Background. Human cytomegalovirus (HCMV) is the leading infectious cause of congenital disabilities. We designed a prospective study to investigate the rate, outcome, and risk factors of congenital CMV (cCMV) infection in neonates born to immune women, and the potential need and effectiveness of hygiene recommendations in this population.

Methods. The study was composed of 2 sequential parts: an epidemiology (part 1) and a prevention (part 2) study. Performance of part 2 depended upon a cCMV rate >0.4%. Women enrolled in part 1 did not receive hygiene recommendations. Newborns were screened by HCMV DNA testing in saliva and cCMV was confirmed by urine testing.

Results. Saliva swabs were positive for HCMV DNA in 45/9661 newborns and cCMV was confirmed in 18 cases. The rate of cCMV was .19% (95% confidence interval [CI]: .11–.29%), and 3 out of 18 infants with cCMV had symptoms of CMV at birth. Age, nationality, occupation, and contact with children were similar between mothers of infected and noninfected newborns. Twin pregnancy (odds ratio [OR]: 7.2; 95% CI: 1.7–32.2; $P = .037$) and maternal medical conditions (OR: 3.9; 95% CI: 1.5–10.1; $P = .003$) appeared associated with cCMV. Given the rate of cCMV was lower than expected, the prevention part of the study was cancelled.

Conclusions. Newborns from women with preconception immunity have a low rate of cCMV, which appears to be mostly due to reactivation of the latent virus. Therefore, serological screening in childbearing age would be pivotal to identify HCMV-seropositive women, whose newborns have a low risk of cCMV.

Keywords. human cytomegalovirus; congenital infection; nonprimary infection; preconception immunity.

In developed countries, human cytomegalovirus (HCMV) is the leading cause of congenital infections, which may result in neurocognitive and psychomotor delay, hearing loss, speech and language disabilities, behavioral disorders, and visual impairment [1]. Approximately 0.6% of newborns are HCMV-congenitally infected [2] and, among these, 20–25%

are symptomatic at birth or will develop long-term sequelae [3, 4], with a substantial public health impact.

Preconception immunity does not provide complete protection against non-primary maternal infection (ie, reactivation of the latent virus or reinfection with a new strain) and vertical transmission. A positive correlation between maternal seroprevalence and rate of congenital HCMV infection (cCMV) was observed, ranging from 0.3% in populations with 30% seroprevalence to 2% in populations with 98% seroprevalence [2, 5]. Whether cCMV after maternal nonprimary infection is the consequence of a reactivation or a reinfection remains undefined, notwithstanding that previous studies have argued that maternal superinfection could play a significant role [6, 7].

A meta-analysis reported similar percentages of symptomatic infants following either primary or nonprimary infections [8]. Finally, it has been estimated that nonprimary maternal

infections account for the majority of HCMV-related hearing deficits [9]. Presently, although actively sought, an HCMV vaccine is not available [10].

The most important route of acquisition of primary HCMV infection is through contact with young children, as they actively shed the virus in saliva and urine. A recent controlled study showed a significant reduction in the seroconversion rate from 7.6% to 1.2% in seronegative women caring for toddlers who received HCMV counseling compared with women who did not receive any information [11].

A study conducted in a highly immune population (Brazil) reported that a significantly higher number of transmitter compared with nontransmitter mothers cared for toddlers [7]. Therefore, HCMV-shedding toddlers may represent a risk of reinfection for seropositive pregnant women as well.

We designed the present study (NCT03973359) to investigate the rate and outcome of cCMV in neonates born to immune women in northern Italy, as well as the potential need and effectiveness of hygiene recommendations in this population.

METHODS

Study Design

The Congenital Human cytomegalovirus Infection in Lombardy (CHILd) Study was a prospective study composed of 2 sequential parts. Part 1 (epidemiology study) was aimed at investigating the incidence and outcome of cCMV in neonates born to women with preconception immunity. Part 2 (prevention study) was designed to investigate the effectiveness of hygiene measures for the prevention of cCMV in this population. We planned to include 10 000 women in part 1 and 13 523 women in part 2, with newborns examined for cCMV. Sample size would have been either confirmed or recalculated based on an interim analysis planned after the examination of 5000 newborns. The study was approved by the Ethics Committee of Fondazione IRCCS Policlinico San Matteo (Comitato Etico Pavia, P-20170011101) and participants signed a written informed consent.

