to stimulation of the micturition tracts. No specific stimulation parameters or lead positions are known to cause these adverse effects, nor do optimal programming or placement strategies exist to avoid these symptoms. For refractory cases, the benefits of SCS should be weighed against the burden of micturition dysfunction. Symptomatic treatment (e.g., botulinum toxin injections for overactive bladder) by an expert urologist might alleviate symptoms while keeping stimulation in place.

The exact mechanisms underlying autonomic side effects in SCS remain elusive, and neural control of micturition is a complex system (its components are summarized in Table 2) [8, 9]. SCS might act locally through interference with the local afferent and interneural network in the spinal cord, which is located mainly in the superficial dorsal horn, dorsal commissure, and intermediolateral region (local spinal reflexes). Passing efferent autonomic or somatic fibers could be modulated in the same way. Furthermore, disrupting the functional connectivity between the spinal cord and supraspinal micturition centers by modulating ascending and descending autonomic spinal tracts involved in micturition could be an alternative mechanism. Indeed, as presented, cervical electrode positions can cause these side effects, remote from the local spinal micturition regions (thoracolumbar and sacral spinal segments). Lastly, modulation of supraspinal micturition regions could possibly explain side effects seen in thoracolumbar and cervical electrodes, as SCS is known to cause both functional and morphometric distant brain effects (e.g., through prefrontal regions and the anterior cingulate cortex, which are regions that are also involved in micturition) [10, 11]. Further research is needed to elucidate patient- and stimulationrelated factors predisposing to stimulation-induced autonomic side effects, as well as mechanisms of action and subsequent therapeutic interventions.
