1 Large-scale, linked drainage systems in the NW European Triassic: insights from the Pb 2 isotopic composition of detrital K-feldspar. 3 4 Shane Tyrrell¹*, Peter D.W. Haughton¹, A. Kate Souders², J. Stephen Daly³ and Patrick M. 5 6 Shannon¹ 7 8 ¹Sand Provenance Centre, UCD School of Geological Sciences, University College Dublin, 9 Belfield, Dublin 4, Ireland 10 11 ²MicroAnalysis Facility, INCO Innovation Centre and Department of Earth Sciences, Memorial 12 University, St. John's, NL A1B 3X5, Canada 13 14 ³National Centre for Isotope Geochemistry, UCD School of Geological Sciences, University 15 College Dublin, Belfield, Dublin 4, Ireland 16 17 18 * Corresponding author (e-mail: shane.tyrrell@ucd.ie) 19 20 Words: 6070, References: 50, Tables: 2, Figures: 8 21 22 Running head: Palaeodrainage in the NW European Triassic 23 24 Abstract: Pb isotopic data from K-feldspars in Middle Triassic (Anisian) sandstones in the Wessex 25 Basin, onshore southwest UK, and the East Irish Sea Basin, some 350 km to the north, show that 26 the same grain populations are present. This indicates that the drainage system (the 27 "Budleighensis" River) feeding these basins originated from the same source/s, most probably the 28 remnant Variscan Uplands to the south. Fluvial and aeolian sandstones have the same 29 provenance, suggesting that if water- and wind-driven sands were originally derived from different 30 sources, this has been obscured through reworking prior to final deposition. Significant recycling 31 of feldspar from arkosic sandstones in earlier sedimentary basins can be ruled out. The 32 provenance data agree with previous depositional models, indicating transport distances in 33 excess of 400 km, with a drainage pattern that linked separate basins. This supports the idea that 34 the regional fluvial system was driven by topography and episodic flooding events of sufficient 35 magnitude to overcome evaporation and infiltration over hundred's of kilometres. Importantly, this 36 drainage system appears to have been isolated and independent from those operating

contemporaneously to the northwest of the Irish and Scottish massifs, where the remnantVariscan Uplands apparently exerted no influence on drainage or sand supply.

39

40

41 The Southern UK and offshore Ireland Triassic succession, comprising the Early - Middle 42 Triassic (Olenekian – Anisian) Sherwood Sandstone Group (SSG) and the Middle – Late Triassic 43 (Ladinian – Norian) Mercia Mudstone Group, represents the deposits of large-scale endorheic 44 drainage systems that accumulated in the arid to semi-arid interior of the Pangaean 45 Supercontinent. Infilling a series of wide, extensional rift basins, the distribution and depositional 46 style of these successions is well constrained, both onshore and offshore UK and include 47 ephemeral fluvial, alluvial and playa lacustrine with sub-ordinate aeolian facies. The Variscan 48 Uplands of west and central Europe are thought to have exerted a strong control on drainage 49 evolution, resulting in large-scale (> 300 km), south-to-north flowing rivers (i.e. the 'Budleighensis' 50 river system; Wills 1970; Audley-Charles 1970; Warrington & Ivimey-Cooke 1992) which fed a 51 series of sedimentary basins and terminated in playa lake environments. It has also been 52 established that the distribution of sedimentary facies in the Triassic basins was controlled by a 53 complex interplay of climate and tectonics (Ruffell & Shelton 1999). Dispersal of clastic material 54 from the uplands into the basins was likely driven by both topography and by climate, and was 55 particularly influenced by periodic (perhaps seasonal) variations in precipitation (McKie and 56 Williams, 2009). Palaeomagnetic data suggest that this area of NW Europe lay between 15 and 57 25° N and was influenced by SW-directed subtropical trade winds giving rise to general semi-arid 58 conditions (McKie and Williams, 2009) but with an annual summer monsoon (Kutzbach & 59 Gallimore 1989; Szulc 1999; Preto et al. 2010). Cyclic variability in sedimentation in the European 60 Triassic (Meadows & Beach 1993; Bourguin et al. 2009) suggests that large scale fluvial systems 61 were more active during phases of increased precipitation (McKie & Williams 2009). The majority 62 of this precipitation likely fell on the high ground and especially on the remnant Variscan Uplands. 63 as this would have been the first significant high ground encountered by the monsoonal weather 64 systems originating from the south. Flooding was, therefore, likely an annual occurrence, driving 65 transport of clastic material from the uplands into the hinterland basins and beyond.

66

The term 'Budleighensis' river was first proposed to account for the deposition of thick, regionallysignificant, fine to medium-grained, red-bed sandstone-dominated facies of Triassic (Olenekian – Anisian) age across south, central and north-east England (Wills 1970; Audley-Charles 1970). Interpreted to flow from south to north, and with deposits apparently related to this system encountered in the Wessex, Knowle, Worcester, Stafford, Cheshire and East Irish Sea basins (and perhaps further north into the Solway and Ulster basins) (Figure 1, 2), it is among the better documented large-scale, climate-controlled fluvial systems of the Triassic. The topographically significant Variscan Uplands to the south are suggested to be the source for these sandstones
(Wills 1950; Fitch *et al.* 1966). However, the source areas of these sedimentary rocks have not
been explicitly demonstrated.

