This Thesis is brought to you for free and open access by the Graduate School at TRACE: Tennessee Research and Creative Exchange. It has been accepted for inclusion in Masters Theses by an authorized administrator of TRACE: Tennessee Research and Creative Exchange. For more information, please contact trace@utk.edu.

To the Graduate Council:

I am submitting herewith a thesis written by Thomas N. Williams entitled "A modified six sigma approach to improving the quality of hardwood flooring." I have examined the final electronic copy of this thesis for form and content and recommend that it be accepted in partial fulfillment of the requirements for the degree of Master of Science, with a major in Forestry.

Timothy M. Young, Major Professor

We have read this thesis and recommend its acceptance:

Brian Bond, Frank Guess, Paul Winistorfer

Accepted for the Council:

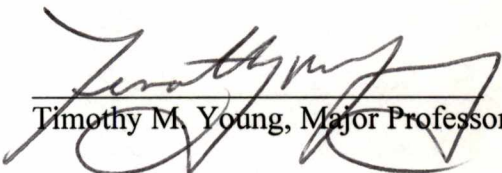

Carolyn R. Hodges

Vice Provost and Dean of the Graduate School

(Original signatures are on file with official student records.)

DEDICATION

This masters thesis is dedicated to my wife:

Nichole,

who provides a loving, caring,

encouraging and supportive atmosphere.

These are characteristics that contribute to the environment

that is always needed to achieve the goals ahead.

To David Bianconi for his support, friendship,

and helping me understand all about life and CHEESE!

To Orsa for helping to relieve the stress!

To the many friends who support me.

ACKNOWLEDGEMENTS

Many people have contributed to my learning experience at the University of Tennessee. I am thankful for my masters thesis advisor, Timothy M. Young, for his insight, thought provoking questions and guidance for my thesis. He has provided growth for my professional career, over the last two years, in more ways than I can express. In addition, I have also benefited from the other members of my thesis committee, Dr. Brian Bond, Dr. Frank Guess, and Dr. Paul Winistorfer, who provided an open door for questions and detailed suggestions that greatly improved my understanding of in-depth research. This work was supported by a special grant from the United States Department of Agriculture (USDA) for wood utilization research, under contract number R11-2218-95 and also funded by University of Tennessee, Agricultural Experiment Station McIntire-Stennis Funding #75.

I would also like to thank other members of the Tennessee Forest Products Center for their support and help through out this process. Many hours of data collecting was accomplished with the help of David Cox and my brother Nick Williams. Lab samples were prepared and tested with the help of Chris Helton.

Thanks to my best friend J.C. for always being there for me even when I could not make time for you. Thanks to David Bianconi for the weekly talks and guidance you shared from your heart and life experiences. Thanks to all the friends that supported me.

Finally, I am indebted to my wife, Nichole, for her continuous support, sacrifice and LOVE that allowed me to complete my masters thesis.

ABSTRACT

Total quality or continuous improvement is a consensus theme used by many industries for improving product quality and service. In the last decade a newer quality philosophy known as "Six Sigma" has become well established in many companies, *e.g.*, *Motorola, General Electric, Ford, Honda, Sony, Hitachi, Texas Instruments, American Express, etc.* Some have suggested that the "Six Sigma" quality improvement philosophy is not only impacting the global business sector, but will also re-shape the discipline of statistics. The "Six Sigma" philosophy for improving product and service quality is based upon existing principles established by other well-recognized quality experts, *e.g.*, *Deming, Juran, and Ishikawa.* The significant departure of the "Six Sigma" philosophy from existing quality philosophies is that it promotes a stronger emphasis on monitoring production yield and manufacturing costs associated with any quality improvement effort. The other significant contribution that "Six Sigma" makes to the quality movement is the detailed structure for continuous improvement and the step-by-step statistical methodology. The goal of any "Six Sigma" improvement effort is to obtain a long-term defect rate of only 3.4 defective parts-per-million manufactured.

The problem definition of the thesis was to determine if a modified "Six Sigma" philosophy for continuous improvement would improve the quality of hardwood flooring. The study was conducted over a six-month time period at a hardwood-flooring manufacturer located in Tennessee.

There were six research objectives: 1) Define the current-state of product variability for hardwood "flooring-veneer" and the specific attributes of "finished blank"

length, width, and “veneer-slat” thickness; 2) Determine the capability of the product attributes defined in objective one relative to specification limits; 3) Determine the current production yield and manufacturing costs associated with the manufacture of “veneer-slats;” 4) Define the sources of variability that influence the product attributes “finished blank” length, width, and thickness, and “veneer-slat” thickness (This involved a detailed understanding of the relationships that existed between key process variables that influenced “finished blank” length, width, and thickness and “veneer-slat” thickness); 5) Recommend to senior management the improvements necessary to enhance the overall quality of “veneer-slats;” 6) If any of the recommendations are adopted from objective five, the first four objectives would be repeated to determine if quality has improved.

There were four major findings resulting from this work. First, there was statistical evidence (at $\alpha = 0.05$) that top (p-value = 0.0007) and bottom (p-value = 0.0167) “veneer-slat” thickness increased as “finished blank” thickness increased. There was no significant statistical evidence (p-value = 0.3904) that indicated the thickness of the three middle “veneer slats” was affected by “finished blank” thickness. Second, 20% of rejected “veneer-slats” were good and 10% were down-gradable. Third, there was statistical evidence (p-value = 0.1126) that indicated “rip-saw” width was in control and the natural tolerance was 0.428 mm, which was within engineering tolerance. Target sizes of “rip-saw” width should be reduced to improve yield. Fourth, drying stresses and honeycomb were present in dried lumber. Drying schedules and proper conditioning of kiln loads were not appropriately executed. There was statistical evidence (p-value =

0.0001) that indicated top and bottom “veneer-slat” width was greater than the middle “veneer-slats” given the drying stresses.

Four recommendations made to senior management were: 1) If “finished blank” thickness variation could be reduced by improving blank molder setup there would be a cost savings of \$520,000 dollars per year; 2) A conservative estimate of the cost savings associated with the recovery of the 20% misdiagnosed “veneer-slats” would be \$500,000 dollars per year; 3) Analysis of the “rip-saw” indicated an 8% yield increase if “rip-saw” target sizes and saw kerf were reduced and; 4) Appropriate drying and conditioning schedules should be followed to reduce “veneer-slat” width stresses and moisture content variation (eliminating top and bottom “veneer-slat” width variation would result in cost savings of \$10,000 dollars per year). None of the previously mentioned recommendations would require capital investment by the company.

Keywords. -- Modified “Six Sigma,” hardwood flooring, continuous improvement, quality improvement, variation reduction, cost savings, yield improvement.

CHAPTER 1

INTRODUCTION

In the early 20th century most U.S. forest products companies enjoyed the benefits of inexpensive raw material and low labor costs. For most forest products companies of this era, technology was a leading constraint to improved production (Maki 1993). Quality of final wood products during this era was of minimal importance to most wood producing companies (Young and Winistorfer 1999).

As the U.S. forest products industry entered the 21st century, they were faced with a panacea of issues. Environmental regulation and preservation interests have reduced the availability of wood fiber and resulted in higher raw material costs. Air quality restrictions have forced many forest products companies to invest in expensive air-quality control equipment. Labor costs are higher in the U.S. relative to labor costs in developing countries. The U.S. forest products industry is also faced with increasing domestic and international market competition from non-wood products such as plastic, aluminum, and concrete. The scenario faced by most U.S. forest products companies is lower profit margins due to higher raw material and manufacturing costs in the context of stable real-prices for final wood products. These economic constraints have forced many U.S. forest products companies to reassess manufacturing practices (Young and Winistorfer 1999). Some U.S. forest products companies have started assessing the potential benefits that may occur from adopting continuous improvement philosophies such as the "Six Sigma" quality philosophy (Young and Winistorfer 1999).

Total quality or continuous improvement is a consensus theme used by many industries for improving product quality and services (Young and Guess 1994; Young and Winistorfer 1999). In the last decade a newer quality philosophy known as “Six Sigma” has become well established in many companies, *e.g., Motorola, General Electric, Ford, Honda, Sony, Hitachi, Texas Instruments, American Express, etc.* (Harry 1997, 1998, 2000; Blakeslee, J.A., Jr. 1999). Some have suggested that the “Six Sigma” quality improvement philosophy is not only impacting the global business sector, but also will re-shape the discipline of statistics (Hahn *et al.* 1999).

The founder of the “Six Sigma” quality philosophy is Mikel Harry (Harry 1997, 2000). Harry’s (2000) significant departure from existing quality philosophies is a stronger emphasis on monitoring production yield and manufacturing costs associated with the continuous improvement effort. Harry’s (2000) other significant contribution to quality is the organization and step-by-step statistical methodology that he feels is necessary for successful continuous improvement.

The phrase “Six Sigma” is derived partially from statistics and capability analysis. A “Six Sigma” company is defined by Harry (2000) as one that produces a product and/or service that has variability, which is approximately six sample standard deviations (*i.e., six sigma $\approx 6s$*) inside the customer’s specification limits. This results in the long-term manufacture of defective product at a rate of only 3.4 parts-per-million. Significant cost savings are associated with this higher level of quality.

Thesis Hypothesis

The hypothesis of this thesis was to determine if a modified “Six-Sigma” quality philosophy can improve the quality of hardwood flooring over a 6-month time frame. Improvements were defined by an improved production yield and decreased manufacturing costs.

Thesis Objectives

There were six research objectives: 1) Define the current-state of product variability for the specific attributes of “finished blank” length, width, and thickness and “veneer-slat” thickness; 2) determine the capability of the product attributes “finished blank” length, width, and thickness and “veneer-slat” thickness as related to engineering specifications; 3) determine the current production yield and manufacturing costs associated with the manufacture of “veneer-slats”; 4) define the sources of variability that influence the “finished blank” length, width, and thickness and “veneer-slat” (This involved a detailed understanding of the relationships that existed between key process variables that influenced the “finished blank” length, width, and thickness and “veneer-slats”); 5) recommend to senior management the improvements necessary to enhance the overall quality of “veneer-slats” and; 6) if any of the recommendations were adopted from objective five, the first four objectives would be repeated to determine if the quality of the product attributes have improved.

Contributions to Research

There were potential benefits of the thesis that may be useful to the forest product industry. The “Six Sigma” philosophy provides a step-by-step quality improvement

methodology that uses statistical methods to quantify variation. The “Six Sigma” philosophy also estimates cost savings and yield improvements from variation reduction.

The results of this thesis work contributed to other quality philosophies by showing that significant sources of variability can be identified in a short period of time. However, modifications of the “Six Sigma” philosophy limit the degree to which quality can be improved in the short-term. The result of this work suggested an estimated large potential cost savings to the cooperating hardwood flooring manufacturer. The results of this thesis also showed that the “Six Sigma” philosophy may represent a long-term cultural shift for many forest products companies with traditional management styles.

CHAPTER 2

LITERATURE REVIEW

Competitive market pressures and economic scarcity of raw material will force many forest products companies to continually improve the quality of manufactured products. Such market pressures, combined with economic scarcity of wood fiber, will also force forest products companies to reassess inefficient and wasteful manufacturing practices.

The quality movement, which arose in Japan in the 1960s and forced the U.S. automotive industry to reassess its quality philosophies in the 1980s, is being adopted again by the U.S. forest products industry at the start of the 21st century. For most wood products companies the driving force in this quality effort is not offshore market competition, but domestic market competition combined with non-wood product substitution and economic scarcity of wood fiber.

U.S. companies in general have attempted to implement many quality and business improvement philosophies during the past quarter of a century, *e.g.*, *Continuous Improvement, Total Quality Management, Reengineering and Six-Sigma Quality* (Deming 1986, 1993, Harry and Schroeder 2000, Juran 1992). Some companies have been successful in improving business profitability through improved quality while many have been unsuccessful (Grant *et al.* 1994, Harry and Schroeder 2000, Young *et al.* 2000). Even though there has been a panacea of quality improvement philosophies, many businesses have struggled to quantitatively define any business improvement after implementing a quality improvement initiative (Hayes *et al.* 1988). Many scholars feel

the distinguishing factor between a successful and unsuccessful quality improvement strategy is that successful strategies have an underlying foundation in statistical methods (Breyfogle 1999, Ishikawa 1987, Juran and Gryna 1993). The contributions made by Deming, Juran, Ishikawa, Taguchi, Feigenbaum, and Harry to the overall quality movement through the use of statistical methods cannot be ignored (Aguayo 1990, Deming 1986 and 1993, Walton 1986).

Historical Perspective of Quality – Contributions by W.A. Shewhart

Quality initiatives began to develop in the early 1930s. Walter Shewhart made a significant contribution to the philosophy of quality improvement with his book “Economic Control of Quality of Manufactured Products” (Shewhart 1939). Shewhart (1939) with a stroke of a pen developed the control chart, which relied on probability and statistical theory to define common-cause and special-cause variation of manufactured products (Wheeler and Chambers 1992). Shewhart’s work provided the statistical basis for many quality improvement initiatives of the 20th century (Shewhart 1931, 1939).

Shewhart’s quality improvement philosophy represented a significant departure from the Scientific Management manufacturing philosophy of the 1930s and earlier (Taylor 1911). Even though Shewhart’s views were being practiced within Bell Laboratories, most manufacturers of this era adopted the ideas and concepts of Scientific Management promoted by Frederick Taylor (Taylor 1911). Taylor is associated with the extreme division of labor and with using time and motion studies to turn people into mindless automatons (Hayes *et al.* 1988). Scientific Management had four basic principles: (1) Find the most efficient way to do a job; (2) Match people to tasks; (3) Supervise, reward and punish; and (4) Use staff to plan and control (Hayes *et al.* 1988).

Many feel that Taylorism led to the birth of managers and collective bargaining (Hayes *et al.* 1988). A statistician's view of Taylorism may find one serious shortcoming, *i.e.*, *Taylorism does not attempt to define the natural variation of a process* (Deming 1986, 1993, Shewhart 1931, Shewhart and Deming 1939, Taylor 1947).

Shewhart continued to enhance his quality improvement philosophy in his second book titled, "Statistical Methods from the Viewpoint of Quality Control" (Shewhart and Deming 1939). Shewhart's second book introduced his colleague W. Edward Deming to many readers interested in quality control and improvement. The general theme conveyed by Shewhart and Deming in the book was that quality and productivity can be continually improved, *i.e.*, "*as quality improves, costs decrease and productivity increases*" (Shewhart 1939). They introduced the notion of the "customer" and they felt the role of the manufacturer was to deliver a product to the customer that not only met their quality needs but also exceeded their expectations (Deming 1986, 1993, Shewhart and Deming 1939). Deming believed, "A satisfied customer is not enough. Business is built on the loyal customer, one who comes back and brings a friend" (Deming 1986, 1993).

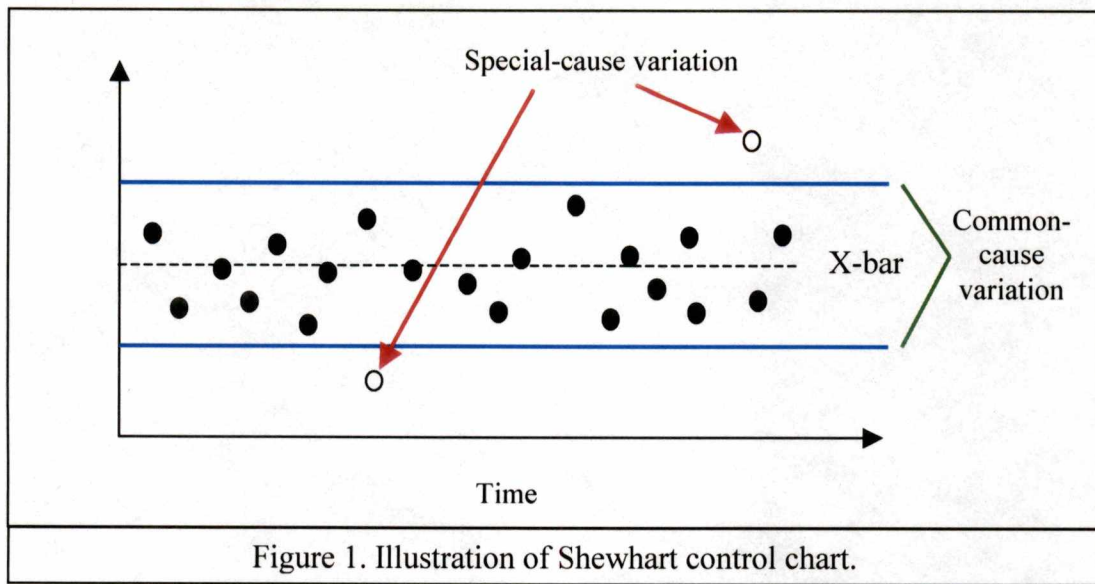

Controlling and reducing variation in manufacturing reduces defective products and rework. Shewhart's philosophy as related to the control chart identifies and quantifies process and product variation. By collecting time ordered data the process can be constantly monitored. The Shewhart control chart defines variation as being either common-cause variation (natural system variation) or special-cause variation. Shewhart defined common-cause variation as variation that is inherent to the manufacturing system. Common-cause variation is caused by day-to-day machinery variation, operator-

to-operator variation, supplier variation, etc. Shewhart defined special-cause variation as variation that occurs from an event in the manufacturing process. The event may be due to downtime, start-up, a new supplier, motor-stop, tool-wear, etc. Shewhart observed that variation due to common-causes exhibited a symmetric or normal distribution whereas variation due to special-causes goes beyond natural variation and does not follow typical statistical laws (Shewhart 1931, Shewhart and Deming 1939).

Shewhart control charts have upper control limits (UCL) and lower control limits (LCL). Control limits should not be confused with specification limits or engineering tolerance.¹ Control limits are approximations of plus (UCL) or minus (LCL) three standard deviations from the process average (\bar{X}), Figure 1. Shewhart calculated control limits as plus or minus three standard deviations from the process average because 99.7% of the data would be contained within these limits, *i.e., the probability of misdiagnosing a data point outside these limits as special-cause variation is 0.003* (Shewhart 1931, Shewhart and Deming 1939, Wheeler 1993).

Shewhart stated “a process will be in control when through the use of past experience, we can predict, at least within limits, how the process will behave in the future” (Shewhart 1931). Special-cause variation is unpredictable and indicates the process is out of statistical control (Shewhart 1931, Shewhart and Deming 1939, Wheeler 1993). The benefit to manufacturers from using Shewhart control charts comes from the ability to predict the future, *i.e., if the process is in a state of statistical control, the limits can be extended out in to the future* (Deming 1943, 1986, 1993). The Shewhart control chart also quantifies the natural variation of a process or product.

¹ Engineering Tolerance is defined as the difference of the upper specification limit (USL) and the lower specification limit (LSL).

Historical Perspective of Quality – Contributions by W.E. Deming

Even though W.E. Deming studied under W.A. Shewhart and was shunned by the U.S. automotive industry in the 1950s, he is considered by many to be the father of the “American Quality Revolution.” In America, Deming became well known in 1984 after a prime-time NBC television broadcast titled, “If Japan can, Why can’t we?” The television broadcast highlighted Japan’s international business success in the 1970s and 1980s against the backdrop of a struggling U.S. economy and a U.S. automotive industry that was closing plants due to a loss of 25% market share due to Japanese competition (Walton 1986). The television broadcast highlighted Deming’s work with the Japanese in the 1950s and 1960s and many feel the television broadcast was the start of the American Quality Revolution of the 1980s (Deming 1986, Scherkenbach 1991, Walton 1986).

Deming emphasized the importance of statistical thinking in the continuous improvement of processes. He felt that Statistical Process Control (SPC) and Shewhart's Plan-Do-Check-Act (PDCA) cycle were important tools to understanding sources of variability and improving processes. The continuous improvement philosophies of Deming were best communicated in his Fourteen Points for Management. His Fourteen Points served as a framework for quality and productivity improvement. Deming's 14 points were:

1. Create constancy of purpose toward improvement of product and service, with the aim to become competitive and to stay in business, and to provide jobs.
2. Adopt the new philosophy. We are in a new economic age. Western management must awaken to the challenge, must learn their responsibilities, and take on leadership for change.
3. Cease dependence on inspection to achieve quality. Eliminate the need for inspection on a mass basis by building quality into the product in the first place.
4. End the practice of awarding business on the basis of price tag. Instead, minimize total cost. Move toward a single supplier for any one item, on a long-term relationship of loyalty and trust.
5. Improve constantly and forever the system of production and service, to improve quality and productivity, and thus constantly decrease costs.
6. Institute training on the job.
7. Institute leadership. The aim of supervision should be to help people and machines and gadgets to do a better job. Supervision of management is in need of overhaul, as well as supervision of production workers.
8. Drive out fear, so that everyone may work effectively for the company.
9. Break down barriers between departments. People in research, design, sales, and production must work as a team, to foresee problems of production and in use that may be encountered with the product or service.

