Abstract

Keratin has been gaining wider acceptance as an efficient biomaterial for application in various sectors. The extraction and degradation process of keratin is the primary and significant aspect of keratin utilization as a biomaterial. This review comprises sustainable degradation of keratin via microbes, fungi, and green solvents, followed by sustainable extraction of keratin, and lastly, the applications of keratin in several areas have been discussed. RCS6 a yeast strain, *Fusarium* species 1A, *Bacillus* species 8A6, *B. subtilis* 8 are the microbes, while NMMO a sustainable solvent are discussed for degradation of keratin. Further, Green phenomenon to extract keratin proteins are with liquid deep-eutectic solvent (urea-sodium acetate), keratin regeneration via sustainable solvent composed of L-cysteine and lactic acid, sustainable medium of the hydrated ionic solution to extract keratin, efficient extraction of keratin via choline chloride and oxalic acid, and keratin extraction via novel ultrafiltration process is mentioned as sustainable keratin extraction processes. Lastly, the possible and potential applications of keratin in areas of bioplastics, cosmetics, tissue engineering, drug release, wound healing, and other industries have been discussed.

Keratin · Keratinase · Extraction · Applications · Bioplastics · Biomedical

Introduction

Keratins are abundantly available and insoluble structural proteins exhibiting high levels of cross-linking, which are the major constituents of strong tissues, like a feather, wool, horn, nail, hair, etc. (Bhange et al. 2016). Since keratin is a naturally derived polymer and possesses physiological characteristics like biocompatibility, toughness, biodegradability, cell proliferation, and attachment thereby suggesting keratin as a potential biomaterial for several applications in tissue engineering, bio-packaging, cosmetics, and industries, etc. (Placone et al. 2017; Aggarwal et al. 2020; Singh et al. 2022; Kakkalameli et al. 2022). The keratin waste is a prominent resource for renewable raw substances, as discarded organic waste material derived from poultry feathers, hair, horns, discarded wool, and keratin waste from leather/textile industries accounts for five million tons of waste at annual basis which can be considerably utilized to develop environment-friendly biomaterial with preferable applications in various fields (Wang et al. 2016a; Sharma et al. 2017; Sharma and Gupta 2016) (Fig. 1). The extraction of keratin is the primary and essential step for the employment of keratin as a biomaterial (Kamarudin et al. 2017; Kumawat et al. 2022). Alkaline extraction, ionic liquids, oxidation, reduction, and DES are some of the prominently used keratin extraction techniques. The keratin extraction via alkaline method requires more quantity of alkaline reagent to neutralize acid thereby influencing the content of amino acids leading to decreased keratin yield. The

Fig. 1 Sources of keratin

reduction method on the other hand preserves the keratin chain framework but exhibits noxious and harmful effects. The oxidation process is convenient to conduct but partial oxidation of cystine to cysteic acid occurs by performin or peracetic acid. Ionic acids and DESs are sustainable solvents demonstrating eco-friendly properties with the relevance of a good yield of keratin (Zhang et al. 2021). DESs have to gain more popularity in comparison to ionic liquids as the ILs have few drawbacks like longer dissolution time, low solubility, high price, etc. (Zhang et al. 2021). Various DESs utilized for keratin extraction are, viz., urea-sodium acetate (90% wt.) in 2:1 molar ratio (Nuutinen et al. 2019), lactic acid, L-cysteine (Shavandi et al. 2021), hydrated ionic solution (Singh and Prasad 2019), and choline chloride and oxalic acid. Other sustainable approaches for keratin extraction were novel ultrafiltration phenomenon (Cassoni et al. 2018). Moreover, keratinolytic microbes, as well as sustainable solvents (NMMO) (Ma et al. 2017), have been reported for the biodegradation phenomenon of the keratin protein so as to reduce the keratin waste and also to remarkably degrade keratin at a large-scale (Gupta et al. 2022a). The extracted and degraded keratin can be possibly employed for applications in the fields of bio-packaging, tissue engineering, agriculture, cosmetics.

Structure, Classification and Properties of Keratin

Keratin is grouped into two categories, viz., β -keratin mostly present in feathers and epidermis and α -keratin mostly present in hair (Deb-Choudhury et al. 2016). The keratin is composed of long amino acid polymerized chains. The β - sheets and

α -helix structures occur because of continuous twisting of polypeptide chain backbone owing to hydrogen bonds between amino groups and carboxyl groups within the peptide chain (Shah et al. 2019). The polypeptide chains in α -helix forms hydrogen bonding with maximum possible interactions between amino groups of one amino-acid and the carbonyl group of another amino-acid. The α -helix structure exhibited a molecular weight of 40 kDa–68 kDa and a diameter of 7 nm–10 nm (Wang et al. 2016b). While β -sheet structure exhibits inter-molecular hydrogen bonds between the amino and carbonyl group and has a molecular mass around 10 kDa–22 kDa with a diameter of 3 nm–4 nm (Chen et al. 2012). Keratin protein is a polypeptide molecule composed of several amino acids having inter-molecular bonding of disulfide-cysteine amino acids along with intra-/inter- molecular bonding of polar and non-polar acids. Keratin are water in-soluble as well as in-soluble in various weak alkaline, acids solutions and organic solvents with resistance to protein-digesting enzymes (trypsin or pepsin). Keratin has low contents of methionine and histidine while have high contents of proline, serine, cystine, and glycine with no or few traces of tryptophan. The cystine significantly specifies the physiochemical properties exhibited by the protein. In comparison to other proteins, keratin have lower solubility and higher stability owing to intra- and inter-chain cysteine disulfide cross-links. Also the other bonds like, ionic, hydrophobic, and hydrogen bonds play a vital part in the properties and stability of keratin. The availability of ionic bonds is dependent on the pH and is significantly high at isoelectric-point ($\text{pH} = 4.9$) which is the zwitterion form of protein ($+\text{H}_3\text{N}-\text{CHR}-\text{COO}-$), whereas under extreme basic and acidic conditions, lowest levels of ionic bonds are present. As a result ionic bonds get reduced via carboxylic groups protonation at lower pH value as well as amine group deprotonation at higher pH value. On the other hand, disulfide bond gives keratin higher resistance toward enzymatic and chemical reactions and provides compact 3-dimensional composite. Based on sulfur content keratin can be soft (50–75% moisture and 2% sulfur) or hard (4–8% sulfur) (Shavandi et al. 2017). As a result, the keratin as a component offers remarkable parameters to be employed as an efficient biomaterial.

Biodegradation of Keratin via Sustainable Approach

The keratinases are peptidases that exhibit the property of keratin degradation and have been prominently described for various bacterial species (Daroit and Brandelli 2014) as well as for dermatophytic fungal species (de Medeiros et al. 2016). One such example of fungal keratin degrading species is anamorphic basidiomycetous yeasts of the *Trichosporon* genus. The availability of keratinolytic species in the tannery waste exhibits significant potential for the bioremediation of contaminated water and soil as well as acts as a resource for efficient biodegradable enzymes to lessen and dehair the effect of the tannery phenomenon (de Medeiros et al. 2016). de Medeiros et al. conducted research to extract and examine keratinolytic yeasts that generate enzymes that can possibly replace a few chemicals reagents utilized for the tanning process during leather production. RC-S6 a yeast strain was putatively

recognized as a strain of *Trichosporon* Loubier on the basis of ribosomal and biochemical DNA analyses (de Medeiros et al. 2016). The strain generated sulfide and rapidly degraded nail keratin at a rate of 193.3 U ml^{-1} . Moreover, gelatinase and keratinase examination demonstrated that the enzymes released via RC-S6 preferably degraded keratin and sulfitolysis is an essential phenomenon for the better action of keratinases/peptidases over keratin filament (Cedrola et al. 2012). Thus, the keratinases from RC-S6 strain have potential abilities for keratin degradation. The keratin waste hydrolysis via microbes is regarded as a good biotechnological alternative to valorization and recycling (Lange et al. 2016). In spite of the resistant structure of keratin wastes, it can be efficaciously degraded with various microbes via keratinase secretion, which is a promising enzyme for different applications and operations such as fertilizers, detergents, and textile and leather industries (Brandelli 2008). With the approach to separate keratinolytic microbes which can possibly reach the commercial application as keratinase producers, Calin et al. assessed the dynamics and phenomenon of the keratin biodegradation with various strains of keratinolytic fungus separated from the soil sample (Călin et al. 2017). The capability of the fungal species to bring about keratin degradation was estimated by Fourier Transform infrared spectroscopy, i.e., FTIR, Scanning Electron Microscope, i.e., SEM, and the thermogravimetric analysis, i.e., TGA. The observations via SEM revealed information about the interactions between structural composites of hair filaments and microbes. On the other hand, FTIR bands spectra at $1035\text{--}1075 \text{ cm}^{-1}$ brought about the appearance of sulfoxide bonds owing to the breaking of S-S bonds, which showed the initiation process of keratin protein biodegradation. As per the TGA analysis, in the zone second of the thermal denaturation, i.e., during keratin degradation, the specimen incubated in *Fusarium* species 1A exhibited the most loss of weight of 71.10%. Therefore, among the strains examined, *Fusarium* species 1A was significantly the most powerful organism during the degradation phenomenon with the active denaturation process of the polypeptide chains. Thereby, *Fusarium* species 1A was chosen as the efficient keratinolytic microorganisms with economic and scientific capabilities (Călin et al. 2017).

The first *Bacillus* sp. with the capability of degrading keratin was isolated by Molyneux (Molyneux 1959). The *Bacillus* species like *B. cereus*, *B. licheniformis*, and *B. subtilis* are commonly known organisms for their keratinolytic abilities (Huang et al. 2020). Huang et al. studied the efficiency of *Bacillus* species 8A6 as a keratin degrader and belonged to the *Bacillus pumilus* species (Huang et al. 2020). On the basis of the comparison between the whole genome, *B. 8A6* was significantly related to the *Bacillus safensis* which also has been reported to exhibit keratin degradation properties. The *B. 8A6* exhibits the parameter of degrading keratin present in feathers after the growth period of 24 h. Moreover, *Bacillus 8A6* culture broth's proteomic examination demonstrated more availability of proteins exhibiting peptidase activity functions. *Bacillus 8A6* showed the expression of a dipeptide, five proteases, and four oligopeptide binding proteins. Furthermore, the keratin of hooves, bristles, and feathers is rich in cysteine-related re-calcitrant protein system (Huang et al. 2020). After the degradation process of hooves, bristles, and feathers via keratinolytic proteases, the resultant oligopeptide which is cysteine-rich can be

preferably used for the generation of glutathione and the glutathione can be hydrolyzed into cysteine-glycine and glutamate which can be directly used by the cells of microbes (Huang et al. 2020; Strasser et al. 2015). Thereby it was reported that along with the T3, M12, and S01A families of bacterial proteases, the S08 family is also involved in the keratin degradation process (Huang et al. 2020). Likewise, He et al. reported the process of keratin degradation via *B. subtilis* 8 (He et al. 2018). The microbe degraded the keratin after a time duration of 48 h. The cystathionine gamma-synthase produced by *B. subtilis* 8 degraded the keratin present in the feather. The percentage degradation of the feather was estimated through weightlessness. The feathers residues in the media following the fermentation process were filtered via speed-filter paper (He et al. 2018). The Keratinase (Gradišar et al. 2005), i.e., KT, disulfide bond-reducing (Prakash et al. 2010) (DRT), and feather weight-loss, i.e., FWS enzyme activities were estimated after fermentation process for 12 h, 24 h, 36 h, 48 h, 60 h, and 72 h. All the three parameters progressively enhanced after 36 h of the fermentation process and couldn't be spotted by naked eyes. FWS attained the maximum value of 83.7% after 60 h of fermentation, thereby indicating complete degradation of feather via *B. subtilis* 8 while the KT attained maximum value at 48 h of 21.6 U/ml. The DRT values attained maximum value at 24 h of 17.4 U/ml. The barbules were degraded completely, leaving behind the feather shaft and residual pinnule after 24 h of fermentation. Moreover, significant feather shaft degradation was observed after 32 h of incubation. After a duration of 48 h, the structure of the feather shaft initiated to collapse with proper and complete degradation at 48 h. During the process of fermentation, 17 amino acids, involving 5 essential amino acids, were generated in the suspension. The concentration estimated for all-total amino acids was around 34.189 nmol/ml (He et al. 2018). Thus, *B. subtilis* 8 can be significantly employed for keratin degradation even at a large scale. An environment-friendly mode of keratin extraction was offered by Ma et al. through the utilization of N-methyl-morpholine N-oxide, i.e., NMMO, a sustainable solvent (Ma et al. 2017). The authors added and dissolved feathers into 50% of NMMO at 110 °C under the influence of mechanical agitation provided with decreased distillation pressure. The feather progressively dissolved after the removal of 100 g water, which signified that the feather could be perfectly dissolved into 75% NMMO suspension. The dissolution phenomenon is eco-friendly and efficacious in comparison to oxidation and reduction processes which involve more use of chemical reagents. The addition of extra water increased the dissolution of keratin as water acts as an anti-solvent for keratin. Further, precipitation of keratin was brought about by the addition of HCl after the centrifugation process. The cross-linkages along with disulfide bonds were ripped during keratin degradation at 100 °C which possibly degraded in to water-soluble polypeptide which was supported by the analyzed outcomes of size-exclusion HPLC for filtrate and amino acid examination where the estimated amount of polypeptide and cystine infiltrate was around 63.7% and 0.34%, respectively (Ma et al. 2017). Thus, NMMO suspension can be considerably utilized as a green solvent to degrade as well as extract keratin proteins from feathers (Fig. 2).

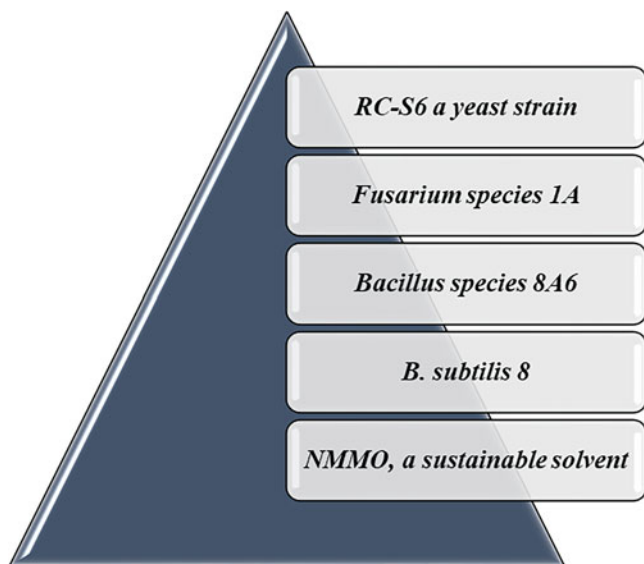

Fig. 2 Discussed biodegradation approach for keratin protein

Extraction of Keratin

Green Phenomenon to Extract Keratin Proteins with Liquid Deep-Eutectic Solvent (Urea-Sodium Acetate)

A huge amount of feathers in form of waste are generated in the poultry industries which are re-cycled, incinerated, or dumped in landfills (Nuutinen et al. 2019). However, the green extraction of protein, i.e., keratin from the feathers provides a more convenient and sustainable approach toward the handling of the disposed feathers. Deep-eutectic solvents or DESs provide a green platform to extract keratin protein from the feathers. Abbott et al. primarily presented DESs as a cost-effective and convenient alternative to ionic liquids (Abbott et al. 2004). DESs possess the properties such as biocompatibility, biodegradability, and non-toxicity which enhances its use as a green solvent to extract keratin. The DESs are acquired when the constituents are mixed properly in the appropriate molar ratio via which the system attains its least melting point (M.P.). The M.P. is decreased owing to the interactions between constituents via hydrogen bonds which reduces the system's lattice energy (Dai et al. 2013). In general, DESs are made of solid constituents which altogether developed a mixture having lower M.P. in comparison to individual constituents (Smith et al. 2014).