77

78 Various approaches have been applied to determine the provenance of Early – Middle Triassic 79 successions in central Europe (e.g. Koppen and Carter 2000), in the North Sea (Mearns et al. 80 1989; Knudsen 2001; Preston et al. 2002), in basins west of Ireland (Tyrrell et al. 2007) and west 81 of Shetland (Morton et al. 2007; Tyrrell et al. 2009) but provenance research specifically on the 82 'Budleighensis' system has been limited. Previous provenance work in the Wessex Basin mainly 83 focussed on the lithological comparison of clast assemblages in conglomeratic horizons 84 (especially in the Budleigh Salterton Pebble Beds, Smith 1990; Smith & Edwards 1991), which do 85 not necessarily share the same provenance as the finer grained sandstones that dominate higher 86 in the succession and that are the focus of this study. Nonetheless, these petrographic studies 87 identified detritus of Variscan granites and gneisses of likely Cadomian affinity, both sourced from 88 northern France. Fitch et al. (1966) utilised detrital muscovite ages to demonstrate the 89 predominance of Variscan-aged detritus in the Cheshire Basin. Detailed analysis of heavy 90 mineral assemblages in feldspar-rich sandstones from the East Irish Sea Basin (Mange et al. 91 1999) was used to correlate barren strata. Mange et al. (1999) argue that local input, particularly 92 from the Welsh Massif, was significant, mostly from reworked metasedimentary and sedimentary 93 rocks. There are also components (especially tourmaline) which indicate a southern, Variscan 94 Upland, source, whereas zircon could not be linked to a specific provenance. Notably, the source 95 areas suggested by Mange et al. (1999) cannot account for the abundance of K-feldspar in these 96 sandstones.

97

98 The sandstones targeted in this study form a regionally important aguifer and a proven reservoir 99 for hydrocarbons in a number of sedimentary basins in the area, including the Wessex and East 100 Irish Sea basins (McKie et al. 2007; Meadows and Beach 1993). Provenance analysis of the 101 drainage system supplying these sands is important because its scale is relatively poorly 102 constrained (<200 km or >500 km?) and it is uncertain as to how far it extends northward, 103 possibly beyond the East Irish Sea Basin and into the Solway (Brookfield 2004) and/or Ulster 104 basins. Furthermore, it is unclear to what extent these separate basins drained internally or 105 whether the envisaged large-scale fluvial system was through-going within the array of 106 sedimentary basins from the Wessex Basin northward to the East Irish Sea Basin. There are also 107 uncertainties as to the relative contributions of axial (i.e. the Variscan Uplands) and more local 108 transverse sources (e.g. the Welsh Massif, the London-Brabant High) and the potential contrasts 109 in sources of fluvial and aeolian sediment. Moreover, it is not certain how or if these systems are 110 related to contemporaneous drainage systems operating further to the north and west in the

111 Atlantic Margin basins. Although it was originally envisaged that Triassic drainage systems in the 112 Atlantic Margin basins were derived from and controlled by the Variscan Uplands to the south 113 (e.g. in the Slyne Basin, Dancer 2005), recent work has shown this not to be the case (Tyrrell et 114 al. 2007; McKie & Williams 2009; Redfern et al. 2010). In terms of the broad regional Triassic 115 system, therefore, it is important to recognise how, and to speculate why, these systems may 116 differ. In broader terms, these types of provenance studies help constrain the pattern of rifting 117 within this part of the Pangaean Supercontinent, as the uplift and availability of specific source 118 domains is recorded in the detrital archive.

119

120 In petrographic terms, the nature of these sandstones poses some additional questions. It is 121 unclear how the interaction of topography, tectonics and climatic factors can produce extensive 122 regional spreads of sandstones such as those seen in the Triassic in NW Europe. The origin and 123 genesis of these widely-dispersed, texturally mature, yet mineralogically sub-mature (arkosic), 124 sandstones is believed to result from the complex interplay of climate and tectonics (Ruffell & 125 Shelton 1999; Brookfield 2004). Establishing the provenance of these sandstones, especially with 126 a method that utilises a key framework component (i.e. K-feldspar), allows for a better 127 understanding of these processes.

128

129 The Pb-in-K-feldspar provenance tool is particularly applicable to addressing some of the above 130 issues, especially given the feldspathic nature of the Triassic sandstones in these basins. Recent 131 studies have demonstrated the value of the Pb isotopic composition of detrital K-feldspar as a 132 regional scale sand provenance tool (Tyrrell et al. 2007, 2009, 2010; Clift et al. 2008). It has been 133 shown that K-feldspar retains the signature of its source despite erosion, transport and 134 diagenesis (Tyrrell et al. 2006). The continental crust exhibits sub-orogenic scale (~100 km) 135 variations in Pb isotopic composition and potential sourcelands can thus be characterised on a 136 scale appropriate to that of major drainage systems. Furthermore, the Pb isotopic signature of a 137 granitic or gneiss does not vary with depth, hence K-feldspar with the same distinct Pb signature 138 will always be supplied for a discrete source area regardless of the erosion level. The method 139 involves in situ Pb isotopic analysis of individual detrital K-feldspar sand grains using laser 140 ablation multi-collector inductively-coupled plasma mass spectrometry (LA-MC-ICPMS) preceded 141 by detailed imaging (Backscatter electron (BSE) and cathodoluminescence (CL) imaging) so that 142 heterogeneities (e.g. inclusions, alteration) can be avoided. The use of ion counters to measure 143 Pb ion beams means that data can be retrieved at a spatial resolution (~30 µm laser spot sizes) 144 similar to that achieved using the ion microprobe technique, but with better analytical precision 145 (Tyrrell et al. 2010). Using LA-MC-ICPMS to analyse the Pb isotopic signal means the data can 146 be acquired rapidly and relatively inexpensively and the technique requires only a previouslyimaged, thick polished section, thereby retaining the grain context within the sedimentary rocksample.

149

150 One of the major advantages of the Pb K-feldspar provenance tool is that, in contrast to 151 provenance approaches that utilise signals in robust grains (e.g. U-Pb zircon), it provides a 152 means of assessing first-cycle sand-grain provenance. Furthermore, where it occurs as a 153 significant framework component (~20% modal abundance), K-feldspar must presumably be 154 more representative of the source area than relatively minor components such as zircon which 155 typically make up << 1% of the mode. In these circumstances, K-feldspar can be a proxy for the 156 source of a large portion of the detrital guartz as there is a reasonable probability both minerals 157 are derived from the same source/s. As fresh detrital K-feldspar is unlikely to survive more than 158 one sedimentary cycle, these grains can be tracked back directly to their basement source, 159 allowing the scale and geometry of the drainage system to be constrained. These types of 160 insights can improve prediction of reservoir sandstone distribution and quality in the subsurface. 161 Importantly, there is much published Pb data from potential basement source areas in the North 162 Atlantic Region with which detrital data can be compared. In this study, additional basement data 163 were collected to provide further constraints on possible sources.