For part 1, women with HCMV serology compatible with a remote infection were enrolled either at the beginning of pregnancy (≤ 13 weeks' gestation) or at delivery, provided that a medical record of HCMV serology at 13 weeks of gestation or less or before pregnancy was available (although not recommended, serological screening for HCMV infection is usually performed). In addition, no HCMV-related hygiene recommendation is given to HCMV-seropositive women in the participating centers as part of normal antenatal care. Blood samples were collected from women enrolled at 13 weeks of gestation or less for retrospective additional testing in case of cCMV. Saliva swabs from newborns were collected by the hospital staff within 72 hours of life and shipped to the central laboratory for HCMV DNA testing. In case of a positive result, the

samples were retested: if positivity was confirmed, newborn urine was requested and tested for HCMV DNA (within 3 weeks after birth). Only when HCMV DNA was detected in urine was the newborn diagnosed with cCMV. In case urine samples were not obtained, congenital infection was confirmed by HCMV DNA detection on the dry blood spots collected at birth for screening of metabolic and genetic disorders. Blood, urine, dry saliva, and vaginal swabs of the mothers of infected newborns were collected after delivery. Part 2 was designed as a continuation of part 1, with the addition of providing hygiene information at enrollment (which had to be performed only at ≤ 13 weeks' gestation).

Infants with documented cCMV were clinically assessed at diagnosis and at 3, 6, and 12 months of age. Maternal and newborn data were collected in an electronic case report form (REDCap platform). Details on the study population, sample size and interim analysis, inclusion and exclusion criteria, and laboratory testing are reported in the [Supplementary Material](#) (and [Supplementary Figure 1](#)). The same protocol was adopted in each center.

Objective and Measures

The primary objective for part 1 was the prevalence and clinical outcomes of cCMV in neonates born to women with preconception immunity. The primary objective for part 2 was the efficacy of hygiene counseling in reducing cCMV in the same population (as compared with part 1). Secondary objectives for part 1 were to identify possible serological parameters associated with nonprimary infection and potential risk factors for cCMV.

Statistical Analysis

Continuous data are described with the median and interquartile range (IQR) and compared with the Mann-Whitney *U* test. Categorical data are reported as counts and percentages and compared with the chi-square test. The rate of cCMV is expressed as a percentage and exact binomial 95% confidence interval (CI). The odds ratio (OR) of potential risk factors for congenital infection and its 95% CI were computed using univariable logistic regression. Analyses were performed using GraphPad Prism software (version 8; GraphPad Software, Inc).

RESULTS

Primary Endpoint: Number and Outcome of Infected Newborns

Between September 2017 and October 2020, 11 222 pregnant women were enrolled ([Figure 1](#)): 8637 at delivery and 2585 at 13 weeks of gestation or less. Of them, 9503 women completed the study (7906 enrolled at delivery and 1597 enrolled at ≤ 13 weeks' gestation). At the end of the study, 9661 newborns and 1 fetus terminated in utero for severe disease from 9503 pregnancies were examined: 18 congenitally infected

Figure 1. Study population and rates of cCMV infection. Abbreviations: cCMV, congenital cytomegalovirus; eCRF, electronic Case Report Form.

newborns/fetuses were observed, with a rate of .11–.29%. Congenital infection rate was similar among women enrolled at 13 weeks of gestation or less or at delivery (Figure 1).

Among the 9661 newborns examined, 45 were positive for HCMV DNA in saliva collected within 72 hours of birth, and congenital infection was confirmed in 17 newborns by repeat testing of that saliva sample and by detection of virus in newborn urine collected 3 weeks after birth for 15 newborns or in dry blood spots for 2 newborns whose urine was either not collected due to the parents' refusal or it was collected 32 days after birth.