10. Eliminate slogans, exhortations, and targets for the work force asking for zero defects and new levels of productivity. Such exhortations only create adversarial relationships, as the bulk of the causes of low quality and low productivity belong to the system and thus lie beyond the power of the work force.
 - Eliminate work standards (quotas) on the factory floor. Substitute leadership.
 - Eliminate management by objective. Eliminate management by numbers, numerical goals.
11. Remove barriers that rob the hourly worker of his right to pride of workmanship. The responsibility of supervisors must be changed from sheer numbers to quality.
12. Remove barriers that rob people in management and in engineering of their right to pride of workmanship. This means abolishment of the annual or merit rating and of management by objective.
13. Institute a vigorous program of education and self-improvement.
14. Put everybody in the company to work to accomplish the transformation. The transformation is everybody's job (Deming 1986, 1993, Walton 1986).

Deming believed that one of the “great evils” of American management was to produce products or services to a “quality standard” or an “acceptable-level” of quality (Deming 1986). He felt that “quality standards” did not promote continuous improvement. He believed that “quality standards” produced numerical quotas, which were often times met “on paper” in the quarterly report but rarely could be verified on the plant floor.

Deming stressed the importance of constantly trying to improve product design and performance through research, development, testing, and innovation. He also emphasized that production and service systems should be continuously improved. He

was emphatic about the idea that quality was not some minor function to be handled by inspectors, but a company's central purpose and a top priority of executive management. Deming felt that employees would not consider quality an important issue if there was not support and communication with executive management level within an organization (Deming 1986, 1993).

Deming understood the reason for Japan's success. He was quoted as saying "Hundreds of Japanese engineers learned the methods of Walter A. Shewhart. Quality became at once in 1950, and ever after, everybody's job, company wide and nation wide" (Aguayo 1990). Deming was also well known for his philosophy that reductions in variation lead to reductions in costs and improved productivity (Aguayo 1990, Deming 1986, 1993, Walton 1986).

Deming deemed that "quality is achieved through the never-ending improvement of the process, for which management is responsible" (Kilian 1992). Deming defined three quality categories: (1) "Quality of design/redesign;" (2) "Quality of conformance;" and (3) "Quality of performance." Quality of design is based on consumer research, sales analysis, and service call analysis and leads to the determination of a prototype that meets the consumer's needs (Gitlow 1987). In considering consumers' needs, the critical aspect is that firms look years ahead to determine what will help customers in the future. Next, specifications are constructed for the prototype and disseminated throughout the firm and back to the suppliers, *i.e.*, "*Quality of Conformance.*" "Quality of performance" is the determination through research and sales/service call analysis of how a firm's products or services are actually performing in the marketplace. "Quality of performance" leads to

“quality of redesign,” and so the cycle of the never-ending improvement continues (Aguavo 1990, Gabor 1998, Gitlow 1987).

Deming was a firm believer in Walter A. Shewhart’s teachings of the “Control Chart.” The understanding of common-cause and special-cause variation was a critical element of Deming’s philosophies. Deming was quoted, “Management must realize that unless a change is made in the system (which only management can make), the system’s process capability will remain the same. This capability will include the common-cause variation that is inherent in any system. Workers should not be penalized for common-cause variation; it is beyond their control” (Deming 1986, 1993, Gitlow 1987, Shewhart and Deming 1939).

Such things as poor-lighting, lack of training, or poor product design lead to common-cause variation. New materials, a broken die, or a new operator could cause special-cause variation. Workers can become involved in creating and utilizing statistical methods so that common and special-cause variation can be differentiated and process improvements can be implemented. Since variation produces more defective and less uniform products, the crucial understanding is that managers know how to reduce and control variation. Understanding and controlling variation can lead to the total achievement of quality (Deming 1986, 1993, Shewhart 1931, Shewhart and Deming 1939).

Managers must understand that there is no easy way to change the current situation. There can be no quick results because what is needed is a continuing cycle of improved methods of manufacturing, testing, consumer research, product redesign, etc.

This view extends to include the company's vendors, customers, and investors. All must play a role in the continuing improvement of quality.

Deming made great contributions to the quality movement through his work in statistical thinking and management philosophies. His work in statistics provided a way to analyze data for the purpose of improving and controlling processes. His idea was to reduce variation in the process by identifying possible sources of variation by using the statistical tools available. Once improvements were made to the process, the PDCA cycle was again reinitiated to promote continuous improvement (Aguayo 1990, Gabor 1998, Gitlow 1987, Walton 1986, Wheeler 1993).

Deming's Influence on Japan's Early Quality Initiatives

After World War II, Japan's economy was suffering from the post-war economic depression. In 1950 Dr. W. Edward Deming was invited by the Japanese Union of Scientists and Engineers (JUSE) to go to Japan. He gave a series of lectures on quality control to Japan's top engineers and managers. Unlike the United States, Japan embraced Deming's principles and began to experience positive results eighteen months after his first lecture.² Deming predicted Japan would begin to successfully compete in international markets within five years after his first visit. In the mid-1950s, Japan began to experience tremendous improvements in the quality of their products (Neave 1990). Deming's prediction was inaccurate. Japan began capturing international market share in the automotive and electronic industries within four years of his first visit (Aguayo 1990, Deming 1993, Walton 1986).

² The America of the fifties and sixties had scorned Deming and his teaching and in effect driven him abroad to find his students. America in those days was rich and unchallenged and there were few competing foreign products (Halberstam 1986).

Japan to this day (the world's 2nd largest economy) attributes their economic success to Dr. W. Edward Deming. Japan awards the coveted "Deming Prize" once a year to a Japanese company that has made the most significant improvements in quality. Japan televises the "Deming Prize" award presentation on prime-time TV in Japan which represents a significant departure from western culture TV programming (Aguavo 1990, Deming 1986, 1993, Gabor 1990, Walton 1986).

Other Important Contributors to the Quality Movement

There were many other scholars that made significant contributions to the quality movement. Joseph M. Juran, Genichi Taguchi, Armand Feigenbaum, and Kaoru Ishikawa are a few of the other recognized scholars that made significant contributions to the quality movement.

Joseph M. Juran

Joseph M. Juran was best recognized for his philosophies of "Total Quality Management" and "Cost of Quality." In the early 1960's, Juran initiated the concept of the cost of quality, which reemphasized management's responsibility for quality. He felt that quality related costs occurred in two categories: "unavoidable" and "avoidable." He felt that design-flaws contributed to "avoidable" costs incurred during manufacturing or from customer complaints. Juran felt that more planning and attention needed to occur at the design stage of products to reduce avoidable costs of poor quality (Juran and Gryna 1951, 1993).

Total Quality Management (TQM) refers to an integrated approach by management to focus all functions and levels of an organization on quality and continuous improvement. TQM emphasizes customer-focused quality not just for

customers of the final product but also for the organization's internal customers (Kilian 1992). Implementation of TQM requires total participation and commitment company-wide.

TQM is not a program to achieve a specific, static goal, but instead is a process committed to continuous quality improvement. The reason why continuous quality improvement is an integral part of TQM is that Juran felt a company must continuously improve to survive in a fast-changing and highly competitive business environment (Grant *et al.* 1994).

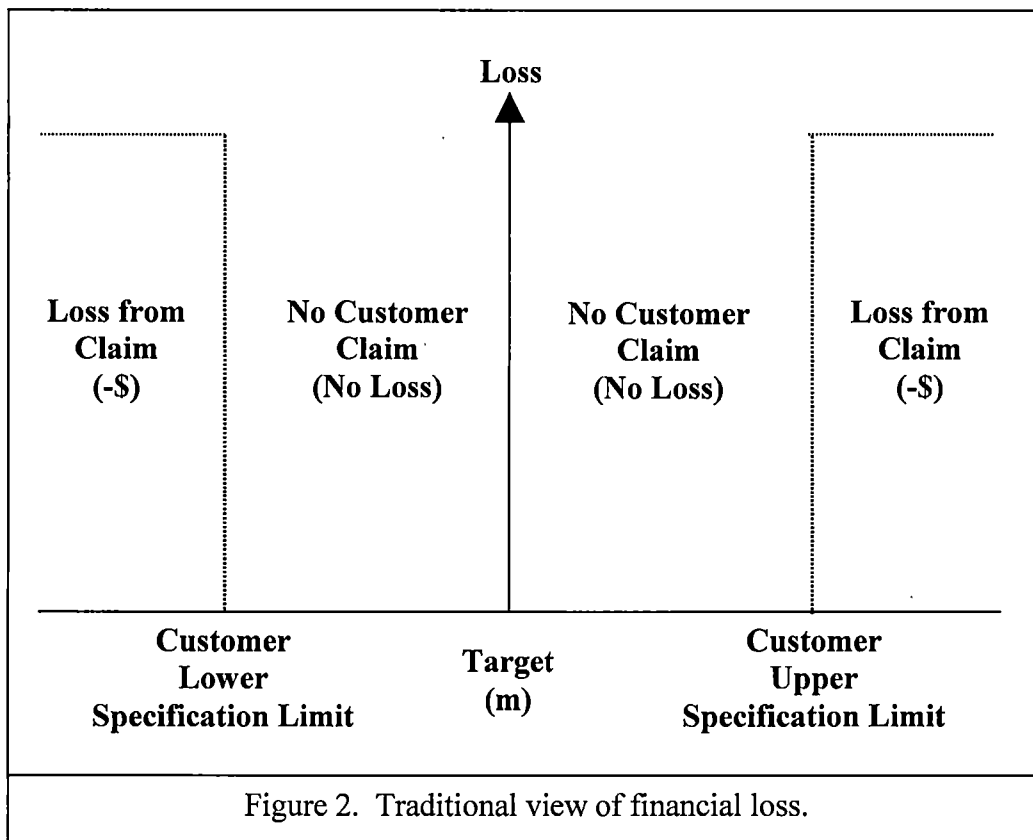

Juran had significant contributions to the development of TQM. Juran believed, quality management's specific task was not only to identify and eliminate variation, but also to serve customer expectations. The entire company must embrace TQM as a customer focused quality improvement initiative (Grant *et al.* 1994, Juran 1992).

TQM comprises a group of techniques for enhancing competitive performance by improving the quality of products and processes (Grant *et al.* 1994). To successfully implement TQM systematic changes in management practice include: redesign of work, redefinition for managerial roles, redesign of organizational structures, learning of new skills by employees at all levels, and reorganization of organizational goals. Proper implementation of TQM has seen numerous financial gains for many companies (Grant *et al.* 1994).

Genichi Taguchi

In the 1960s Genichi Taguchi was best known for the development of the "Taguchi Loss Function." This function measures financial loss to an organization due to product variation. Taguchi emphasized in the "Taguchi Loss Function" the importance

of manufacturing product that is “on-target.” Taguchi felt that if variation were minimized around the target, the cost due to variation would also be minimized. Taguchi stressed that any deviation from the target will result in increased cost. In the Taguchi Loss Function the financial loss to an organization increases as a quadratic function the farther the product deviates from the target. Taguchi’s Loss Function is in extreme contrast to traditional quality control where it is assumed that a financial loss does not occur until the product is outside of specification, *e.g., customer rebate or claim* (Figure 2). Taguchi and Deming felt that it was too late once a product was manufactured outside of customer specifications, *i.e., the customer may be lost forever* (Deming 1986, 1993). Taguchi’s philosophy promoted the continuous reduction of variation (Fuller 1998, Ishikawa 1987, Taguchi 1993, Young and Winistorfer 1999).

Figure 3. Illustration of the Taguchi Loss Function.

Taguchi's function is defined by an objective characteristic y (e.g., *thickness*) as it deviates from a target value m (Figure 3). The financial loss from deviations from target can be assumed to be a function of y , which is designated $L(y)$. If $y = m$, $L(y) \cong 0$. The Taguchi Loss Function shows that even small deviations from target induce financial loss even though the product remains usable to the producer or consumer (Young and Winistorfer 1999).

Deming stated, "The most important use of the Taguchi Loss Function is to help us change from a world of meeting specifications, to continue reduction of variation about the target through process improvements" (Deming1993). Deming's main

argument was that conforming to some engineering tolerance limits was not good enough. Deming believed, manufacturing products that meet the target specification are closer to achieving continuous improvement than products that are not on target.

Taguchi also made contributions to the statistical discipline known as Design of Experiments (Taguchi 1993). Taguchi's "Robust Design" methodology consisted of three elements: "system design," "parameter design," and "tolerance design" (Nicholas 1998). "System design" is achieved through careful selection of parts, materials, and equipment. "Parameter design" is to produce a robust product or process that will remain close to target and will perform well under a range of variation elements in the production environment. "Tolerance design" is to reduce variation around the target value by tightening tolerances on factors that will affect the variation (Nicholas 1998).

Armand Feigenbaum

Armand Feigenbaum's major influence on the quality movement was his concept of "Total Quality Control." Feigenbaum defined "Total Quality Control," as "an effective system for integrating the quality-development, quality-maintenance, and quality-improvement efforts of the various groups in an organization to enable marketing, engineering, production and service at the most economical levels which allows for full customer satisfaction" (Feigenbaum 1991).

The word "Total" in "Total Quality Control" implied that quality control was everyone's job. Feigenbaum's definition of quality was to obtain complete customer satisfaction by providing a product and service that is designed, built, marketed, and maintained at the most economical cost. He felt that this philosophy would provide

motivation for all company employees, from top management through assembly workers; including office personal, dealers, and service people (Feigenbaum 1991, 1996, 1997).

The scope of “Total Quality Control” relied on the underlying principles of quality to identify customer requirements. A complete measurement of customer requirements does not end until the product was placed in the hands of the consumer who continually remains satisfied. “Total Quality Control” was designed to guide synchronized actions of people, machines, and information to achieve the goal of customer satisfaction (Feigenbaum 1991, 1996, 1997).

The key features of Feigenbaum’s concept of “Total Quality Control” were:

- Communication of quality in company-wide and plant-wide activities;
- Strategic planning for quality;
- Competitive market leadership through strong customer quality assurance;
- Measure of profitability improvement and return-on-investment from quality initiatives;
- Rapid product development and introduction;
- Maintaining and updating technology;
- Elimination of work building relationships with vendors and suppliers;
- Identifying key factors within an organization that lead to “Total Quality Control.”

Kaoru Ishikawa

Kaoru Ishikawa is considered by many scholars to be the founder and first promoter of the “Fishbone” diagram (or Cause-and-Effect Diagram) for root cause analysis (Ishikawa 1987). He also is recognized for the concept of Quality Control (QC) circles. The philosophy of the “Fishbone” or Cause-and-Effect diagram represents a

structured brainstorming approach to problem solving. The basic idea of the “Fishbone” diagram was to make a listing of all of the possible causes that may have an effect on a known problem. Ishikawa categorized the “Fishbone” diagram into five main categories (Materials, Methods, People, Machines, and Measurement), Figure 4. Ishikawa felt that the “Fishbone” diagram was a key tool to be used by workers for problem solving in Quality Control (QC) circles. Ishikawa felt strongly about the proper use of problem solving tools in the improvement of quality.

His concept of the Quality Control (QC) circle was to bring production workers, maintenance, design engineers, and managers together in organized meetings to solve problems. The QC circles were critical in the complete root-cause analysis of any problem. The QC circles were responsible for diagnosing problems and developing permanent solutions for problems (Hermens 1997, Ishikawa 1987, Nicholas 1998).

Traditional Quality Control versus Continuous Improvement

Traditional quality control was replaced in the 1980s in many U.S. companies with the philosophy of continuous improvement (Deming 1986, Juran 1992, Juran and

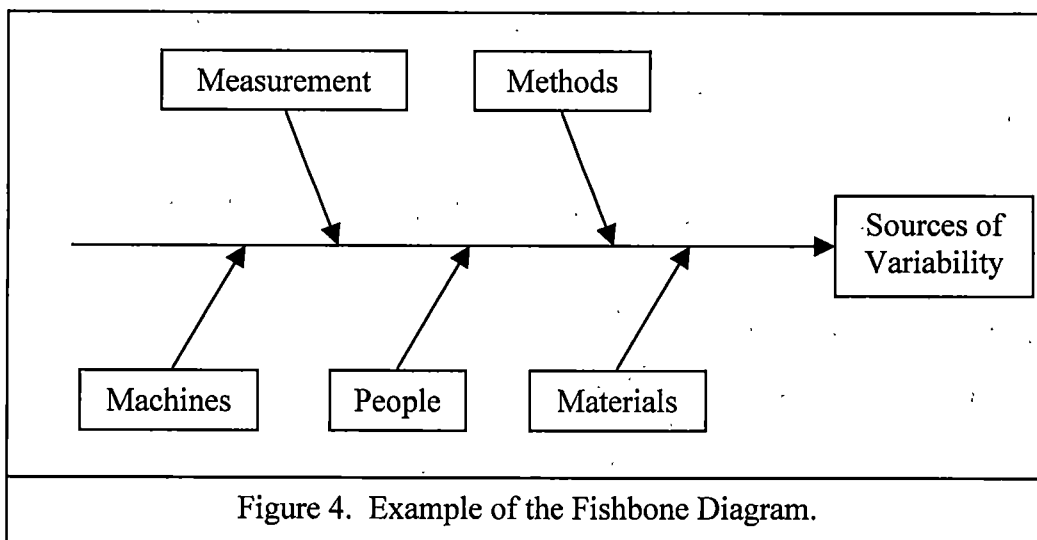

Figure 4. Example of the Fishbone Diagram.

Gryna 1993). Unfortunately, many U.S. forest products companies continue to practice the traditional philosophy of quality control (Young and Winistorfer 1999).

Key features of traditional quality control as defined by Cole (1998):

- Conformance checks to specification limits;
- Quality control is defined as a functional specialty within the company;
- Quality control is a specialized function carried out by technical experts;
- Focus is on inspection after the product is manufactured which promotes “reactive” behavior;
- No attempt to quantify variation;
- Product is manufactured to a standard within the framework of company quality goals, *e.g., quality goal in 2001 will be 96% A-grade*;
- Quality standards are agreed upon through consensus decision-making with executive management.

Traditional quality control does not focus on continuous improvement but is focused on conforming to specifications or engineering tolerance. There is no feedback-loop or cycle within the decision-making process of workers that promotes the improvement of quality through the reduction of process variation. Traditional quality control is reactive and focuses on the sorting of unacceptable product from acceptable product (Cole 1998, Deming 1986, Feigenbaum 1997, Fuller 1999). Traditional quality control concepts rely on technical experts to improve quality instead of involving all employees.

Continuous improvements initial focus is on defining customer needs and expectations. Continuous improvement contrasts with traditional quality control in that it involves all employees of the company and does not place the burden for quality

conformance solely on the shoulders of technical experts. Key features of continuous improvement as defined by (Deming 1986, 1993, Juran 1992, 1995):

- Customer preferences are internalized in the design and manufacture of product;
- Continuous improvement is integrated in all aspects of a company's business culture;
- Quality of manufactured product or service is used to distinguish a company from other competitors;
- All employees are involved in the quality effort;
- Focus is on preventing the manufacture of defective product and not on reacting to product outside of specification;
- Cycle of continuous improvement that never ends (Plan-Do-Check-Act);
- All employees are trained in statistical methods and quality philosophies;
- Emphasis on communication across departments;
- Use of statistical methods to quantify variation and separate "fact" from "opinion;"
- Marketing function attempts to predict changes in customer needs and expectations.

Even though continuous improvement philosophies are present in many American industries (automotive, electronics and aerospace), many forest products companies tend to practice traditional quality control (Young and Winistorfer 1999). The "Technical Director" of a plant is responsible for quality and the testing-lab in which conformance checks are made (Young and Winistorfer 1999). Even though the aspect of "quality control" is important to the forest products industry, quality control by itself does not ensure the continuous improvement of processes and products.

The “Six Sigma” Quality Philosophy

The most recent quality philosophy to be adopted by businesses around the world is known as “Six Sigma.” The founder of the “Six Sigma” philosophy is Mikel Harry (Harry and Schroeder 2000). Mikel Harry developed and implemented his “Six Sigma” philosophy with the Motorola Corporation and the philosophy has had great success at the GE Corporation (Harry and Schroeder 2000). Many companies such as Ford, Xerox, Intel, Honda, Sony, Hitachi, Texas Instruments, American Express, etc., have adopted the “Six Sigma” quality philosophy.