164

165 This study is specifically focussed on Middle Triassic sandstones. Although there are 166 uncertainties with the definitive ages within the Triassic system due to the scarcity of 167 biostratigraphic markers, Rhyncosaurs provide constraints on the Otter Sandstone Formation 168 (Hounslow and MacIntosh 2003) in the Wessex Basin and palaeomagnetic data helps constrain 169 the age of the Ormskirk Sandstone Formation in the EISB (Meadows 2006). These sandstones 170 units are considered to correspond to the upper part of SSG, are very likely of Anisian age and 171 are both near contemporaneous (Figure 1, 2). Both units lie directly above a distinct and widely 172 recognised discontinuity, namely the Hardesgan Unconformity (McKie & Williams 2009; McKie & 173 Shannon 2011). Correlated well log data illustrate that Otter Formation sandstones comprise a 174 relatively thin succession within the Wessex Basin, but their equivalents are thicker in the basins 175 to the north (Figure 2; McKie & Williams 2009). This thickening is not as significant as that seen in 176 the Early-Middle Triassic sandstones (Lower SSG) where the increased accommodation space to 177 the north is likely due to a combination of differential subsidence and tectonism. In the EISB, the 178 Ormskirk Formation sandstones are interbedded with thin mudstones and mud-prone 179 sandstones, likely of playa lake and damp aeolian sandsheet origin, and may reflect the onset of 180 termination of the drainage system (McKie & Williams 2009).

- 181
- 182
- 183 Methods:

184 Sampling and petrography:

185 Cores from four East Irish Sea Basin wells (Figure 1) were sampled at the Department of Energy 186 and Climate Change (DECC) core store, Edinburgh, UK. The choice of EISB sandstone samples 187 was guided by extensive sedimentary logging carried out by Meadows (2004). The sampling 188 strategy was designed to target the same range of stratigraphy and facies from four wells 189 penetrating the Ormskirk Sandstone Formation. Coastal outcrops of Budleigh Salterton Pebble 190 Beds and the overlying Otter Sandstone Formation were also sampled at Budleigh Salterton in 191 the Wessex Basin. New basement samples were collected in the field, or, in the case of granites 192 from southwest UK and northern France, selected from petrographic collections based at the 193 UCD School of Geological Sciences (see table 2 for locations). Thin sections of all samples were 194 examined using standard optical petrography.

195

196 Backscatter electron and cathodoluminescence imaging:

After initial petrographic assessment, sections of ~300µm thickness were prepared from which Kfeldspar grains were selected and imaged using backscatter electron (BSE) and cathodoluminescence (CL) at the Electron Microprobe Laboratory, Geowissenschaftliches Zentrum, Göttingen, Germany. Further BSE images K-feldspars were collected using a Hitachi TM-1000 desktop scanning electron microscope at the School of Geological Sciences, University College Dublin, Ireland.

203

204

205 *Pb analysis:*

Pb, U and Th concentrations were determined at the Microanalysis Facility, InCo Innovation Centre, Memorial University, Newfoundland (MUN), using an ELEMENT ICPMS connected to a Geolas 193nm Excimer laser. Pb isotopic analyses were carried out both at MUN and at the National Centre for Isotope Geochemistry (NCIG) at UCD, Dublin, using NEPTUNE MC-ICPMS instruments. A New Wave 193nm excimer laser was employed to ablate the target grains at NCIG.

212

213 Two different collector configurations were used during analysis. An ion counter collector 214 configuration was implemented at MUN, allowing Pb analysis from ~30 µm laser ablation pits, 215 which is only slightly larger than spot sizes used to collect Pb isotopic data using secondary ion 216 mass spectrometry (SIMS) (e.g. Clift et al. 2008), but with much lower errors and better 217 reproducibility. A Faraday collector array was utilised at the NCIG, where tracks of <150 µm with 218 a spot size of 75 µm were ablated in preference to single spots. The larger volume of material 219 was ablated when using the Faraday collectors, as these are not as sensitive as the ion counters. 220 Repeat analyses of the same grains replicated the initial data within error (Table 1).

221

222 The analytical technique is described in more detail in Tyrrell et al. (2009, 2010). ²⁰⁴Pb, ²⁰⁶Pb, ²⁰⁷Pb and ²⁰⁸Pb were measured. ²⁰²Hg was also measured during analysis in order to correct for 223 isobaric interference of ²⁰⁴Hg on ²⁰⁴Pb. In the case of the Faraday collectors, ²⁰³TI and ²⁰⁵TI were 224 225 measured and utilised in the standard-sample bracketing fractionation corrections. For both 226 collector configurations, these instrumental mass bias corrections were based on isotopic ratios 227 measured in either standard glasses BCR2g or NIST 612. Analytical uncertainties (20 on 228 ²⁰⁶Pb/²⁰⁴Pb) are <0.1%. Within each analytical run, standard glasses, including NIST 612 and 229 BCR2g and samples of Shap Granite feldspar (which has a well-characterised and narrow range 230 of Pb isotopic composition) were run as unknowns in order to verify the data reduction. The 231 values obtained for these "unknown knowns" standards and the Shap Granite K-feldspar are 232 within error of published values, which have been obtained through isotope dilution thermal 233 ionisation mass spectrometry.