In 11 newborns with a positive saliva screen and a positive result on repeat testing of that saliva specimen, congenital infection was not confirmed because HCMV DNA was not detected in a urine sample. In 17 newborns with a positive saliva screen with less than 250 copies/mL of HCMV DNA, retesting of that sample was negative; urine was not tested and congenital infection was not confirmed (see Table 1 for the infected newborns and Supplementary Table 1 for results of the 45 newborns with positive saliva screening).

Levels of HCMV DNA in saliva swabs of the 17 confirmed cases were above 500 copies/mL in resuspension medium (median level: 5.6×10^4 ; range: 0.5×10^3 – 3.2×10^6 copies/mL), whereas levels of HCMV DNA in saliva swabs of the 28 non-confirmed cases were below 250 copies/mL (median level: 1.7×10^1 ; range: 0.5×10^1 – 2.5×10^2 copies/mL) (Figure 2).

One additional case of cCMV was diagnosed by HCMV DNA detection in the amniotic fluid (Table 1): prenatal diagnosis was performed at 21 weeks of gestation because of abnormal

findings at ultrasound examination (periventricular hyperechogenicity, corpus callosum hypoplasia). Cordocentesis showed 3 of 4 altered parameters (among viral load, platelet count, HCMV-specific immunoglobulin [Ig] M [IgM], and B2 microglobulin), suggesting symptomatic fetal infection. Fetal magnetic resonance imaging confirmed pathological cerebral findings. The pregnancy was terminated and histological examination showed the following: severe brain damage in the form of multiple necro-inflammatory foci predominantly affecting the cortex, white matter, and germinal matrix, often accompanied by calcifications. Data on the infected newborns are shown in Table 1. Two infected newborns were twins (monochorionic diamniotic gestation), and another infected newborn had a noninfected twin brother (dichorionic diamniotic gestation). Symptomatic congenital infection was observed in 3 of 18 (17%) newborns/fetuses, whereas the other 15 asymptomatic newborns did not show sequelae at 1 year of age.

Characteristics of the Mothers of Congenitally Infected Children

Data from the 17 mothers with cCMV newborns/fetus are shown in Table 2. No women had HCMV-specific IgM at the beginning of pregnancy. Moreover, a possible periconceptional infection could be definitively be ruled out in 13 of 17 mothers due to previous serology reports showing positive HCMV-IgG and negative HCMV-IgM before the index pregnancy, or high HCMV-IgG avidity on the serum collected at enrollment.

For 9 women (53%), 1 or more concurrent medical conditions during pregnancy were reported (Table 2). After delivery, HCMV DNA was detected in bodily fluids or blood in all but 2

women. Four women enrolled at the beginning of pregnancy had whole-blood samples stored and HCMV DNA testing gave negative results.

In order to attempt to make a distinction between HCMV reinfection or reactivation, genotype-specific IgG response to glycoprotein (g)B and gH was analyzed in 7 of the 17 transmitting women for whom serum samples were available both at the beginning of pregnancy and at delivery (Supplementary Table 2). Genotype-specific IgG to gB was detected in 3 women at the beginning of pregnancy (all anti-gB2/3). The same IgG antibody specificity was detected at delivery. Among the 4 women with no anti-gB genotype-specific IgG antibody at the beginning of pregnancy, 1 woman (VI 369-143) showed the appearance of anti-gB2/3 IgG at delivery. Six of the 7 women had detectable anti-gH genotype-specific IgG antibody at the beginning of pregnancy, and the same genotype specificity was detected at delivery. VI 369-143 showed IgG specific for both gH1 and gH2 genotypes in the 2 time points analyzed. Thus, a potential reinfection with a new HCMV strain was detected in 1 of 7 women tested.