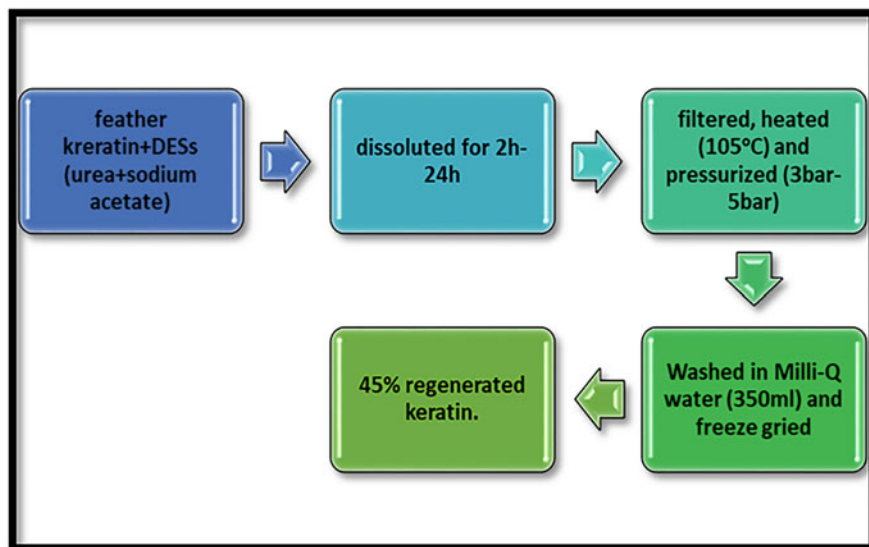

Fig. 3 Green phenomenon to extract keratin proteins with liquid deep-eutectic solvent (urea-sodium acetate)

Nuutinen et al. proposed the use of DESs to process the feathers with a liquid DES solvent to generate uniform feedstock of keratin (Fig. 3) (Nuutinen et al. 2019). The utilized DESs consisted of urea-sodium acetate (90% wt.) in a 2:1 molar ratio. Following the treatment with DESs, water was utilized to dilute constituents of DES and thereby revive a dissolved form of keratin. The optimum conditions for processing were based on the yield of keratin and properties with varied timings of dissolution varying between 2 h and 24 h with temperatures between 80 °C and 100 °C. Moreover, thermal specifications of the utilized DES were obtained by using thermogravimetric analysis and differential-scanning-calorimetry. The 6-h dissolution time led to the 45% regeneration of the yielded keratin and caused 86% of feathers to be dissolved. The regenerated keratin via the experiment predicted that a higher dissolution temperature as well as longer dissolution time, decreased the total content of sulfur and disulfide with increased ranges for molecular weights while the crystallinity and few ordered secondary systems were lost. The structural variation of the re-generated keratin and dissolution of the keratin occurred owing to the capability of liquid DES to alter the interactions in the keratin of feather causing the cleavage of disulfide bonds as well as partially breaking keratin's polypeptide backbone. Thus, the characteristics and yield of keratin can be preferably optimized by tuning the molar ratio and dissolution parameters of the DES (Nuutinen et al. 2019).

Keratin Regeneration via Sustainable Solvent Composed of L-Cysteine and Lactic Acid

Production of waste wool accounts for approximately >10,000 tons annually (Shavandi et al. 2021). The waste wool is composed of 95% keratin by weight (Su et al. 2020) which can be regenerated conveniently by using sustainable solvents like L-cysteine and lactic acid. L-cysteine was used as a sustainable reducing agent by Wang et al. for dissolution of wool in which L-cysteine was combined with concentrated urea solution of 8 M, with pH value >10 by utilizing NaOH, resulting in 72% dissolution after heating for 5 h at 75 °C (Wang et al. 2016a). Lactic acid, on the other hand, makes the stratum corneum soft in order to absorb polar groups exhibited by chains of keratin and further decrease interactions between the chains without enhancing the content of water within the stratum corneum (Shavandi et al. 2021).

Shavandi et al. employed a novel sustainable solvent composed of lactic acid and L-cysteine to regenerate keratin from wool (Fig. 4) (Shavandi et al. 2021). Primarily the authors defatted wool via Soxhlet extraction by using hexane/dichloromethane v/v in a 1:1 ratio for a time period of 16 h. Then 0.4 g of defatted and dried wool was combined and treated with 2 g of L-cysteine and 20 mL of lactic acid at 95 °C for a time period of 3.5 h. The sustainable solvent destabilized the macromolecular systems by losing intra and inter molecular forces and breaking of disulfide bonds enhances the dissolution and extraction of keratin from the wool without any damage to the peptide bonding (He et al. 2020). Moreover, the strength and stiffness of wool are because of various inter- and intramolecular bonds of disulfide owing to more

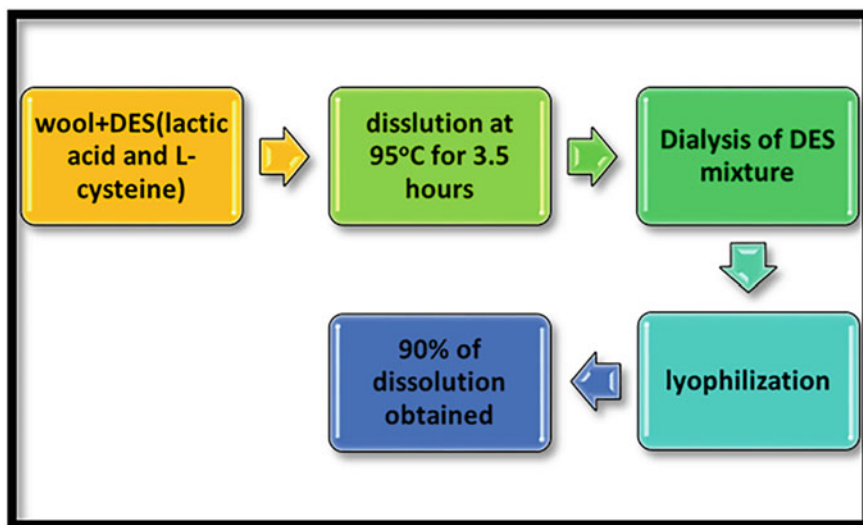

Fig. 4 Keratin regeneration via sustainable solvent composed of L-cysteine and lactic acid

amount of cysteine residues within the polypeptide backbone. Heating of wool in the availability of lactic acid causes the crystalline compact system of keratin to denature thereby leading to the formation of an amorphous structure with softened and swollen wool which enhances the penetration power of L-cysteine as well as leads to the exposure of disulfide bonding toward L-cysteine which subsequently decreases disulfide bonds and increases wool dissolution. The regenerated keratin exhibited β -sheets while the α -helix disappeared. Furthermore, keratin was extracted after the dialysis process of the sustainable solvent followed with lyophilization. Also, by employing the combined mixture of L-cysteine and lactic acid didn't require regularly used chemicals like sodium hydroxide, urea, and sodium sulfite. However, the solubilization phenomenon of keratin still requires optimization for processing parameters like ratio of liquid to solid, time and temperature for processing. Thus, lactic acid and L-cysteine mixture can be preferably utilized as sustainable solvent for the regeneration of keratin protein without the loss of peptide chains (Shavandi et al. 2021).

Employing Sustainable Medium of the Hydrated Ionic Solution to Extract Keratin

The ionic liquids or ILs are one of the convenient and suitable solvents for processing different biopolymers such as proteins like keratin (Schröder 2017). ILs are standardly utilized to produce various chemicals and to treat lignocellulose biomass. The treatment of lignocellulose biomass led to the high production of glucose (Xu et al. 2016). The imidazolium composed ILs have been reported to be used for keratin dissolution at a high temperature of 130 °C and longer time duration. On the same line, 1-butyl-3-methyl-imidazolium chloride composed ILs was employed for the dissolution of keratin present in human hair. Likewise, dimethyl phosphate composed ILs efficiently extracted keratin from wool at a reduced dissolution time duration (Singh and Prasad 2019).

Singh et al. compared the activity of dissolution among three different aqueous ILs: tetrabutyl ammonium bromide, i.e., TBAB; tetrabutyl ammonium acetate, i.e., TBAA, choline hydroxide; and tetrabutyl ammonium hydroxide, i.e., TBAH, all in the same proportions in water (Fig. 5) (Singh and Prasad 2019). The authors observed that TBAH solubilized 25% (w/w) of the human hair, choline hydroxide solubilized 10% (w/w) of human hair, while the other ILs didn't solubilize the human hair at room temperature. Moreover, the dissolution of human hair with TBAH for 9 h caused the complete dissolution of human hair and didn't show the availability of insoluble fibers of human hair when the aliquots were observed under optical light microscopy. Further, the water was evaporated from the solution containing keratin to get a viscous suspension, and acetone addition to the suspension caused the precipitation of opaque or white-colored crude keratin. The extracted keratin was separated via centrifugation process and then washed with the acetone solution and finally placed in a desiccator under decreased pressure conditions in order to procure dry keratin powder. The IL which was left behind following the

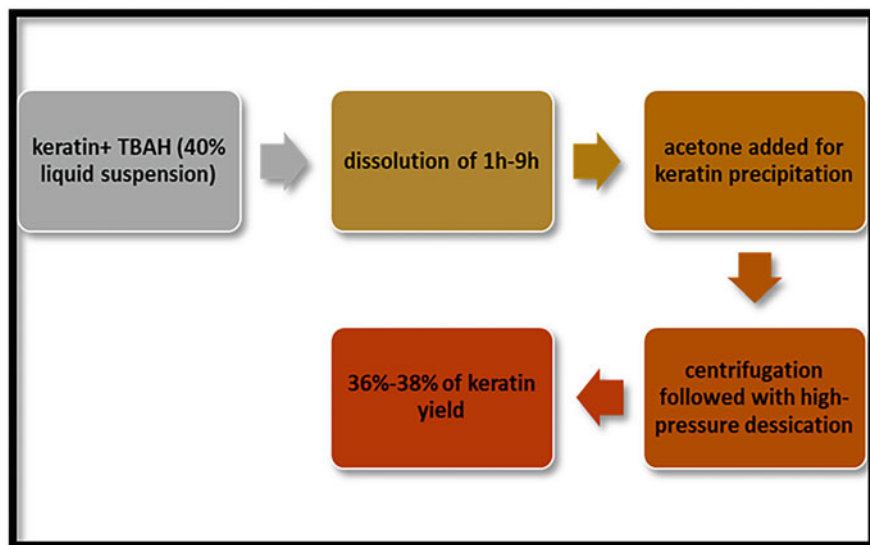

Fig. 5 Employing sustainable medium of the hydrated ionic solution to extract keratin

separation of protein demonstrated a good amount of nitrogen which could be utilized to fortify an aqueous seaweed plant bioreactor that exhibits low nitrogen concentrations. Furthermore, The, α - helix structure and β -sheet structure of keratin protein of human hair were not altered following the regeneration of keratin thereby indicating stability exhibited by the keratin structures even after dissolution within aqueous ILs. The value of E-factor (Paquin et al. 2015) calculated for the keratin regeneration via ILs was 4.25×10^{-2} , which specified that an almost negligible amount of waste was formed during the extraction phenomenon thereby demonstrating the regeneration process via ILs to be sustainable and green in nature (Singh and Prasad 2019).

Efficient Extraction of Keratin via Choline Chloride and Oxalic Acid

The combination of choline chloride, i.e., ChCl, and oxalic acid, i.e., OA, forms an efficient DES system. The DES is particularly a solvent platform prepared through the complexation phenomenon of the hydrogen bond donor and the hydrogen bond acceptors (Abbott et al. 2003). The development process of a DES is important and it is crucial to develop a significant dissolution platform as per the objective and purpose of the required action. When various types of hydrogen donors are attached with the hydrogen acceptors, the efficiency of dissolution exhibited by the DES has also changed accordingly (Zhang et al. 2021). For instance, Wang et al. employed urea, citric acid, oxalic acid, and hexadiol as hydrogen donors and ChCl as a hydrogen recipient to examine the dissolution for the DES developed for the hair

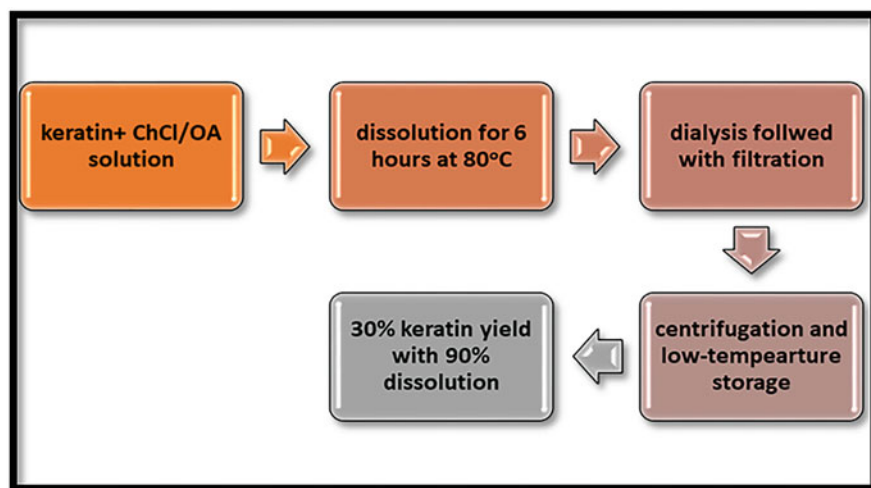

Fig. 6 Efficient extraction of keratin via choline chloride and oxalic acid

of rabbit and concluded that ChCl and OA exhibit the best dissolution effect (Wang et al. 2018).

On the same line, Zhang et al. employed various molar ratios of ChCl and OA to regenerate keratin from feathers (Fig. 6) (Zhang et al. 2021). The authors combined ChCl with OA with a specific molar ratio along with an appropriate proportion of water to develop a dissolution platform. The feathers were completely dissolved into the dissolution platform to procure the extracted keratin, which exhibited water-insoluble and soluble fractions which were segmented via filtration process. The feathers were placed into various dissolution platforms for 4 h at 90 °C to examine the effect of the different compositions of the developed dissolution platforms over the dissolution of feathers. The ChCl/OA molar ratio greatly influenced the dissolution efficacy of the feathers. As, when the ChCl/OA molar ratio altered from 3:1 molar ratio to 1:3 molar ratio, the suspension color intensified progressively from amber color to dark brown color, which can be owing to the liberation of melanin protein between the cellular bodies of feathers cortex at the time of dissolution. Moreover, the rate of dissolution enhanced gradually, which was because of the enhanced concentration of OA within the dissolution platform as well as the increased concentrations of free available hydrogen protons within the platform (Zhang et al. 2021). The free available hydrogen protons could develop strong bonds with amino and imino groups in the keratin, thereby increasing the possibility for large concentrations of OA to be significantly attracted toward protein and consequently deconstructing the feather by breaking the bonds of hydrogen between and within the composites of keratin (Bai et al. 2017). Further, the increased proportions of OA slowed down the enhancement rate of dissolution. The estimated rate of dissolution for ChCl/

OA (1:3) and ChCl/OA (1:2) was 98.75% and 97.89% respectively, with no considerable difference. While, the increased content of OA in DES, increased the acidity of the dissolution platform gradually, which intensified the degradation process of keratin resulting in keratin with less molecular weight. Thus, ChCl/OA with the molar ratio of 1:2 is a more convenient process condition (Zhang et al. 2021).

