**Eight weeks of self-resisted neck strength training improves neck strength in age-grade rugby union players: a pilot randomised controlled trial.**

## **Abstract**

**Background:** Greater neck strength is associated with fewer head and neck injuries. Neck strengthening programmes are commonly burdensome, requiring specialist equipment or significant time commitment, which are barriers to implementation.

**Hypothesis:** Completing a neck strengthening programme will increase isometric neck strength in age-group rugby players.

**Study Design:** A pilot randomised controlled exercise intervention study.

**Level of evidence:** 2\*

**Methods:** Twenty-eight male under-18 regional age-group players were randomised (intervention n=15 / control n=13). An 8-week exercise programme was supervised during pre-season at the regional training centre. Control players continued their 'normal practice' which did not include neck-specific strengthening exercises. The 3-times weekly trainer-led intervention programme involved a series of 15-second self-resisted contractions, where players pushed maximally against their own head, in forwards, backwards, left and right directions.

**Outcome measure:** Peak isometric neck-strength (force N) into neck flexion, extension, and left and right side-flexion was measured using a handheld dynamometer.

**Results:** Post intervention between-group mean differences (MD) in isometric neck-strength change were adjusted for baseline strength and favoured the intervention for total neck-strength ( $ES = 1.2$ ,  $MD \pm 95\%CI = 155.9N \pm 101.9$ ,  $P = .004$ ) and for neck-strength into extension ( $ES = 1.0$ ,  $MD \pm 95\%CI = 59.9N \pm 45.4N$ ,  $P = .012$ ) left side-flexion ( $ES = 0.7$ ,  $MD \pm 95\%CI = 27.5N \pm 26.9$ ,  $P = .045$ ) and right side-flexion ( $ES = 1.3$ ,  $MD \pm 95\%CI = 50.5N \pm 34.4N$ ,  $P = .006$ ).

**Conclusion:** This resource-efficient neck strengthening programme has few barriers to implementation and provides a clear benefit in U18 players' neck strength. While the present

study focussed on adolescent rugby players, the programme may be appropriate across all sports where head and neck injury are of concern and resources are limited.

**Clinical Relevance:** Greater neck strength is associated with fewer head and neck injuries including concussion. Performing this neck exercise programme independently, or as part of a whole-body programme like ACTIVATE, could contribute to lower sports related head and neck injuries.

**Key words:** Concussion, neck strength, rugby football, injury-prevention.

## 1 Introduction

2 Concussion is the most common rugby match-play injury in Men’s professional<sup>9</sup>,  
3 community<sup>1,28</sup>, university<sup>30</sup> and youth<sup>19</sup> levels of the game. Concussion is also the most  
4 common rugby match-play injury in Women’s Premiership 15<sup>31</sup> and collegiate<sup>26</sup> levels of the  
5 game. The consequences of concussion have been shown to occur over varying time frames,  
6 such as associated increases in subsequent injury risk<sup>8,23</sup> and documented links with decrements  
7 in later-life cognitive function<sup>20</sup>. Despite the uncertainty surrounding the long-term effects of  
8 concussion in former players, reducing the incidence of concussion across rugby is recognised  
9 as a priority<sup>27</sup>.

10

11 Youth rugby (U18) players have significantly lower neck strength compared to adult rugby  
12 players<sup>16,10</sup> which may predispose these players to injury if this discrepancy is not addressed,  
13 particularly when transitioning to the adult game. Greater neck strength has been associated  
14 with decreased acceleration of the head during rugby contact events<sup>11</sup> and increasing neck  
15 strength is speculated as a potential means to help reduce incidence of concussion<sup>6</sup>. In  
16 professional<sup>24</sup>, adult<sup>1</sup> and youth<sup>19</sup> players, lower head & neck injury incidence has been  
17 attributed to implementation of neck strength resistance exercises, although players’ neck

18 strength wasn't always measured in these studies. Maximal loading improved neck strength in  
19 professional players<sup>15</sup> and in recreationally active college students neck resistance-exercises  
20 resulted in neurological adaptation, specifically reduced cross-sectional muscle recruitment for  
21 submaximal contractions and increased cross-sectional muscle contribution for maximal  
22 contractions<sup>7</sup>. These studies demonstrate that neck muscle function can be altered with targeted  
23 resistance training, but the time and equipment demands are barriers to their implementation<sup>25</sup>.  
24 As the self-resisted neck exercises of the Activate programme<sup>29</sup> require minimal time and no  
25 specialist equipment to complete, barriers to exercise implementation are few, in this context,  
26 whether the self-resisted neck exercises can improve neck strength warrants further  
27 investigation.