“Six Sigma” derived its name from the Greek letter sigma (σ). Sigma is used in statistics to define the parametric statistic “population standard deviation” (Pyzdek 1999). Six sigma is defined in statistics as six population standard deviations, which in a parametric sense would encompass 99.74% of the data population. The “Six Sigma” quality philosophy should not be confused with the statistical definition. Even though the “Six Sigma” quality philosophy derives its name from a statistic, it is a broad quality philosophy that focuses on using statistical methods to improve quality, decrease cost, reduce waste, rework, and streamline business operations (Breyfogle, 1999). The “Six Sigma” quality philosophy incorporates many of the traditional quality philosophies established by Shewhart, Deming, Juran, Taguchi, and Ishikawa. The “Six Sigma” philosophy enhances many of the established philosophies by developing an organized framework for continuous improvement (Harry and Schroeder 2000). The “Six Sigma” philosophy departs from traditional quality philosophies in its detailed focus on financial performance and its harsh treatment of employees that do not show a financial return from a “Six Sigma” quality initiative.

If “Six Sigma” quality is obtained, a company will only produce a long-term³ rate of 3.4 defects per million parts produced (Figure 5, page 27). Financial benefits are substantial when an operating system performs at 6-sigma quality instead of 3-sigma quality where control limits equal the specification limits. At the operational level, the goal of implementing “Six Sigma” is to move product or service attributes within the zone of customer satisfaction and reduce process variation (Blakeslee 1999, Hahn *et al.* 1999, Harry and Schroeder 2000). “Six Sigma” closely examines companies’ repetitive processes using statistical methods and translates customers’ needs into separate tasks by defining the optimum specification for each task (Defeo 1999, Harry 1999).

The term “Six Sigma” is defined by Harry as producing products or services in the long-term that are on target and that are six sample standard deviations (s) within the specification limits, *i.e.*, *only 3.4 parts will be outside the specification limits*. Each control limit in the short-term⁴ in a “Six Sigma” process is three standard deviations inside the corresponding specification limit. The number of defects produced at a short-term “Six-Sigma” quality rate would manufacture one part defective per billion opportunities (Figure 6, page 28). Harry (2000) realized that most manufacturing processes have a changing process average. To account for this Harry (2000) defined long-term “Six Sigma” quality as producing products or services that are at least 4.5 sample standard deviations within the specification limits due to a wandering process average around the target.

³ Long-term process capability shifted 1.5σ takes into consideration wandering process average (Figure 5, page 27).

⁴ Short-term process capability centered being able to achieve six sigma standards, without taking into account a wandering process average (Figure 6, page 28).

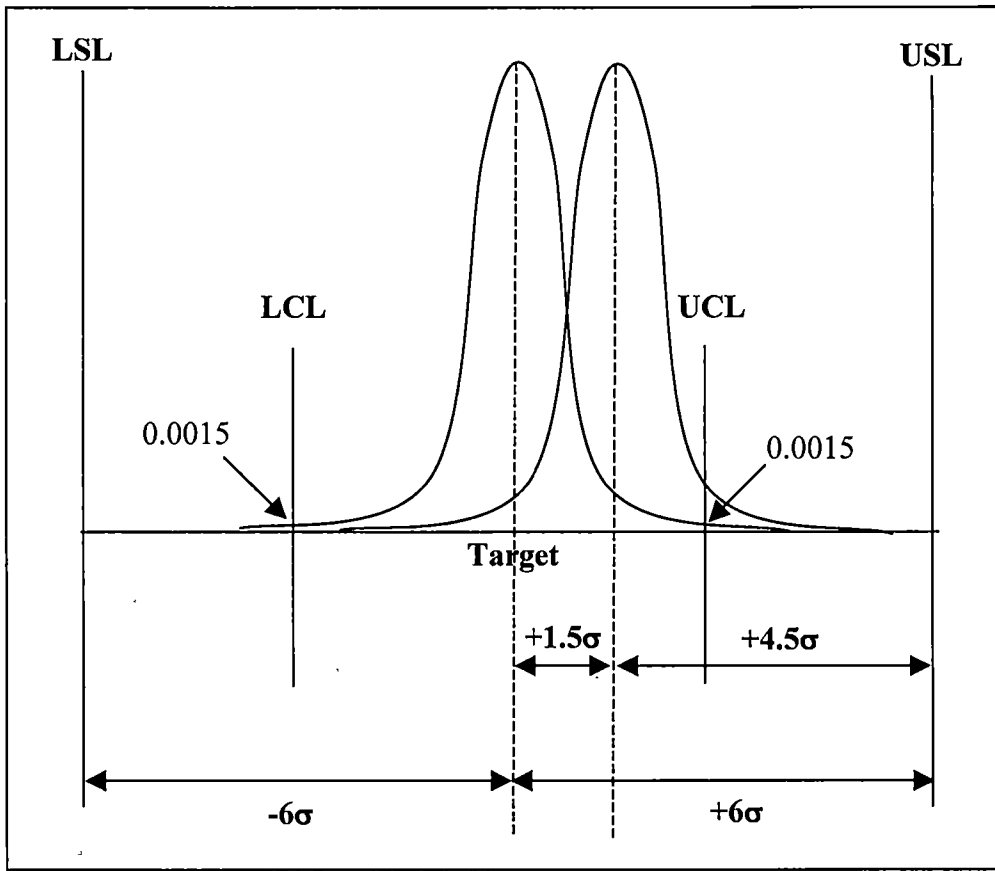

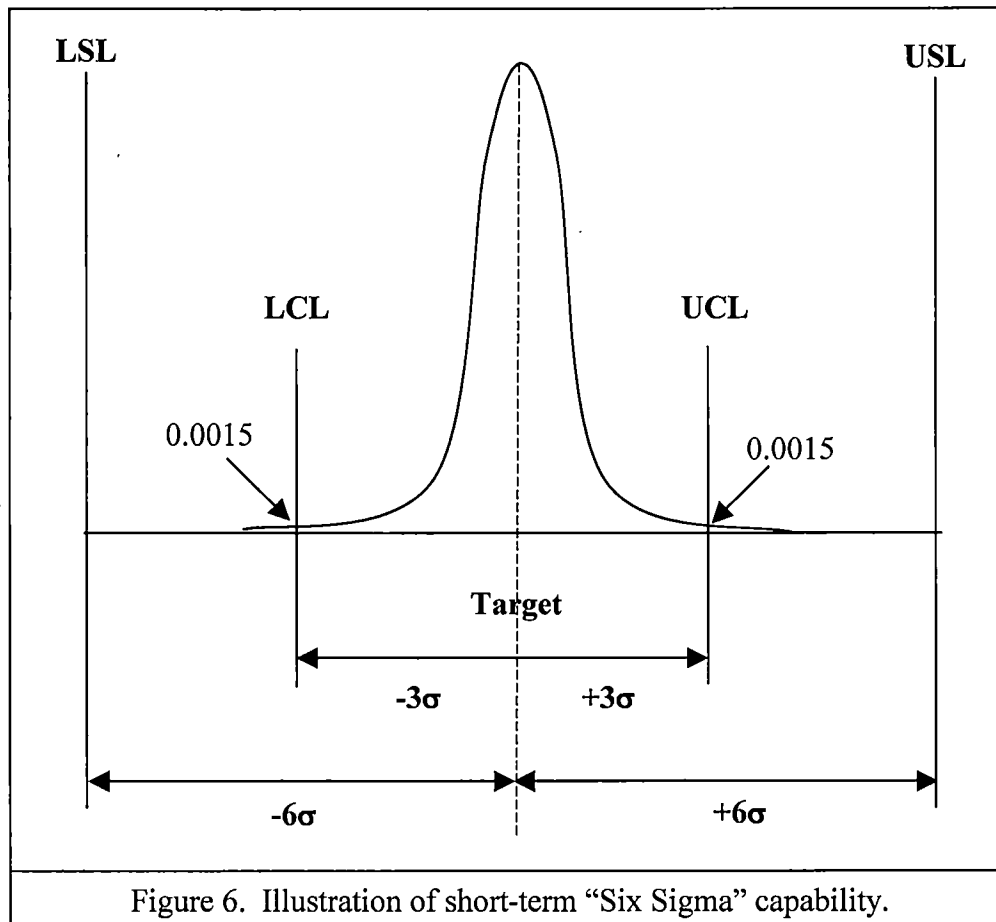

Figure 5. Illustration of long-term "Six Sigma" capability.

The Breakthrough Strategy

Mikel Harry's "Six Sigma" step-by-step methodology is further defined by Harry (2000) as the "Breakthrough Strategy" (Table 1, page 30). The "Breakthrough Strategy" consists of four stages: (1) Identification; (2) Characterization; (3) Optimization; and (4) Institutionalization. Each "Breakthrough Strategy" stage has several subcomponents (Harry and Schroeder 2000).

The "Recognize and Define" phase falls under the "Identification Stage." The "Recognize and Define" phase defines the inputs that influence customer expectations during this phase. The "Measure and Analyze" phase falls under the "Characterization

Table 1. The “Six Sigma” Breakthrough Strategy.

The “Six Sigma” Road Map			
BREAKTHROUGH STRATEGY	Stages	Breakthrough Strategy Phases	Objectives
	Identification	Recognize and Define	Define inputs to defining customer expectations
	Characterization	Measure and Analyze	Measure variability and current capability
	Optimization	Improve and Control	Optimize the process to attain “Six Sigma” defined capability and control process variation to maintain the desired capability level
	Institutionalization	Standardize and Integrate	Transform corporate culture

Stage.” Aspects critical to quality are measured and described during this phase. The “Improve and Control” phase is part of the “Optimization Stage.” This phase involves optimizing the process to attain “Six Sigma” defined capability and controlling process variation to maintain the desired capability level, *i.e.*, $\pm 6\sigma$ within the specifications. The “Standardize and Integrate” phase is part of “Institutionalization Stage.” In this phase, the methods and results used in the previous three stages are woven into the corporation’s culture (Harry and Schroeder 2000).

Identification Stage. -- Business success ultimately depends on how well companies meet customer expectations in terms of quality, price, and availability. In order to satisfy this customer value set, any process must be in statistical control and within the customer specification limits, *i.e.*, *the process must be capable*. Variation within the process has a direct impact on business results in terms of cost, cycle time, and

the number of defects, which affect customer satisfaction. This stage helps companies define customer expectations and defines what impact the variation has on profitability (Harry and Schroeder 2000).

Characterization Stage. -- The “Characterization Stage” assesses the current state of a process and establishes goals. This stage establishes a baseline, or benchmark for quality, which provides a starting point for measuring improvements. The “Measure and Analyze” phase is the key component of the “Characterization Stage.” An action plan is developed in this stage to narrow the gap between the current state of the process (natural variation) and the company’s goal to meet customer expectations (specifications). A process flow diagram is a key tool in this stage. The process flow diagram defines the process flow in step-by-step detail. The process flow diagram helps define components of the process that are wasteful or flawed. The process flow diagram is revised and is a template for process improvement (Harry and Schroeder 2000).

Optimization Stage. -- The “Optimization Stage” identifies the necessary steps for reducing variation. Adjustments and improvements to key process variables are defined in this stage using thorough statistical tools, *e.g., Design of Experiments, regression analysis, correlation analysis, etc.* The goal of the “Optimization Stage” looks at a large number of variables in order to determine the vital-few variables that have the greatest impact on reducing variation (Harry and Schroeder 2000). Once the vital-few variables are defined, the next step is to define improvement strategies to reduce variation in the context of the PDCA cycle. Statistical process control is used to control the process once the desired level of variability is attained.

Institutionalization Stage. -- The “Standardize and Integrate” phases make up the “Institutionalization Stage.” This phase involves institutionalizing the improvement strategies developed in the previous stage by developing communication tools for analyzing and monitoring the process. The goal of this stage is to make continuous improvement part of the corporate culture. As stated by Harry (2000), “As companies improve the performance of various processes, they should standardize the way those processes are run and managed. Standardization allows companies to design their processes to work more effectively by using existing processes, components, methods, and materials that have already been optimized and that have proven their success.”

The strength of the “Breakthrough Strategy” comes from the interaction within all levels of the company that are necessary to complete all four stages. The four stages overlap to ensure that the company completes each of the stages in a methodical and disciplined way. The “Breakthrough Strategy” can be very beneficial if it is carried out in the prescribed manner (Harry and Schroeder 2000).

Production Yield and Manufacturing Cost Variation

Harry’s departure from some existing quality philosophies is that it has a very strong emphasis on monitoring production yield and manufacturing costs associated with the continuous improvement effort (Harry and Schroeder 2000). Harry has indicated that a dollar amount can be associated with variation (Recall the Taguchi Loss Function). By reducing variation within the process, a company can reduce manufacturing and warranty costs, and increase the amount of available capital. Harry’s philosophy as related to monitoring production yield and costs parallels the philosophies of Shewhart, Deming, Juran, Taguchi and Ishikawa. Harry (2000) departed from previous quality philosophies

in the sense that all production yield and costs should be defined and monitored in the context of any quality initiative. He further departed from previous quality philosophies by indicating that a financial return should be estimated from any quality initiative.

Harry (2000) showed the financial significance of reducing the defective parts manufactured by reducing variation (Table 2). Many companies take false comfort in that if quality goals are met if the natural variation (natural tolerance $\sim 6s$) is equal to the specification limits (engineering tolerance). If control limits equal specification limits, 2,700 defective parts per million are produced. For example, one can only imagine the chaos that would occur in the U.S. if telephone communications had a defect rate of 2,700 errors per million communication attempts.

If natural variation is approximately three standard deviations within the specification limits (*i.e.* "Six Sigma" quality) and the process average is equal to the target, 0.002 defective parts per million are produced. The reduction in defects from 2,700 defective parts to 0.002 defective parts per million represents significant cost savings and profitability improvement to any organization (Blakeslee 1999, Breyfogle 1999, Defeo 1999, Harry and Schroeder 2000, Hild *et al.* 2000, Pande *et al.* 2000).

Harry (2000) gives an example of the financial significance of reducing process variation. Suppose a company has its natural tolerance equal to engineering tolerance (control limits = specification limits) and the manufacturing cost is ten dollars per manufactured part. If the company produces 100,000 parts per day, 270 parts would be defective (Breyfogle 1999, Harry and Schroeder 2000).

Table 2. Number of defective parts as related to process standard deviation.

Specification Limit	Percentile	Defective Parts per Million (ppm)
± 1 sigma	68.27	317,300
± 2 sigma	95.45	45,500
± 3 sigma	99.73	2,700
± 4 sigma	99.9937	63
± 4.5 sigma (long-term)	99.99966	3.4
± 5 sigma	99.999943	0.57
± 6 sigma (short-term)	99.9999998	0.002

The direct loss to the company, assuming the parts cannot be reworked, is \$2,700 per day or \$985,500 per year (Note that the loss in this example does not take into account additional profitability loss). In this example, a one standard deviation improvement (defined by Harry as a one sigma improvement), equates to 6.3 parts defective per 100,000 parts manufactured. The direct loss from a one standard deviation reduction in natural variation is \$63 per day or \$22,995 per year. The direct cost savings in this scenario would equate to \$962,505 per year. Additional savings would also be realized from increased profitability due to improved yield.

Even though Mikel Harry's "Six Sigma" philosophy appears to rely on existing quality philosophies, acceptance in the 21st century of "Six Sigma" quality by the business sector cannot be ignored (Breyfogle 1999). Perhaps the organizational structure of "Six Sigma" is easier to interpret and implement by companies. The focus on monitoring yield and cost improvements associated with variation reductions due to "Six Sigma" is aligned well with many corporate cultures and business philosophies of the 21st century (Harry and Schroeder 2000).

The Forest Products Industry and Quality

In the early 20th century most U.S. forest products companies enjoyed the benefits from inexpensive raw material and low labor costs. For most forest products companies of this era, technology was a leading constraint to improved production (Maki 1993). Quality of final wood products during this era was of minimal importance to most wood producing companies (Young and Winistorfer 1999).

As the U.S. forest products industry entered the 21st century, they were faced with a panacea of issues. Environmental regulation and preservation interests have reduced the availability of wood fiber and resulted in higher raw material costs. Raw material costs of the furniture and wood flooring manufacturers are their highest costs of production. Air quality restrictions have forced many forest products companies to invest in expensive air-quality control equipment. Labor costs are higher in the U.S. relative to labor costs in developing countries. The U.S. forest products industry is also faced with increasing domestic and international market competition from non-wood products such as aluminum and concrete. The scenario faced by most U.S. forest products companies is lower profit margins due to higher raw material and manufacturing costs in the context of stable real-prices for final wood products. These economic constraints have forced many U.S. forest products companies to reassess manufacturing practices (Young and Winistorfer 1999). Some U.S. forest products companies have started assessing the potential benefits that may occur from adopting continuous improvement philosophies such as the "Six Sigma" quality philosophy (Young and Winistorfer 1999).

Quality initiatives are not new to the forest products industry. The pulp and paper industry in the 1960s used statistics to monitor variation in pulp yield and paper caliper

(Fadum 1987, Taguchi 1993). Statistical sampling methods were used in the pulp and paper industry in the final inspection process. There is also some documentation of the use of Statistical Process Control (SPC) by the pulp and paper industry in the early 1980s (Young and Winistorfer 1999). However, statistical methods for the continuous improvement of processes and final product were replaced in this industry by ISO9000 initiatives and a stronger interest in engineering process control (Murrill 1991, Nicholas 1998).^{5,6} A review of current published literature for the pulp and paper industry did not indicate any substantial continuous improvement initiatives.

In the 1980s some plywood and wood composite panel manufacturers had began using SPC. At this time the application of SPC was scarce and often times driven by company defined quality initiatives (Young and Winistorfer 1999). Today there are more wood composite companies using SPC. The use of SPC has been seen in the fiber drying operation, resin and wax addition, etc.

The softwood lumber industry implemented some SPC and quality control programs in sawmills in the Pacific Northwest in the late 1970s, which expanded through Canada and the United States in the early 1980s (Brown 1995). In a sawmill controlling and reducing sawing variation is a key element for quality improvement initiatives (Brown 1979, 1982, 1992, 1997). Sawing variation leads to excessive thickness variation and actual thicknesses tend to be greater than targets. Log to lumber recovery is reduced by thick lumber (Brown 1995). Reductions in target sizes of 0.100" have led to annual

⁵ ISO9000 – an international set of quality assurance standards to achieve and assess the level of quality a company performs. ISO standards serve to articulate, clarify and systematize the different types of information within a company (Nicholas 1998).

⁶ Engineering Process Control – is the use of mathematical algorithms in the context of programmable logic controllers (PLCs) to control the production process, *e.g., motor speed, belt-speed, valve opening, etc.* (Murrill 1991).

savings at some sawmills of \$250,000 (Young *et al.* 2000). Maki (1993) states, "Statistical Process Control is an important step in minimizing sawing variation that can be attributed to problems such as dull saw blades, misplacement of the log, or feeding the log too fast through the saw." These problems can cause within and between board variations. Control charts for each machine center allow for such problems to be detected and minimized (Maki 1993).

Although SPC is commonplace in the softwood sawmill industry, SPC applications in the hardwood lumber industry are virtually non-existent (Cassens *et al.* 1994, Young and Winistorfer 1999). There have been some success stories among several companies that have adopted SPC (Young *et al.* 2000). Brown (1995), Cassens *et al.* (1994) and Young *et al.* (2000) have documented financial gains from using SPC to reduce hardwood lumber target sizes. Even though financial gains from using SPC have been reported in the literature, the hardwood lumber industry as a whole has not embraced continuous improvement (Young and Winistorfer 1999).

In the furniture and cabinet industries a survey was conducted in early 1990s to determine the current level of involvement in the use of statistical methods for quality control in manufacturing operations (Patterson and Anderson 1996). The survey indicated that only a small number of furniture and cabinet industries were using statistical methods to reduce process variation and improve final product quality.

The furniture and cabinet industry have been investing in automated processing centers. The processing centers use robotic technology such as Computer Numerically Control (CNC) machines to machine parts. The CNC centers have led to improved consistency and uniformity in manufactured parts. Some companies have started

incorporating SPC principles in the monitoring of CNC system performance (Patterson and Anderson 1996).

Like the U.S. automotive industry of the 1980s, the forest products industry of the 21st century is reassessing their management and manufacturing philosophies. This reassessment involves assessing the benefits of continuous improvement using statistical methods. Even though the U.S. forest products industry will not face loss of market share due to Japanese competition, the industry is faced with higher raw material and manufacturing costs in the context of stable final product prices (Young and Winistorfer 1999). The adoption of continuous improvement philosophies such as “Six Sigma” may improve the competitiveness of many forest products companies by reducing costs and improving final product value (Young and Winistorfer 1999). The potential benefits to society are better product value, more jobs and a wiser use of the forest resource.