234

235 Results

236 The sampled arkosic sandstones are generally medium-grained and well-sorted with feldspar 237 contents (dominantly K-feldspar) varying between 12.5% and 22.5%. The sandstones contain 238 patchy dolomite cements, authigenic quartz and K-feldspar overgrowths. SEM imaging of K-239 feldspars show a variety of inclusions, dominantly albitic lamellae, albitic veins and quartz, and 240 often display areally restricted alteration. This alteration usually comprises discrete zones of the 241 grains which have undergone albitisation, but less frequently the K-feldspar has been further 242 altered such that only a skeletal framework remains. In any case, altered zones were avoided 243 during laser ablation. Rounded K-feldspar grains are common, both in fluvial and aeolian 244 sandstones, and there is no obvious association between grain morphology and sedimentary 245 facies. Authigenic K-feldspar overgrowths are common in all the sampled sandstones, often 246 modifying the primary detrital K-feldspar grain shape (Figure 3). CL imaging proved particularly 247 useful in indicating the overgrowths, with the authigenic component often picked out by a darker 248 CL response in contrast to the bright luminescence of the original detrital grains (Figure 3B). 249 Although the overgrowths were not wide enough to analyse, they were avoided during analysis in 250 case their Pb signal differed from that in the detrital grains.

251

The Pb concentration (where analysed) and isotopic composition of 187 individual K-feldspar grains from 20 samples are shown in Table 1. This dataset comprises analyses of 73 K-feldspars from the Ormskirk Sandstone Formation in four wells (110/14-3; 110/13-5; 110/8a-5; 110/2-6) in the East Irish Sea Basin (locations shown in Figure 1) and 114 K-feldspars from the Otter Sandstone Formation and 2 K-feldspar crystals from a clast of feldspar porphyry from the Budleigh Salterton Pebble Beds (BSPB), both from coastal outcrops in the Wessex Basin. Ninety one of the 114 K-feldspars analysed from the Otter Sandstone Formation were obtained using the
 Faraday collector configuration (see above). This included the re-analysis of several grains, the
 results of which replicated the initial data (see data marked "repeat" in table 1).

261

262 Where measured, Pb concentrations of K-feldspar grains varied between 5 and 200 ppm (mean = 263 75 ppm). U and Th concentrations for measured grains and are typically < 0.01 ppm. A small 264 number of grains had U and Th concentrations in excess of 0.5 ppm, but the vast majority had 265 sufficient U or Th to require corrections to the common Pb signature for radioactive decay. There 266 is no discernable link between the Pb. U and Th concentration and the isotopic composition of the grains. Pb isotopes from the K-feldspars are generally radiogenic with ²⁰⁶Pb/²⁰⁴Pb in the range 267 17.124 to 18.561 (mean = 18.136) and ²⁰⁷Pb/²⁰⁴Pb in the range 15.289 to 15.849 (mean = 268 269 15.591). The more radiogenic grains are more abundant, with the most dense grouping in the ²⁰⁶Pb/²⁰⁴Pb range of 18.1 to 18.5 (Figure 4). 270

271

272 Detrital K-feldspar data can be compared directly with Pb data from basement rocks in NW 273 Europe, comprising both K-feldspar and whole rock analyses. These comparative datasets are 274 compiled from published work and are supplemented with new basement data (Table 2). 275 Published data come from numerous sources, summarised in Tyrrell et al. (2006, 2007, 2009, 276 2010). New data comprise analysis of K-feldspars in granitic rocks from northern France, south 277 east Ireland and the south east UK and Carboniferous sandstones from NW Ireland. Rocks from 278 northern France were analysed in order to verify the Pb isotopic signature of K-feldspar from 279 Variscan Granites in this area and to constrain that of older granites and granitic rocks in the 280 region. Data from Variscan Granites in Normandy and Brittany largely agree with published 281 values from Vitrac et al. 1981, although they form a broader range (Figure 5A, 5B). However it 282 should be noted that although the range of new data includes a 2 σ error, the errors are not shown 283 for the previously published data. Pb K-feldspar analyses of Cadomian-aged granites from the 284 same region yield less radiogenic Pb than the Variscan granites (Figure 5A, see discussion 285 below). Analysis of Variscan Granite from Cornwall (the Lands End Granite) yields a slightly more 286 radiogenic signature than the pene-contemporaneous granites from northern France (Figure 5A). 287 Further new analyses from granitic rocks from south east Ireland constrain the Pb isotopic 288 signature of the Carnsore and Leinster Granites and a granitic vein cutting the Rosslare Complex 289 (Figure 5C). Although these could potentially be a source of K-feldspar themselves, especially for 290 the EISB K-feldspars, they also may be a reasonable proxy for the Pb isotopic signature of the 291 Welsh Massif (see discussion below). It is worth noting that although the Caledonian-aged 292 Leinster Granite has a Pb isotopic signature which is almost identical to other Caledonian 293 granites along structural strike, south of the Southern Uplands (i.e. the Shap Granite, Figure 5C, 294 D), the Carnsore Granite (also Caledonian in age) has a less radiogenic signature and has more in common with the Cadomian granite of northern France (Figures 5C, A). The Pb isotopic
 composition of detrital K-feldspar from arkosic Lower Carboniferous sandstones (Mullaghmore
 Sandstone Formation) in NW Ireland was analysed (Figure 6) in order to constrain potential
 second-cycle K-feldspar sources on the Irish Massif.

299

300

301

302 Discussion:

303 The 'Budleighensis' river system:

304 The Pb isotopic composition of detrital K-feldspar grains in contemporaneous Middle Triassic 305 sandstones from 1) the Ormskirk Sandstone Formation from exploration well cores in the EISB 306 (offshore East UK); and 2) outcrops of Otter Sandstone Formation in the Wessex Basin (onshore 307 southwest UK) broadly show the same ranges of Pb isotopic composition (Figure 4C). There is a subtle difference in that, although the range of ²⁰⁶Pb/²⁰⁴Pb is almost identical between the two 308 sandstone units, the ²⁰⁷Pb/²⁰⁴Pb range and average is slightly lower in the Wessex Basin 309 310 sandstones (Figure 4A, B). This variation is small and, although it might reflect differences in the 311 relative proportions of grains derived from each contributing source areas, it does not suggest a 312 significantly different provenance (Figure 5). The suggestion of common source areas for both 313 these sandstone units indicates that the drainage system supplying the two basins was linked, 314 suggesting they lay along the same regional sand dispersal path which threaded northward 315 through the intervening basins and sub-basins.