Keratin Extraction via Novel Ultrafiltration Process

A new environment-friendly process for keratin extraction from hair was developed by Cassoni et al. (Fig. 7) (Cassoni et al. 2018). The authors employed commercially available detergent related to the class of degreasers, capable for efficacious and rapid dissolution of hair, and subsequently followed by a standard filtration process to eliminate residues present from the trimmings of skin with lard and fat (Cassoni et al. 2018). The obtained solution was then processed via ultrafiltration process to attain a suspension with increased purity and protein content. The digestion and cleaning steps at optimized conditions of temperature and time (6 h) with the standard Mistolin solvent resulted in a suspension with nil hair fibers thereby depicting complete dissolution. Mistolin is a biodegradable solvent reagent with biodegradability >90% and is prominently utilized by food-related industries. The resultant final product is turned into brown liquid by the Mistolin with 12.5 pH owing to NaOH; however, products comprising of NaOH do not bear adverse impact over the environment (USEPA 1992). Moreover, the subsequent filtration process removed solid residues and fat present within the digested suspension. Small residues were present in the brown-colored filtered suspension which was eliminated later via centrifugation or microfiltration process

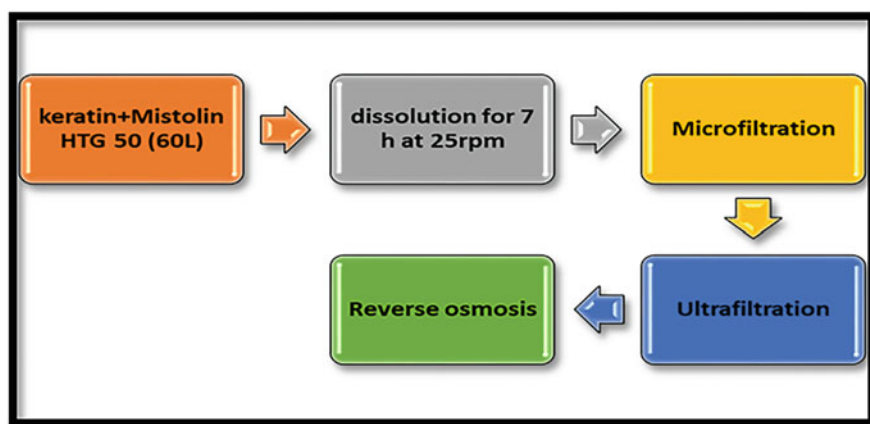

Fig. 7 Keratin extraction via novel ultrafiltration process

while the suspension obtained after the precipitation process was green colored with small residues. Further, the ultrafiltration process executed at the laboratory level gave a satisfactory yield of protein. In addition, executing ultrafiltration at the pilot-scale level produced a decreased protein yield owing to protein loss during the microfiltration method. The utilization of organic membrane can enhance the extraction process of keratin at pilot scale and could possibly be purer in form. The utilization of ultrafiltration method, is an economical membrane separation platform employed to sustain macromolecules, which have more-throughput of product, convenient to level up for industrial generation (Baldasso et al. 2011; Saxena et al. 2009). The membranes of ultrafiltration are reusable thereby decreasing the production cost of keratin. Furthermore, ultrafiltration decreases the time for execution and makes the extraction process convenient as the process can extract keratin within 9 h of duration. Also, solvent recovery is possible as well as significant optimization for the cleaning phenomenon of the solvent could be prepared to eliminate dust particles as a result of the digestion process. Therefore, the standard protocol followed for keratin extraction by novel ultrafiltration method was the digestion of hair (pig) by Mistolin followed by a filtration process, continued with centrifugation at laboratory level and microfiltration at pilot scale level, subsequent treatment under ultrafiltration process with reverse osmosis being optional at pilot scale and ultimately procuring keratin suspension (Cassoni et al. 2018).

Comparison Among the Discussed Extraction Methods

The first method, i.e., Green phenomenon to extract keratin proteins with liquid deep-eutectic solvent (urea-sodium acetate) exhibited 45% of keratin yield with 86% of keratin dissolution after 2–4 h of dissolution process. The next method, keratin regeneration via sustainable solvent composed of L-cysteine and lactic acid demonstrated 90% of keratin dissolution after 3.5 h (a time period less than that of first method) at 95 °C. The third method, employing sustainable medium of the hydrated ionic solution to extract keratin, revealed 36%–38% of keratin yield after 1–9 h of dissolution process but unlike DESs ionic solutions are toxic, expensive, and difficult to prepare. The fourth method, efficient extraction of keratin via choline chloride and oxalic acid depicted 30% keratin yield with 90% dissolution after 6 h of dissolution process at 80 °C. The last method, Keratin extraction via novel ultrafiltration process suggested 50% keratin yield after 7 h of dissolution at 25 rpm. Of all the discussed methods, second process didn't require extra solvents and had less dissolution time for keratin extraction. In case of large-scale extraction process, the ultrafiltration method is the most suitable one with highest keratin yield of 50%. For small-scale keratin extraction L-cysteine and lactic acid can be used owing to less dissolution time and cost-effectiveness (Fig. 8).

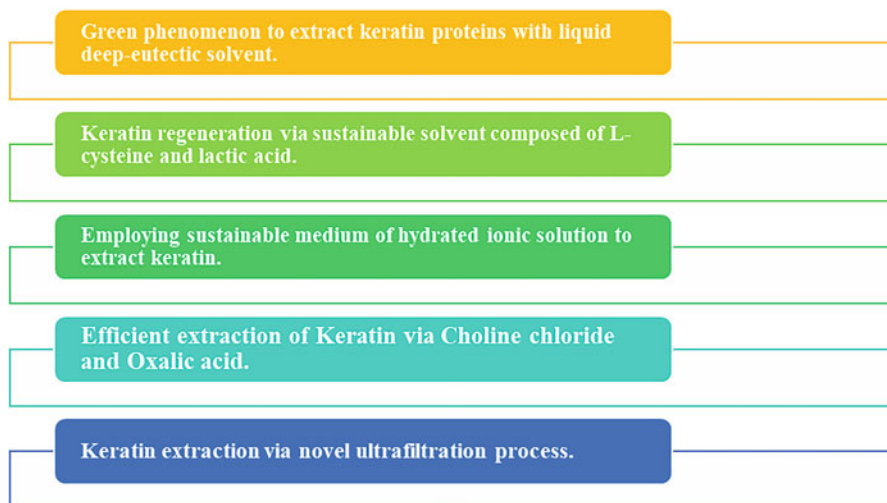

Fig. 8 Discussed sustainable extraction approach for keratin protein

Applications of Keratin

Keratin and Bioplastics

The bioplastics are the perfect alternative to normal plastic composites, demonstrating eco-friendly characteristics. Keratin-based bioplastics are one of the efficient construction materials for the development of bioplastics as employing keratin can lead to decreased keratin waste in the environment and subsequent generation of bioplastics with environment-friendly parameters (Alashwal et al. 2020; Sharma et al. 2018; Gupta et al. 2022b). Various studies have been conducted for developing keratin-based bioplastics. For instance, Dou et al. extracted hydrolyzed keratin feather from chicken feathers by utilizing the economical process of acid precipitation and alkaline extraction equipped with sodium sulfide and urea treatment with the aim of developing and characterizing environment-friendly films dependent over hydrolyzed keratin feathers with different glycerol concentrations via the thermoplastic method (Dou et al. 2016). Glycerol with lower molecular mass and convenient diffusion properties with the polar molecules of protein acts as an efficacious plasticizer for developing protein-dependent materials. The thermal examination revealed that high pressure and high temperature enhanced the relative compatibility between molecules of hydrolyzed feather keratin and glycerol and also that the water addition during the hot-pressing phenomenon of films is a necessary factor. Moreover, the glass-transition temperature of hydrolyzed keratin feather and glycerol mixture reduced as the concentration of glycerol increased which could be because of the development of hydrogen bonds between keratin composites and glycerol, thereby losing internal interactions within the protein matrix. Moreover, the glycerol

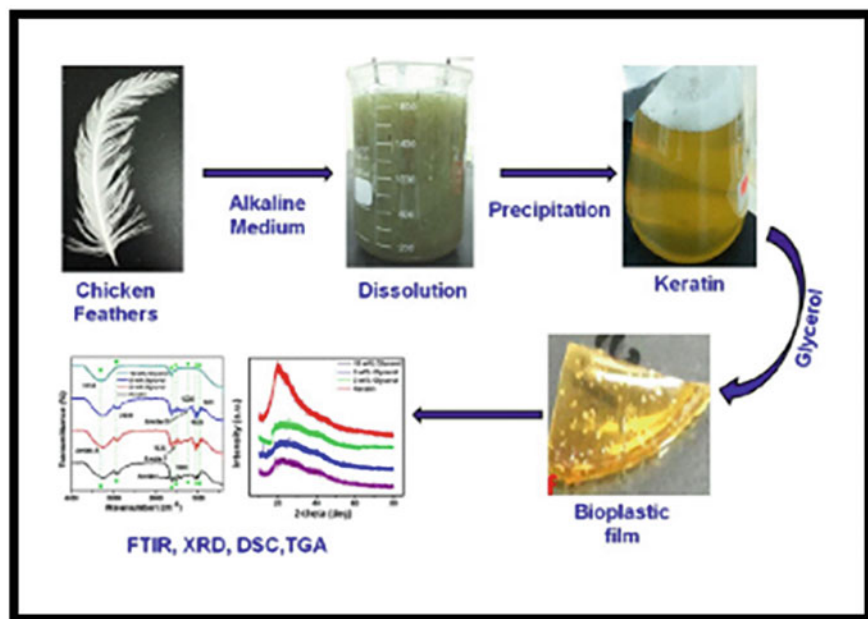

Fig. 9 Graphical representation for the development of keratin based bioplastics (Ramakrishnan et al. 2018)

concentration considerably impacted the water resistance, tensile properties, water barrier factors, and microstructure of the hydrolyzed keratin feather, hence enhancing the commercial applications of the developed bioplastic film (Dou et al. 2016). Similarly, Ramakrishnan et al. synthesized bioplastic by utilizing keratin derived from chicken feathers and treated the extracted keratin suspension with various glycerol concentrations ranging from 2% to 10% (Fig. 9) (Ramakrishnan et al. 2018). The mixture of glycerol and feather was constantly stirred under magnetic stirring for 5 h at 60 °C. Subsequently, the mixture was poured in to the aluminum weighing system and then dried for 24 h at 60 °C in the oven. The bioplastic developed from 2% (wt.) glycerol and keratin mixture exhibited efficient thermal and mechanical characters. The constructed bioplastic demonstrated efficacious compatible structures without holes, cavities, and edges which was confirmed by SEM test. Thus the constructed bioplastic exhibited biodegradable properties with the potential of substituting fossil oil-dependent substances (Ramakrishnan et al. 2018). On the same line, Fernández-d'Arlas reported a new film of bioplastic made of wool keratins developed by protein suspension in a mild alkaline oxidative process that degrades disulfide bonds (Fernández-d'Arlas 2019). The original structure exhibited by the macromolecules of keratin was modified partially upon the extraction as demonstrated by the reduced ratio of α -helices to β -sheets with higher molecular mass fractions which permitted plastic properties of films and film formation. Sodium-dodecyl-sulfonic acid and glycerol were used as a plasticizer

for developing keratin films which provided various hydrophobic properties to the bioplastics. The water concentration within the keratin film depended on the humidity, being capable to absorb water content up to 35 wt. % at 80% of humidity. Also, with spectroscopy, it was analyzed that the developed bioplastic film could absorb UV light, an acknowledged application for packaging. Thermo-mechanical and thermogravimetric analysis showed more stability for keratin composites up to 200 °C with nil inherent thermal transition (Fernández-d'Arlas 2019). Likewise, Sharma et al. extracted keratin molecules to construct a bioplastic by inserting micro-crystalline cellulose acting as a nano additive agent (Sharma et al. 2018). The estimated yield for keratin from 25 g (w/w) feathers was around 80.2%. The keratin powder was mixed with 3.5% glycerol and 0.2% micro-crystalline cellulose in sodium hydroxide at 60 °C at 48 h. The estimated tensile strength and thickness for bioplastic film were 3.62 ± 0.6 MPa and 1.12×10^{-4} , respectively, thereby depicting commercial applications (Sharma et al. 2018). Furthermore, Pulidori et al. fabricated a one pot micro-wave equipped method for environment-friendly extraction of keratin from the feathers waste followed with direct electro-spinning process of extracted raw material, with any further purification processes, to procure keratin dependent bioplastics (Pulidori et al. 2021). The extracted keratin was mixed with gelatin in order to develop keratin-dependent biocompatible and biodegradable bioplastic through electron-spinning, utilizing 3-(Glycidyloxypropyl) trimethoxysilane (GPTMS) as an agent for cross-linking and thereby constructing an efficient bioplastic film with considerable commercial applications (Pulidori et al. 2021).

Keratin and Cosmetics

The application of keratin in form of keratin hydrolysates has attained considerable recognition as a potential cosmetic substrate. Keratin hydrolysates have been widely utilized as a standard constituent in nail and hair cosmetics along with skincare products (Mokrejs et al. 2017). Mokrejs et al. added keratin hydrolysates to the ointment base to understand the effect of keratin hydrolysates as a moisturizer (Mokrejs et al. 2017; Mokrejš et al. 2017). Various formulations were developed containing keratin hydrolysates (2%, 4%, 6%) on the basis of ointment base weight. The moisturizing characteristics of the keratin hydrolysates were examined by estimating a trans-epidermal loss of water, skin pH, and skin hydration. In the case of skin hydration, an ointment base with 2% keratin hydrolysates was optimal, as the elevation of 14–23% occurred in the hydration of the stratum corneum. In the case of trans-epidermal loss of water, an ointment base with 4% of keratin hydrolysates was optimal, as 26–46% of decrease was observed. Keratin hydrolysates bind the water composites at low levels of the epidermis with stratum corneum and thereby act as a humectant as well as is a good occlusive. No phase separation was observed in keratin hydrolysates/ointment base even after the storage time of 6 months, hence depicting efficient cosmetics properties (Mokrejs et al. 2017). Similarly, Barba et al. studied the topical applications for protein (keratin) hydrolysates over skin elasticity,

appearance, feel, and moisturization (Barba et al. 2008). The hydrolyzed peptides of keratin with <1000 Da molecular mass were fabricated from the wool and examined over the skin in two different formulations: an internal wool-lipids liposome solution and an aqueous suspension. Considerable differences were spotted between the treated sites and the control. The treated sites showed an elevation in elasticity and hydration due to the application of keratin peptide. Also, the formulation of keratin reinforced the integrity of the skin barrier and improved skin's water holding ability thereby demonstrating efficacy as a novel cosmetics product (Barba et al. 2008). K31 is type-1 acidic keratin, one of the major proteins present in the keratin complex of human hair and is important to maintain the tensile strength of hair (Basit et al. 2018). Basit et al. expressed the Keratin K31 gene (46 kDa) at a concentration of around 35% of all-total cell proteins in *E. coli* and protein was expressed in form of insoluble inclusion entities (Fig. 10) (Basit et al. 2018). The protein expressed was re-folded and subsequently purified via fast-performance liquid-chromatography utilizing the anion-exchange column. The re-folded and purified keratin31 protein, when used over chemically treated hair, enhanced the hair diameter up to 49%. Also, bleached hair's mechanical strength elevated almost twofold after just a single K31 treatment. K31 efficiently straightened the curly hair after a single K31 treatment for 1 h. K31 application significantly increased mechanical strength, smoothness, and diameter of damaged, harmed hair (Basit et al. 2018). Likewise, Fernandes et al. reported a peptide fragment of a type II keratin circular protein. Keratin protein

Fig. 10 (a) Untreated curly hair, (b) curly hair as control, (c) curly hair treated with K31 (Basit et al. 2018)

exhibits properties as a strengthening agent for relaxed weakened hair (Fernandes et al. 2012). The suspension of the peptide was developed both in organic solvent formulation, i.e., OF and liquid water formulation, i.e., WF to study the difference of action for both formulations in the recovery of hair. Both the formulations of peptides improved thermal and mechanical characters of damaged hair with OF peptides demonstrating the stronger effect. However, while studying the genotoxicity and cytotoxicity impact of the formulations over the skin, it was noted that OF caused irritation over the skin and possessed carcinogenic properties while WF peptides did not exhibit genotoxicity and cytotoxicity at any concentration. Therefore, WF was considered as a potential hair-strengthening agent with non-toxic effects (Fernandes et al. 2012).