CHAPTER 3

METHODS

Problem Definition

The problem definition of the thesis was to determine if a modified "Six Sigma" philosophy for continuous improvement can improve the quality of hardwood flooring. This problem definition was studied over a six-month time period and included an analysis of production yield and manufacturing costs.

Research Objectives

1. Define the current-state of product variability for hardwood "veneer-slat" thickness and the specific attributes of "finished blank" length, width, and thickness (Table 3, page 43).
2. Determine the capability of "veneer-slat" thickness and the "finished blank" attributes length, width, and thickness as related to engineering specifications (Table 3, page 43).
3. Determine the current production yield and manufacturing costs associated with the manufacture of "veneer-slat" (Table 3, page 43).
4. Define the sources of variability that influence the "finished blank" length, width, and thickness, and "veneer-slat" thickness. This will involve a detailed understanding of the relationships that may exist between key process variables that influence the "finished blank" length, width, and thickness and "veneer-slat" thickness (Table 3, page 43 and Table 4, page 44).

5. Recommend to senior management the improvements necessary to enhance the overall quality of “veneer-slats” (Table 3, page 43).
6. If any of the recommendations are adopted from objective five, the first four objectives would be repeated to determine if the quality of “finished blank” length, width, and thickness and “veneer-slats” thickness improved (Table 3, page 43).

Selection of Hardwood Flooring Manufacturer for the Thesis Study

Three secondary wood products manufacturers were interviewed as potential candidates for participation in the thesis. A hardwood flooring manufacturer in Tennessee was selected as the best candidate for this thesis given the strong level of interest in continuous improvement that was exhibited by senior management. The company also had a well-defined quality control system and quality control support personnel.

The selected company had a strong interest in focusing the thesis effort on one component (“veneer-slat”) of the “eight-foot strip” hardwood composite flooring product. This product had a high profit margin and was considered to have a higher level of customer value relative to other flooring products.

Modified Six Sigma Philosophy

Part I: Identification Stage

Harry’s (2000) “Six Sigma” philosophy for continuous improvement emphasizes the importance of understanding customer expectations and value. Harry’s philosophy is based on the belief that it is impossible to improve a company’s quality or overall

competitive position without aligning its products and/or services with customer expectations and value. An example of customer expectations and value as related to this thesis would be hardwood flooring that is aesthetic, durable, affordable, uniform, and quiet when walked upon.

A detailed assessment of customer expectations and value was beyond the scope of this thesis. An interview of the senior management revealed a strong knowledge of customer value as related to their “eight-foot strip” hardwood composite flooring product. The “veneer-slat” component of the “eight-foot strip” hardwood composite flooring product was considered to have a direct impact on thickness uniformity, aesthetics, and durability.

Part II: Characterization Stage

The characterization stage established a baseline or benchmark for product quality and was the starting point for measuring improvements (Harry 2000). To establish the financial benchmark a detailed analysis of production yield and manufacturing costs was attempted. A general description of the process flow for “veneer-slats” production is given in Figure 7, pages 45 to 47.

The first step in this stage was to establish a baseline or benchmark for product variation and quality (Pyzdek 1999). This was accomplished by conducting a detailed capability analysis of “veneer-slats” and the process variables that were inputs into the manufacture of “veneer-slats.” The process capability study was conducted for “finished blank” length, width, and thickness and “veneer-slats” thickness. The capability analysis

used traditional C_{pk} , C_p and contemporary Taguchi C_{pm} capability indices to establish a benchmark (Breyfogle 1999; Taguchi 1993).⁷

This step also included an assessment of the components of total product variance for “finished blank” thickness, width, and length of “veneer-slats” thickness. Total product variance (σ_T^2) was defined as the summation of process variance (σ_p^2) and measurement variance (σ_m^2), *i.e.*, $\sigma_T^2 = \sigma_p^2 + \sigma_m^2$.

Total process variance (σ_p^2) was estimated using the manufacturer’s data and data collected as part of the thesis sampling plan. Total process variance within the manufacturing system for “veneer-slats” consisted of variability due to material, machines, operators, methods, and measurement.

Total measurement variance (σ_m^2) was estimated from a “Gauge R&R” study combined with a discrimination ratio statistic developed by Wheeler (1989). The gauge R&R study quantified the measurement variance (σ_m^2) as the summation of gauge variance (σ_g^2) and appraiser variance (σ_o^2), *i.e.*, $\sigma_m^2 = \sigma_g^2 + \sigma_o^2$.

Part III: Optimization Stage

The optimization stage focused on understanding and quantifying the relationships that existed between the “vital few” input process variables that influenced the length variance, width variance, and thickness variance of “finished blanks” and “veneer-slat” thickness. Harry (2000) believes this is the critical stage in improving and

⁷ C_{pk} is defined as the minimum of $[(USL - Average)/3s, (Average - LSL)/3s]$
 C_p is defined as $(USL - LSL)/6s$
 C_{pm} is defined as $(USL - LSL)/\{6[(Average - Target)^2 + s^2]^{1/2}\}$
 where, USL is the upper specification limit
 LSL is the lower specification limit
 s is the sample standard deviation
 s^2 is the sample variance

controlling a process. This stage provides the company with an array of improvements that ultimately improves profitability and customer satisfaction (Harry 2000). The key step in this stage is to understand the relationships that exist between process variables and key product attributes. Ishikawa diagrams were critical first steps in this stage.

The final step of this stage was conducted when recommendations were made to senior management. These recommendations included manufacturing system changes, management practice adjustments, and changes to existing quality control methods.

Part IV: Institutionalization Stage

The institutionalization stage is defined in the "Six Sigma" philosophy as the stage of standardizing procedures and processes. These standards are based on the outcomes of the characterization and optimization stages. This stage also includes a continuous monitoring of the control and capability of the process. Documentation of improvements to product quality, production yield, and manufacturing costs are an important aspect of this stage.

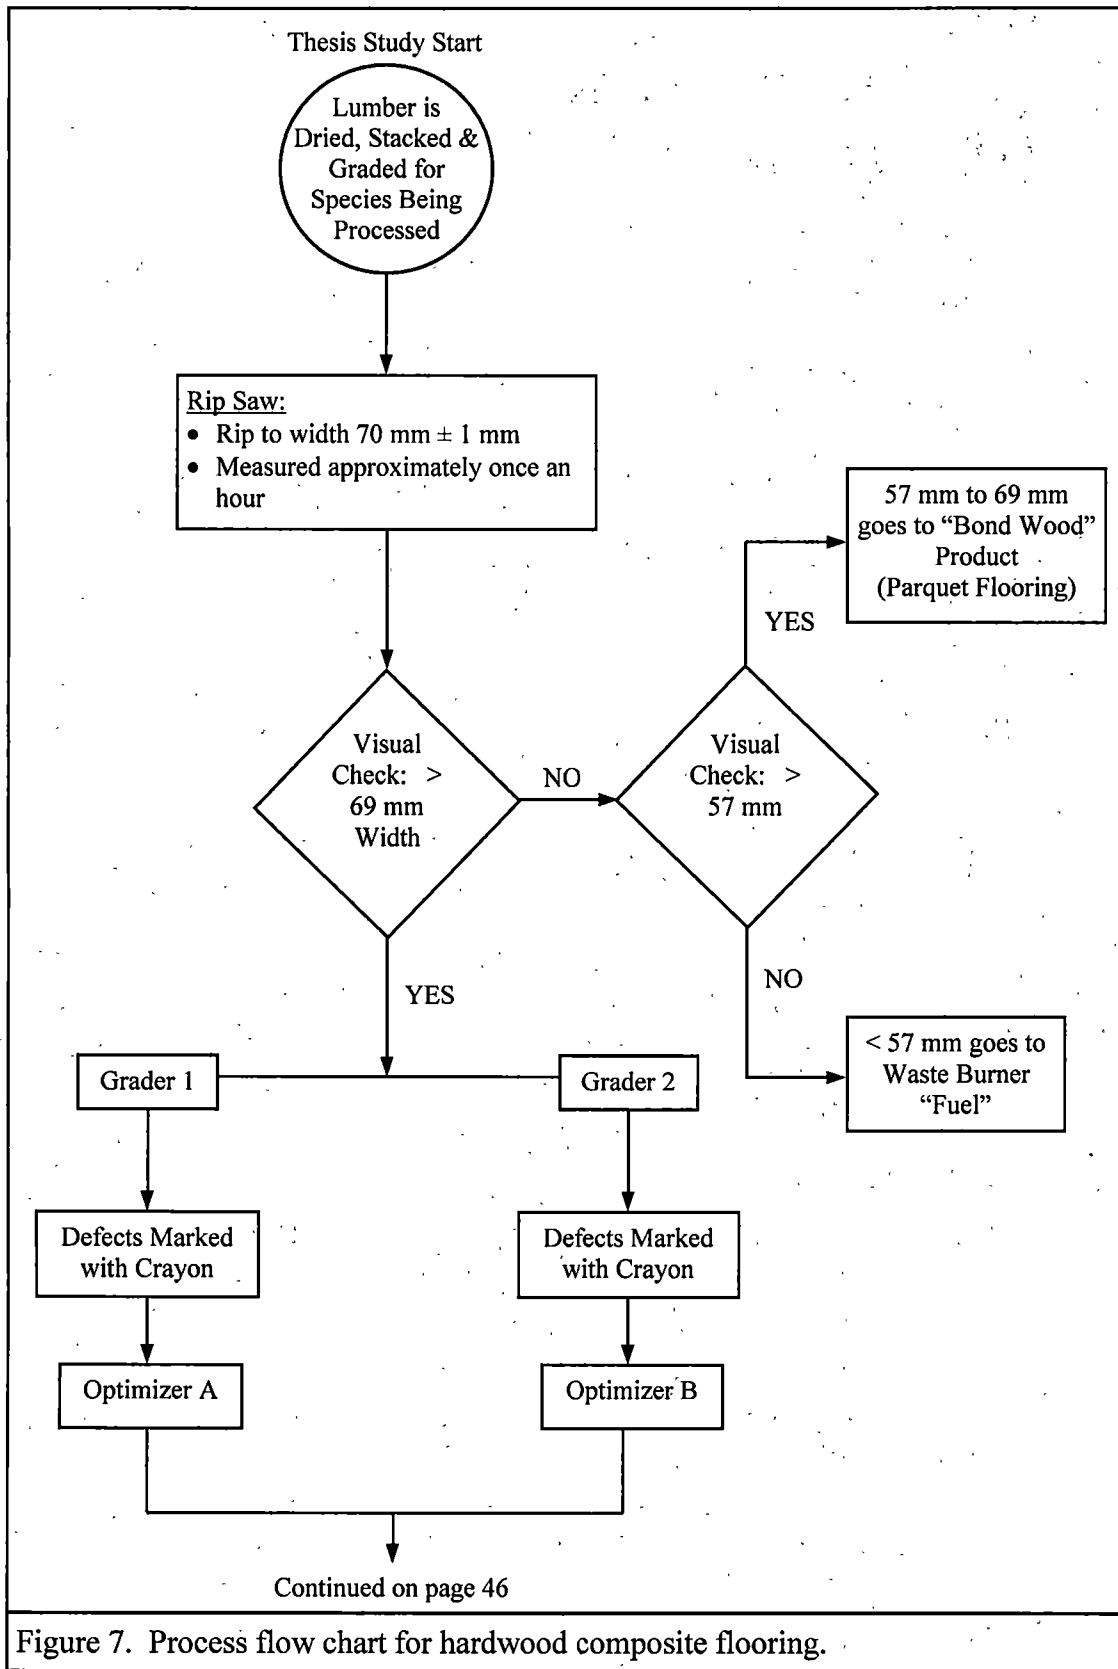

Due to the six-month time frame of this thesis it was not feasible to monitor long-term improvements in "vener-slats." Also, there was a significant change in senior management that led to the elimination of the quality control department. The new senior management did not allow any implementation of "Institutionalization Stage."

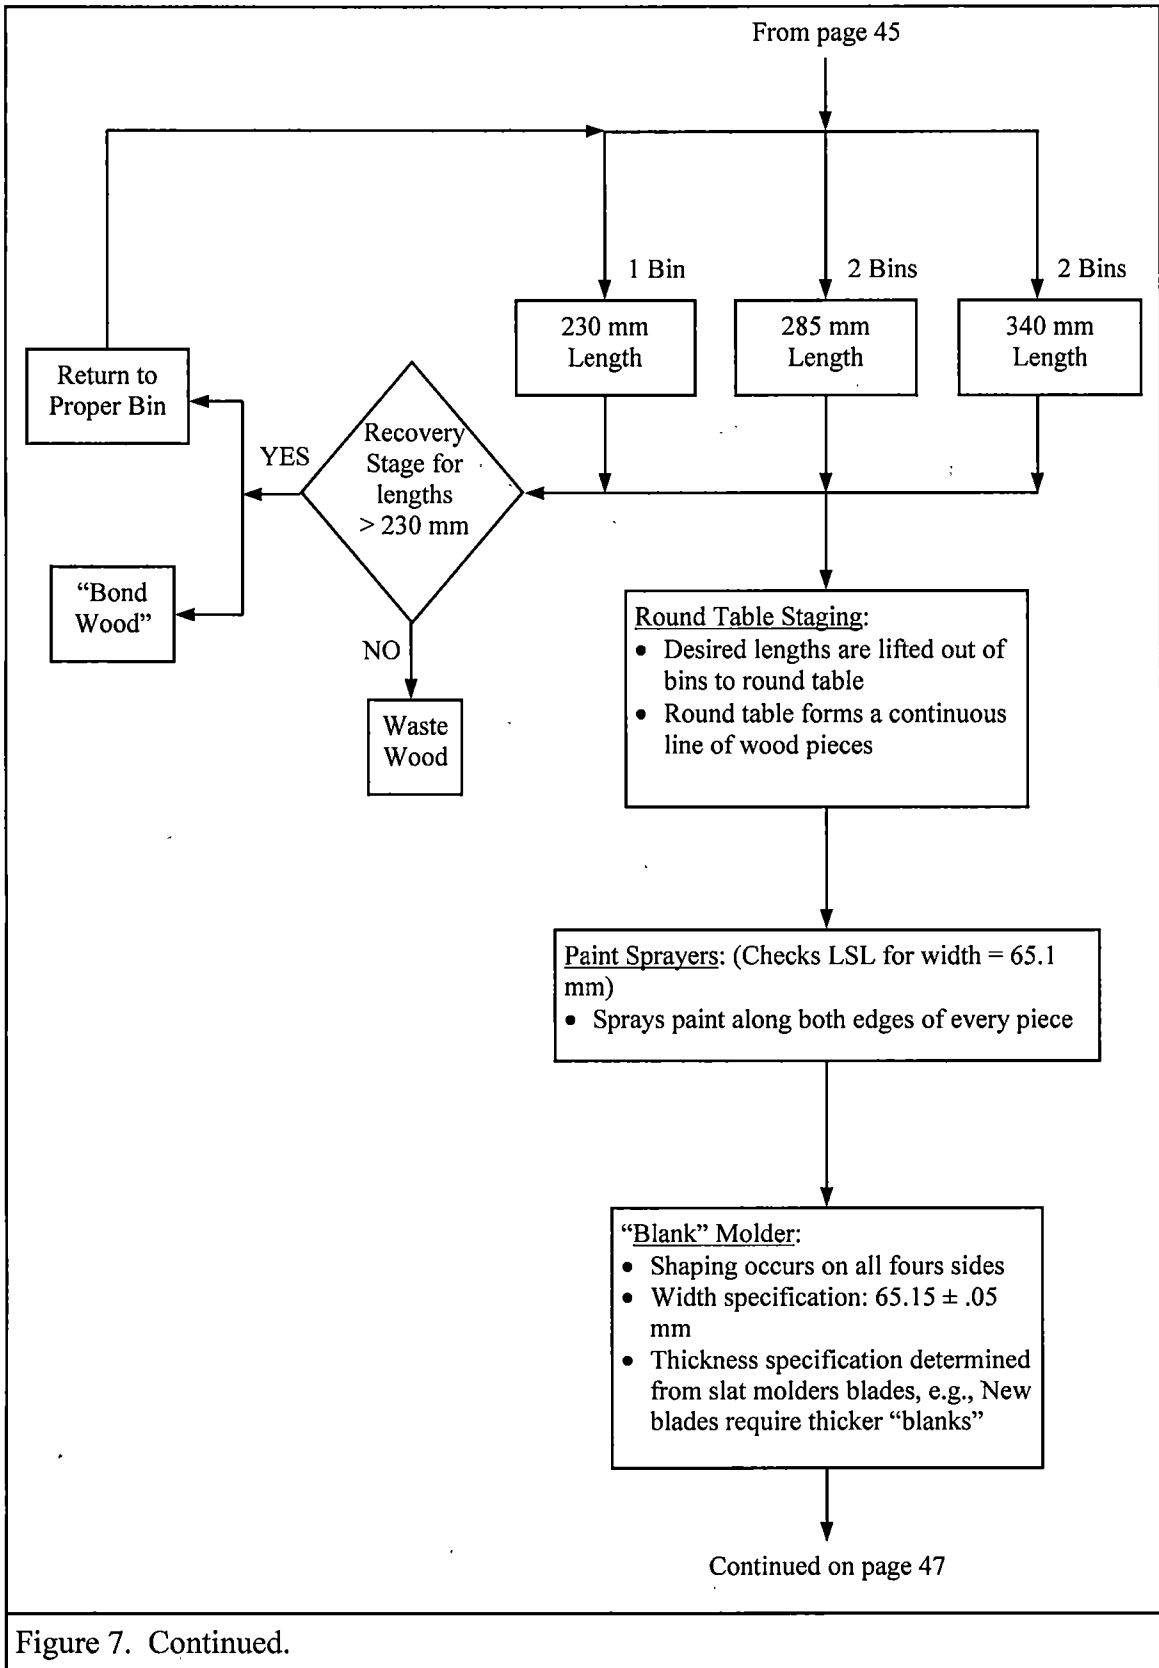

Table 3. A modified structure to the organization of the Six Sigma philosophy.

Implementation Stage	Objective	Methods	Assumptions
Stage I. Identification	Define Customer Expectations and Value for Hardwood Flooring.	Marketing surveys and research	Company has defined the customer expectations and value
Stage II. Characterization	<ol style="list-style-type: none"> 1. Define the current state of product variability "finished blank" thickness, length and width and "veneer-slat" thickness of hardwood composite flooring. 2. Define the current state of the capability for all product attributes. 3. Define current state for production yield and manufacturing costs. 	<ul style="list-style-type: none"> • Shewhart control charts • Capability Analysis • Cost Accounting • Taguchi Loss Function 	None
Stage III. Optimization	<ol style="list-style-type: none"> 1. Define the sources of variability in the manufacture of product attributes. 2. Figure 7. Continued.

CHAPTER 4

RESULTS AND DISCUSSION

The modified Six Sigma methodology as applied to a Southeastern United States hardwood-flooring manufacturer led to the identification of significant sources of variability. Even though it was not determined if a modified Six Sigma methodology could be used instead of a complete Six Sigma methodology (Harry 2000), five of the six thesis objectives were satisfied. The first objective of quantifying variation was satisfied, *i.e. define the current-state of product variability for the specific product attributes of "finished blank" thickness, length and width, and "veneer-slat" thickness.* The second objective was also satisfied when the capability of the product attributes were quantified for the last 15-months. Estimates of current production yield and some manufacturing costs were collected over a 15-month study period, which partially satisfied objective three. Objective three was only partially satisfied given that the management was reluctant to reveal all cost data. Significant sources of variability were defined and quantified in the thesis study, which satisfied objective four. The fifth objective was satisfied when recommendations for improving the process and reducing variability were presented to senior management of the hardwood-flooring manufacturer on April 11, 2001. The sixth objective was not satisfied. The hardwood-flooring manufacturer did not allow any further investigation of the hardwood-flooring plant process after improvement recommendations were made on April 11, 2001.⁸ In attempt to partially

⁸ All data has been coded and changed to millimeters to protect the confidentiality of the company. The hardwood-flooring manufacturer had a change in an executive management position during the course of the thesis study. The new Vice President of the company did not allow any further investigation.

fulfill objective six, a Gauge R&R⁹ study was conducted under controlled conditions at The Tennessee Forest Products Center. An attempt was also made to estimate the potential cost savings from implementing the recommendations developed in objective five.