316

317 The most likely source (i.e. the best fit given the range of data) for the bulk of the K-feldspar 318 grains are granites and granitic rocks of Variscan and older age comprising the remnant Variscan 319 Uplands to the south, especially those from northern France (Brittany and Normandy; Figure 5A) 320 and, to a lesser extent, the French Massif Central and the Pyrennes (Figure 5B). There is also 321 input from more local sources on the Cornubia Massif, though the data indicate this is a relatively 322 minor component compared to the contribution from northern France sources (Figure 5A). 323 However, data are from one granite (the Land's End granite) and there may have been a larger 324 contribution from other granites such as the volumetrically significant Dartmoor Granite for which 325 Pb isotopic data are not yet available.

326

New Pb basement data suggests that the less radiogenic Pb K-feldspar (i.e. ²⁰⁶Pb/²⁰⁴Pb < 18) is likely derived from Precambrian granites and gneisses within the Variscides (Figure 5A). These rocks, either associated with the Cadomian orogeny or of older ambiguous origin, comprise part of modern Brittany, Normandy and the Channel Islands. Although there are data from only one rock unit of this affinity (the Carolles Granite) it is postulated that basement of Cadomian and preCadomian affinity was partly/wholly reworked on a regional scale to produce Variscan granites, so the Pb component in the later granites was inherited from early basement (Vitrac *et al.* 1981). The reworking of Cadomian basement Pb into Variscan granites is also recorded in central Europe (Klötzli *et al.* 2001). This agrees with the new data, where Pb in Cadomian K-feldspar is less radiogenic than its Variscan successor, and hence these rocks are an appropriate source for the less radiogenic populations in the Triassic detrital record.

338

The Pb isotopic signature of the authigenic K-feldspar overgrowths is not known and it remains unclear how these might relate to that of the detrital grains. An understanding of these could provide constraints on the nature and source of early pore fluids. With smaller spot sizes and optimised ICPMS conditions it should be feasible in future to measure the Pb isotopic composition of these thin grain coating rims.

344

These data suggest minimum drainage length-scales in excess of 400 km for the 'Budleighensis' river system. This is in agreement with published palaeoflow data and with palaeogeographic reconstructions for the period (Audley-Charles, 1970). However, sources from farther south cannot be ruled out and it is consistent with the Pb data that some grains have been transported from the Pyrenees or the Massif Central. This would imply drainage scales in excess of 800 km.

350

351 There are some ambiguities within the data which prevent the ruling out of certain sources. For 352 example, basement data from Southern Uplands granites partially overlap with Variscan Pb 353 domains. Hence, feldspar data from the WB corresponds well with that from Southern Uplands 354 Granites (Figure 5D), but it is extremely difficult to envisage a process where this could be a 355 major source for sandstones in the Wessex Basin. This 'sourcing' would also conflict with the 356 wealth of published palaeocurrent data indicating northward transport. However, the Southern 357 Uplands could reasonable contribute a minor source for sand in the more proximal EISB. In 358 addition, feldspar data from the EISB partially overlaps with the range of Shap Granite K-feldspar 359 (Figure 5D). This, therefore, is a possible source for some of the sand in the EISB, but the lack of 360 significant grains from a broader area of Northern England or the Scottish Massif suggests this 361 area was, at most, a minor contributor of K-feldspar.

362

There are no comparative basement Pb data available from the Welsh or the London-Brabant Massifs, therefore it remains uncertain to what extent these areas could be a source for clastic detritus during the Triassic. There is little evidence to suggest that the London-Brabant Massif comprised significant sources of K-feldspar. New Pb K-feldspar basement data from Caledonian granites (Carnsore and Leinster Granites), and a mylonitised granitic vein (cutting the Rosslare Complex, a terrane of Avalonian affinity, correlated with the Monian of NW Wales (Gibbons and 369 Horak 1996)) and published galena data from the Irish Massif (Figure 5C) are likely a reasonable 370 proxy for the Pb isotopic basement composition of the Welsh Massif as these southern Irish 371 domains extend along strike north-eastward. Although there is some overlap between these 372 basement data and the detrital data, the same range of data is not seen in the detrital dataset 373 (Figure 5C), indicating that the Welsh Massif was likely only a minor source for the K-feldspar 374 grains in the EISB and WB. There are also grains with Pb isotopic compositions that outlie the 375 range of characterised Variscan or Cadomian K-feldspar (Figure 5E) and do not appear to 376 correspond to any other specific source. These grains may represent uncharacterised Variscan, 377 Cadomian or a more minor contributory basement source and their presence supports the 378 preferred models of palaeodrainage which envisage detrital contributions from a wide catchment 379 via an extensive tributary system.

380

381 The work of Mange et al. (1999) concluded that a significant fraction of the heavy mineral detritus 382 in the Ormskirk Sandstone Formation was recycled, speculatively from the Welsh Massif. It is 383 sensible to assume that a portion of the detrital zircon present was also recycled from older 384 sedimentary successions. Geochronological data from zircons in these sandstones are likely. 385 therefore, to have yielded a "mixed" and non-unique range of ages, due to the incorporation of 386 recycled and/or inherited zircon from the numerous igneous, sedimentary and meta-sedimentary 387 sources which may have been available. Its is possible to imagine such diverse sources for 388 recycled zircon as Lower Palaeozoic meta-sedimentary successions on the Welsh Massif, Old 389 Red Sandstone and Culm-facies equivalents from Cornubia, or from Upper Carboniferous 390 sandstones from the Pennine Basin. It would be extremely challenging to unravel this potential 391 mix of contributors, especially as it would likely be impossible to distinguish first cycle from 392 polycyclic material. However, it is worth noting that the modal abundance of K-feldspar in these 393 Triassic sandstones (between 12.5 and 22.5%) implies that lithologies with high K-feldspar 394 contents (granites and gneisses) must have supplied a significant portion of the sand. Rocks with 395 little or no K-feldspar must also have contributed – at the very least contributions from the country 396 rocks surrounding the granitic sources would be anticipated and these, being dominantly 397 sedimentary and metasedimentary in nature, are the likely sources for the recycled components 398 recognised by Mange et al. (1999). A more rigourous methodology, incorporating a multiproxy 399 approach, may enable recycled components to be distinguished and quantified, especially if 400 tailored such that signals in both stable and more labile components are interrogated. Preliminary 401 work (Tyrrell et al. 2009) has shown that an integration of the Pb-K-feldspar and zircon 402 geochronological techniques can aid in the recognition of recycled components, and 403 consequently can lead to an improved understanding of palaeodrainage.