Keratin and Drug Release and Tissue Engineering

Keratin exhibits potential application in tissue engineering and delivery of the drug. Various studies have been conducted to examine the potential of keratin as a biomaterial for drug delivery and tissue engineering. For instance, Srinivasan et al. fabricate a porous scaffold of keratin which was developed from a reduced suspension of keratin and showed efficient cell viability property which made it a relevant option for use in the cell seeding process (Srinivasan et al. 2010). A liquid suspension of reduced protein (keratin) was extracted by utilizing urea mixture, mercaptoethanol, water, sodium dodecyl sulfate at 60 °C from the horn meal. The molecular weight estimated for extracted keratin was ranging between 225KDa and 150KDa. The β -sheets and α -helix were confirmed by FTIR and peptide bonding for 1, 2, 3 amides were assigned as absorption bands. Thus, the developed keratin showed capability as a biomaterial for drug delivery and tissue engineering field (Srinivasan et al. 2010). On the same line, Dou et al. developed a blended film comprising of polyvinyl alcohol and feather keratin, cross-linked with dialdehyde starch for considerable drug delivery function (Dou et al. 2015). The cross-linking with dialdehyde starch improved the compatibility of polyvinyl alcohol/feather keratin mixture with a 50% decrease in melting peak and crystallinity of polyvinyl alcohol/feather keratin film. The in-total soluble weight of the constructed film inside the water at 37 °C was less than 35%, thereby depicting better film stability inside water. The release of Rhodamine-B dye tests depicted that the rate of release reduced with the increase in dialdehyde starch content. Hence, the developed film exhibited potential drug delivery parameters (Dou et al. 2015). Similarly, Cui et al. investigated the effect of transglutaminase or TGase over the characteristics of keratin from wool (Cui et al. 2013). The reported film modified with TGase was used for drug delivery and cell proliferation. TGase (30 U/g keratin) treatment at 40 °C for 18 h improved the film tensile strength from 5.18 ± 0.15 to 6.22 ± 0.11 MPa while reducing the break elongation from 83.47 ± 1.79 to $72.12 \pm 3.02\%$. Also, SEM confirmed increased compact cross-sections and a rough surface. TGase modified film showed increased molecular weights of proteins. The diclofenac release results depicted that both the films, i.e., with or without treatment of TGase caused higher

Fig. 11 PHB and PHB-10 k electrospun composite ($p < 0.05$) contact angle (Naderi et al. 2020)

release in PBS while it was relatively constant in case of gastric juice (artificial). The experiments on cell cultures indicated that the keratin films cross-linked via TGase showed better compatibility factor and thereby could be possibly utilized in tissue engineering prospects (Cui et al. 2013). Furthermore, Naderi et al. prepared new biomimetic scaffold comprising of keratin (5–15 wt. %) and poly (3-hydroxybutyrate) or PHB via electrospinning process (Fig. 11) (Naderi et al. 2020). The electrospun scaffolds exhibited 3-dimensional composites with high hydrophilicity and interconnected porosity. The presence of hydrogen bonding between 2 polymers and keratin within electrospun scaffolds was indicated by FTIR. Also, keratin presence within scaffolds increased the thermal characteristics and decreased the crystallinity of the biomimetic scaffold. The scaffolds' tensile strength elevated from 2.29Mpa to 2.92Mpa with the addition of 10(wt. %) keratin. MG-63 cell culture depicted increased proliferation and viability with the addition of keratin composites to the fabricated scaffold. Thus, significant characteristics of the electrospun PHB-10 k scaffold made it a potential substitute biomaterial for the application of bone-tissue engineering (Naderi et al. 2020). Likewise, Kakkar et al. prepared a biomimetic scaffold comprising of gelatin, keratin, and chitosan via freeze drying technique (Kakkar et al. 2014). FTIR revealed that the original structures of each utilized biopolymers were retained in the final product. Differential-Scanning-Calorimetry and TGA indicated increased thermal denaturation temperature of 200 °C–250 °C for the scaffold. Also, the keratin scaffold demonstrated compression strength of 8.5 kPa, water up-take capacity of >1700%, and tensile strength of 96 kPa in comparison to the control (collagen) with good pores interconnectivity and porosity. The cells of NIH-3 T3 fibroblast showed good cell viability for developed keratin scaffolds, hence suggesting potential biomaterial for applications in the field of tissue engineering (Kakkar et al. 2014). A mixture of hydroxycalcite comprising diclofenac and keratin for the purpose of drug release was

presented by Posati et al. (2018). The formulated hybrid film demonstrated increased thermal stability and decreased porosity, degradation, and pronounced swelling in comparison to keratin films (pure) comprising of free diclofenac. The keratin/hydroxycalcite supported fibroblast cells' growth and adhesion thereby indicating promising attributes for applications in drug release systems and tissue engineering (Posati et al. 2018).

Keratin and Wound Healing

Keratin has also demonstrated explicit application in the area of a wound dressing. Several studies have been conducted to employ keratin as a biomaterial for the dressing of wounds (Kumaran et al. 2017). For instance, Lin et al. integrated two types of naturally available polymers, keratin, and chitosan to fabricate a mobile composite membrane through UV irradiation (Lin et al. 2018). The UV-crosslinking process without any use of additional chemical reagents made the development process more relevant by utilizing reducing reactants while avoiding the use of residual noxious chemicals. The composites could possibly perform synergistic operations benefitting from keratin and chitosan as well as including better biodegradability, cell proliferation, biocompatibility, cell adhesion, and mechanical strength. The constructed novel biocomposite membrane could be employed as a wound healing biomaterial (Lin et al. 2018). On the same line, Yuan et al. reported wound healing biomaterial made from nanofibrous PHBV-Keratin composites (Yuan et al. 2012). Primarily the keratin was extracted from raw material and then chemically enhanced to attain stable keratin composite (m-keratin) following this the m-keratin was mixed with poly (hydroxybutylate-co-hydroxyvalerate) or PHBV and consequently electrospun to develop nanofibrous mats. Through 3-(4,5-dimethylthiazol-2-yl)-2, 5-diphenyltetrazoliumbromide, or MTT assay, it was revealed that the addition of keratin increased the cell proliferation mechanism. Also, histological tests and wound-healing examinations suggested that the keratin/PHBV composite mats enhanced recovery of wound significantly in comparison to the control (PHBV) thereby, depicting as a potential candidate for wound dressing (Yuan et al. 2012). Similarly, Yao et al. constricted an efficient two-layered membrane with polyurethane acting as the outer layer while gelatin/keratin electrospun nanofibrous composites acted as the inner layer for the application of wound dressing (Yao et al. 2017). The SEM indicated that the gelatin/keratin composites exhibited uniform morphology with a bead-free system and an average diameter of fiber around 160.4 nm. Also, 3-(4,5-Dimethylthiazolyl)-2,5-diphenyltetrazolium bromide test by utilizing fibroblast cells of L929 depicted that the residual release from gelatin/keratin nanofibrous film enhanced cellular proliferation. Experiments based on cell attachment indicated that the adhered cellular bodies migrated deeper and spread better in to the gelatin/keratin mat in comparison to alone gelatin nanofibrous film. The developed bilayer membrane when treated on animals resulted in the development of more blood vessels and an enhanced reduction at the wound site within 4 days, as well as efficient wound healing at 14 days exhibiting thicker

Fig. 12 Effect of FKDP-AgNP (fur-keratin-derived-powder involving silver nanoparticles) dressing on skin wound healing. Mice-numbers at day five, N = 20; day eight N = 12; day fifteen, N = 6 (Konop et al. 2020).

epidermis layer and increased production of newly developed hair follicles (Yao et al. 2017). Furthermore, Konop et al. studied the potential role of the keratin-based insoluble fur powder comprising of silver nanoparticle or AgNP on full thickness allogenic surgical skin-wound model in a diabetic mice (Fig. 12) (Konop et al. 2020). SEM revealed the presence of silver nanoparticles (single layer) over the keratin surface. Microbiological assay indicated the growth of *Staphylococcus aureus* and *Escherichia coli* to a little extent over keratin/AgNP composite. The in vitro tests revealed that the keratin/AgNP composite does not hinder the growth of fibroblast or initiate hemolysis and in vivo tests utilizing the model of diabetic mice suggested biocompatible characteristics of the developed composite. The AgNP/keratin film considerably enhanced epithelization and wound closure at days five and eight in comparison to control. Histological assays of inflammatory -response indicated that keratin/AgNP treated wounds comprised mainly of macrophages thereby favoring tissue healing and re-modeling. Hence the AgNP/keratin dressing showed considerable wound healing properties (Konop et al. 2020). A novel wound dressing having antibacterial properties was prepared from human hair and carboxymethyl cellulose or CMC with the topical clindamycin release by Sadeghi et al. (2019). Human hair was used for the extraction of keratin and various sponges were developed by altering keratin to CMC ratio which was further compared and characterized. Halloysite nano-tubes were utilized as a carrier material to manage the release of clindamycin. SEM revealed the formation of porous morphologies with inter-connected pores and uniform dispersion of clindamycin-loaded halloysite nano-tubes in the porous frame. The increase in keratin proportions with CMC

hydrogels significantly reduced rate of water vapor transmission to a relevant range and increased the water stability for CMC hydrogels in wound repair. Also, the prepared dressing efficaciously inhibited growth of *S.aureus* after 24 h. The fibroblast culturing over dressing indicated increased proliferation, spreading and cellular attachment with the elevated amount of keratin (Sadeghi et al. 2019). Likewise, Ranjbar-mohammadi et al. produced antibacterial hybrid scaffolds comprising of polyvinyl alcohol/keratin and poly (ϵ -caproactone) for the application in the field of skin regeneration (Ranjbar-mohammadi 2021). The fabricated nanofibers exhibited appropriate mechanical strength and modulus same as natural skin. The scaffold exhibited increased levels of hydrophilic properties thereby improving cell adhesion and enhanced proliferation and growth of fibroblast cell bodies. Thus, demonstrating potential dressing for wound healing (Ranjbar-mohammadi 2021).

Keratin and Industries

The keratin is also widely utilized in industries for various purposes. Research work has been conducted to study the potential of keratin in industries (Vinayak et al. 2022). For instance, Bhavsar et al. studied the characteristics of hydrolyzed keratin, generated with the help of sustainable hydrolysis method, to be utilized as the foaming reagent in the dyeing of foam for wool and cotton fabrics (Bhavsar et al. 2017). The properties such as molecular weight, blow ratio, surface suspension bubble size, and foam stability for hydrolyzed keratin in liquid suspension with dyeing auxiliaries and without dyeing auxiliaries were examined. The dyeing factors like wet pick-up were estimated to recognize the impact over color strength and dye fixation. The properties of foam dyeing were relatively compared with the standard pad-steam method and cold-pad batch for wool and cotton, respectively. The constructed hydrolyzed keratin showed decreased surface tension, better foam stability, and bubble size of 0.02–0.1 mm and 10:1 as blow ratio thereby exhibiting functions as a foaming reagent. The wool and cotton fabrics were dyed utilizing acid and reactive dyes, respectively, over a horizontal padding-mangle. Hydrolyzed keratin acted like a carrier molecule for dye and the phenomenon of dyeing depended on the particular pH of keratin, fiber, and dye solution. Foam dyeing for wool showed more color strength while cotton showed similar color strength in comparison to the conventional dyeing method. The rubbing and washing fastness of wool and cotton foam dyed material was the same as conventional dyed material. The integration of sustainable hydrolyzed keratin generation and its utilization as a biodegradable, environment-friendly foaming reagent in less add-on foam dyeing method resulted in more saving of energy and water with a minimized environment and effluent load (Bhavsar et al. 2017). Similarly, Santha Kalaikumari reported bio-utilization of waste feathers from poultry for keratinase generation and its applicable applications in the leather industry (Santha Kalaikumari et al. 2019). The keratinase was extracted from *Bacillus paralicheniformis*-MKU3, a keratinolytic bacterium from waste feather. Statistical assays were performed to increase the performance of extracted keratinase which subsequently improved

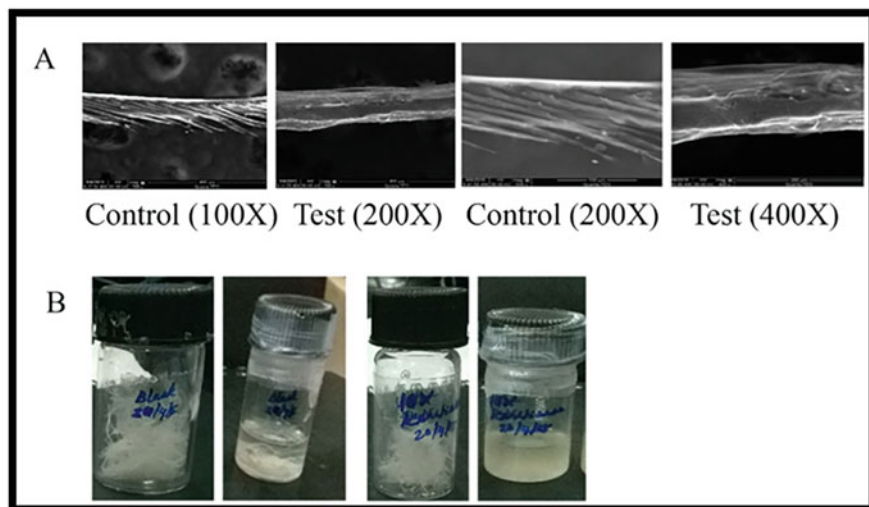

Fig. 13 Chicken feather hydrolysate, Blank 0 h (Feather before water addition), Blank 24 h Feather after 24 h in water (Control), Test 0 h (Feather before Enzyme addition, Test 24 h (Feather after 24 h of the enzymatic treatment) (Santha Kalaikumari et al. 2019)

enzyme activity by sixfold with a maximum yield of 1872.5 U/ml and a specified performance of 1143.19 U/mg in 72 h. The extracted keratinase hydrolyzed 90% of the waste feather and caused 100% dehairing of sheepskin which was confirmed by histochemical assays and SEM (Fig. 13). The processed crust of leather demonstrated efficient histo-chemistry and physical strength (Santha Kalaikumari et al. 2019). On the same line, Zhang et al. isolated keratinase generating bacterium from the duck ranch-soil and classified it as an *Acinetobacter* species R-1 on the basis of 16S rDNA sequence and biochemical properties (Zhang et al. 2016). The extracted keratinase exhibited low activity of collagenase and high activity of keratinase. Also, the keratinase enzyme was purified by electrophoretic homogeneity suggesting 25 kDa ad molecular weight, 2.68 folds purification with 6.69% recovery. The significant keratinase activity was indicated a pH 11, temperature 50 °C, and elemental presence of Li^+ , Ca^{2+} , and Na^+ while decreased in presence of EDTA thereby characterized as Metallo-keratinase. The wool surface was considerably modified and the goat skin was thoroughly depilated by the extracted keratinase, hence suggesting as a potential biomaterial for use in textile and leather industries (Zhang et al. 2016). Furthermore, Niculescu et al. fabricated a biocomposite derived from keratin and collagen retrieved as a by-product from the leather industry (Niculescu et al. 2019). The keratin and collagen were extracted from the by-products of sheep wool and bovine leather and further cross-linked with suitable chemical reagents for decreased environmental impact. The developed biocomposites depicted properties like controlled nitrogen release, pelliculogenic nature, and rape seedlings nutrition, thereby suggesting it as a potential candidate for

agricultural applications while the properties like leather finishing indicated the utilization of developed biocomposite in industries. Moreover, the integration of odorous factors with optimized release demonstrated the eco-friendly property of biocomposite (Niculescu et al. 2019). Hussain et al. fabricated a sponge from the keratin waste and tested it to eliminate chromium traces from wastewater (Hussain et al. 2020). The desorption mechanism revealed that at 10 pH or above, the developed sponge could be re-used with feasible chromium recovery. The continuous flow method and sorption process were carried out to examine the industrial relevance of the sponge. The keratin sponge could be utilized to manage the industrial treatment method as a fix-bed column for the continuous elevation of chromium ions, the elimination results depicted that the keratin sponge could attain 91% of elimination efficiency with 270.27 mg/g as adsorption capacity (Hussain et al. 2020) (Table 1).