28

29 The aim of this research was to investigate the effect of self-resisted neck exercises on neck  
30 muscle strength in U18 male regional age-group rugby union players. If neck muscle strength  
31 increases post intervention, implementing the resistance programme may benefit sporting  
32 populations where higher neck muscle strength is desirable.

33

## 34 **Method**

### 35 *Study design and participants*

36 This pilot parallel group randomised controlled trial was designed in accordance with the  
37 CONSORT framework<sup>33</sup> and was conducted between mid-July 2019 and end-September 2019.

38 A convenience sampling method was used as one of the study team (LJWH) was the strength  
39 and conditioning coach for the U18 regional age group, who delivered the programme. The  
40 players were informed of the risks involved in the research. Written informed consent (players)  
41 and assent (parent/legal guardian) was provided prior to participation. Data collection and

42 intervention implementation were conducted at a regional training centre in Wales. Ethical  
43 approval was granted from the institution's ethics board (ref: PGT-1315).

44

#### 45 *Sample size*

46 Using published data<sup>15</sup> sample size calculation indicated a minimum sample of 20 players  
47 (intervention = 10, control = 10) would be necessary to identify a 15% change in neck strength.

48 All players (n=34, mean  $\pm$  SD; age =  $16.9 \pm 0.6$  years, height =  $180 \pm 8$  cm, mass =  $87.8 \pm 14.0$   
49 kg) were contacted for recruitment as a sample of thirty-four players would allow for a 30%  
50 drop-out rate, while maintaining sufficient power.

51

#### 52 *Eligibility*

53 Players were male members of the U18 regional age-group and had to be fit to participate in  
54 all training and matches; be free from upper limb, head & neck injury at enrolment and  
55 throughout the trial period; must not have completed targeted neck-strengthening exercises  
56 within the previous 6-months nor undertake targeted neck strengthening exercises during the  
57 study period beyond those prescribed within the study; and have no current, nor any history of  
58 undiagnosed neck pain.

59

#### 60 *Randomisation and blinding*

61 Thirty-four players were stratified according to their playing position (forwards/backs) and  
62 randomised to either intervention or control group on a 1:1 basis by a member of the research  
63 team using a computer-generated list post enrolment (Figure 1). The tester (the team's strength  
64 and conditioning coach) was not blinded to group allocation due to also leading the  
65 intervention. Control players were not blinded to the intervention groups protocol. Analysis

66 was performed blind by a member of the research group. Six players dropped out of the study  
67 (control: injury n=1, other reason n=3; intervention: injury n=1, other reason n=1).

68 \*\*INSERT FIGURE 1 NEAR HERE\*\*

69

#### 70 *Training protocols.*

71 Three times per week, for eight weeks, the team's strength and conditioning coach attended  
72 U18 squad training and led the intervention group protocol. An 8-week trial was considered  
73 sufficient stimulus for neuromuscular adaptation within the pre-season period and could be  
74 completed before any competitive fixtures were scheduled. Training days followed players'  
75 normal training patterns (Monday, Wednesday, Friday) and any injuries sustained within  
76 training sessions were reported to the team's Physiotherapist. Following the normal team  
77 warm-up, intervention players performed one maximal contraction in each direction (into neck  
78 flexion, extension, left-side flexion and right-side flexion) by pushing against their own head  
79 using their hands (Figure 2). Each contraction lasted 15-seconds and was performed with 30-  
80 seconds of rest between frontal and sagittal plane movements reflecting the Activate<sup>29</sup>  
81 programme. Neck exercises, intensity and volume were maintained throughout the trial period.  
82 The total time taken for all exercises was three minutes. Intervention players then continued  
83 their normal rugby training. Control group players maintained their normal training, which did  
84 not involve neck specific muscle strengthening exercises (see supplementary material).