404

405 K-feldspar grains from aeolian and fluvial facies in the EISB cannot be distinguished on the basis 406 of their Pb isotopic compositions (Figure 4D). Therefore, if there were different input points 407 associated with different transport mechanisms into the basin/s (or into sediment storage areas 408 adjacent to the basin), this information has been lost through reworking and mixing of this signal 409 by the last transport prior to deposition. Furthermore, as noted above, rounded feldspar grains of 410 likely aeolian origin are common within the fluvial sandstones of the Otter Sandstone Formation. 411 These phenomena are perhaps expected given that aeolian sediments will be reworked by fluvial 412 mechanisms during wet periods and vice-versa during dry periods and have been described in 413 the Triassic Helsby Sandstone Formation in the Cheshire Basin (Mounteney and Thompson 414 2002). This is therefore in agreement with models of Triassic climate which evoke an annual 415 monsoon and associated flooding (see above; (Kutzbach & Gallimore 1989; Szulc 1999; Preto et 416 al. 2010). It would be anticipated that monsoon weather systems, pulled from the south during 417 summer continental heating and carrying moist air from Tethys, would shed much of their 418 precipitation upon reaching the remnant uplands resulting in large-scale north-directed flooding 419 (McKie & Williams 2009). Such reworking, associated with flooding and wet-dry fluctuations, is 420 observed in the evolution of modern monsoon-influenced drainage systems such as the Indus 421 (Alizai et al. 2011).

422

423 It has been previously suggested that K-feldspar in the EISB Triassic could have been recycled 424 and supplied from Upper Carboniferous sandstones (the Millstone Grit Group of the Pennine 425 Basin) cropping out to the east of the basin (Meadows 2004, 2006). However, published Pb 426 analyses of K-feldspars from these sandstones (Tyrrell et al. 2006) show that they contain a 427 distinct bimodal distribution of grains, including an unradiogenic population (ultimately linked to a 428 Lewisian or Greenland source) which is not found in the EISB Triassic (Figure 6). This suggests 429 that the Millstone Grit Group in the Pennine Basin 1) was not available as a source for sediment 430 in the EISB during the Triassic; 2) was eroding at this time but sediment was "trapped" in the 431 hangingwalls adjacent to the eastern basin-bounding faults; or 3) contributed detritus but the K-432 feldspar component did not survive a second sedimentary cycle.

- 434

435 Implications for regional palaeodrainage and sandstone distribution:

The provenance interpretation presented in this paper indicate that the sand carried by the 'Budleighensis' river system was dominantly sourced from the Variscan Uplands (Figure 7). This interpretation supports the original drainage models based on sedimentology and palaeocurrent data (Wills 1950; Wills 1970; Audley-Charles 1970; McKie & Williams 2009). Other regional basement highs, such as the Welsh and Cornubia massifs appear to make more minor contributions. 443 The drainage directions within the Budleighensis system contrast with those interpreted from 444 feldspar provenance data in Triassic sandstones from basins west and north of the Irish and 445 Scottish Massifs. It has been demonstrated (Figure 6) that K-feldspar grains from apparent SSG 446 equivalents in the Atlantic Margin basins (including data from the Corrib Gasfield in the Slyne 447 Basin, from the Foula Formation, Strathmore Field in the Faeroe-Shetlands Basin and from the 448 Dooish Gas Condensate accumulation on the eastern margins of the Rockall Basin, which, it 449 should be noted, is of uncertain age) comprise unradiogenic Pb and there are no grains which 450 could have been derived from the Variscan Uplands or from any southern source. This suggests 451 no discernable Variscan influence in these areas, and grain populations are dominantly derived 452 from Archaean and Proterozoic rocks in Greenland, NW Scotland, various now semi-obscured or 453 poorly characterised basement highs in on the present continental shelf and possibly from 454 Grenville-affinity rocks from eastern Canada (Tyrrell et al. 2007, 2009, 2010; Redfern et al. 2010). 455 McKie & Williams (2009) envisage southern derivation directions for SSG equivalents hosting the 456 Corrib Gasfield in the Slyne Basin. This interpretation is in agreement with palaeoflow directions 457 suggested by orientated core (Dancer et al. 2005). These interpretations do not consider the 458 significance of K-feldspar grains of Archaean affinity in these sandstones which is strongly 459 indicative of ultimate sand dispersal and input from a northern or northwestern source. However, 460 it is possible to reconcile both datasets, with the provenance data indicating the orientation of the 461 transport system into the Slyne Basin, and the palaeocurrent data recording the orientation of 462 drainage system within the confines of the basin (Figures 7, 8).