Manufacturer's Characteristics

There were seven species of hardwood flooring manufactured by the company. The seven species were: red oak (*Quercus rubra*), white oak (*Quercus alba*), hard maple (*Acer sacchrum*), Brazillian cherry (*Jatoba*), ash (*Fraxinus americana*), black cherry (*Prunus serotina*), and Merbau (*Instia spp*) (Figure 8). Red oak flooring comprised approximately 50% of the manufacturers annual production (Figure 8). The thesis study was conducted on red oak (*Quercus rubra*), white oak (*Quercus alba*), and hard maple (*Acer sacchrum*) flooring "veneer-slats." These species consumed about 75% of annual production (Figure 8).

Figure 8. Annual usage of hardwood lumber by species.

⁹ Gauge R&R – The evaluation of measuring instruments to determine capability to yield a precise response. Gauge repeatability is the variation in measurements considering one part and one operator. Gauge reproducibility is the variation between operators measuring one part (Breyfogle, 1999).

Figure 9. Bar chart on production of “veneer-slats” for species and length categories.

Three different lengths of blanks were manufactured for each species studied (215 mm, 270 mm, and 325 mm). Each species and length category had the product attributes of “finished blank” thickness, length, width, and “veneer-slat” thickness. The annual production of “veneer-slat” was predominately red oak (Figure 9). Measurements were taken for each product attribute using a Mitutoyo caliper (Figure 10, page 51)

Quantifying Process Variability - Objective 1

“Finished Blank” Thickness for Target Length 270 mm

The sample standard deviation, s , was used as an estimate of process variability. The sample average and medians were used as estimates of the process location (\bar{X}). The variability as represented by the standard deviation in “finished blank” thickness varied from 0.05 mm to 0.25 mm from January 2000 to March 2001 (Figure 11, page 52). The runs chart in Figure 11, page 52, were samples of “finished blank” thickness taken by the manufacturer. Measurements as part of the thesis plan were taken in September 2000, and January and February 2001, in an attempt to gather additional data to estimate

Figure 10. Product attributes measurements.

variance from which a sampling scheme was later determined. Thesis sampling plan estimates of standard deviation and the manufacturers estimates of standard deviation did not coincide (Appendix A, page 132-144). The thesis sampling plan sample size was larger than the manufacturer's sample size. Even though the standard deviation in Figure 11, page 52, may indicate a slight downward trend for hard maple (*Acer saccharum*), a statistical test of significance for the standard deviation was not conducted given the small sample sizes, unequal sample sizes, and normality could not be assumed.

The process location (\bar{X}) of "finished blank" thickness as represented by the average and median varied over time (Figure 12). The median was not stable and there was evidence of a statistical difference in the median at an $\alpha = 0.05$ for the three species studied (Tables 6-8, pages 53-54). Hard maple (*Acer saccharum*), white oak (*Quercus alba*) and red oak (*Quercus rubra*) were the three predominate wood species manufactured and represented approximately 75% of the annual production.

* Blank cells indicate that no data were available.

** Statistics in parenthesis were estimates that were taken as part of a sampling study.

Figure 12. Medians for “finished blank” thickness for target length 270 mm.

There was statistical evidence that the process location for “finished blank” thickness was not stable month-to-month. Instability in “finished blank” thickness may result in lower production yields when thin “finished blanks” result in unacceptably thin “veneer-slat” thickness. Thick “finished blanks” may result in lower production yields by causing excessive tool wear at the planer and may cause slower line speeds.

“Finished Blank” Length for Target Length 270 mm

The sample standard deviation, *s*, was also used as an estimate of process variability for “finished blank” length. The sample averages and medians were used as estimates of the process location. The variability as represented by the standard deviation in “finished blank” length varied from 0.04 mm to 0.25 mm from January 2000 to March 2001 (Figure 13, page 54). The line graph in Figure 13 represented samples taken by the manufacturer. The standard deviation in Table 9, page 55, displays the amount of dispersion for “finished blank” length 270 mm. A statistical test of significance for the standard deviation was not conducted given small sample sizes, unequal sample sizes, and normality could not be assumed.

*** Rows with dissimilar letters have significantly different medians at an $\alpha=0.05$, i.e., "a" is for January-2000 and is compared with each month thereafter; "b" is for February-2000 and is compared with each month thereafter.

The process location of “finished blank” length as represented by the average and median varied over time (Figure 14). The medians, in some cases, were significantly different from month-to-month at a $\alpha = 0.05$ for all three species studied (Tables 10-12, pages 56-57).

There was evidence that the process locations for “finished blank” length were not stable month-to-month, *e.g.*, results from *Non-parametric Wilcoxon Rank Sums Test*.

“Finished blank” lengths were longer than the 270 mm target lengths, which were necessary given the variation of the process. Recall the Taguchi Loss Function and the effect of variation and deviations from target on manufacturing costs (Taguchi, 1993).

Taguchi penalizes for the process location (\bar{X}) deviating from the target specification.

“Finished Blank” Width for Target Length 270 mm

The sample standard deviation, s , was used as an estimate of process variability for “finished blank” width. The sample average and medians were used as estimates of process location for “finished blank” width. The variability as represented by the standard deviation in “finished blank” width varied from 0.02 mm to 0.08 mm from January 2000 to March 2001 (Figure 15, page 60). The line graph in Figure 15 represented samples taken by the manufacturer. The sample points in Figure 15 represents samples taken as part of the thesis sampling plan. The thesis sampling plan estimates of standard deviation and the manufacturers estimate of standard deviation were almost identical, indicating accuracy for both measurements taken (Figure 15, page 60, and Table 13, page 62). A statistical test of significance for the standard deviation was not conducted given small sample sizes, unequal sample sizes, and normality could not be assumed. In a non-stochastic sense, the dispersion of “finished blank” width appears to be stable.

The process location of “finished blank” width as represented by the median can be seen in Figure 16, page 63. There was a significant difference, in some cases, in the medians from month-to month at a $\alpha = 0.05$ for the three species studied (Tables 14-16, pages 61-62).

Instability in “finished blank” width may have a direct relationship with the number of blanks that can be cut from rough lumber as related to the width of the rough lumber. This relationship may affect production yield.

“Veneer-Slat” Thickness for Target Length 270 mm

The sample standard deviation, s , was used as an estimate of process variability for “veneer-slat” thickness. The sample average and median were used as estimates of the process location for “veneer-slat” thickness. The variability as represented by the standard deviation in “veneer-slat” thickness varied from 0.04 mm to 0.10 mm from January 2000 to March 2001 (Figure 17, page 64). The line graph in Figure 17, page 64, represented samples taken by the manufacturer. The sample points in Figure 17, page 64, represented samples taken as part of the thesis sampling plan. The thesis sampling plan estimates of standard deviation and the manufacturers estimate of standard deviation were close in value, indicating accuracy with both sets of data (Figure 17, page 64, Table 17, page 64). A statistical test of significance for the standard deviation was not conducted given small sample sizes, unequal sample sizes, and normality could not be assumed. In a non-stochastic sense, the dispersion of “veneer-slat” thickness appeared to be stable.

The process location of “veneer-slat” thickness as represented by the median varied over time (Figure 18, page 65). There was a significant difference, in some cases, in the medians from month-to month at a $\alpha = 0.05$ for the three species studied (Tables 18-20, pages 65-66).

Differences in “veneer-slat” thickness may represent serious quality problems in that they affect the final product (composite wood flooring), which is used by the customer. They may also represent a direct loss to the company if the “veneer-slat” thickness is thinner than the minimum “veneer-slat” thickness specification. “Veneer-slats” that are too thick may represent additional tool wear during sanding.

Figure 17. Standard deviation (mm) for “veneers-slat” thickness for target length 270 mm.

Capability Analysis - Objective 2

A capability analysis was conducted by using the following capability indices: C_p , C_{pk} , C_{pm} .^{10,11,12} C_p and C_{pk} were used for the capability analysis in the thesis because the two indices are widely used by practitioners in capability studies (Breyfogle 1999).

Taguchi's C_{pm} capability index was used because the result penalizes the manufacturer from deviating from target. Taguchi's penalty for deviating from the target is important because deviations from target may represent a direct loss to the organization. Note that the $C_{pm} = C_p$ if the process average is equal to the target. The C_{pm} is an extension of Taguchi's philosophy (Taguchi 1993) of reducing variability around the target and is also consistent with Harry's (2000) philosophy of obtaining "Six Sigma" quality relative to the target.

The process is considered to be capable of meeting specifications if each capability index has a value greater than or equal to one (Juran 1992). Recall Deming's views on capability indices presented in Chapter 2, *i.e.*, *capability indices may be a hindrance to continuous improvement when it is used as a static quality goal*. Also recall (Harry 2000) views that a capability index of one produces 2,700 parts per million that are defective. Due to the significant differences, in some cases, from month-to-month in the medians a $\alpha = 0.05$ may be a reason for the majority of the capability indices

¹⁰ $C_p = (USL - LSL) / 6s$, where USL = upper specification limit, LSL = lower specification limit and s = sample standard deviation.

¹¹ $C_{pk} = \min \{ [(USL - \bar{X}) / 3s], [(\bar{X} - LSL) / 3s] \}$, where "X-bar" is the sample average.

¹² $C_{pm} = (USL - LSL) / 6[(\bar{X} - T)^2 + s^2]^{1/2}$, where T = target.

indicating processes not capable of meeting specification (Appendix C, Figures 1c to 25c, page 180-189).

For all products and species that were studied over the 15-month study period there were only 10 cases out of the possible 405 opportunities where the C_p value was greater than one. There was one incident out of the possible 405 where the C_{pk} value was greater than one. Taguchi's C_{pm} capability index was never greater than one for all 405 possible opportunities. One may question the manufacturer's process capability rationale in the context of the defined specifications, *i.e., are the specifications realistic and helpful for the employees in process improvement efforts?* The specification limits the manufacturer are trying to hold are unrealistic because the largest specification was eight hundredths (0.08) of an inch to the tightest specification of four thousandths (0.004) of an inch. The tightest specification, on average, is the thickness of a piece of paper. Four thousandths of an inch is generally seen as specification for manufacturing of metal pieces.

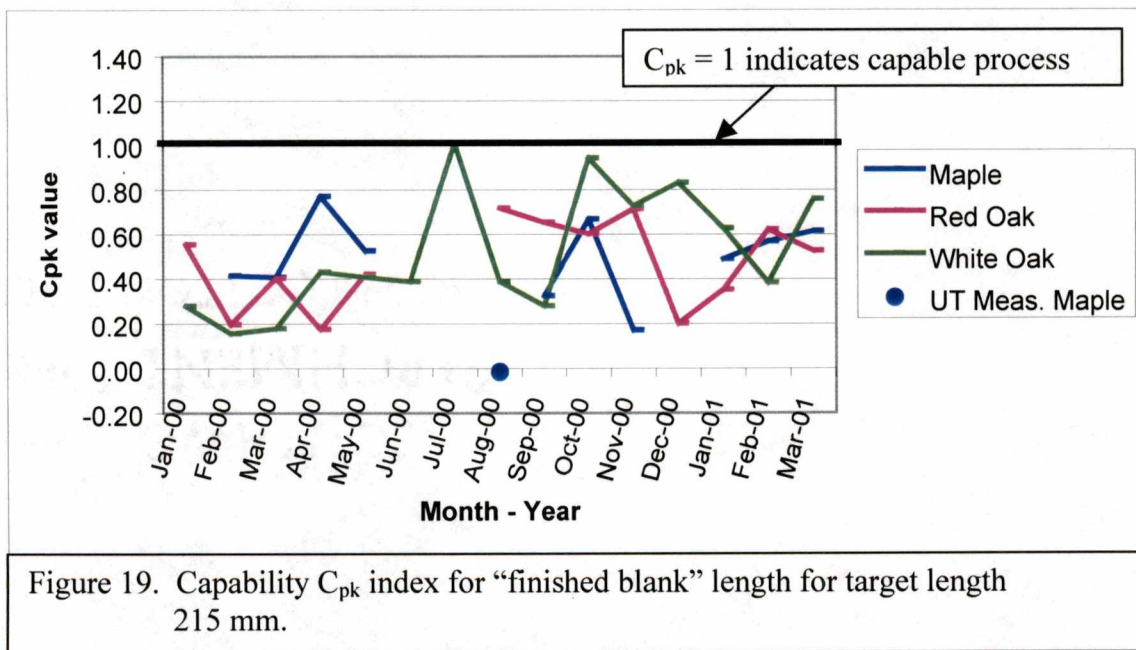

"Finished Blank" Thickness for Target Lengths 215 mm, 270 mm, and 325 mm

A capability analysis was not conducted for "finished blank" thickness because this product did not have complete specifications as defined by the manufacturer. There was a minimum specification (LSL), but a target (T) and upper specification limit (USL) were not defined. The manufacturer may be missing a significant cost savings opportunity by not defining a target or USL for "finished blank" thickness. If the manufacturer allows "finished blanks" to be processed at extreme thicknesses, optimization of blank recovery from lumber may not be obtained. Excessive thickness

and thickness variation of within and between “finished blanks” may lead to additional tool-wear and final “veneer-slat” thickness variation.

“Finished Blank” Lengths for Target Lengths 215 mm, 270 mm, and 325 mm

The capability indices for “finished blank” lengths of 215 mm, 270 mm, and 325 mm suggested that the process was not consistently capable of meeting specifications from January 2000 thru March 2001 (Figures 19-21, pages 69-70). The C_{pk} capability index for the “finished blank” length of 215 mm for white oak (*Quercus alba*) during the month of July 2001 (Table 21, page 72) was equal to one, *i.e.*, process variation was *within specification*.

Figure 20. Capability C_{pk} index for "finished blank" length for target length 270 mm.

Figure 21. Capability C_{pk} index for "finished blank" length for target length 325 mm.

The capability statistics for “finished blank” length for target lengths of 270 mm and 325 mm indicated only a few months that had a C_p value greater than one (Tables 22 and 23, page 71-72). There were no months where the C_{pk} or C_{pm} values were greater than one. The months where the C_p value was greater than one for target length 270 mm were December 2000 (hard maple), February and November 2000 (white oak). For the target length of 325 mm, $C_p > 1$ for May 2000 (red oak). The manufacturer has an opportunity to investigate the months where C_p was capable. They would investigate reason why their process was capable that month to potentially learn ways to continually hold there process within their specifications. Fishbone diagrams may help identify reasons for C_p being capable. For most months $C_p \neq C_{pk}$ which further indicated that the process location was not stable.

Harry’s (2000) philosophy indicates that a long term “Six Sigma” quality level produces only 3.4 defective parts per million. The approximate number of defects produced for “finished blank” length for all target lengths and the three species studied were 300,000 defective parts per million. This may equate to a 30% loss rate for the hardwood-flooring manufacturer. However, most process averages and medians were greater than the target value, which would imply that not all products were produced as reject but that yield and recovery was not being optimized. Capability indices for “finished blank” length for target lengths 215 mm, 270 mm, and 325 mm suggested that the manufacturer was not capable of meeting specifications (Table 21, page 71).

Table 21. Capability indices for “finished blank” length for target length 215 mm.

“Finished Blank” Width for Target Lengths 215 mm, 270 mm, and 325 mm

The capability indices for “finished blank” width for target lengths 215 mm, 270 mm, and 325 mm suggested that the process was not consistently capable of meeting specifications from January 2000 thru March 2001 (Figures 22-24, pages 73-74). The C_p capability index for the “finished blank” width for the target length of 215 mm for hard maple (*Acer saccharum*) during May 2000 and 270 mm for white oak (*Quercus alba*) during February 2000 (Tables 24 and 25, page 75) were greater than one. The C_{pk} and C_{pm} capability indices for these months were not greater than one. This indicated that even though the process dispersion was capable of meeting the engineering tolerance, the process was not on target or centered within the specifications.

Figure 22. Capability C_{pk} index for “pre-finished blank” width for target length 215 mm.

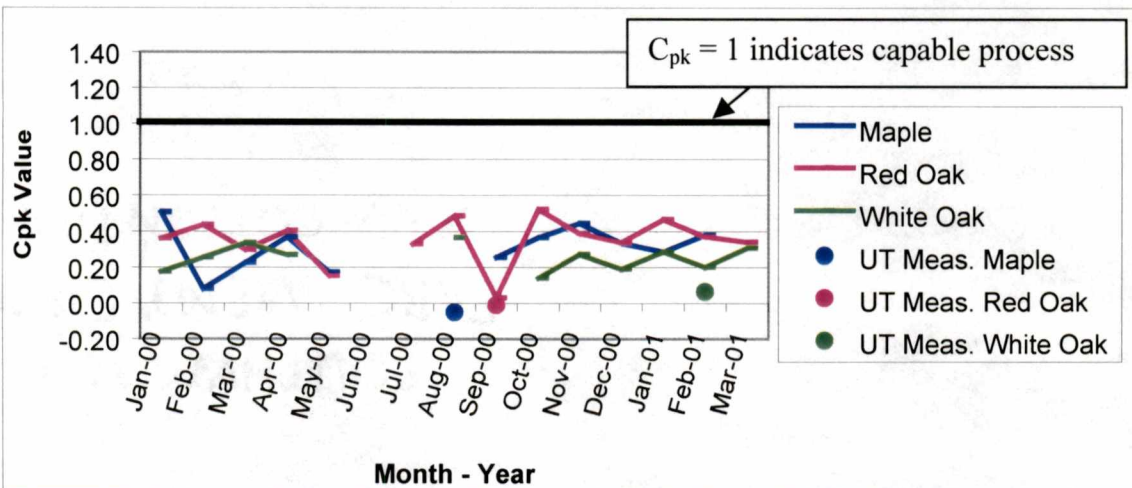

Figure 23. Capability C_{pk} index for “pre-finished blank” width for target length 270 mm.

Figure 24. Capability C_{pk} index for “pre-finished blank” width for target length 325 mm.

There were only two occurrences where the natural dispersion of “finished blank” width was capable of meeting the engineering tolerance, hard maple (May 2000) and white oak (February 2000), see Tables 24-26, pages 75-76. These occurrences may be due to the specification limits allowing only a 0.05 mm movement around the average. The specification tolerance only allows the width of a “veneer-slat” to vary by the thickness of a piece of paper, which is on average four thousandths (0.004) of an inch. A “veneer-slat” width There were no months where the C_{pk} or C_{pm} values were greater than one for any “finished blank” width for any species and target length. In some cases the C_{pk} values were negative, *i.e.*, the process average was above the USL. In this study the manufacturer was processing their material wider than the USL.

The approximate number of defects produced for “finished blank” width for all species and target lengths were approximately 350,000 defective parts per million. Note a defective part may not necessary equate to reject. Even though the manufacturer feels a part is acceptable, it still may have a negative effect on yield and recovery.

“Veneer-Slat” Thickness for Target Lengths 215 mm, 270 mm, and 325 mm

The capability indices for “veneer-slat” thickness lengths of 215 mm, 270 mm, and 325 mm suggested that the process was not consistently capable of meeting specifications from January 2000 thru March 2001 (Figures 25-27, pages 77-78). The C_p, C_{pk}, and C_{pm} indices for the “veneer-slat” thickness did not have any value greater than one for all species and length categories (Tables 27-29, pages 78-79).

The capability C_{pk} indice for “veneer-slat” thickness in some cases was negative which indicated in this study that the process average was above the USL (Figures 25-27, pages 77-78 and Tables 27-29, pages 78-79). The approximate number of defects produced for “veneer-slat” thickness was 350,000 defective parts per million.

Figure 25. Capability C_{pk} index for “vener-slat” thickness for target length 215 mm.

** Statistics in parenthesis were estimates that were taken as part of a sampling study.

Production Yield And Manufacturing Costs - Objective 3

The third objective of the thesis was partially satisfied. Even though the senior management of the hardwood-flooring manufacturer agreed early in the study to provide production yield and manufacturing cost data on a monthly basis, the data were never provided, *e.g., monthly production yield data were not provided even though it was requested.* The species red oak (*Quercus rubra*), white oak (*Quercus alba*), and hard maple (*Acer saccharum*) represented about 75% of total production. Red oak represented about 50% of total production, white oak 16% and hard maple 9%.

Monthly Lumber Usage by Species

The average monthly lumber usage from January 2000 to December 2000 for the three species studied was approximately 560 MBF. The average monthly usage for red oak was 286 MBF, white oak 163 MBF, and hard maple 112 MBF (Table 30, Figure 28, page 82).

“Finished Blank” Production

Approximately 15,000,000 “finished blanks” were produced from January 2000 to February 2001. Average “finished blank” production on a monthly basis by species was as follows: 183,000 (red oak); 107,000 (white oak); and 70,000 (hard maple), (Table 31-33, page 86-87).

The predominate target length for each species studied was 325 mm (Figure 29). The reason for the greater number of blanks at length 325 mm might be due to a higher rejection rate for longer blanks or the blank can be recovered at a shorter length. Some of the rejected longer blanks were recovered and re-manufactured into smaller blank sizes depending on defect location, also low grade lumber allows more shorter parts to be cut.