Risk Factors for Vertical Transmission

The median age of transmitting mothers was 33 years (IQR: 30–38 years), similar to the median age of nontransmitting mothers: 33 years (IQR: 30–37 years). Occupation and nationality (Italian or foreigner) were not significantly different between the 2 groups (data not shown), or was the presence of living children and contact with young children younger than 36 months of age (for family or professional reasons) (Table 3). On the other hand, twin pregnancy was more common in transmitting mothers (OR: 7.2; 95% CI: 1.7–32.2; $P = .037$). Most interestingly, the presence of concomitant medical conditions was more frequent in transmitting than in nontransmitting mothers (OR: 3.9; 95% CI: 1.5–10.1; $P = .003$). Among the specific concomitant pathologies observed, diabetes (OR: 4.1; 95% CI: 1.9–14.5) and thyroid dysfunction (OR: 2.9; 95% CI: .9–8.8) were more commonly associated with cCMV.

Withdrawal of the Prevention Part

The planned interim analysis was conducted after the examination of 5260 newborns. HCMV DNA was detected in the saliva

of 31 newborns and congenital infection was confirmed in 12 newborns (.23%; 95% CI: .12–.39%) from 11 mothers (1 twin pregnancy). The 0.4% expected rate of cCMV in the uninfected population was beyond the upper limit of the 95% CI of the observed rate of cCMV. No particular characteristics of transmitting women were identified, since age, nationality, occupation, and close contact with young children were similar between mothers of infected and noninfected newborns. Therefore, data from the interim analysis indicated that the study did not need to proceed to part 2 (prevention part). The final analysis of part 1 (epidemiology) confirmed the interim analysis results and justified the decision to withdraw the prevention part.

DISCUSSION

Results of the CHILd study show that the prevalence of cCMV among newborns/fetuses from mothers with preconception immunity is .19% (95% CI: .11–.29%) in northern Italy. Maternal age and close contact with young children are not associated with cCMV in this population, whereas the presence of maternal medical conditions during pregnancy is associated.

The prevalence of cCMV in immune mothers of the CHILd study was lower than that reported in immune mothers from the highly seroprevalent (98%) population of Brazil, where the rate of cCMV was 0.5% [13]. On the other hand, our results are close to what was reported in Finland [14], where an overall 0.2% prevalence of cCMV was observed (although the rate of cCMV in immune mothers was not determined) in a population with a seroprevalence rate (70%) similar to that in Italy [15, 16]. In France, an overall 0.37% prevalence of cCMV was reported, with a 0.2% prevalence of cCMV in a subgroup of mothers with known preconception immunity [17] (see [Supplementary Table 3](#) comparing the cCMV frequency in studies assessing maternal seropositivity at the beginning of pregnancy).

We diagnosed cCMV by saliva screening and subsequent confirmation by urine (or dry blood spot) testing. Our analysis found that 28 of 45 (62%) newborns with HCMV DNA–positive saliva were not congenitally infected, confirming that saliva testing alone has a poor positive-predictive value [14, 17, 18]. False-positive saliva had significantly lower viral load, and a cutoff value greater than 2.5×10^2 HCMV DNA copies/mL identified infected newborns, similarly to what was reported by Eventov-Friedman et al [18]. HCMV shedding in genital secretions or breast milk is a potential cause of peripartum or postpartum saliva contamination in noninfected newborns. Therefore, saliva testing alone may overestimate the actual prevalence of cCMV. Although the validation of a viral load cutoff may improve the reliability of saliva testing, currently it should be considered as a preliminary screening to be subsequently confirmed on urine sample.

Among potential maternal risk factors, we did not find a younger age in mothers of cCMV newborns, as instead observed in Brazil [5] and France [17]. Most important, we did not find an association between caring for young children and cCMV. This result contrasts with what was observed in immune mothers in Brazil [7] but is in line with what was reported in France, where contact with young children was associated with cCMV in seronegative but not seropositive mothers [17]. Since young children are the major source of HCMV exposure in seronegative women, this finding suggests that exposure to HCMV and reinfection was unlikely to be the major cause of cCMV in immune mothers of our cohort. Conversely, reactivation of the latent virus may have been the more common cause of cCMV in both the CHILd and the French studies. We previously reported the results of a nested study conducted in a subgroup of pregnant women enrolled [19], showing that contact with children was not associated with nonprimary infection during pregnancy.

Among laboratory testing, HCMV-specific IgM antibodies were not detected at the beginning of pregnancy in the transmitting women. Additionally, HCMV DNA was not detected in the blood of the 4 cases tested.