463

442

464 This change in dominant drainage direction suggests that the Irish and Scottish Massifs (south of 465 the Great Glen Fault; Figure 7) divide areas draining different catchments during the Early to 466 Middle Triassic. There is currently no K-feldspar provenance data from Ormskirk Sandstone 467 Formation equivalent rocks in the Solway or Ulster basins; hence it is not possible to assess or 468 limit the potential dispersal of Variscan detritus northward beyond the EISB. Interestingly the 469 Ulster Basin appears to thread through and link between the two areas with contrasting drainage 470 regimes (Figure 7, 8). Intriguingly, although the Irish and Scottish massifs appear to act as 471 drainage divides separating systems influenced by and independent from the Variscan Uplands, 472 Pb data from crystalline basement comprising these massifs are insignificant contributors of K-473 feldspar detritus to either the Atlantic Margin basins (Tyrrell et al. 2007, 2010) or to the 474 Budleighensis system (Figure 7, 8). Furthermore, new Pb-in-K-feldspar data from arkosic 475 sandstones of Visean age within the Irish NW Carboniferous Basin (Mullaghmore Sandstone 476 Formation), onshore northwest Ireland, show similar grain populations to those seen in the 477 Serpukhovian-Bashkirian of the Pennine Basin (i.e. they have a bimodal distribution of grains 478 sourced from Archaean – Palaoproterozoic rocks and more proximal Caledonian Granites; Figure 479 6). These data rule out recycling of K-feldspars into the Atlantic Margin basins from older 480 Carboniferous sandstones on the Irish Massif. In overall terms, therefore, these data suggest 481 that, although the Irish and Scottish Massifs were of sufficient relief to form a barrier to evolving 482 drainage, they remained topographically subdued such that precipitation on, and ensuing 483 associated clastic transport from, these areas was minimal. It could have been the case that the 484 interior was too arid for these areas to be significant sources, with sediment dispersal relying on 485 runoff from the wetter catchments outside the arid interior. This would agree with 486 palaeogeographic and climate models for these areas during the Middle Triassic (Naylor & 487 Shannon, 2011). Alternatively, these areas may have been buried beneath now-eroded 488 sedimentary rocks so as not to have been available as a source for K-feldspar-bearing siliclastic 489 sediments during the Triassic. It is possible that there were significant uplands, but that these 490 dominantly comprised carbonates. However, apatite fission track data (Allen et al. 2002) suggest 491 low denudation rates during the Triassic and similar data from the Scottish Massif suggests that 492 significant post-Caledonian uplift did not take place until the Cenozoic (Lewis et al. 1992; Hall & 493 Bishop 2002), supporting the idea that these areas remained relatively tectonically quiescent and 494 topographically subdued during much of the early Mesozoic.

495

496 It is clear that climate and topography played an important role in sediment dispersal and mixing, 497 but these must have also impacted on sediment release rates. In the envisaged arid environment, 498 low humidity and presumed minimal biogenic activity would result in slow rates of chemical 499 weathering, as suggested by the overall abundance of K-feldspar in the preserved sedimentary 500 products. Mechanical weathering was most likely the dominant process of rock disaggregation. 501 Sediment can be 'stored' and 'pre-sorted', perhaps in areas more proximal to their ultimate 502 source (e.g. as alluvial fans), prior to ultimate deposition (Figure 8). Alternatively, the textural 503 maturity may simply be due to repetitions of aeolian winnowing and fluvial transport during 504 downstream migration of sediment. Dryland systems typically show the progressive sorting 505 producing the mineralogically sub-mature, texturally mature sandstones ubiquitous in both the 506 Lower and Middle Triassic basins of NW Europe.

507 508

509 **Conclusions**:

510 K-feldspar sand grains in Middle Triassic sandstones in the Wessex and East Irish Sea basins 511 appear to share the same sources, indicating that the drainage system supplying these sands 512 was through-going and extended northward from the SW England to offshore North Wales. The 513 sand grains were likely derived from the Variscan Uplands to the south, implying drainage length 514 scales in excess of 400 km. Populations are mixed at thin section scale and different facies 515 display the same populations, perhaps indicating that some or possibly all of the sediment was 516 mixed and reworked by fluvial and/or aeolian processes and accumulated in intermediate storage 517 areas prior to final deposition. These observations agree with the current understanding of 518 Triassic palaeogeography and climate models, where both topography and flooding associated 519 with an annual monsoon are thought to have been responsible for the transport of sediment from 520 the uplands. This combination of processes can also account for the overall textural maturity and 521 mineralogical sub-maturity of the sandstones. Comparison with K-feldspar provenance data from 522 Atlantic Margin basins show that the latter sandstones have a different provenance, were 523 dominantly supplied from Archaean and Proterozoic rocks from the north and west, and that there 524 was no input from the Variscan Uplands. The Triassic K-feldspar provenance data collected to 525 date from all basins in the region indicate the presence of two drainage domains (the 526 'Budleighensis' and the Atlantic Margin basins), separated by a NE-SW oriented drainage divide. 527 The drainage divide comprised the Irish-Scottish massifs and, although these areas were of 528 sufficient topography to act as a barrier to evolving drainage, they themselves were not a 529 significant source of K-feldspar detritus. Carboniferous arkosic sandstones from the Irish Massif 530 and from the Pennine Basin, Northern England can also be ruled out as sources in both drainage 531 regimes, supporting the idea that detrital K-feldspar in sandstones cannot readily survive 532 reworking and is, therefore, likely first-cycle detritus.

535

536 ST is funded by the Department of Communications, Energy and Natural Resources under the 537 National Geoscience Programme 2007-2013 (Griffiths Geoscience Awards). This research forms 538 part of a larger study funded by a Science Foundation Ireland Research Frontiers Programme 539 grant (GEO029) awarded to PDWH. The National Centre for Isotope Geochemistry (NCIG), 540 Dublin, is a joint venture of UCD, Trinity College Dublin and University College Cork, and was 541 funded mainly by Science Foundation Ireland. Mike Tubrett and Paul Sylvester (Microanalysis 542 Facility, Memorial University, Newfoundland, Canada) are thanked for assistance with ICPMS. 543 Dick Sutherland (DTI core store, Edinburgh, UK) is acknowledged for facilitating core sampling. 544 Andreas Kronz (Electron Microprobe Laboratory, Geowissenschaftliches Zentrum, Göttingen, 545 Germany) is thanked for assistance with BSE and CL imaging and EMPA. Tom Culligan (UCD) is 546 thanked for skilful thin section preparation. Two anonymous reviewers are thanked for 547 constructive and helpful comments and suggestions which improved the manuscript.