“Veneer-Slat” Production

Approximately 62,000,000 “veneer-slats” were produced from January 2000 to February 2001 for all species and lengths. The average number of “veneer-slats” produced per month by species were as follows: 775,000 (red oak), 425,000 (white oak), and 315,000 (hard maple) (Tables 34-36, pages 85-86, Figure 30, page 87).

Even though more “finished blanks” at a target length of 325 mm were produced on a monthly basis, the average number of “veneer-slats” produced per month were similar for all three target lengths. The data suggested for hard maple that it takes more “finished blanks” to produce “veneer-slats” for target length 325 mm relative to the 215 mm and 270 mm target lengths.

Figure 30. Average monthly “veneer-slat” production by species and target length.

“Veneer-Slat” Yield

An analysis of the “veneer-slat” yield at the grading station suggested that the manufacturer was rejecting approximately 20% of good “veneer-slats.” The analysis consisted of taking a random sample of white oak “veneer-slats” over a four-hour period for target lengths 215 mm and 270 mm ($n = 371$). The data also included “veneer-slat” production from two shifts. The second shift rejected more “veneer-slats” that were good than the first shift (Figure 31, page 88). Discussions with supervisors and quality control staff indicated that the estimate of 20% rejection of good “veneer-slats” may be representative.

The incorrect grading of “veneer-slats” represented a substantial finding during the production yield study because this was an area of greatest loss to the manufacturer. The potential costs savings from correcting this problem of rejecting good “veneer-slats” is a savings of \$500,000 per year. One of the limitations of the “veneer-slat” yield study

was that it was only conducted once for each shift. More “veneer-slat” yield studies were planned but the hardwood-flooring manufacture did not allow further investigation of “veneer-slat” yield. This represented a serious limitation of accomplishing the third objective because yield statistics could not be developed for the thesis. The hardwood flooring manufacturer did not have any existing yield statistics for “finished blanks” or “veneer-slats.”

Manufacturing Costs

The total manufacturing costs from January 2000 to February 2001 for “finished blanks” by species were: red oak (\$6,462,167), white oak (\$3,782,956), and hard maple (\$2,308,905), see Table 37, page 89. “Finished blanks” for target length 325 mm cost more to manufacture than the other target lengths.

Table 37. Total manufacturing costs for “finished blanks” by species and target length from January 2000 to February 2001.

Target Length	hard maple	red oak	white oak	Total
215 mm	\$433,378	\$1,256,674	\$708,218	\$2,398,270
270 mm	\$743,310	\$2,067,727	\$1,284,149	\$4,095,186
325 mm	\$1,132,217	\$3,137,766	\$1,790,589	\$6,060,572
Total	\$2,308,905	\$6,462,167	\$3,782,956	\$12,554,028

Table 38. Total manufacturing costs for “veneer-slats” by species and target length from January 2000 to February 2001.

Target Length	hard maple	red oak	white oak	Total
215 mm	\$269,286	\$755,138	\$407,029	\$1,431,452
270 mm	\$374,015	\$969,441	\$534,990	\$1,878,446
325 mm	\$458,982	\$1,215,193	\$673,296	\$2,347,470
Total	\$1,102,283	\$2,939,771	\$1,615,314	\$5,657,368

The total manufacturing costs from January 2000 to February 2001 for “veneer-slats” by species were: red oak (\$2,939,771), white oak (\$1,615,314), and hard maple (\$1,102,283), see Table 38. The manufacturer’s accounting staff indicated that it cost manufacturing cost \$0.09 to manufacture a “veneer-slat.”

Sources Of Variation - Objective 4

Ishikawa Diagrams

Ishikawa diagrams (fishbone diagrams) were developed as the first step in identifying sources of variability that influence product attribute variability. The Ishikawa diagrams were developed from discussions with senior management, quality control staff and operators. Potential sources of variability were initially investigated using the results of the interviews with senior management, quality control staff and operators. Sources of variability for the following product attributes were investigated:

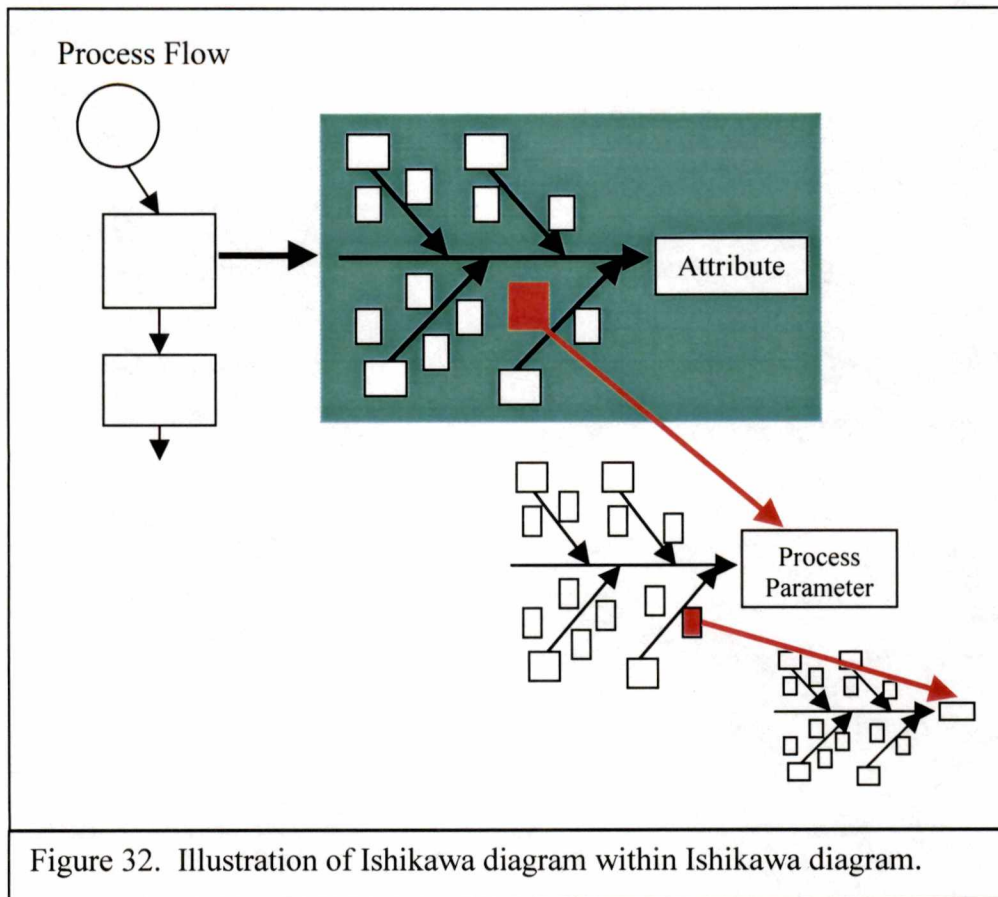

- “Veneer-slat” thickness variation;
 - Measurement Error;
 - “Finished blank” thickness;

- Lumber Thickness Variation.
- “Veneer-slat” width variation;
 - Lumber moisture content variation.
- “Lumber rip” width variation;
 - Rip width location.

Sources of variability were identified for product attributes other than the product attributes initially studied. The other product attributes were identified to help reduce variability and improve production yields, *e.g.*, “*veneer-slat*” width and “*lumber rip*.” After the sources of variability were defined for the additional product attributes, management at the hardwood flooring plant indicated that the additional product attributes were important, *i.e.*, *the thesis study improved the management’s awareness of other important product attributes.*

In lieu of the thesis and in an effort to develop a better understanding of the hardwood-flooring “veneer-slat” process, a process flow was developed before the Ishikawa diagrams were developed. The process flow diagram was invaluable in developing a better understanding of the process was essential for initial discussions with plant personal (refer to Figure 7, pages 45 to 47).

Ishikawa diagrams were developed for each key product attribute (*e.g.*, “*veneer-slat*” thickness). Once a key process parameter was identified for a given product attribute, another Ishikawa diagram was developed. This process of developing Ishikawa diagrams within Ishikawa diagrams led to a detailed root cause analysis of sources of variability (Figure 32, page 91). The use of Ishikawa diagrams for root cause analysis is consistent with Harry’s (2000) philosophy.

“Veneer-Slat” Thickness Variation

The first fishbone was completed for sources of “veneer-slat” thickness variation (Figure 33, page 93). The scope of the thesis did not allow for all potential sources of variability to be investigated. However, significant sources of variability for “veneer-slat” thickness were discovered. The following sources of variability for “veneer-slat” thickness were investigated:

- “blank” molder setup,
- “finished blank” thickness,
- moisture content,

- feed rate of slat molder,
- measurement variation,
- slat molder setup,
- and “veneer-slat” molder blade alignment.

“Finished Blank” Thickness Variation

An Ishikawa diagram was developed for “finished blank” thickness variation (Figure 34, page 94). Possible factors that were investigated for “finished blank” thickness variation were:

- lumber thickness,
- moisture content,
- planer blade setup,
- misalignment of planer blades,
- groove depth of blank,
- measurement variation.

“Blank Molder” Machine Variability

An Ishikawa diagram was developed for “blank molder” machine variability (Figure 35, page 95). Possible factors that were investigated for “blank molder” machine variability were:

- machine setup,
- groove depth setup,
- feed rate,
- thickness setup,
- width setup.

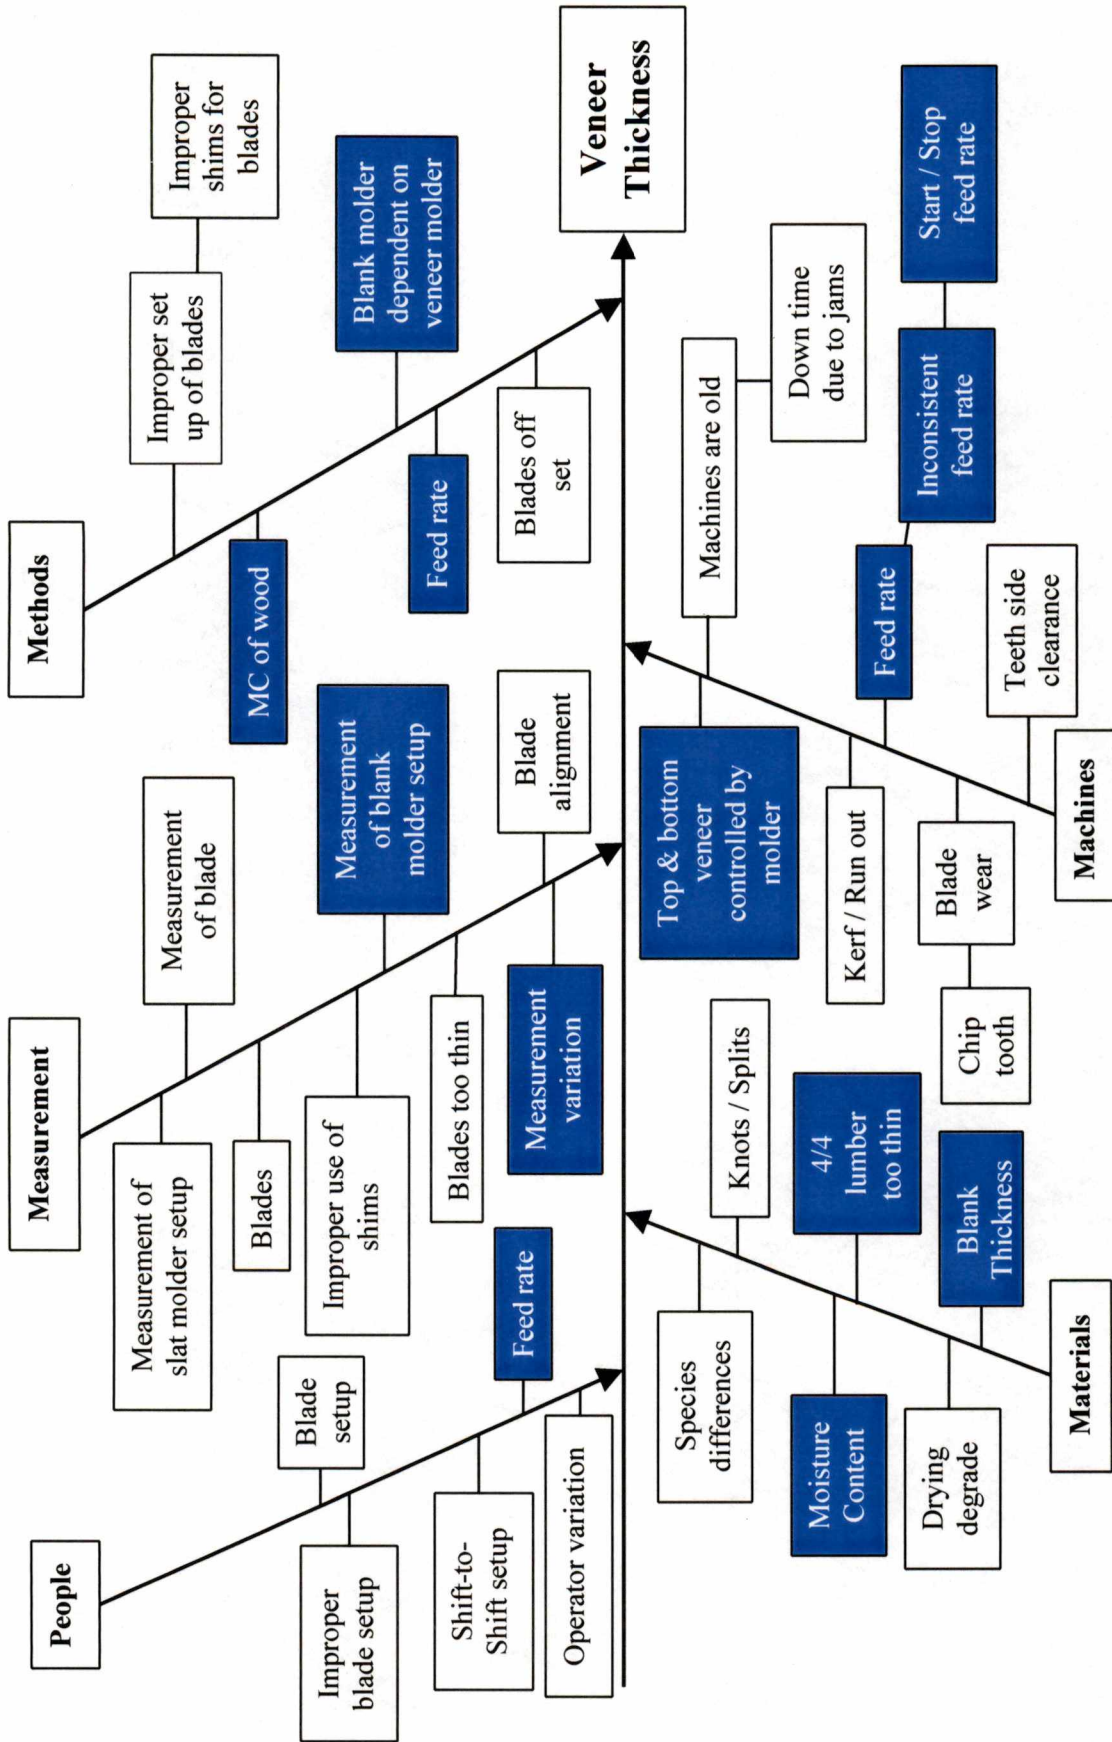

Figure 33. Fishbone diagram for "veneer-slat" thickness variation.

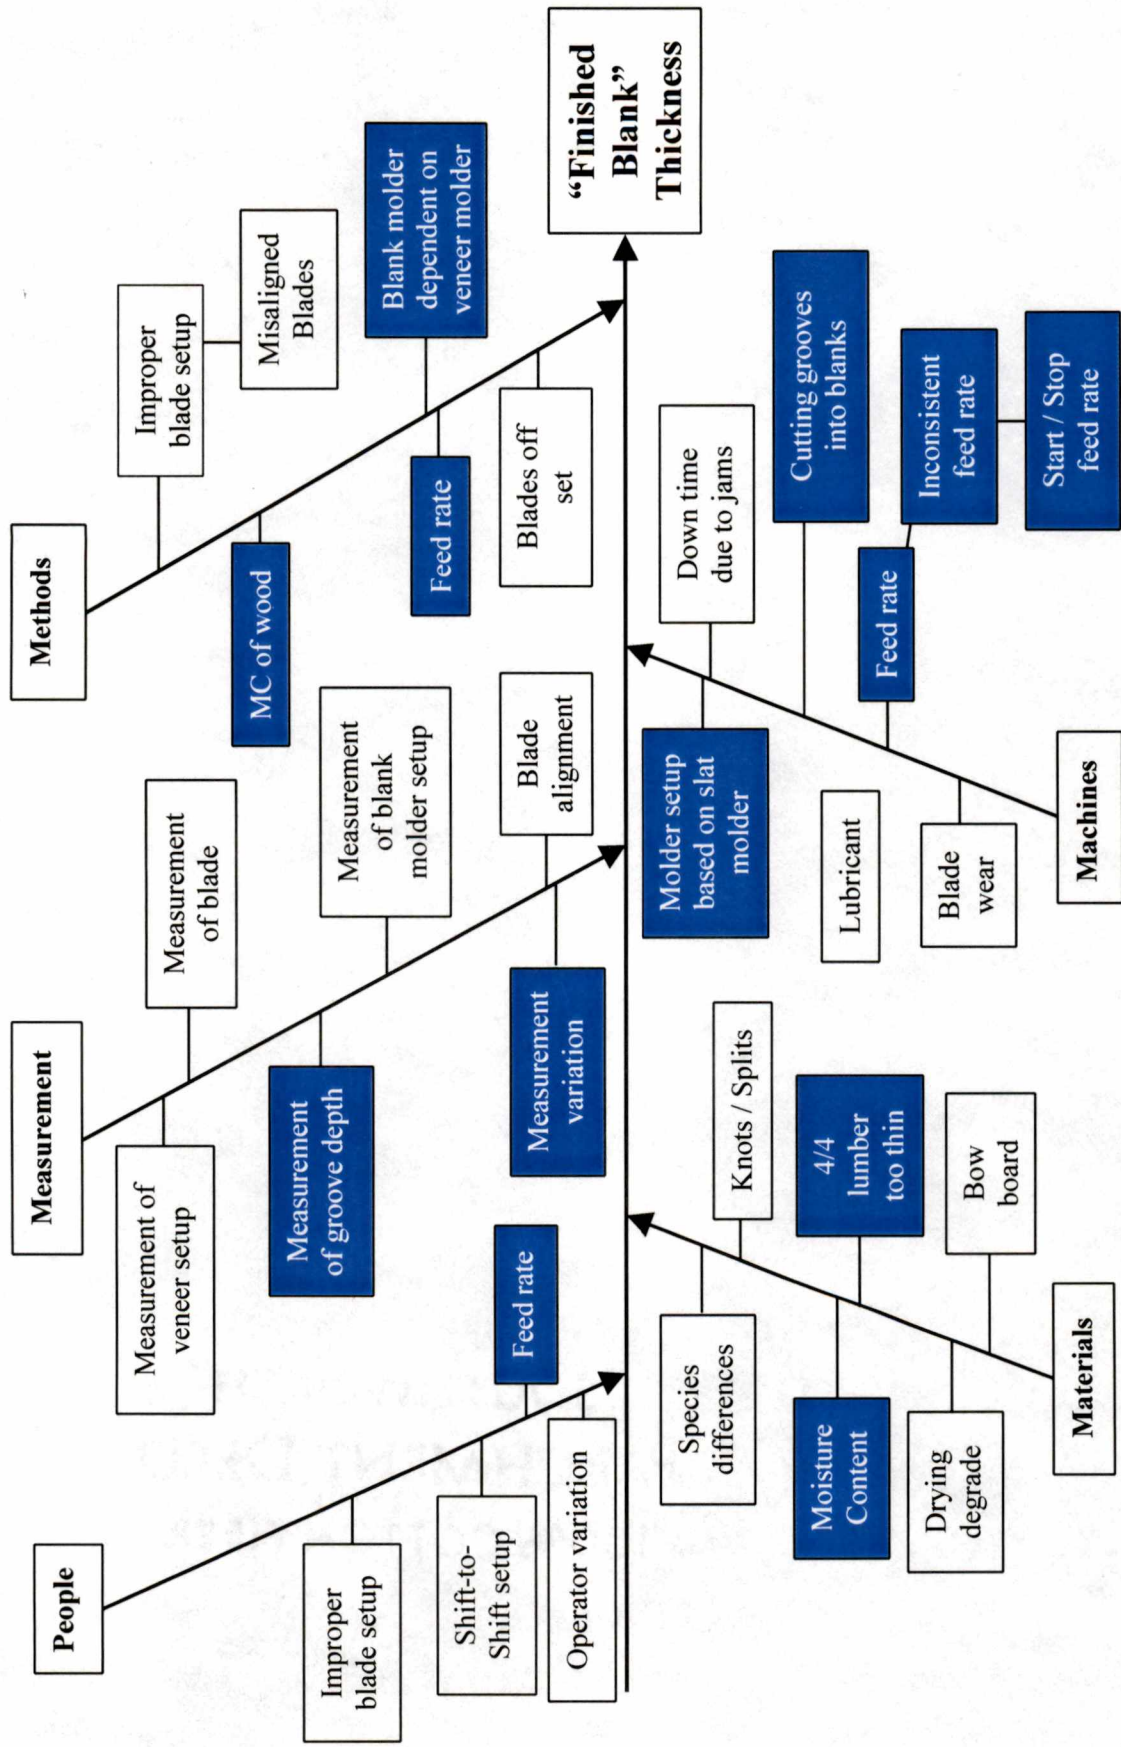

Figure 34. Fishbone diagram for “finished blank” thickness variation.