Advancement in Keratin-Derived Three-Dimensional Structures

The bio-scaffold printing via three-dimensional method is an acknowledged technique. Three-dimensional keratin scaffolds can be customized and quick to develop thereby suggesting patient-specific medical approach. Various advancements have been witnessed in the development of 3-D keratin scaffolds. For instance, biomaterial based on keratin-lignin biocomposite indicated considerable potential to develop fourth dimensional response following three-dimensional printing (Grigsby et al. 2020). Moreover, digital-light-process/three-dimensional printing-based bioink (four-arm-polyethylene-glycol-acrylate/silk fibroin) printed excellent keratin film and hence depicted a quick printing technique with optimized fabrication of thin large-sized hydrogels multilayers of several designs (Kwak et al. 2019). The fibers generated from the combined composite of poly lactic acid/chitosan/keratin exhibited applications in tissue engineering with applicability in bone regeneration (Rojas-Martínez et al. 2020). The keratin hydrogels composed of hydroquinone-SPS-riboflavin (inhibitor-catalyst-initiator), photo-sensitive suspension demonstrated efficient cell adhesion and migration properties for effective use in the fields of regenerative medicine and tissue engineering (Placone et al. 2017). Therefore, three-dimensional printed keratin scaffolds have undergone various developments with still studies under process for clinical and large-scale applications in various fields, specifically tissue engineering and regenerative medicines.

Challenges and Future Prospects

The main challenge which lies in keratin application is the extraction method. The till-date used extraction methods are non-biodegradable, laborious, and expensive. Though sustainable methods have been proposed but still large-scale employment is under progress. Also, the regular effective use of keratin films in the field of bioplastics, cosmetics, drug delivery, and tissue engineering, wound healing and

Table 1 Discussed applications of keratin

Application	Keratin employed	Substrate	Eco-friendly property	Analyzed parameters/outcomes	Use	References
Bioplastics	Acid precipitation and alkaline: The hydrolyzed keratin	Glycerol concentrations via a thermoplastic method	Yes	Water addition during hot-pressing and glycerol concentration	Agriculture, packaging	Dou et al. (2016)
Bioplastics	Alkaline extracted keratin	The mixture of glycerol and feather	Yes	2% (wt.) glycerol and keratin mixture	Substitute for fossil oil-dependent substances	Ramakrishnan et al. (2018)
Bioplastics	Keratin derived from a mild alkaline oxidative process	Sodium-dodecyl-sulfonic acid and glycerol	Yes	Water content up to 35 wt. % at 80% of humidity, thermal stability(50-200oC)	Regenerative medicine, coatings	Fernández-d'Arlas (2019)
Bioplastics	Alkaline extracted keratin	3.5% glycerol and 0.2% micro-crystalline cellulose in sodium hydroxide	Yes	Tensile strength and thickness for bioplastic film were 3.62 ± 0.6 MPa and 1.12×10^{-4} , respectively	Industries	Sharma et al. (2018)
Bioplastics	Keratin derived from one pot micro-wave	Keratin/gelatin/GPTMS	Yes	GPTMS/keratin concentrations	Purification membranes, bio-packaging	Pulidori et al. (2021)
Cosmetics	Keratin hydrolysates	Ointment base	Yes	2%, 4% of keratin hydrolysates	Skin moisturizer	Mokrejs et al. (2017)
Cosmetics	Keratin hydrolysates	An internal wool-lipids liposome solution and an aqueous suspension	Yes	Internal wool-lipids liposome	Skin moisturizer	Barba et al. (2008)
Cosmetics	Keratin insoluble inclusion entities	K31 gene	Yes	Straightened the curly hair after a single K31 treatment for 1 h and hair diameter up to 49%	Hair treatment	Basit et al. (2018)

Cosmetics	Reported peptide fragment of a type II keratin circular protein.	Organic solvent formulation i.e. OF and liquid water formulation i.e. WF	Yes	WF peptides did not exhibit genotoxicity and cytotoxicity at any concentration.	Relaxed weakened hair	Fernandes et al. (2012)
Drug release and tissue engineering	Reduced suspension of keratin	The porous scaffold of keratin	Yes	Keratin molecular mass 225KDa to 150KDa with the presence of β -sheets and α -helix	Biomaterial for drug delivery and tissue engineering field	Srinivasan et al. (2010)
Drug release	Feather keratin	Polyvinyl alcohol/feather keratin/dialdehyde starch	Yes	Conc. Of dialdehyde starch	Drug delivery parameters	Dou et al. (2015)
Tissue engineering	Wool keratin	TGase	Yes	TGase (30 U/g keratin) treatment at 40 °C for 18 h improved the film tensile while reducing the break elongation	Drug delivery and cell proliferation.	Cui et al. (2013)
Tissue engineering	Keratin powder	PHB/keratin	Yes	Keratin concentration	Bone - tissue engineering	Naderi et al. (2020)
Tissue engineering	Keratin precipitation via SDS	Gelatin, keratin and chitosan	Yes	The scaffold compression strength of 8.5 kPa, water up-take capacity of > 1700%, and tensile strength of 96 kPa	Biomaterial for tissue engineering	Kakkar et al. (2014)
Drug delivery	Sulfitolysis extracted keratin	The mixture of hydrothermalite comprising diclofenac and keratin	Yes	Increased thermal stability and decreased porosity, degradation, and pronounced swelling	Drug release platform	Posati et al. (2018)
Wound healing	Reduced keratin	Keratin/chitosan/UV-crosslinking	Yes	Better biodegradability, cell proliferation, biocompatibility, cell adhesion, and mechanical strength	Wound healing bio-material	Lin et al. (2018)

(continued)

Table 1 (continued)

Application	Keratin employed	Substrate	Eco-friendly property	Analyzed parameters/ outcomes	Use	References
Wound healing	m-keratin	PHBV-keratin composites	Yes	Keratin concentration	Wound healing biomaterial	Yuan et al. (2012)
Wound healing	Acid precipitation of human hair keratin	Polyurethane/gelatin/keratin	Yes	Reduction at the wound site within 4 days, as well as efficient wound healing at 14 days	Wound dressing bio-material	Yao et al. (2017)
Wound healing	Keratin-based insoluble fur powder	Keratin/AgNP	Yes	The AgNP/keratin film considerably enhanced epithelization and wound closure at day five and eight	Wound dressing bio-material	Konop et al. (2020)
Wound healing	Reduced keratin precipitated from human hair	CMC/keratin	Yes	Appropriate keratin concentration	Wound dressing bio-material	Sadeghi et al. (2019)
Wound healing	SDS precipitate wool keratin	Polyvinyl alcohol/keratin and poly (ε-caproactone)	Yes	50:50 ratio of keratin and polyvinyl alcohol	Skin regeneration	Ranjbar-mohammadi (2021)

Industries	Hydrolyzed keratin	Dyeing auxiliaries	Yes	The pH of keratin, fiber, and dye solution	Foaming reagent in the dyeing of foam for wool and cotton fabrics	Bhavsar et al. (2017)
Industries	The keratinase from bacillus paralichemiformis-MKU3	Keratinase	Yes	The extracted keratinase hydrolyzed 90% of the waste feather and caused 100% dehairing of sheepskin	Leather industry	Santha Kalaikumari et al. (2019)
Industries	Keratinase from Acinetobacter species R-1	Keratinase	Yes	The keratinase activity was indicated a pH 11, temperature 50 °C, and elemental presence of Li ⁺ , Ca ²⁺ , and Na ⁺	Textile and leather industries	Zhang et al. (2016)
Industries	Reduced keratin as a by-product from sheep wool	Keratin/collagen	Yes	Keratin/collagen increase biomass by 38% for rapeseed	Agricultural applications and leather finishing	Niculescu et al. (2019)
Industries	Reduced keratin a waste from the leather industry	Keratin/glutaraldehyde/acetone/liquid nitrogen	Yes	10 pH or above, the developed sponge could be re-used with feasible chromium recovery.	Wastewater treatment	Hussain et al. (2020)

industries is under improvement rate. Thereby, specific studies must be conducted so as to develop sustainable, cost-effective, and efficient keratin extraction methods and keratin bio-based films to enhance the versatility of the biomaterial in various sectors, fields, and areas of life.

Conclusion

Keratin is a promising naturally derived protein possessing notable properties which increase its commercial significance. The degradation and extraction of keratin is the primary and important prospect for the employment of keratin as a biomaterial. The discussed microbes (RCS6 a yeast strain, *Fusarium* species 1A, *Bacillus* species 8A6, *B. subtilis* 8) and green solvent (NMMO) suggested efficient and eco-friendly degradation of keratin which preferably could be used for large-scale keratin degradation with a considerable reduction of keratin waste in the environment. Further, the mentioned sustainable solvents, urea-sodium acetate, L-cysteine and lactic acid, hydrated ionic solution, Choline chloride and oxalic acid, and ultrafiltration process demonstrated effective, eco-friendly, and better regeneration of keratin with good keratin yield from the keratinous waste. Moreover, developed keratin films exhibited explicit properties such as cell attachment, biodegradability, cell proliferation, biocompatibility, mechanical strength, increased thermal stability and decreased porosity, degradation, pronounced swelling, better skin moisturizing ability, toughness, etc. which remarkably increase the commercial application of keratin in several sectors. However, sustainable extraction of keratin should be promoted to convert and efficaciously use the keratin waste for developing better keratin films with considerable applications, thereby promoting sustainable development which is the need of the hour.

Abstract

Gelatin, a well-known biocompatible polymer, is a derivative of collagen obtained by the heat denaturation of collagen. The properties of gelatin vary depending on the sources and extraction techniques. Gelatin is remarkably known for its special gel-forming ability, which makes it a suitable material for exploring the fundamental functional features in colloid studies. Gelatin is widely explored by the scientific community because of its unique characteristics and is highly demanded by various industries such as food, pharmaceutical, cosmetic, photographic, etc. This chapter focuses on the various sources, extraction, and properties of gelatin and provide an insight into gelatin in recent applications.

Introduction

The word “gelatin” is derived from the Latin word “gelata.” This refers to the substance’s ability to generate water gels, which is its most unique property (Haug and Draget 2009). One of the most widely used proteins, gelatin, is produced by hydrolyzing collagen, which makes up the majority of the natural components of skin, bones, and connective tissues (Rigueto et al. 2021). It can also be derived through fish and insects in addition to the skin and bones of land animals. It is well known that gelatin has biocompatible and biodegradable properties similar to that of collagen. Gelatin is a fairly common protein that is made by denaturing collagen (Ki et al. 2005). Although collagen and gelatin have approximately the same relative quantities as well as sequencing of the various amino acids, they differ greatly in terms of physical properties.

Collagen is the main component of all white fibrous connective tissues that are present in animal bodies including cartilage, skin, the translucent sheaths that enclose muscles and muscle fibers, as well as ossein. Gelatin is easily dissolved in water, when heated to temperatures exceeding the denaturation temperature of natural collagen, however, collagen is insoluble in water. Under the same circumstances, collagen just contracts and loses its capacity to store water (Gómez-Guillén et al. 2009). At the same time, gelatin displays unique characteristics that collagen either lacks or just slightly develops (Ockerman and Hansen 1999). Due to the presence of both single and double open chains, gelatin has hydrophilic nature (Wittaya 2012). Gelatin expands when submerged in a liquid because it absorbs moisture. The inflated particles melt as the liquid is heated, creating a sol (fluid colloidal system) that thickens as it cools and solidifies to form a gel. At higher temperatures, the gel state can be reversed into a sol state, and the sol can be converted back to a gel through cooling. Temperature, protein, and sugar concentration all influence setting time and tenderness.

In general, depending on how collagen is pretreated, two types of gelatin, viz. A- and B-type gelatin, can be synthesized. Acid-treated gelatin is type A and its isoelectric point is at pH 6–9. The Pig skin’s collagen has a lower degree of covalent cross-linking which on acid treatment can form type A gelatin. The alkaline-treated collagen can be named as B-type gelatin, which has an isoelectric point at pH 5 (Al-Nimry et al. 2021). Type B gelatin can be synthesized from the collagen present in cow skins. Aramwit and Srichana claim that type B gelatin nanoparticles have a higher degree of cross-linking than type A gelatin nanoparticles, which results in a slower rate of disintegration (Aramwit et al. 2015). B-type gelatin nanoparticles have a range of physicochemical characteristics that would allow them to release and interact with different substances that have an impact on these groups. Owing to the

presence of the functional amino acid group, gelatin exhibits an overall amphoteric behavior, having both acidic and basic activities (Su and Wang 2015).

Due to its low cost, abundance, availability, film-forming capacity, flexibility, odorlessness, and capacity to serve as a good carrier, gelatin has come to be recognized as a biopolymer material (Chanchal et al. 2014). The fact that gelatin molecules include both carboxyl and amine functional groups is the first feature of gelatin that all biopolymers share. The second characteristic of gelatin that sets it apart from other polymers is its capability to produce a precise type of triple-stranded helical structure (this structure is formed in solutions at low temperatures). The types of amino acids present and the strength of the gelatin in the solution are only a few of the variables that affect how quickly a helical structure forms. The distinctive interaction of gelatin with water, which is dissimilar from synthetic hydrophilic polymers, is the third feature of gelatin as a biopolymer. This peculiarity controls the solid-state structural and physicomachanical characteristics of gelatin (Lin et al. 2018).