548

Figure 1: Schematic palaeogeographic reconstruction of the Middle Triassic (right) after Scotese
 2002; Eide 2002; McKie & Williams 2009; Bourquin *et al.* 2011; McKie & Shannon 2011) showing
 the distribution of massifs and sedimentary basins with summarised Triassic stratigraphy of some
 NW European basins (left, after McKie & Williams 2009, Tyrrell *et al.* 2010). Also shown are the

553 locations (geographic and stratigraphic) from which Pb K-feldspar provenance data have been 554 obtained, and a map of the East Irish Sea Basin (EISB; inset; after Meadows 2004) showing the 555 location of wells sampled in this study. AM = Armorican Massif; CM = Cornubia Massif; FC = 556 Flemish Cap; HP = Hebridean Platform; IM = Irish Massif; LB = London-Brabant High; PH = 557 Porcupine High; RB = Rockall Bank; SM = Scottish Massif; SP = Shetland Platform. ChB = 558 Chesire Basin; CNB = Central North Sea Basin; CSB = Celtic Sea Basins; EISB = East Irish Sea 559 Basin; FSB = Faeroe Shetland Basin, NNB = Northern North Sea Basin; RBa = Rockall Basin; SB 560 = Slyne Basin; SNB = Southern North Sea Basin; WB = Wessex Basin; WoB = Worcester Basin; 561 ggf = Great Glen Fault.

562

Figure 2: Stratigraphic panel for the Middle - Upper Triassic from the Wessex Basin northward through the East Irish Sea Basin and into the Ulster Basin adapted from McKie & Williams (2009) and based on their correlation of 10 wireline logs. The datum is the top Triassic. The line of section is shown on Figure 1.

567

Figure 3: Backscatter electron (A, C, D) and cathodoluminescence (B) images of K-feldspar grains from East Irish Sea and Wessex basins illustrating, A) authigenic overgrowths on Kfeldspar which are only visible in CL (B), modifying the primary rounded grain shape; C) authigenic overgrowth on K-feldspar grain (from Wessex Basin), visible in backscatter; and D) three K-feldspar grains (each with visible overgrowths), with laser ablation pits shown on the largest grain.

574

575 Figure 4: ²⁰⁶Pb/²⁰⁴Pb vs. ²⁰⁷Pb/²⁰⁴Pb plots showing A) K-feldspar data from the East Irish Sea 576 Basin (EISB) Ormskirk Sandstone Formation sandstones; B) K-feldspar data from the Wessex 577 Basin (WB) Otter Sandstone Formation; C) the enclosed range of Pb isotopic composition of all 578 K-feldspar grains from EISB and WB sandstones, illustrating clear overlap between the two and 579 suggesting that the sandstones from each basin have the same provenance; and D) the Pb 580 isotopic composition of all K-feldspar grains analysed from EISB fluvial facies, EISB aeolian 581 facies and WB fluvial facies sandstones, indicating that there are no significant differences in the 582 Pb composition of K-feldspar grains from either facies. 'Far.' indicates grains analysed using 583 Faraday collector configuration, 'IC' indicates ion counter collector configuration used. When not 584 indicated, the IC configuration was used.

585

Figure 5: ²⁰⁶Pb/²⁰⁴Pb vs. ²⁰⁷Pb/²⁰⁴Pb plots of EISB and WB K-feldspars against A) new data from Variscan granites (Brittany, Normandy and Cornwall), Cadomian Granite and a single clast of feldspar porphyry from the Budleigh Salterton Pebble Beds (BSPB) ; B) published data from Variscan Granites from Brittany, Cornwall, the French Massif Central and the Pyrennes; C) new and published data from Irish Massif granites, granitic veins (cutting the Rosslare Complex) and
galena; D) published data from Scottish granites and granitic rocks and granites from northern
England; E) summary of potential groupings and suggested sources for the feldspars. Pb
basement data from Blaxland *et al.* 1979; Vitrac *et al* .1981; Kinnaird *et al.* 2002; Tyrrell *et al.*2006. New basement data are shown in Table 2.

595

Figure 6: ²⁰⁶Pb/²⁰⁴Pb vs. ²⁰⁷Pb/²⁰⁴Pb plot showing the Pb isotopic composition of all K-feldspar grains analysed from the East Irish Sea (EISB) and Wessex (WB) basin Triassic sandstones. Also shown is the range of compositions found in detrital K-feldspars Permo-Triassic and Triassic sandstones in basins more marginal to NW Europe, from Upper Carboniferous sandstones in the Pennine Basin (Data from Tyrrell *et al.* 2006, 2007, 2009, 2010) and Lower Carboniferous sandstones in the Irish NW Carboniferous Basin (Data in table 2).

602

603 Figure 7: Schematic palaeogeographic reconstruction of the Middle Triassic (after Scotese 2002; 604 Eide 2002; McKie & Williams 2009; Bourguin et al .2011; McKie & Shannon 2011) showing the 605 distribution of massifs and sedimentary basins, with potential K-feldspar sources highlighted. Also 606 highlighted are potential drainage directions and sedimentary input points for the 'Budleighensis' 607 system, as suggested by the data presented in this paper, and for the Triassic basins more 608 marginal to NW Europe (after Tyrrell et al. 2010). Abbreviations are listed in caption figure 1. The 609 approximate palaeogeographic location of Pb basement data in Figure 4 is shown; B&C = 610 Brittany and Cornwall granites; BfG = Barfleur Granite; BrG = Brech Granite; CG = Carnsore 611 Granite; CIG = Carrolles Granite; FIG = Flamanville Granite, FMC = French Massif Central 612 granites; LEG = Land's End Granite; LnG = Leinster Granite; MmS = Mullaghmore Sandstone 613 Formation. PY = Pyrennes Granites; ShG = Shap Granite; Slga = southern Ireland Galena data; 614 SUG = Southern Uplands granites; RC = Rosslare Complex.

- 615
- 616

Figure 8: Schematic block diagram showing the distribution of uplands in the Middle Triassic, with suggested drainage routes and sediment storage areas highlighted. The block diagram shows that there is major topography within the remnant Variscan Uplands and perhaps within the Greenland Massif, but that the topography of the Scottish and Irish Massifs is relatively subdued. The Scottish and Irish massifs act as a drainage divide separating systems influenced by the Variscan Uplands from those with no Variscan input.