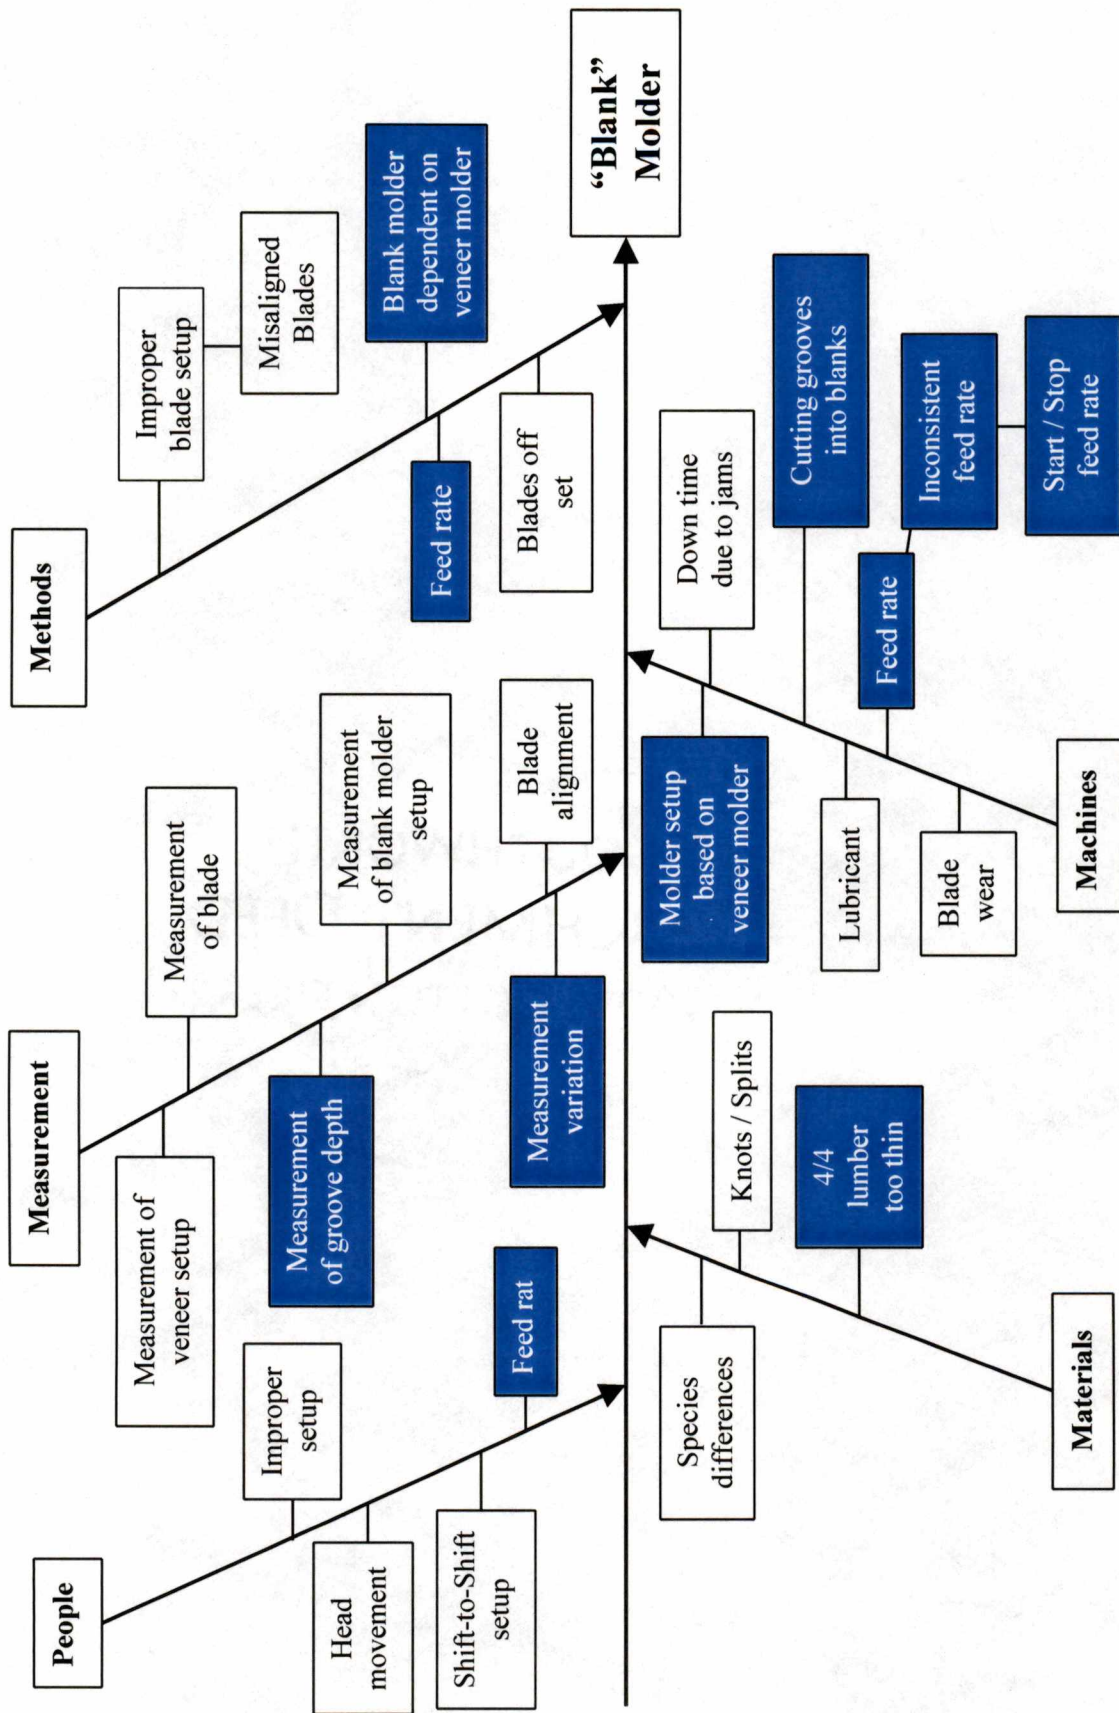

Figure 35. Fishbone diagram for "blank" molder machine variability.

Lumber Thickness Variation

In order to conduct a controlled study that may identify the effect that lumber thickness has on “finished blank” thickness, three categories of lumber thickness were developed: thin (0.9” to 1.1” – category 1), target (1.1” to 1.3” – category 2), and thick (>1.4” to 1.5” – category 3), (Figure 36, page 97). The lumber thickness variation study was conducted in January 2001 for hard maple. Each piece of lumber was coded and followed through each process and measured. The process follows the process flow (Figure 7, page 44-46).

There was evidence lumber thickness effects “finished blank” thickness. Lumber thickness category 3 was significantly greater ($p\text{-value} = 0.0001$) than lumber thickness categories 1 and 2 (Figure 36, page 97). Lumber with thickness between 25.5 mm and 27 mm will have more variation than lumber with thickness between 28 mm and 33 mm. Discussions with operators concerning this relationship indicated that the “blank molder” for this particular day was setup for thicker incoming lumber due to the new blades on the “veneer-slat” molder. New blades result in a larger saw kerf than usual. Lumber thickness category three ($s = 0.047$) had less “finished blank” thickness variation lumber thickness categories one ($s = 0.25$) and two ($s = 0.18$).

Additional analyses were conducted on the relationship between lumber thickness and “finished blank” length and “finished blank” width. There was no statistical evidence that suggested lumber thickness affected “finished blank” length or “finished blank” width.

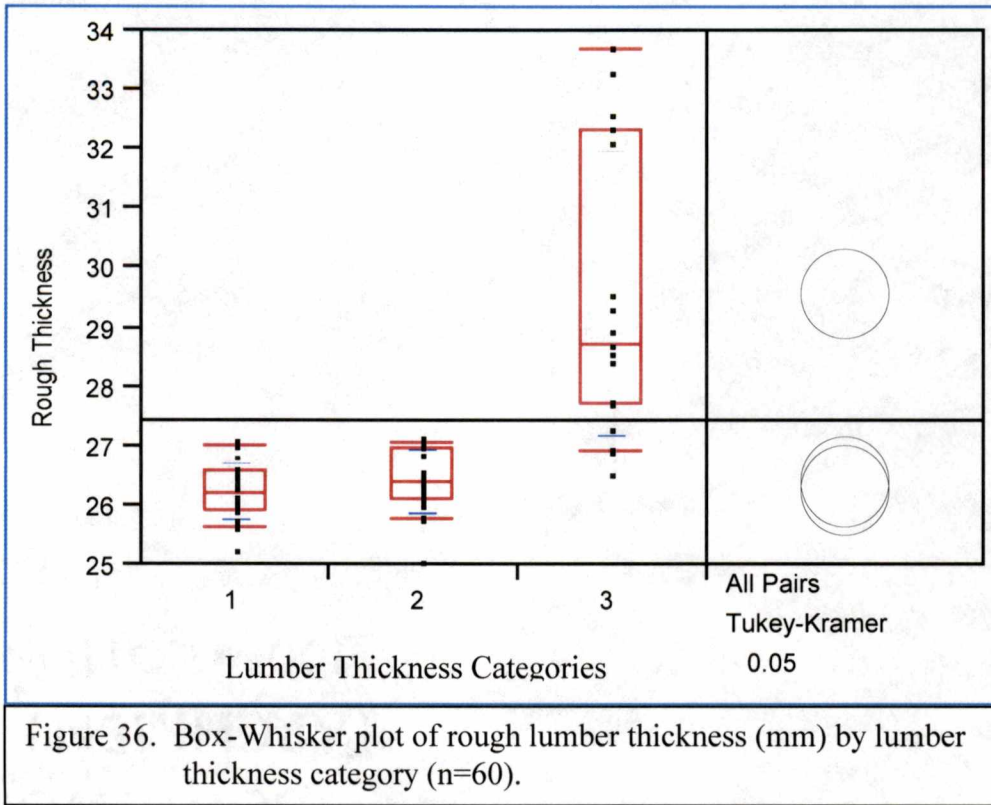

Figure 36. Box-Whisker plot of rough lumber thickness (mm) by lumber thickness category (n=60).

Figure 37. Box-Whisker plot of “finished blank” thickness (mm) by lumber thickness category (n=60).

Individual “Veneer-Slat” Thickness Variation (Top “Veneer-Slat”). -- The average thickness for the top “veneer-slat” was effected by lumber thickness (Figure 38, page 98). There was statistical evidence that a linear relationship existed between top “veneer-slat” thickness and lumber thickness, *i.e., the thicker the lumber the thicker the top “veneer-slat.”* The correlation between the top “veneer-slat” thickness and “finished blank” thickness was 0.46 (Figure 39, page 99). The variation in “finished blank” thickness is absorbed partially in the top “veneer-slat” because the process flow has been established in this fashion.

Figure 38. Box-Whisker plot of top "veneer-slat" thickness (mm) by lumber thickness category (n=330).

Figure 39. Correlation between top “veneerslat” thickness (mm) and “finished blank” thickness (mm) (n=50).

Individual “Veneer-Slat” Thickness Variation (Middle “Veneer-Slat”).--

There were no significant differences between middle “veneerslat” thickness by lumber thickness category (Figure 40, page 100). The correlation between the middle “veneerslat” thickness and “finished blank” thickness was 0.13 (Figure 41, page 101).

Individual “Veneer-Slat” Thickness Variation (Bottom “Veneer-Slat”). --

There was statistical evidence at an $\alpha = 0.05$ that the average thickness for the bottom “veneerslat” was effected by lumber thickness (Figure 42, page 102). The correlation between the bottom “veneerslat” thickness and “finished blank” thickness was 0.34 (Figure 43, page 103).

The data also indicated that the top and bottom “veneerslat” had more variation than the middle location “veneerslat” (Table 39, page 102). The top “veneerslat” had more variation than the bottom “veneerslat.”

Figure 40. Box-Whisker plot of middle "veneer-slat" thickness (mm) by lumber thickness category (n=330).

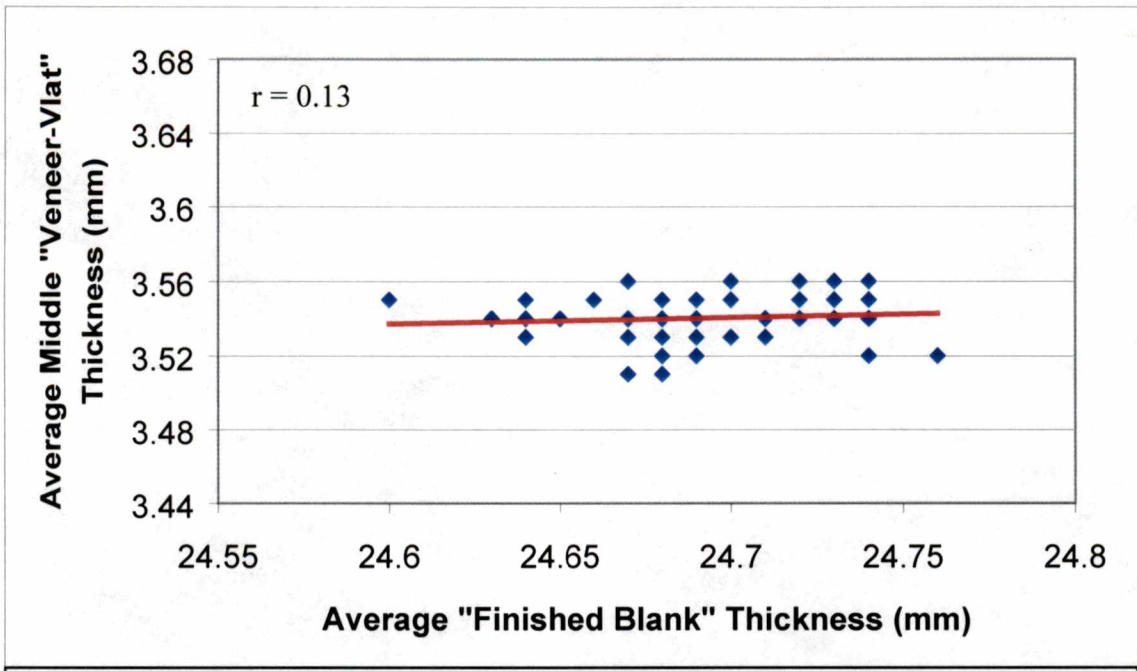

Figure 41. Correlation between middle "veneer-slat" thickness (mm) and "finished blank" thickness (mm).

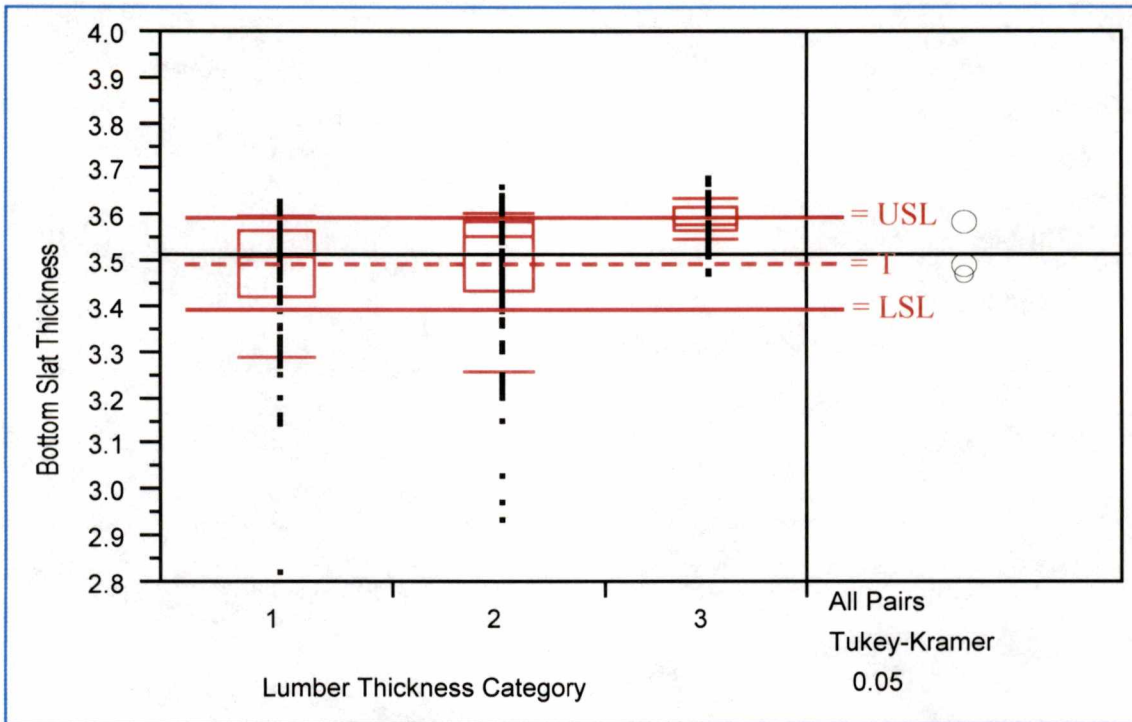

Figure 42. Box-Whisker plot of bottom “veneerslat” thickness (mm) by lumber thickness category (n=330).

Table 39. Standard deviation by “veneerslat” location.

Lumber Thickness Category	Top “veneerslat” Standard Deviation (mm)	2 nd “veneerslat” Standard Deviation (mm)	Middle “veneerslat” Standard Deviation (mm)	4 th “veneerslat” Standard Deviation (mm)	Bottom “veneerslat” Standard Deviation (mm)
1	0.2134	0.0182	0.0197	0.0196	0.1336
2	0.1599	0.0228	0.0180	0.0221	0.1430
3	0.1077	0.0192	0.0193	0.0203	0.0378

Talking to operators, management, and analysis of a fishbone diagram indicated that "finished blank" thickness variation can be caused by lumber thickness variation and "blank molder" setup. By reducing "blank molder" setup variation improvements can occur with "finished blank" thickness variation and top and bottom "veneer-slat" thickness variation.

"Veneer-Slat" Width Variation

Lumber Moisture Content. -- The moisture content was identified as potential causes for variation with product attribute by senior management and fishbone diagrams. A drying study was conducted for three different lumber moisture content categories: low (4.0% to 5.2%- category 1), target (5.2% to 6.4%- category 2), and high moisture content

(6.4% to 7.6%- category 3). The study consisted of selecting three white oak boards at the different moisture content categories and following them through the process taking measurement after each station (Figure 7, page 44 - 46). All the “blanks” were selected from each of the boards, measured, and followed through the process.

Stress samples were taken to identify if the variation in product attributes were more related to moisture content and/or stresses. Stresses within the wood add to the variation. Evaluation of internal lumber stresses was determined by a “stress test” in which individual samples were cut from sample boards for each moisture category (Figure 44, page 105). Four stress samples were taken for each board and stresses were excessive stresses were identified in two of the boards or 8 of the 16 samples. Stresses in wood are often caused by improper drying schedule and conditioning in the dry kiln.¹³ “Honeycombing” was also found to be present in the wood, which indicated poor drying practices (Figure 45, page 105).

There was statistical evidence at an $\alpha = 0.05$ that suggested that the moisture content of lumber effected “veneer-slat” width variation. The top and bottom “veneer-slat” widths were greater than the middle “veneer-slat” width due to moisture content.

Analyses were conducted on lumber moisture content and “veneer-slat” thickness and length. There was no significant statistical evidence that indicated a relationship existed between lumber moisture content and “veneer-slat” thickness and length.