As one of the most adaptable biopolymers, gelatin has an extensive range of uses in food, sweets, medical items, cosmetics, and technical goods. Even before this, gelatin was utilized in cuisine, and scientists have been researching and studying it at least since the early twentieth century. Gelatin is mostly utilized in the solid state, with the exception of the food industry (Karim and Bhat 2008).

However, because to their hydrophilic properties, gelatin-based polymers have some limits in high-moisture environments and perform poorly mechanically. Reinforcing additional materials into the polymeric matrix as composites or nano-fillers is one way to get around these constraints.

Sources of Gelatin

Gelatin is extracted from sources of collagen which are mainly bovine, porcine, fish, poultry, camels, and even amphibians such as frog and salamander (Abedinia et al. 2017; Ahmed et al. 2020; Al-Hassan 2020; Chakka et al. 2017; Jin et al. 2019; Karnjanapratum et al. 2017; Lv et al. 2019; Nik Muhammad et al. 2018; Sultana et al. 2018). Of these, hide from hog is the prominent precursor in the manufacture of gelatin. Pork skin accounts for around 45% of all gelatin produced globally and bovine hides at around 30%. Approximately 23% of gelatin is made from the bones of cows and pigs. Fish and chicken are additional sources; however, they only contribute 1.5% to the annual global gelatin production (Karim and Bhat 2009).

Despite the fact that gelatin has a broad spectrum of uses, some consumers are apprehensive about its consumption and usage. This is primarily attributed to religious sentiments because Hindus are concerned about using bovine meat and bones, while Islam and Judaism condemn the usage of pork-related products (Karim and Bhat 2008).

Concerns regarding probable virus and prion contamination, such as the bovine spongiform encephalopathy (BSE) prion, which caused the human Creutzfeldt-Jakob

Fig. 1 Sources of gelatin

disease (CJD) in the 1980s, are also mentioned in addition to religious considerations (Karim and Bhat 2008).

According to latest researches, fish scales and skin could serve as an alternate resource of gelatin. Since fish skin/scales gelatins have lower gel strengths and melting temperatures than mammalian gelatins, they might be a superior option for some applications. For some food systems, these qualities may be desired since they make it easier for flavors to release, which improves the sensory qualities (Karim and Bhat 2009). Another alternative source of gelatin is insects. Gelatins extracted from *Agonoscelis pubescens* (sorghum bug) and *Aspongopus viduatus* (watermelon bug) were found to be suitable for human consumption and were similar to mammalian gelatins in structure, properties, and uses (Mariod et al. 2011). The various sources of gelatin are depicted in Fig. 1.

Extraction of Gelatin

Hydrolysis of collagen is the most critical and basic step in the course of extraction of gelatin (Baziwane and He 2003). There are five fundamental steps involved in the transformation of raw materials into gelatin: washing, extraction, purification, concentration, and drying (Johnston-Banks 1990). Optimizing the pH, temperature, and extraction time is pivotal since the extraction procedure is intended to produce the highest yield along with the most useful characteristics. Water extractions are carried out thrice or four times at progressively higher temperatures to obtain gelatin. Typical temperatures from 55–90 °C are used for the extractions. Collagen can be hydrolyzed into gelatin by essentially two different methods. One is the acid method,

which mostly uses raw materials like pig skin, sea fish hide, and occasionally ossein. Here, collagen is heated gradually in order to denature and solubilize the collagen into type A gelatin (Reich et al. 1962).

The second method is the alkali process, which is mostly applied to cattle skin (Cole and Roberts 1996). Prior to extraction, collagen is exposed to processing with sodium hydroxide that swiftly cleaves the side chains of asparagine and glutamine, giving gelatin its conventional isoionic point between four and five. This gives type B gelatin (Veis 1964).

To eliminate the suspended insoluble materials such as lipids or unhydrolyzed collagen fibers, the extracted solution of gelatin is subsequently passed filtered using a diatomaceous earth filter. After that, additional refining is done using ion exchange or ultrafiltration columns, which removes inorganic salts and brings the pH level to 5.0–5.8, as required for commercial gelatin. Dehydration (mostly by spray drying), sterilization, and drying make up the last step. To reduce the loss of physicochemical properties of the resulting gelatin, these three-unit operations are carried out as rapidly as possible. The finished product is subsequently put through a series of qualitative analysis tests, including ones for composition, viscosity, bloom strength, and microbiological testing.

Chemical Composition and Structure of Gelatin

Gelatin consists of 18 different amino acid residues having a fundamental repeating unit Gly-Pro-*x*- or Gly-*x*-Hyp, where *x* is a basic or an acidic amino acid. Glycine, proline, and hydroxyproline make up about 56% of the chemical composition of gelatin and glutamic acid, alanine, arginine, and aspartic acid making up the remaining 44% roughly. Glycine or alanine account for approximately 33–50% of amino acid residues. Glycine is the most prevalent N- terminal amino acid in alkali-processed gelatin, whereas alanine is more dominant in the acid-processed one. A 25% of the amino acid residues are proline or hydroxyproline, and nearly 25% is basic or acidic. The lack of the essential amino acid tryptophan and aromatic acid residue in gelatin has been indicated. Figure 2 depicts a typical gelatin structure (Bender et al. 1953; Charley 1992; Cole 2000; Djagny et al. 2001; Loofbourow et al. 1949; Sultana et al. 2018).

Gelatin is a heterogeneous mixture of various polypeptide chains having 300–4000 amino acids. There are α -chains, which are single chains; β -chains, which are two α -chains having covalent bonding between them; and γ -chains which consist of three α -chains having covalent linkage among them and has a molecular mass of around 15–400 kD (Alipal et al. 2021; Bagal-Kestwal et al. 2019). An approximate percentage of the various amino acids in bovine gelatin is given in Fig. 3 (Aykın-Dinçer et al. 2017). Gelatin contains 25.2% O, 6.8% H, 50.5% C, and 17% N (Hanani et al. 2014).

Fig. 2 Basic chemical structure of gelatin

Fig. 3 Approximate percentage of various amino acids in bovine gelatin

Properties of Gelatin

Gelatin, a water-soluble protein, is a hydrolyzed product of collagen. It is generally an odorless, tasteless, translucent, and fragile solid. It appears pale yellow to amber in color (Anding 1951). It is a high molecular weight polypeptide ranging from 15–40 kDa. The molecular weight varies depending on the processing conditions.

The moisture content of gelatin is found to be 8–13%. It has a specific gravity of 1.3–1.4. Gelatin forms swollen particles when soaked in water and dissolves to form solution on warming. Behavior of gelatin solutions is influenced by temperature, pH, ash content, method of manufacture, thermal history, and concentration (Gelatin Handbook 2012). The solubility of gelatin depends on the nature and polarity of solvents. Gelatin dissolves in hot water, and is soluble in aqueous solutions of polyhydric alcohols such as glycerol, propylene glycol, etc. In contrast to less polar organic solvents like benzene, acetone, primary alcohols, and dimethylformamide, it is dispersible in organic solvents with high polarity including acetic acid, trifluoroethanol, and formamide (Gelatin Handbook 2012).

Fish and poultry gelatin have drawn a lot of interest in the past few years. Mammalian and fish gelatins both share similar functional properties. It comes from swim bladder, scales, fins, bones, or skin. Giménez et al. found that adding more gelatin hydrolysates to squid gelatin films decreased pierce force and enhanced water vapor permeability (WVP) (Giménez et al. 2009). According to Haug et al., the main imino acid differential between fish gelatin and its mammalian analogues may be the cause of the lower gelling and melting temperatures as well as the low gel modulus (Haug et al. 2004). In fact, the imino acid level in gelatin varies with the origin of fish. Gelatin derived from warm water fishes like tilapia and bigeye tuna have lower imino acid contents than those derived from cold water (such as halibut and cod) (Eastoe and Leach 1977).

The functional properties like gel strength (bloom index), viscosity, setting behavior, and melting point are related to their molecular weight distribution, amino acid combination, etc. Gelatin having higher levels of amino acids tends to show higher gel strength (in units of bloom) and melting point. Gel strength, also referred to as bloom value, is a measurement of the stiffness and strength of gelatin that takes into account the average molecular weight of its constituents (Haug and Draget 2009). It indicates the resilience of a jelly sample of known strength tested under standard conditions. It typically ranges from 30–300 bloom (below 150 is regarded as a low bloom, between 150 and 220 as a medium bloom, and between 220 and 300 as a high bloom). Greater gelatin strength is indicated by higher bloom values. Gel strength and viscosity are the most useful properties of gelatin which are gradually weakened on prolonged heating in solution above 40 °C. Gel strength depends on the α and β chain components in gelatin. Applications of gelatin is determined by the gel strength. For instance, the confectionary industry uses mainly type B gelatine having gel strengths in the range 125–250. Gelatin with a lower gel strength of 70–90 (type A gelatine) is used for the fining of wine and juice (Wittich 2005). According to Sarbon et.al, gelatin made from chicken skin exhibited more gel strength (355 g) and stability than beef gelatin (259 g) (Sarbon et al. 2013). The amino acid compositions of gelatin vary with the species from which it is derived, as previously described, especially with regard to the amino acids glycine (Gly), proline (Pro), and hydroxyproline (Hyp). With regard to its gelling capabilities, proline and hydroxyproline content of gelatin is mainly crucial. The molecular weight distribution and amino acid composition are the primary elements that affect the physical and structural characteristics of gelatin, as well as the mechanical and

barrier properties of the resultant films. Gelatin films are translucent and have good gas barrier characteristics.

The nature of gelatin, concentration, duration, and temperature have a significant effect on the viscosity of gelatin. The intrinsic viscosity of gelatin processed by acid (type A) and alkali (type B) appears to be slightly different, however there is no discernible difference in their melting points. The setting point of a gelatin solution is determined by its thermal and mechanical conditions. In contrast to brisk cooling, delayed cooling of the solution results in higher setting temperatures. Setting temperatures of gelatin can be hindered or delayed by mechanical agitation (Simon et al. 2003).

Gelatin is a material that is created in powdered or granulated form and has no flavor or odor. It can be utilized as a fastening, gelling, foaming, emulsifying, and film-forming agent. Due to its hygroscopic nature, gelatin will collect moisture based on the humid conditions at which it is dried and kept (Karim and Bhat 2008).

Gelatin is amphoteric in nature, capable of behaving either as an acid or as a base. Isotonic point of gelation ranges from pH 5.0–9.0 depending on the source and manufacturing techniques. Acid-processed type A gelatin has isoionic point ranges from 7–9, and that of type B it is between 4.8 and 5.1. The isoionic point, together with dispersion and gelation, are the most crucial factors in governing how gelatin is used, particularly in the food industry (Kobayashi 1996).

Gelation property of gelatin is not clearly explained until today. Several mechanisms were suggested. The presence of both acidic and basic functional group in the gelatin molecules gives gelatin specific features. It can form triple-stranded helical structure. Another peculiarity of gelatin is its specific interaction with water molecules which governs the structural and physicommechanical properties of gelatin (Kozlov and Burdygina 1983).

Gelatin can dissolve in water at about 35–45 °C and forms gel on slow cooling (Bagal-Kestwal et al. 2019). It is suggested that a several gelatin molecules unite to form crystallites. These crystallites form a three-dimensional network that can immobilize the liquid, converting to a gel. As reported by Ferry, hydrogen bonds and van der Waals forces help to bind the gelatin molecules to form a gel whereas Bello and Vinograd proposed peptide linkage (Bello et al. 1962). The properties of gelatin gels depend on the speed of cooling and degree of acidity. The proper orientation of gelatin molecules on gelation can be achieved during slow cooling. The gel setting time can be prolonged and the liquifying temperature can be lowered as acidity increases. A very low liquifying temperature of about 28 °C is shown by majority of edible gelatin gels (Kobayashi 1996). On heating the gel, it melts and turns back into solution. Thus the sol-gel conversion is reversible and is recognized as thermoreversible gel (Bagal-Kestwal et al. 2019). Gelatin solution can have film-forming ability, when poured evenly on a smooth surface and dried. This property can be made useful in the manufacture of soft and hard capsules and microencapsulation (Bagal-Kestwal et al. 2019). Additionally, gelatin has been said to have antioxidant properties and antibacterial properties. Gelatin was one of the earliest materials employed to transport bioactive components (Gennadios et al. 1994). The ability of gelatin to interact with other substances, especially macromolecules, is of

great implication for explicating its applications in various fields, particularly in food and pharmaceutical industry. The major part of many investigations focuses on the compatibility of gelatin with food components (Djagny et al. 2001).

Applications of Gelatin

Gelatin is a multipurpose natural macromolecule that finds an extensive spectrum of applications such as in food industry, biomedical, photography, cosmetics, environmental applications, and various other applications. An illustration of the various applications of gelatin is given in Fig. 4.

Food Applications of Gelatin

Gelatin is a partly decayed by-product of collagen found in animal connective tissue. It is a white or yellowish, transparent, glossy solid. Due to its functional qualities, such as its capacity to bind water, produce gels, operate as a water vapor barrier, form films, create foam, and have an emulsification propensity, gelatin is generally utilized in the diet, pharmaceutical, photographic, and makeups sectors (Bailey and Paul 1998). Although the gelatin exhibits excellent water absorption and swelling properties, it has poor mechanical resistance and is permeable to water vapor molecules (Xiaoqing et al. 2010). As a result, gelatin's usage as a wrapping material is restricted due to its poor barrier performance (Sazedul et al. 2011). By

Fig. 4 Applications of gelatin. (Images sourced from Internet)

combining gelatin with other useful components and active substances, this can be improved (Rhim et al. 2013).

The creation of safe and sanitary edible coatings and films is currently gaining popularity in food preservation packaging industry, taking into account the influence food safety has on consumer health. Due to their high biocompatibility and consequently increased biological and technological utility, biopolymers are frequently utilized in the food sector to create films and coats.

By causing a thorough or limited flocculation or sedimentation of liquified substances or suspended fragments for turbidity, gelatin is used to achieve the clarity of a solution and the durability of this clarity. Gelatin should only be used for these purposes in drinks and foods that contain tannins. The production of marshmallows, that is a staple of the American diet, also uses gelatin. Gelatin is frequently used in bakery goods as a stabilizing agent or setting agent in pies, breadstuffs, and cakes. Considerable amounts of edible gelatin are used in the meat business, one of the main sources of food, most notably in the production of canned hams, meat jellies, meat loaves, sausages, and cheese.

Due to their significant role in the food sector, the utilization of gelatin in frozen fruit pulp desserts and turkey goods as well as the manufacture of jellied items must be mentioned (Djagny et al. 2001). Due to the excessive protein and amino acid content of gelatin, it is frequently employed as a dietary ingredient and in nutritious foods. Through the use of processing processes such defatting, pulverization, freezing, and drying, edible gelatin is created from animal skin and bone (Fu et al. 2000).

Gelatin has several uses in the food sector due to its distinctive hydrocolloidal structure. These can be categorized into four main groups, including milk products (to provide stabilization), nonveg foodstuffs (to provide water binding), confectionery (primarily for offering texture and lather stabilization), and jelly confectionaries (to provide creaminess, fat lessening, and to make physical sensation in the mouth). Hydrolyzed gelatin applications can also be found in these categories (Nishimoto et al. 2005; Karim and Bhat 2009).