85 \*\*INSERT FIGURE 2 NEAR HERE\*\*

86

#### 87 *Familiarisation*

88 Two weeks preceding baseline testing, all players were exposed to the neck testing protocol to  
89 reduce likelihood of a learning effect. This involved performing each neck strength testing  
90 measure twice per player, limiting performances to 50% perceived effort.

91

92 *Data Collection*

93 Participants' height (m) (Leicester Height Measure, Seca, UK) and mass (kg) (SC-240 body  
94 composition monitor, Tanita, USA) was recorded to help describe the sample population. Neck  
95 strength [peak isometric force (N)] was measured using a handheld dynamometer  
96 (HHD)(Hoggan Scientific MicroFet 2, Saltlake City, USA) in frontal (right and left neck side-  
97 flexion) and sagittal planes (neck flexion, extension) and was re-assessed after 8-weeks of  
98 intervention. A register of attendance was taken at each training session while intervention  
99 players performed neck strength exercises to enable reporting of compliance during the study.

100

101 Neck strength measurement

102 Testing took place in the gymnasium of the regional training centre. Following a 24-hour rest  
103 period, where players were requested not to perform any vigorous activity, neck strength  
104 testing took place prior to players' evening training. Before all testing sessions, each player  
105 was reminded of the testing procedures and performed a standardised warm-up including  
106 range of motion exercises of the cervical spine and shoulder joints.

107 Participants sat on a 40-cm box in an upright position adjacent to a squat rack (Power Rack,  
108 Performance Power Rack, Perform Better Limited, Southam, Warwickshire). A trunk fixation  
109 belt (Fixation Belt, Physique Management Company Limited, U.K) was placed around the  
110 upper torso of the participant and an upright of the squat rack. The dynamometer was placed  
111 in-line with the participant's forehead behind the upright of the squat rack and held in position  
112 by the rater. A second fixation belt ('head belt') was placed around the participant's head (level  
113 with their eye-brows anteriorly, and occiput posteriorly), the upright of the squat rack and the  
114 dynamometer such that when the player contracted their neck muscles, the belt pulled the

115 dynamometer into the upright of the rack. This method was devised to overcome the reliability  
116 of measures being affected by tester strength<sup>36</sup>. During neck flexion strength measurement,  
117 players sat facing away from the squat rack with their back against the upright of the squat  
118 rack. During extension strength measurement players sat facing towards the squat rack. For left  
119 and right-side flexion strength measurements, players sat with their right or left shoulder  
120 touching the front of the squat rack, respectively (Figure 3).

121 Following a “ready, steady, start” instruction from the tester, players performed three maximal  
122 isometric contractions in each of the four directions; flexion, extension, right and left side  
123 flexion each separated by a 1-minute rest period. Ordering of measurements was randomised  
124 to reduce risk of systematic bias. Participants were instructed to gradually build up to a  
125 maximal contraction within 5-seconds. Players head position was monitored by the rater who  
126 encouraged a neutral head position was maintained during testing. All scores were recorded  
127 and the highest score was used for analysis.

128 **\*\*INSERT FIGURE 3 NEAR HERE\*\***

129

### 130 *Analysis*

131 Descriptive characteristics and neck strength were reported as mean and standard deviation.  
132 Overall compliance was measured as the number of compliant player-sessions/total potential  
133 compliant player-sessions. Due to the nature of attendance at regional training, players were  
134 assumed to have ‘completed exercises as directed’, thus, if they were in the intervention group  
135 and they attended training, then the neck exercises were performed. Differences in neck  
136 strength at 8-weeks (into flexion, extension, left side-flexion, right side-flexion, total [the sum  
137 of force in all directions]) compared to baseline was calculated for each player and expressed  
138 as a percentage relative to the player’s baseline strength. Between-group mean difference (%)  
139 in neck strength change and 95% confidence interval were calculated. Between-group in neck