¹³ Conditioning -- following the final stage of a lumber drying schedule a conditioning treatment is done which causes a redistribution of moisture into the faces for the lumber in order to relieve some of the stresses that are in compression (Simpson 1997).

Figure 44. Stress test sample from manufacturers kiln dried lumber.

Figure 45. Example of honeycomb sample from manufacturer.

Individual “Veneer-Slat” Width Variation (Top “Veneer-Slat”). -- The top “veneer-slat” width by moisture content category indicated that moisture content was a cause for the variation in the widths. A nonlinear relationship was identified for moisture content categories and “veneer-slat” width (Figure 46). The variations present in the “veneer-slat” width due to moisture content variations were unexplainable. Typically, as wood increases in moisture content wood swells and the reverse occurs when the moisture content decreases. The reason for the nonlinear pattern may be due to the conditions the lumber was exposed to after removed from the dry kiln.

Individual “Veneer-Slat” Width Variation (Middle “Veneer-Slat”). -- The middle “veneer-slat” width was not significantly different by moisture content category at an $\alpha = 0.05$ (Figure 47). Most middle “veneer-slats” widths were within the specification limits (Figure 47).

Individual “Veneer-Slat” Width Variation (Bottom “Veneer-Slat”). -- The bottom “veneer-slat” width by moisture content category indicated that moisture content for category one was statistically different than the moisture content for category three at an $\alpha = 0.05$ (Figure 48, page 108). There was an indication of a linear relationship between bottom “veneer-slat” width and moisture content, *i.e., the higher the moisture content, the wider the bottom “veneer-slat.”*

Figure 47. Box-Whisker plot of middle “veneer-slat” width (mm) by moisture content category (n=165).

It was evident in the thesis study that moisture content had an effect on the top and bottom “veneer-slats” widths. There was evidence that the hardwood-flooring manufacturer may be able to reduce “veneer-slat” width variation by reducing variability in the moisture content of dried lumber by implementing better drying practices.

“Veneer-Slat” Thickness Measurement Error

There was evidence that indicated that measurement error for “veneer-slat” thickness was a significant source of variability. A Gauge Repeatability¹⁴ and Reproducibility¹⁵ (Gauge R&R) was conducted three different times for two shifts in the thesis study. The six Gauge R&R studies had three different appraisers with the exception of 2nd shift 4/4/01 which had two appraisers. The measurement device used for the Gauge R&R was the hardwood manufacturer’s Mitutoyo 0” to 1” caliper that was the typical device used for measuring “veneer-slat” thickness, (Figure 10, page 51). The Gauge R&R studies attempted to estimate “appraiser error,” “gauge error,” and a “discrimination ratio.”¹⁶

The predominate source of measurement error for both shifts was due to “appraiser error” (Tables 40-41, page 110). The percent of total measurement error due to “appraiser error” varied from 71% to 94% when three appraisers were assessed. The sources of variability for “appraiser error” that were observed during the Gauge R&R study were:

¹⁴ Repeatability – the variation in measurements obtained with one measurement instrument when used several times by one appraiser, while measuring the identical characteristic on the same part.

¹⁵ Reproducibility – the variation in the average of the measurements made by different appraisers using the same measuring instrument when measuring the identical characteristic on the same part.

¹⁶ The “discrimination ratio” represents the number of discrete intervals in which the measurement device is capable of defining (Wheeler 1989).

Table 40. Gauge R&R results for first shift.

Gauge Repeatability and Reproducibility First Shift				
Date	Appraiser (σ_e)	Gauge (σ_m)	Discrimination Ratio (D_R)	$\sigma_{R\&R}$
6/28/00	94%	6%	3	0.055
8/22/00	71%	29%	12	0.026
4/4/01	85%	15%	8	0.049

Table 41. Gauge R&R results for second shift.

Gauge Repeatability and Reproducibility Second Shift				
Date	Appraiser (σ_e)	Gauge (σ_m)	Discrimination Ratio (D_R)	$\sigma_{R\&R}$
6/28/00	81%	19%	5	0.058
8/22/00	78%	22%	8	0.031
4/4/01	40%	60%	8	0.014

- no zero calibration of caliper before starting measurement;
- no gauge calibration for 12.7 mm and 25.4 mm intervals;
- appraisers varied the angle of caliper feet when measurements were taken;
- appraisers applied different pressures to the caliper feet when measurements were taken.

The “discrimination ratio” varied from 5 to 12 for “veneer-slat” thickness, e.g., a “discrimination ratio” of 3 implies that the measurement device is capable of distinguishing between low, medium and high intervals.

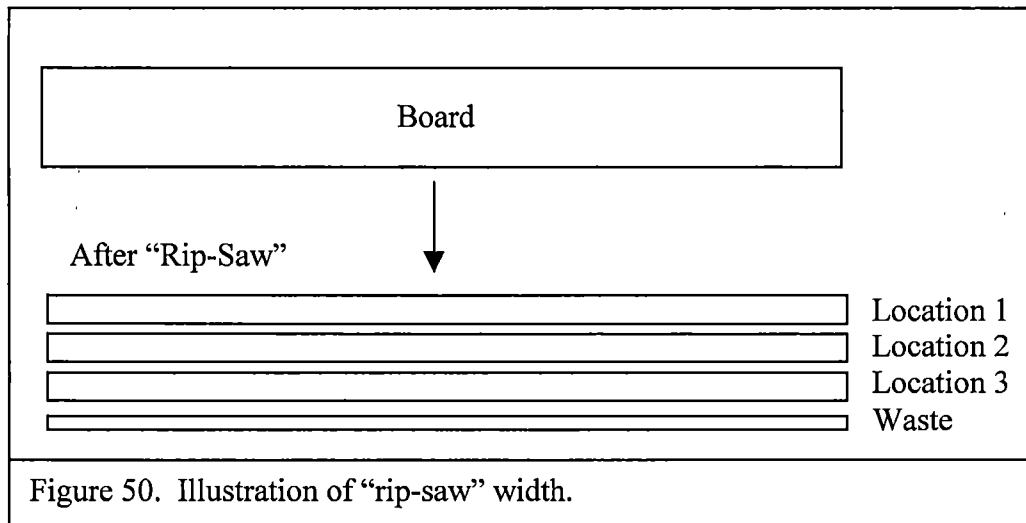

“Rip-Saw” Width

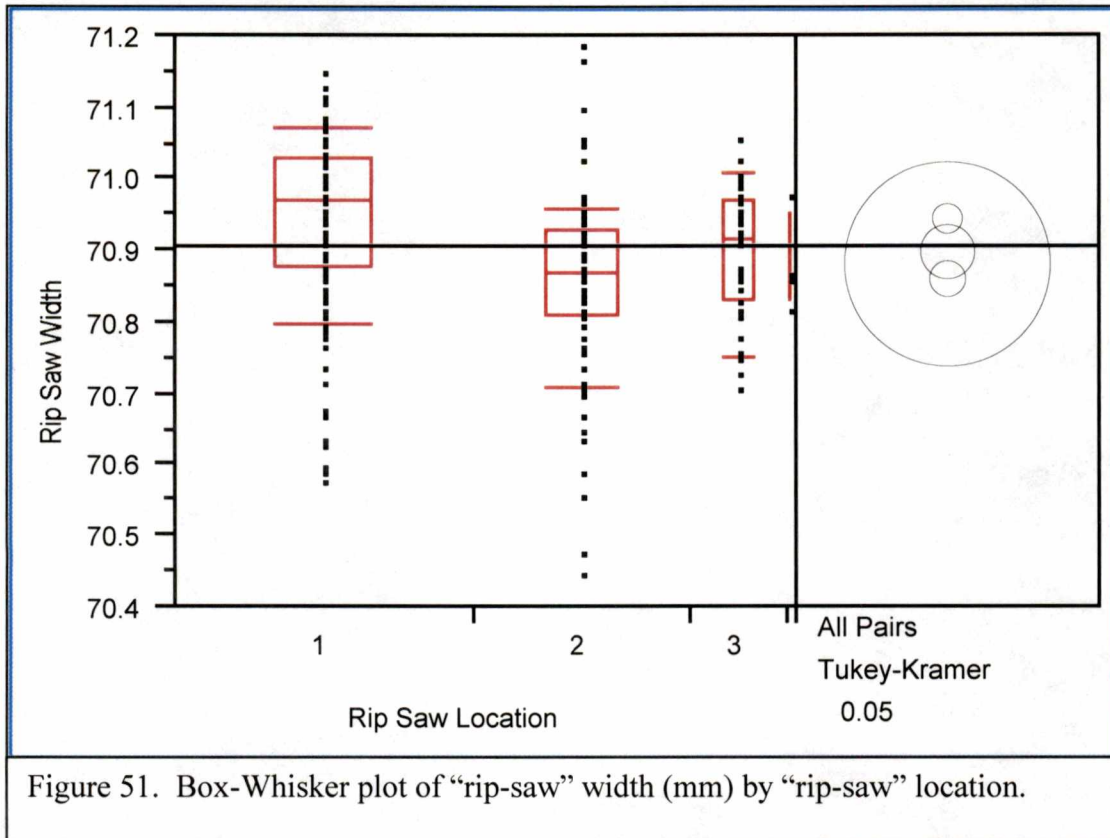

Another source of variability identified in the thesis was “rip-saw” width. A potential improvement in yield may be realized if the manufacturer reduces the “rip-saw” width of incoming lumber.

The “rip-saw” cuts lumber into long, thin strips (Figure 50). The specifications of the manufacturer for “rip-saw” width were: LSL = 69 mm; target = 70 mm; and USL = 71 mm.

For 120 samples of “rip-saw” strips, the standard deviation of “rip-saw” width was 0.0714 mm. The natural tolerance of “rip-saw” width was 0.428 mm and the average width was 71.16 mm (Figure 51, page 111). Note that the engineering tolerance of “rip-saw” width was 2 mm.

It may be possible to lower the target “rip-saw” width given the low amount of variation and its highly capable state, *i.e.*, $NT < ET$. If the process target was lowered to 68.5 mm and the saw-kerf was reduced by 1 mm there would be a 3.5 mm savings for each “rip-saw” strip. An increase in yield of approximately 8% may be realized from the reduction in target and saw-kerf.

Recommendation – Objective 5

Recommendations were made to the hardwood flooring manufacturer management on April 11, 2001. Recommendations were:

"Finished Blank" and "Veneer-Slat" Thickness Variation

The conclusions identified from evaluation of the "finished blank" and "veneer-slat" studies were that the top and bottom "veneer-slats" had more variation than the middle "veneer-slats." The variation in the top and bottom "veneer-slats" was correlated to "finished blank" thickness. Variations within the "finished blank" thickness were partially due to inconsistent molder setup. The recommendation was to establish standard operating procedures and develop a systematic sampling plan to ensure proper

molder setup based on discussions with operators, management, and fishbone diagram analysis.

Drying Practices

Drying stresses and honeycomb were present in the wood indicating improper drying. The top and bottom "veneer-slat" width was greater than the middle "veneer-slat" width indicating improper conditioning of lumber. The recommendation was that all lumber should be conditioned and an appropriate drying schedule should be followed along with a systematic sampling plan to ensure proper moisture content.

Measurement Error

There was a large amount of measurement error that was due to appraiser error. Appraiser error was due to improper use of the measurement device. A recommendation was made to retrain operators on proper use of calipers.

Sampling Plan

A stratified random sampling plan was recommended to senior management to help identify proper sampling plans for "finished blank" thickness and "veneer-slat" thickness (Levy and Lemeshow 1991). Three different levels of certainty were recommended as potential choices, *e.g.*, 90%, 95%, and 99% with a 5% error level. Sampling plans were estimated for "finished blank" thickness (Tables 42-44, pages 114) and "veneer-slat" thickness (Tables 45-47, pages 115) using the most recent data from the companies database. A sampling plan was recommended because in some cases the manufacturer had not taken an adequate number of samples. The best sampling plan to implement would be the 99% certainty level sampling plan. This would allow the company to have more confidence in the data and sampling plan is not excessive.

Table 42. Sampling scheme for "finished blank" thickness for a 5% error level and 90% certainty level.

"Rip-Saw" Width

An evaluation of the "rip-saw" width suggested that a decrease in the "rip" width to 69 mm and a decrease in the saw kerf from 3/16 inch to 1/8 inch could have an approximate 8% increase in yield. If these ideas were implemented for the first rip there would be a 3.5 mm "rip" width reduction at "rip" location one. The extra material gained by lowering the target and saw kerf would leave more opportunities for the "rip" width to clean up better in the other "rip" locations. An extra "rip" cannot be expected for each board. The studies conducted indicated on three different occasions boards had the potential to increase yields of 12.5%, 9.7%, and 7.7% for a for a random sample size of four-hundred. The recommendations were to conduct additional studies to validate the potential gains.

"Veneer-Slat" Grading Line

Approximately 20% of rejected "veneer-slats" were identified as good "veneer-slats" and 10% were "down-gradable." In order to improve yield due to the improved grading of "veneer-slats," retraining of graders and posting of visual grading standards were recommended.

Potential Financial Savings and Measurement Improvements - Objective 6

The total potential cost savings from the elimination of thin "veneer-slats" was estimated to be \$520,000 dollars per year. The total potential cost savings for recovering 20% of rejected "veneer-slats" that were good was estimated to be approximately \$500,000 dollars per year. If the manufacturer were to operate at a "Six Sigma" quality level they would increase their number of "veneer-slats" by at least 7,500,000.

Measurement variation was excessive and could be improved. A lab study was conducted to determine a theoretical measurement error level for the measurement device. In a controlled lab environment with proper instruction in the use of Mitutoyo calipers appraiser error consumed 15% of the total measurement error and the gauge consumed 85% of the total measurement error (Table 48). Note that the $\sigma_{R\&R}$ was reduced from 0.043 (1st shift) and 0.034 (2nd shift) to 0.004 (lab study).

Table 48. Gauge R&R results for lab-controlled study.

Date	Appraiser (σ_e)	Gauge (σ_m)	Discrimination Ratio (D_R)	$\sigma_{R\&R}$
Average 1 st Shift	83%	17%	8	0.043
Average 2 nd Shift	66%	34%	7	0.034
Lab Study	15%	85%	12	0.004

CHAPTER 5

CONCLUSIONS

Forest products companies enjoyed the benefits of inexpensive raw material and low labor costs in the early 20th century. As competition increased, the demand for quality products increased. Given the increased demand for companies to improve quality, industries have reached out to statistical methods.

As the U.S. forest products industry enters the 21st century, they are faced with a panacea of issues. Environmental regulation and preservation interests have reduced the availability of wood fiber and resulted in higher raw material costs. Air quality restrictions, are forcing many forest products companies to invest in expensive air-quality control equipment. Labor costs are higher in the U.S. relative to labor costs in developing countries. The U.S. forest products industry is also faced with increasing domestic and international market competition from non-wood products such as plastic, aluminum, and concrete. The scenario faced by most U.S. forest products companies is lower profit margins due to higher raw material and manufacturing costs in the context of stable real-prices for final wood products. Some U.S. forest products companies have started reassessing the importance of continuous improvement. The "Six Sigma" quality philosophy provides the forest products industry with a contemporary approach to continuous improvement.

The hypothesis of this thesis was to determine if a modified "Six Sigma" quality philosophy can improve the quality of hardwood flooring manufactured by a Tennessee producer in a 6-month time frame. The hypothesis of the thesis could not be rejected

given the lack of quantifiable evidence in the 6-month time frame. However, there was enough evidence to confirm that if more time was allowed improvements can be made.

There were six research objectives: 1) define the current-state of product variability for the specific attributes of “finished blank” length, width, and thickness and “veneer-slat” thickness; 2) determine the capability of the product attributes “finished blank” length, width, and thickness and “veneer-slat” thickness as related to engineering specifications; 3) determine the current production yield and manufacturing costs associated with the manufacture of “veneer-slats;” 4) define the sources of variability that influence the “finished blank” length, width, and thickness and “veneer-slats;” 5) recommend to senior management the improvements necessary to enhance the overall quality of “veneer-slat” and; 6) if any of the recommendations were adopted from objective five, the first four objectives would be repeated to determine if the quality of the product attributes improved. Four of the six objectives were completely satisfied. The sixth objective was not satisfied because of a senior management change, which did not support the study. The “Six Sigma” philosophy strongly emphasizes the importance of senior management support for continuous improvement.

All of the objectives were satisfied except objective six. In regard to objective one the current state of product variability was defined. For each product attribute and each species there was, in some cases, a significant difference from month-to-month for the medians indicating the process location was not stable. Objective two was satisfied when the capability indices were defined for each product attribute. The capability analysis indicated that the manufacturer was not capable of meeting product specifications. There was only one case out of 405 opportunities for all species and

product attributes where the process variability was within specification. This resulted in product being produced outside of specification limits, which resulted in excessive sanding or defective product. Objective three was completed when yield statistics were developed for the product attributes and species studied. Additional analysis as related to objective three indicated that approximately 20% of the rejected "veneer-slats" were good, and 10% "veneer-slats" were usable or "down-gradable." The cost of rejecting good or "down-gradable" "veneer-slats" was approximately \$500,000 per year. Significant sources of variability were defined in objective four. Top and bottom "veneer-slat" thickness represented most of the variation in total "veneer-slat" thickness variation. There was a greater correlation present between "finished blank" thickness and top and bottom "veneer-slat" thickness than the thickness of middle "veneer-slats." Moisture content had the largest influence on "veneer-slat" width. Most of the measurement error was due to appraiser error. It was determined that an 8% yield increase for incoming lumber may be obtained by lowering the target and saw kerf for the "rip" width. The fifth objective was completed when recommendations were made to senior management on April 11, 2001. No recommendations were adopted by senior management given a management change and the senior management's unwillingness to continue the study.

Support of senior management is essential for the survival of any quality improvement initiative. The thesis was evidence of the importance of management support. For future studies on this topic it is advised that the researchers have strong support from senior management. In this study good relationships were maintained with

the company, but a change in senior management resulted in a redirection of company quality initiatives.

The thesis has demonstrated that no risk investments in continuous improvements may result in cost savings of almost \$1,000,000 per year. The "Six Sigma" philosophy provides forest products manufacturers with an accepted and structured framework for continuous improvement.

*Blank cell indicates no data was available.

** Statistics in parenthesis were estimates that were taken as part of a sampling study.

*** Rows with dissimilar letters have significantly different medians at an $\alpha=0.05$, i.e., "a" is for January-2000 and is compared with each month thereafter, "b" is for February-2000 and is compared with each month thereafter.

Appendix C

(Graphs 1c to 9c)

Graph 1c. Capability indices for "finished blank" length for target length 215 mm.

Note: C_p , C_{pk} , or C_{pm} value equal to 1 indicates process is capable.

Graph 2c. Capability indices for "finished blank" length for target length 270 mm.

Note: C_p , C_{pk} , or C_{pm} value equal to 1 indicates process is capable.

Graph 3c. Capability indices for "finished blank" length for target length 325 mm.

Note: C_p , C_{pk} , or C_{pm} value equal to 1 indicates process is capable.

Graph 4c. Capability indices for "finished blank" width for target length 215 mm.

Note: C_p , C_{pk} , or C_{pm} value equal to 1 indicates process is capable.

Graph 5c. Capability indices for "finished blank" width for target length 270 mm.

Note: C_p , C_{pk} , or C_{pm} value equal to 1 indicates process is capable.

Graph 6c. Capability indices for "finished blank" width for target length 325 mm.

Note: C_p , C_{pk} , or C_{pm} value equal to 1 indicates process is capable.

Graph 7c. Capability indices for "vener-slat" thickness for target length 215 mm.

Note: C_p , C_{pk} , or C_{pm} value equal to 1 indicates process is capable.

Graph 8c. Capability indices for "veneer-slat" thickness for target length 270 mm.

Note: C_p , C_{pk} , or C_{pm} value equal to 1 indicates process is capable.

Graph 9c. Capability indices for "vener-slat" thickness for target length 325 mm.

Note: C_p , C_{pk} , or C_{pm} value equal to 1 indicates process is capable.

VITA

Thomas N. Williams was born in Corning, New York on February 10, 1975. He attended a boarding school in Mercersburg, PA, graduating from The Mercersburg Academy High School in June 1994. He entered the University of Tennessee in June, earning a Bachelor of Science in Forestry with a concentration in Wood Utilization. In August of 1999, he entered the masters program in Tennessee Forest Products Center at the University of Tennessee. He graduated with a Masters of Science in Forestry with a minor in Statistics and a concentration in wood utilization and management. Upon graduation he started working with Georgia-Pacific Corporation working as a Quality Control Manager in Oxford, Mississippi.