In general, gelatin is employed in cookery as a yoghurt thickener, liquid refreshments and juice clarifier, and dessert thickener. Another usage is as a stabilizer in ice cream and cheese, as well as in food stuffs and fruit salads. Other uses comprise fruit toppings for pastries, quick pottages and soups, and appetizing films for confectionary items (Karim and Bhat 2008). Additionally, gelatin is used to coat beef products to prevent color deterioration; this coating is equally effective when stored in the light or dark (Antoniewski et al. 2007). To contain the liquids lost during cooking and to act as an excellent heat transfer medium, gelatin is utilized in preserved nonveg food stuffs such as red meat, breads, Vienna sausages, and dried, tinned pigs. In addition, gelatin is utilized in creamed meats and gelled goods at quantities extending from 0.5–3 well-designed qualities for use in food applications, gelatin is absolutely extraordinary. Table 1 below lists some of the functional aspects of gelatin in diet (Mariod and Adam 2013; Turner 1988).

Gelatin is compatible with a number of biodegradable polymers that are frequently employed in appetizing coats and films, which are frequently utilized in fresh items and enhance their preservation value. As a result of its special

Table 1 Functional aspects of gelatin

Application	Gelatin function
Gelling agent	Cold meat, sweetmeat, pate, porridge, and gelled desserts
Creaming agent	Chiffons, mousses, soufflés, nougats, marshmallows, and whipped cream
As lyophilic colloid for protection	Ice cream, frosting, and other frozen sweets
Connecting agent	Rolls of meat, canned meats, sweets, cheeses, and dairy goods
Clear up agent	Vinegar, fruit juices, beer, and wine
Binders	Covering for meats and fruits
Hardener	Dairy goods, bouillon, gravies, sauces, soups, puddings, jellies, and powdered drink mixes
Processing aid	Microencapsulation of vitamins, oils, tastes, and colors
Compounding	Cream-based sauces, soups, meat pastes, confections, and dairy products
Preserver	Ice cream, chocolate milk, yoghurt, cream fillings, and cream cheese
Glueying agent	Nonpareils, coconut, and other ingredients to sweets; to bind layers of sweets together; to adhere frostings to baked goods; and to adhere seasonings to meat preparations

antibacterial and antioxidant qualities, it is a useful material for keeping fresh food. Food packaging is severely constrained owing to the high water-soluble and viscous properties of gelatin, which are both strongly influenced by atmospheric humidity and weather. It is challenging to produce the perfect fresh appearance when conserving crops and marine items because the surface structure of gelatin film is damaged when soluble matter and liquid are lost.

In order to overcome the fundamental disadvantages of virgin gelatin film, which is readily soluble in water, scientists generally combine gelatin with a common biopolymer and add certain naturally occurring active components to make reformed edible composite films and coatings. The reformed synthesized films have advantageous biological (antimicrobial and oxidation resistance properties) and physiochemical (barrier property, pH, etc.) traits that help to overcome some of the drawbacks of gelatin composite film and broaden its potential for use in food conservation and future industrialization. Gelatin film can currently be made through coating, casting, extruding, and electrospinning, although it is still difficult to create films using extrusion molding.

When compared to mammalian gelatin, aquatic gelatin (also known as fish gelatin) is a significant hydrocolloid of food grade that is obtained from aquatic sources. Gelatin, which is naturally composed of protein, carbohydrates, and phenolics, is a promising biological material that has gained a lot of courtesy in current years.

In recent years, the utilization of natural diet supplements with antibacterial and/or antioxidant characteristics deprived of detrimental impacts on social health has expanded in an effort to decrease the usage of synthetic chemical food additives. These organic additions can stop or lessen food deterioration brought on by

oxidation or microbiological impacts, preserving and prolonging food shelf life (Atarés and Chiralt 2016).

To ensure the film's stability in humid circumstances for food packaging applications, the gelatin structure must be preserved. Cross-linking has been done using glutaraldehyde, but it has a significant drawback in that it is a systemic and cell hazardous chemical (Biscarat et al. 2015). He also created substitute matrices based on gelatin type A with some other chemicals which are less harmful to manufacture films by dry casting in order to avoid using glutaraldehyde (Biscarat et al. 2015).

The development of cutting-edge food packaging technologies with smart materials in gelatin matrices that extend the safety and superior quality of food products has been the focus of the current research. For instance, Musso et al. created biofilms by casting glycerol, bovine gelatin, and three pH-sensing acid-base indicators such as methyl orange, neutral red, and bromocresol green (Musso et al. 2016).

Vegetables

Vegetables are preserved with gelatin. Vegetables are a great source of fiber, vitamins, and minerals. These elements are crucial to a healthy eating routine. However, owing to their high humidity content (75–95%), vegetables have a short shelf life and spoilage and degradation happen quickly (Arfat et al. 2014). Fruits and vegetables control inhalation and exhalation rate to modify O₂ and CO₂ concentrations and provide comparatively steady metabolic processes. Freshly selected veggies must be packaged and coated since they are susceptible to bacterial, yeast, and mold-related deterioration (Plackett 2011).

Due to the incessant use of ethylene maturing agents, overripening, decrease in water content, and rot cause the appearance and quality of fresh fruits to degrade during the processes of picking, storing, and transportation. The ability of gelatin-based edible films and coatings to persist the shelf life of various fruits has been tested.

Aquatic Products

Aquatic goods are unpreserved because they have significant levels of polyunsaturated fatty acids, proteins, free amino acids, and endogenic enzymes that make them susceptible to oxidation and microbial degradation (Arfat et al. 2014).

As a result, the food becomes rotten and discolored. Aquatic items can be given an edible coating to increase product quality and shelf life (Pirayesh et al. 2013). Because of its excellent film-forming and glutinous qualities, as well as its low aroma and excellent barrier capabilities, gelatin is frequently employed in food packaging (Valdés et al. 2016).

Meat

The human diet's high-value food source, meat, contains a number of the important fatty acids that the body needs. However, meat products are susceptible to spoiling and depreciation during production, processing, and storage, and the presence of microbes and endogenous enzymes will alter the freshness of the meat (Moon et al. 2011). To preclude the growth of microbes and preserve the textural features of

meats, edible films and coatings which are gelatin based are now frequently used in the preservation of meat products. This is done by changing the gelatin-based packaging.

When gelatin film was combined with nanochitosan and essential oil, the outcomes demonstrated that the well-treated chicken meat displayed preferable remarkable features such as color, taste, and odor during the entire storage time (Rhim and Kim 2014). Comparing the samples enveloped in pure poly(lactic acid) with the control, the antibacterial activity was also markedly improved. Various gelatin matrices utilized in the coatings and edible films for meat and fish items are tabulated in Table 2.

Baking

Foods (bread, cakes, and biscuits) that are baked are rich in nutrients (protein, fat, fiber, and sugar). They quickly oxidize and grow mold, which damages the product. Mold-induced food spoiling can cause significant financial losses and release dangerous consequential metabolites (mycotoxins) which have an effect on human health. In order to retain the desired qualities of bread quality, papain is added to the gelatin film. This procedure boosts the volume of bread and improves the quality of frozen dough bread. After 60 days of frozen storage, the amount of thiol groups (-SH) and the degree of depolymerization of the glutenin macropolymer both significantly decreased, but there were no appreciable alterations in the secondary structure delaying the harmful deterioration of the frozen dough. The frozen dough might be efficiently protected by gelatin and papain (Hosseini et al. 2015; Panzavolta et al. 2014).

Biomedical Applications of Gelatin

Gelatin in Pharmaceutical Industry

Gelatin serves as a significant and effective ingredient for pharmaceutical and medical applications. It is widely utilized in these applications as a consequence of the fact that it exhibits excellent properties like nontoxicity and hypoallergenicity, exceptional biocompatibility, good solubility in biological fluids at body temperature, high purity, ability to form a robust film having a homogeneous structure, limited serological activity, and amenable physical characters.

A significant quota of gelatin consumed by the pharmaceutical industry is utilized primarily for hard and soft gelatin capsules (softgels), as well as tableting, tablet coating, granulation, encapsulation, and microencapsulation, since it limits oxidation and enhances the palatability of the composition (Eaton 1989; Nishimoto et al. 2005; Stringer 1989; Withered 1986).

Correll et al. reported the formation of a nonantigenic, sterile, absorbable, and water-insoluble gelatin film (Gelfilm™) using a specially prepared gelatin/formaldehyde solution (Correll 1950). In the encapsulation of the fat-soluble vitamins, gelatins with bloom values ranging from 0–140 are advised. Fish gelatins are commonly used for microencapsulation since they have exceptional film forming

Table 2 Various gelatin matrices utilized in the coatings and edible films

Food applicability	Product	Matrix	Processing method and final product	Reference
Meat products	Angus steaks	Chitosan and bovine type B gelatin together	Entering matrix solution (coating)	(Cardoso et al. 2016)
	Boar sausages	Blends of gelatin, pectin, and sodium alginate	Extrusion (film)	(Liu et al. 2007)
	Lamb loin	Animal gelatin	Penetrating the gelatin matrix (coating)	(Herring et al. 2010)
	Dry sausages from Kabanosy	Glycerol, kappa carrageenan, and pork gelatin	Entering matrix solution (coating)	(Tyburcy and Kozyra 2010)
	Chicken breasts	Gelatin made from skate skin and essential thyme oil	Casting (film)	(Lee et al. 2016)
	Fresh beef	<i>Thymus vulgaris</i> and <i>Rosmarinus officinalis</i> essential oils are combined with gelatin and Tween 80	Entering matrix solution (coating)	(de Oliveira et al. 2013)
	Turkey bologna	Nisaplin, glycerol, gelatin, and the antibacterial additives Guardian CS1-50	Casting (film)	(Min et al. 2010)
	Bacon	Gelatin	Casting (film)	(Nowzari et al. 2013)
Fishery products	Rainbow trout	Chitosan, glycerol, and fish skin from cold water	Casting and dipping into matrix solution (film and coating)	(Gómez-Estaca et al. 2010)
	Cod fillets	Clove essential oil combined with bovine hide gelatin, chitosan, sorbitol, and glycerol	Casting (film)	(Nowzari et al. 2013)
	Minced fillets of trout	Red grape seed extract, cold water fish skin gelatin, chitosan, glycerol, and <i>Ziziphora linopodioides</i> essential oil	Casting (film)	(Kakaei and Shahbazi 2016)
	Filletts of rainbow trout	Laurel leaf essential oil, glycerol, sorbitol, food-grade gelatin, and sorbitol	Casting (film)	(Alparslan et al. 2014)
	Tuna meat	Several plasticizers, gelatin, and protein from red pepper seed meal	Casting (film)	(Lee et al. 2016)
	Fish sausages	Gelatin from warm water fish, chitosan, concentrated shrimp, Tween 80, and glycerol	Casting (film)	(Alemán et al. 2016)

(continued)

Table 2 (continued)

Food applicability	Product	Matrix	Processing method and final product	Reference
	Atlantic salmon	Gelatin, lignin, sorbitol, and glycerol	Casting (film)	(Ojagh et al. 2011)
	Salmon	Barley bran protein, grapefruit seed extract, sorbitol, and porcine skin gelatin	Casting (film)	(Song et al. 2012)
	Cold smoked salmon	Chicken feather protein, sorbitol, clove oil, and pork gelatin	Casting (film)	(Song et al. 2014)
	Shrimps	Tween 20, orange leaf extract, sorbitol, glycerol, and gelatin	Entering matrix solution (coating)	(Alparslan et al. 2016)

properties (Morimura et al. 2002). The earlier comments regarding gelatin capsules does not refer to any of the constituents other than the medications encapsulated. Current constitutions, on the other hand, contain a wide range of other ingredients, each with their own advantages (Gold et al. 1997).

Gelatin capsules are frequently used for the encapsulation of a diverse range of foods, nutraceuticals, and drugs. The encapsulated materials are secured from humidity, temperature, or other drastic environments, improving their durability and sustainability, and this has led to a boom in applications for this procedure (Gibbs et al. 1999). Gelatin is used as an excipient in medicinal preparations like vaccines and tablets (Sam 2000). Gelatin films derived from the skins of warm water fish species such as *Lates niloticus* (Nile perch) manifested fracture strain akin to gelatin obtained from the bone of cattle (Muyonga et al. 2004). However, fish gelatin film demonstrates a lesser permeation of water vapor than bovine and pigskin gelatin (Gómez-Guillén et al. 2007).

Gelatin as Tissue Engineering Scaffolds

Gelatin is a commonly used biopolymer for the generation of scaffolds, with the ability to replace native extracellular matrices (ECM) (Tayebjee et al. 2003; Jiang et al. 2014). For a material to be used as a scaffold in tissue engineering, three basic prerequisites must be fulfilled: (1) the substance that holds up the matrix must be compatible biologically and capable of being molded into the intended shape; (2) the relation between the substance and the host cell must comply with tissue-specific constitutional and metabolic requirements; and (3) the matrix's performance must be appraised within the living organism as well as in the artificial environment by quantifiable molecular and histopathological diagnostics (Langer and Vacanti 1993). Gelatin fulfills these requirements as it is biodegradable, has good cell proliferation capability, and has low immune response (Hayashi et al. 2012; Horch et al. 2000; Pati et al. 2012).

Since gelatin is manufactured from collagen by means of hydrolysis, the cleavage of intermolecular bonds leads to the separation of the chains in the α -helical structure. However, the discrete chains retain their primary structure, which offers the RGD amino acid motif (arginine [Arg]–glycine [Gly]–aspartic acid [Asp]), which is the identification array for cell adhesion facilitated by integrin (Yamada et al. 2014). Gelatin, when used as a scaffold material, enhances permeation, binding, spreading, and multiplication of cells on the scaffolds. Microspheres of gelatin, cross-linked using genipin, exhibited enhanced proliferation of exceedingly viable hepatocellular carcinoma cells (Lau et al. 2011).

A better and refined outline is a cell microcarrier with opened, vacant, and casing-like structure developed using gelatin, by cross-linking strategy and further solubilizing the substances which were not cross-linked (Su et al. 2011). The system had a higher loading efficiency and good compatibility, which supports cell binding, faster multiplication, and well-regulated differentiation.

Natural biopolymers have a favorable influence on signal recognition, allowing the cells to penetrate deeper within the scaffold. Furthermore, the creation of new cavities or extension of the already prevailing ones is expedited by the increased elasticity and deformability. Hydroxyapatite (HA), a mineral present in the nature, which makes up a part of the bone, has been coated with gelatin to construct a composite with improved mechanical properties. Because gelatin increases toughness by bridging material cracks in HA, the refinement in properties was found to be proportional to the amount of gelatin in the composite (Dressler et al. 2011).

Composites of gelatin integrated with other natural polymers such as collagen, hyaluronan, chitin, and silk have good biocompatibility and can be employed in biomimetic strategies (Kundu et al. 2014; Wan and Tai 2013). The composites of hyaluronan and gelatin have been constructed to harvest the beneficial properties of both these materials. While hyaluronan is a polysaccharide with excellent water retention and numerous binding sites for molecules, its hydrophilicity deters protein adsorption and in consequence prevents binding of cell. The incorporation of gelatin with hyaluronan was found to increase the cell proliferation (Park et al. 2014). Silk was used to fortify gelatin scaffolds, which resulted in higher tensile and deforming strength (Zhang et al. 2015).

Gelatin has also been combined with agarose or alginate to develop a phase transfer cell culture (PTCC) system, with gelatin serving as the porous material with prolonged solubility (Gong et al. 2010; Su et al. 2012). For the transplantation of therapeutic cells, a 3D scaffold-free living gristle graft was also created (Lau et al. 2012; Su et al. 2012).