140 strength change (N) was assessed using general linear model (One-Way ANCOVA), where the  
141 group (intervention / control) x 'neck strength change' interaction was adjusted for baseline  
142 neck strength (covariate). Levene's test was conducted and assumptions were met. Bonferroni  
143 post-hoc test was used to explore differences between groups and was reported as adjusted  
144 mean difference (MD) and 95% confidence interval (95%CI). Effect size (*ES*) was estimated  
145 using Cohen's-*d* and quantified using standard effect size analyses<sup>5</sup> (negligible = < 0.2, small  
146 > 0.2 to 0.5, medium/ moderate > 0.5 to 0.8, large > 0.8 to 1.2, and very large > 1.2). A priori  
147  $p < 0.05$  was accepted for all analysis, and exact  $p$ -values are stated.

148

## 149 **Results**

150 Twenty-eight players completed the study [intervention (n = 15, mean  $\pm$  SD; height =  $179 \pm 7$   
151 cm; mass =  $87.8 \pm 14.0$  kg; neck circumference =  $38.2 \pm 2.7$  cm): control (n = 13, mean  $\pm$  SD;  
152 height =  $181 \pm 5$  cm; mass =  $87.9 \pm 14.9$  kg; neck circumference =  $37.5 \pm 2.2$  cm)]. Mean  
153 compliance across groups was 88% (intervention = 94% (253/270 player-sessions attended),  
154 control = 81% (189/234 player-sessions attended)). Baseline and post-trial neck strength is  
155 displayed in Table 1.

156

157 \*\*\*INSERT TABLE 1 NEAR HERE\*\*\*

158

159 One-way ANCOVA identified significant differences in the magnitude of neck strength change  
160 between arms for Total neck strength ( $F_{25,2} = 8.794$ ,  $P = .001$ , figure 4), as well as neck strength  
161 into right side-flexion ( $F_{25,2} = 9.765$ ,  $P = .001$ ), left side-flexion ( $F_{25,2} = 5.302$ ,  $P = .012$ ) and  
162 extension ( $F_{25,2} = 10.547$ ,  $P < .001$ ). The magnitude of neck strength change into flexion was  
163 not significant ( $F_{25,2} = 2.328$ ,  $P = .118$ ) between arms.

164 \*\*\*INSERT FIGURE 4 NEAR HERE\*\*\*

165

166

167 Post hoc analysis indicated a large effect ( $ES = 1.2$ ,  $P = .004$ ) in favour of the intervention for  
168 increase in Total neck strength (MD = 155.9N, 95%CI = 54.0N - 257.8N) compared to control,  
169 a very large effect ( $ES = 1.3$ ,  $P = .006$ ) in favour of the intervention for increase in right side-  
170 flexion neck strength (MD = 50.4N, 95%CI = 16.0N - 84.7N) compared to control, a moderate  
171 effect ( $ES = 0.7$ ,  $P = .045$ ) in favour of the intervention for increase in left side-flexion neck  
172 strength (MD = 27.5N, 95%CI = 0.6N – 54.4N) compared to control and a large effect ( $ES =$   
173  $1.0$ ,  $P = .012$ ) in favour of the intervention for increase in extension neck strength (MD =  
174 59.9N, 95%CI = 14.5N – 105.3N). The effect of the intervention on neck strength into flexion  
175 was small ( $ES = 0.3$ , MD = 8.8N, 95%CI = -20.2N – 37.7N) compared to control.

176

177 **\*\*INSERT FIGURE 5 NEAR HERE\*\***

178

179

## 180 **Discussion**

181 This is the first randomised controlled trial to evaluate the efficacy of self-resisted neck strength  
182 exercises on isometric neck strength in adolescent male rugby players. At 8-weeks, the  
183 intervention group total neck strength demonstrated a significant 24% increase over that of the  
184 control group. As lower neck strength has been associated with higher risk of injury<sup>6</sup>, this time  
185 efficient neck strength programme, which requires no equipment to complete, may provide an  
186 important clinical benefit for players.