The detection of new strain-specific serological responses has already been adopted in the attempt to discriminate between HCMV reinfection and reactivation as the cause of cCMV [6, 7]. In our study, only 1 in 7 women examined had serological evidence of reinfection. However, genotype-specific antibody testing may lack sensitivity in detecting reinfections.

The contrasting results observed between European countries and Brazil [7, 13] may be due to the different socioeconomic conditions and HCMV seroprevalence of the 2 populations. Higher exposure may occur in countries with high seroprevalence and, thus, favor the occurrence of reinfections, which instead appear infrequent in Europe.

Instead, we found an association of cCMV with twin pregnancy, as also reported elsewhere [5], and with the presence of comorbidities. The latter finding also suggests that reactivation may be at the basis of cCMV in seropositive women. Conditions such as diabetes [20], which may alter immunological responses [21], immunosuppressive treatments [12], or concurrent infections may have favored HCMV reactivation.

The strength of the CHILd study is the analysis of cCMV frequency in a large cohort of pregnant women with known seropositivity at the beginning of pregnancy. Limitations reside in the low prevalence of cCMV, which made it impossible to identify definite risk factors and to investigate the potential effectiveness of hygiene recommendations in preventing cCMV in seropositive women, and in the lack of direct comparison with the rate of cCMV in pregnant women without preconception immunity. In addition, the relative contribution of reinfection or reactivation was investigated in a small sample, and not finding evidence of infection with a new gB or gH serotype does not completely rule out reinfection.

The major outcome is that the risk for cCMV in immune mothers is quite low (<2 cases in 1000 pregnancies) in Italy and, most likely, in European countries, where the seroprevalence is approximately 70%. This risk appears at least 10 times lower than that observed in seronegative mothers in contact with young children (8 cCMV cases out of 315 seronegative mothers; ie, 2.5%) in a previous study [11]. A 4-fold higher risk for seronegative women to deliver a cCMV newborn was also reported in France [17]. Close contact with young children, the main risk factor for primary infection, is not associated with cCMV in seropositive mothers in high-income countries. This epidemiological evidence suggests that most congenital infections may be due to reactivation of the latent HCMV rather than reinfection with a new strain. Although the study was initially designed to verify the effectiveness of hygienic measures to prevent cCMV in immune mothers, the prevention part of the study was withdrawn due to the actual low prevalence of cCMV, and no clear risk factor was identified to select women who may take advantage of behavioral interventions. However, the lack of association between contact with children and

cCMV argues against the potential effectiveness of such measures.

In conclusion, these results support the protective role of maternal preconception immunity in preventing cCMV, thus endorsing the potential effectiveness of vaccination strategies whenever an HCMV vaccine should become available. Finally, preconception screening in childbearing age would be pivotal to identify HCMV-seropositive women, who have a low risk of cCMV. Conversely, the identification, counseling, and prospective monitoring of seronegative pregnant women [22, 23] are even more crucial now that secondary prevention of cCMV through timely intervention with antivirals after primary infection appears to be effective [24], and administration of hyperimmunoglobulin provided promising results [25].

Supplementary Data

Supplementary materials are available at *Clinical Infectious Diseases* online. Consisting of data provided by the authors to benefit the reader, the posted materials are not copyedited and are the sole responsibility of the authors, so questions or comments should be addressed to the corresponding author.

Notes

Acknowledgments. The authors thank the women participating in this study and the personnel of participating centers. A contract research organization (Consorzio Italiano per la Ricerca in Medicina, Italy) was responsible for the regulatory aspects of the study and verification of source documents.

Data sharing. Access to the eCRF of enrolled women will be granted upon request to the corresponding author.

Financial support. This work was supported by Fondazione Regionale per la Ricerca Biomedica (grant number FRRB 2015-0043).

Potential conflicts of interest. The authors: No reported conflicts of interest. All authors have submitted the ICMJE Form for Disclosure of Potential Conflicts of Interest. Conflicts that the editors consider relevant to the content of the manuscript have been disclosed.