187

188 Previous studies have investigated the effect of different neck strengthening programmes with  
189 varying results. Strengthening programmes which involved 50%-70%MVC during exercises

190 for 5 – 6 weeks, resulted in no clinically meaningful changes in total neck strength in male  
191 under-19 rugby players<sup>2</sup> or professional rugby players<sup>24</sup>. A 5-week programme involving  
192 maximal resistance to an external load applied by a strength and conditioning coach resulted  
193 in a clinically significant ~19% increase in total neck strength compared to baseline in  
194 professional rugby players<sup>15</sup>. Exercises performed by amateur rugby players at 80 to 100% of  
195 maximal effort for 6-weeks, resulted in 12-24% mean increase in neck strength compared to  
196 control<sup>18</sup>. The present study prescribed exercises at 100% of ‘self-resistance’ (the equivalent  
197 of 10/10 RPE) and resulted in a 24% increase in total neck strength compared with controls at  
198 8-weeks in adolescent male rugby players. As the weekly exercise prescriptions (2-3 times  
199 weekly) and study durations (5-8 weeks) were relatively similar across studies, it appears near  
200 maximal to maximal loads may be required to induce meaningful changes in neck strength  
201 when considering isometric or isotonic neck exercises.

202

203 Post trial, both intervention and control groups demonstrated improvements in neck strength  
204 from baseline, despite the control group not performing targeted neck specific strength  
205 exercises. In Premier rugby players, a significant ~10% increase was measured for total  
206 strength compared to non-contact control players over a 20-week season<sup>32</sup>, suggesting neck  
207 strength increases with exposure to contact training/match-play. As such, improvement in  
208 control group neck strength was anticipated. Across this study’s trial period, players likely  
209 received sufficient stimulus for strength adaptation from their normal training (a combination  
210 of strength and conditioning (3 x 1-hour weekly), and rugby specific activities (3 x 1-hour  
211 weekly)). Muscles including the upper trapezius, erector spinae and sternocleidomastoid  
212 stabilise the neck during scrummaging<sup>3</sup>, and limit shoulder depression and excessive neck  
213 movement during the tackle<sup>19</sup>. As such these muscles receive stimulus within ‘normal training’.  
214 However, the 24% increase in total neck strength of the intervention group above that of the

215 control group demonstrates programme efficacy. This is a very encouraging result and supports  
216 implementation of these neck strength exercises within elite age-group training environments.  
217  
218 Intervention group player-level compliance was high (94%), which is reflective of a regional  
219 training environment, where players are likely keen to maximise their training exposure. Club  
220 level compliance was 100% (3 of 3 sessions per week), though this is due to a researcher being  
221 the strength and conditioning coach for the club. For comparison, club and school level mean  
222 compliance to Activate was 66% (2 of 3 sessions per week)<sup>1,19</sup>. To be effective as an injury  
223 prevention measure in the real-world<sup>12</sup>, players must comply with the injury-prevention  
224 programme<sup>22</sup>. Two neck strengthening programmes required equipment such as weights  
225 machines<sup>2,24</sup> or head harnesses<sup>18,24</sup>, required ~8 minutes<sup>15</sup> to 20-minutes<sup>2</sup> per player to perform,  
226 and one required trained personnel such as strength and conditioning coaches to apply  
227 resistance<sup>15</sup>. Time, personnel, and equipment are common barriers to compliance, particularly  
228 within non-professional settings<sup>25</sup>. Our exercise programme, reflecting neck exercises  
229 recommended in Activate<sup>1,19,29</sup>, was completed by all players simultaneously with no  
230 equipment requirement and required just 3-minutes for the whole squad to complete. With  
231 limited resources available to adolescent players, we believe this exercise programme has  
232 potential to be an effective means for improving neck strength.

233

234 Before implementing a training programme, particularly where injury prevention is concerned,  
235 the return on investment of implementation should be considered<sup>13</sup>. In cluster RCT settings,  
236 Activate resulted in lower injury rates, including concussion, in rugby players<sup>1,19</sup>. A proposed  
237 mechanism for the lower concussion rate was increased neck strength following players'  
238 exposure to isometric neck strengthening exercises<sup>1,19</sup>. The present study employed neck  
239 strength exercises of Activate<sup>1,19,29</sup> and demonstrated significant large increases in total neck

240 strength in the intervention group compared with control. This study offers evidence that one  
241 potential mechanism for injury and concussion reduction when using the Activate programme  
242 was an increase in neck strength. As whole-body approaches to injury prevention (such as FIFA  
243 11+) have been suggested to provide a positive return on investment for clubs compared to  
244 individual exercises (such as the Nordic hamstring exercise)<sup>13</sup>, implementation of the full  
245 Activate programme in adolescent rugby settings is recommended.

246

#### 247 *Strengths and limitations*

248 Strengths of the study include the use of a representative sample from regional age-group  
249 rugby. Neck-strength research involving U18 players has previously been limited to front-row  
250 players only<sup>10,16</sup>. Another strength of this study is the results are valid across elite age-group  
251 environments as ‘real-world’ methodology was employed. For instance, the effects of the  
252 intervention occurred despite less than 100% adherence, reflecting that in real life, players miss  
253 training and thus do not receive the ideal training load as was intended. Further, no player  
254 reported any adverse event associated with the programme to the team’s Physiotherapist during  
255 the trial.

256 A major limitation of this study is that the method of measuring neck strength is not well  
257 established and has not been published in the peer-reviewed literature. However isometric neck  
258 muscle testing is well validated<sup>14,21,4,17,34</sup>, and this study’s technique overcomes limitations of  
259 previous hand-held dynamometer methods relating to tester strength<sup>36</sup>, the potential for  
260 eccentric strength capture as per a ‘break contraction’ method<sup>10,15</sup>, and maintaining a  
261 standardised head position compared to self-testing<sup>34</sup>. Reviewing the force output measured  
262 during this study, the players strength was similar to that of under-18 school rugby players  
263 (Mean  $\pm$  95%CI = 333.4N  $\pm$  79.4N) which was a similar population<sup>17</sup>. Another limitation is  
264 that the exercises were self-administered by players and the actual load applied by players was

265 not evaluated and could have been inconsistent. Due to the strength and conditioning coach  
266 delivering the intervention and performing neck strength testing, they could not be blinded and  
267 thus could have influenced players' efforts. Finally, the number of players tested was small and  
268 this should be viewed as a pilot study.

269

270 There is growing evidence that performing neck strengthening exercises as part of a warm-  
271 up<sup>1,19</sup>, or within strength and conditioning sessions<sup>24</sup> has been associated with fewer head and  
272 neck injuries, including concussion in rugby. Higher neck strength has also been associated  
273 with reduced concussion in high school athletes<sup>6</sup>. The present study demonstrates that a 3-  
274 minute neck strength programme taken from Activate offers an efficacious means for  
275 adolescent rugby players to improve their neck strength. In the absence of evidence suggesting  
276 the programme could cause harm, there is compelling evidence that neck strengthening should  
277 be included within players' training, ideally three times weekly and, as it has been shown to  
278 reduce incidence of injuries in rugby, as part of the Activate programme. The minimal time  
279 burden and no need for equipment, means neck strengthening has few barriers to  
280 implementation and provides a clear beneficial improvement in players neck strength. While  
281 the present study focussed on adolescent rugby players, this approach to neck strengthening  
282 may be appropriate across all sports where head and neck injury occur.

283

#### 284 **Key Points**

285 **Findings:** Implementing self-resisted neck strength exercises three times per week increased  
286 age-group rugby players' neck strength compared to players' normal practice.

287

288 **Implications:** As greater neck strength has been associated with lower risk of head and neck  
289 injury including concussion in athletes, this approach to neck strengthening may be appropriate  
290 across all sports where head and neck injury area a concern.

291

292 **Caution:** Inferences made regarding associations between higher neck strength and lower  
293 concussion risk have not been established in clinical trials and should be interpreted with  
294 caution.