Man-made macromolecules have the advantage of tuneable and modifiable material chemistry. But most of them lack cellular identification arrays and attachment sites (Toh and Loh 2014). Exploiting gelatin's cell recognition ability and binding sites in the form of composites with synthetic polymers can be beneficial for engineering scaffolds. The composite designed by combining gelatin and polyamide exhibited cell recognition as well as biomechanical properties. When transplanted into rats, it also promoted wound healing (Ulrich et al. 2014).

Ozkizilcik and Tuzlakoglu developed gelatin-poly(lactic-co-glycolic acid (PLGA) composite particles, and the chondrocytes cultured on these exhibited enhanced proliferation, viability, and deposited glycosaminoglycan more than PLGA alone. This system can be injected and has the potential be used to deliver chondrocytes to articular cartilage defects, which are very common in clinical practice (Ozkizilcik and Tuzlakoglu 2014). Electrospinning technique can also be employed to combine PLGA and gelatin. The composite fibers outperformed PLGA alone in terms of cell adhesion and proliferation. Incorporation of gelatin into PLGA facilitates tunable release kinetics and improved biocompatibility (Meng et al. 2010).

For the treatment of the injury of cartilage and underlying bone in rabbits, gelatin was stocked with either insulin-like growth factor 1 (IGF-1), TGF- β 3, or both and were incorporated in the gristle section of a bilayered oligo(poly(ethylene glycol) fumarate) (OPF) design. This composite was able to discharge growth factors for 25 days in vitro (Kim et al. 2013). Gelatin-OPF composite could potentially be used for the regeneration of tissues such as the interface between bones and cartilage.

Gelatin in Drug Delivery

Biodegradable polymers like polysaccharides and proteins can be used as effective delivery systems for the structured and targeted drug release, with the intention of improving the efficacy and minimizing the complications of the medicines (Kumari et al. 2010). Inclusion of gelatin within other matrixes can offer systems for the delivery of therapeutics. These have the combined properties of both the materials making them excellent agents for drug delivery.

Nanoparticles of gelatin are also utilized to deliver protein and peptide-based therapeutics. Gelatin nanoparticles encapsulated in PLGA and loaded with bovine serum albumin (BSA) indicated sustained release features, along with the ability to arrest the denaturation of protein (Tang et al. 2012). Won et al. investigated recombinant human gelatin (rHG) nanoparticles for delivery properties using fluorescein isothiocyanate-labeled bovine serum albumin (FITC-BSA). The sustained release of rHG nanoparticles was accompanied by a lower initial burst. Other protein drugs, such as insulin, bone morphogenetic protein-2 (BMP- 2), alkaline phosphatase (ALP), tissue-type plasminogen activator (t-PA), and angiogenic bFGF, were also incorporated into gelatin nanoparticles, with the result that the efficacy of these drugs was maintained within the living systems (Won et al. 2012).

Gelatin nanoparticles are also widely exploited for the discharge of both water-soluble and water-insoluble antineoplastic agents, with the goal of prolonging discharge, improving the targeting efficacy, and reducing toxicity. The advantages of gelatin nanoparticles as antineoplastic drug delivery agents are very low cytotoxicity, reproducible synthesis, and low cost. Gelatin nanoparticles also possess passive targeting ability, as result of which they remain at site of the tumor for longer periods so as to facilitate the complete release of the drugs. Gelatin nanoparticles loaded with the anticancer drug Paclitaxel exhibited approximately 2.6 times higher concentrations in tumor-affected cells when correlated with that loaded in the Cremophor-ethanol (CrEL) vehicle following intravesical administration in the dogs (Lu et al. 2004). The exceptional efficacy of antineoplastic agent-loaded gelatin

nanoparticles as correlated to free agents was revealed both *in vitro* and *in vivo*. An increase in the tumor volume to about 20 times relative to the initial volume was observed in mice medicated with free 17-allylamino-17-demethoxygeldanamycin (17-AAG), in comparison to about 15 times in 17-AAG loaded in recombinant human gelatin modified with alpha-tocopheryl succinate (rHG-TOS) (Won et al. 2011).

Doxorubicin loaded into glutaraldehyde cross-linked gelatin nanoparticles injected into peritoneal cavity of rats increased the efficacy of the anticancer agent. However, repeated administrations were found to cause notable cardiotoxicity (Kommareddy et al. 2007).

In addition to anticancer and protein drug delivery, gelatin nanoparticles are employed for the discharge of a variety of chemotherapeutic agents like antiviral, antimalarial, antifungal, antitubercular, anti-inflammatory, analgesic, antispasticity, and antispasmodic agents and antidiabetic agents. In all these cases, gelatin nanoparticles could prolong the drug release, reduce the side effects of the drugs, and improve the efficacy of the drugs. Gelatin nanoparticles could prolong the release of the antimalarial agent cryptolepine to as long as 192 h (Kuntworbe and Al-Kassas 2012). The incorporation of the antitubercular antibiotic rifampicin into gelatin nanoparticles led to the improved assimilation of the drug by the cells in the lungs, thereby increasing its availability and efficacy in mouse infected with tuberculosis (Saraogi et al. 2010). The loading of the antifungal antibiotic amphotericin B and antimalarial agent cryptolepine into gelatin nanoparticles could reduce the nephrotoxic and haemolytic effects of the medicines, respectively (Kuntworbe et al. 2013).

Cosmetic Applications

Gelatin is a key component of cosmetic products because of how well suited its qualities are for encasing bath oils and for usage in moisturizing lotions and skin creams. The cosmetic industry has recently paid a lot of attention to gelatin films made from fish. To boost the antioxidant activity, essential oils derived from citrus fruits such as bergamot, kaffir lime, etc. were added to fish gelatin films (Tongnuanchan et al. 2015). Gelatin hydrolysates are crucial ingredients in skin care products due to their capacity to give skin firmness, suppleness, and hydration. They enhance hair shine and make combing easier in hair care products. Additionally, gelatin derived from by-products or derivatives of pigs and cows is used in cosmetic items. Many cosmetic products, such as face creams, body lotions, shampoos, hair sprays, sunscreens, bath salts, and bubble bath, use gelatin as a gelling agent. The primary function of the skin is to protect the body from the elements, especially sunlight. Free radicals are produced during the oxidative process of skin aging. The skin does, however, have a built-in antioxidant defense system. Melanin, the skin's natural pigment, absorbs ultraviolet (UV) light (Aguirre-Cruz et al. 2020). Fish gelatin hydrolysates were utilized for the protection from UV radiation and to enhance water binding ability and minimize dehydration. They restored the skin's structural integrity by keeping the skin's lipids in equilibrium because of their

antioxidant qualities (Al-Nimry et al. 2021). Antioxidant enzymes in the body, which shields the skin from oxidative stress, are reduced as a result of UV radiation exposure. Studies on mice were conducted to ascertain the antiaging and antioxidant effects of polypeptides produced from Pacific cod (*Gadus macrocephalus*). These studies revealed that gelatin hydrolysates considerably boosted the activity of antioxidant enzymes. On experimental mice, oxidation of lipids was also decreased, and levels of inflammatory cytokines were downregulated. This may be because NF- κ B was inhibited. In a different study, the protective properties of salmon fish gelatin and its hydrolysates were assessed on mouse skin. Lipid peroxidation was reduced and down again, it was discovered that the levels of antioxidants enzymes were raised by gelatin and its hydrolysate, reducing the negative effects of UV light (Chen and Hou 2016). Gelatin and its hydrolysates also increase immunity by increasing the thymus index and hydroxyproline in the skin, which serves as a marker for the collagen content, in order to defend against UV radiation. The tilapia (*Oreochromis niloticus*) gelatin hydrolysates were discovered to have a scavenging action against reactive oxygen species generated by UV radiation which harm skin and induce early aging (Sun et al. 2013). Therefore, fish gelatin/hydrolysates could be viewed as a unique source of ingredient with potential for use in skin antiaging products in the future.

Environmental Applications

Huge quantities of industrial effluents containing dyes are mainly produced by textile, leather, food, cosmetics, and polymer industries. Effluents containing dyes can affect the aquatic life by preventing the penetration of sunlight and oxygen. Humans also get affected due to the fact that dyes are not biodegradable and deposit in the body, causing diseases like cancer and skin allergies. Gelatin-based composite materials are widely used in the adsorption of dyes, hazardous metals, phosphate and nitrate, and greasy pollutants. To improve the efficiency of adsorption, different materials such as chitosan, carbon nanotubes, calcium alginate nanofiber membranes, acrylamide and 4-styrenesulfonic acid sodium salt, etc. are incorporated into gelatin-based composite materials (Rigueto et al. 2021).

Removal of Dyes

The process of adsorption of dyes is dependent on pH parameter used in the solution. pH value has an impact on the surface charge of the adsorbent and the structure of the dye molecules (El-Aassar et al. 2018). As a result, it is governed by the characteristics of the dye under investigation and adsorbent's zero-point charge (pH(PZC)). When pH is greater than pH(PZC), cationic dyes are more likely to adsorb, whereas anionic dyes are favored at a lower pH than pH(PZC) (He et al. 2015). As reported by Wang et.al, amphoteric carboxymethyl chitosan/gelatin microspheres were less effective in adsorbing methyl orange (anionic dye) with decrease in pH and an opposite trend was observed with methylene blue (cationic dye) (Wang et al. 2020). Similar behavior was observed when methylene blue dye was adsorbed by fibrous

Fig. 5 Process of dye adsorption by gelatin-based adsorbents

sepiolite clay-incorporated gelatin biopolymer. The adsorption capacity was enhanced from 195 to 467.4 mg. g⁻¹ when pH of the dye solution was raised from 4–12 (Sabzi et al. 2019). The electrostatic interactions between the cationic dye and the anionic composite can account for this. Figure 5 depicts the schematic representation of the process underlying in the dye adsorption by the gelatin-based adsorbents.

The electrostatic interaction between gelatin and dyes governs the adsorption of dyes. The pore size, surface volume, and other peculiar features of the adsorbent also determine the adsorption. Additional processes that contribute to the adsorption include sorption, cation-anion exchange, dipole-dipole interactions, and hydrogen bonding.

Removal of Toxic Metals

The metals most frequently identified in industrial effluents, according to Barakat, include cadmium (Cd), chromium (Cr), copper (Cu), nickel (Ni), arsenic (As),

lead (Pb), and zinc (Zn) (Barakat 2011). Toxic metals can harm the environment and harm both marine and terrestrial biotas because of pollution of rivers, lakes, soils, and use of contaminated water by animals as well as human. The human body can suffer considerable harm from toxic metals, ranging from minor symptoms like headache and diarrhea to cancer (Barakat 2011). According to Perumal et al., gelatin and chitosan hydrogel particles that were embedded in graphene oxide led to the elimination of more than 75% of metals like Pb (II), Cd (II), Hg (II), and Cr (III) (Perumal et al. 2020).

A hybrid aerogel of silica and mesoporous gelatin created by Herman et al. could eliminate 91% of aqueous Hg (II), in the presence of additional metal ions like Cu (II), Cd (II), Co (II), Pb (II), Ni (II), Ag (I), and Zn (II). Equilibrium was achieved in 15 min and was possible to recycle the adsorption capacity five times without suffering appreciable losses (Herman et al. 2019).

In addition to groups like imidazole and thiol, amino groups also significantly contributed to the removal of metals like Cd (II) and Pb (II), employing composites made from a gelatin solution with polyethyleneimine (Li et al. 2016). Similar to the previous study, Wang et al. (2018) investigated the elimination of Cd (II) and Pb (II), but they did so using a mixture of gelatin and manganese dioxide. The success of their method was due to the presence of amino, imidazole, and thiol groups in the adsorbent (Wang et al. 2018).

Removal of Phosphates and Nitrates

The scientific community has investigated gelatin-based composites for the removal of phosphates and nitrates from aquatic matrices. Kumar and Viswanathan developed gelatin composites which has high adsorption capacity for phosphates and nitrates and reusability upto four cycles (Kumar and Viswanathan 2019). Among five adsorbents developed, Fe₃O₄ gelatin composite has shown greater phosphate adsorption efficiency above 75%. Organophosphate pesticides from waste water could also be removed using gelatin-based adsorbents.

Removal of Oily Contaminants

Oily effluents are produced in a wide concentration range by the manufacturing sectors such as food industry, textile mills, paper mills, and metal industry. These effluents can take on different forms, including fats, lubricants, chemical additives, and hydrocarbons. The petroleum industries are also responsible for wastewater with petroleum and hydrocarbon derivatives. Many studies have been developed in this field for the recovery of oily contaminants from wastewater. Various adsorbents like activated charcoal, sawdust, vermiculite, and other biopolymers have been reported to be effective in removing oily contaminants. But biopolymers, like gelatin, are desirable since they allow for chemical changes through the addition of other components (Elanchezhian et al. 2018).

Gelatin-based ferrogel composite with 15% gum Arabic has been found to have high oil retention stability and was good up to the fourth cycle. Nevertheless, around 60% of the oil was lost subsequently.

Photographic Applications

Gelatin is an extensively used material in the photographic industry. It can be utilized to make paper and photographic film. Additionally, it can be used to create photo-sensitive materials. It is a crucial component of photography supplies. It makes up a sizable portion of photoemulsion films; for example, for color print papers and color-negative films, it accounts for around 60% and 40% of the weight, respectively. Extremely sensitive photographic emulsions have developed as a result of the demands of modern photography. The photographic emulsion is without a doubt the most well-known sensitive substance (Mees 1954; Walls and Attridge 1977). Silver halide, the emulsion's light-sensitive component, should be utilized with gelatin as a binder. Although various binders, such as polyvinyl alcohol, have been employed, gelatin is the best. Gelatin for photographic purposes is often derived from pig skin and cattle bones (Ward and Courts 1977).

Gelatin's Function in the Emulsion

When exposed to light, silver chloride and silver bromide in the combination of a photographic sheet discolor and break down into their component elements. This blackening is a relatively gradual process unless chemically augmented by the use of a "developer," which releases silver from the uncovered grains without harming covered grains. The majority of the energy required to create an image comes from this process. The manufacture of emulsion is important to take into consideration, because the qualities of an emulsion, which usually often involve gelatin as the primary colloid, are critical in determining the condition of the picture acquired.

Emulsion Production

The first step in the synthesis is precipitation of silver chloride or silver bromide precipitate or crystals from alkaline bromides and silver nitrate. The reaction is conducted in a colloidal media in order to maintain the precipitate of silver salts.

The combination then goes through a process of physical evolution or aging, during which the precipitates of silver salts enlarge. After that, the residual soluble components are washed out of the solution. This process required gelling the colloidal suspension over a long period of time followed by dialysis of the soluble components by cleansing the gel in icy water. Nowadays, the majority of producers rely on salts or organic reagents, such as modified gelatins for the flocculation of colloid, which flocculate in an acidic environment. The second stage is a chemical ripening. The creation of reactive centers on the precipitate of the silver salts is now stimulated by a few crucial additions. The ripening process is stopped, the emulsion's covering is stimulated, the emulsion is hardened, and then the emulsion is rendered insoluble to the developer by the employment of various chemicals. The emulsion is then chilled after being overlaid into its support. It is protected with a coating of gelatin that will not interfere with photographs (Lestra 1985).

What Gelatin Does

The colloid of choice for making emulsions is typically gelatin. The silver salts are kept in suspension during precipitation and physical ripening by this substance, which is also significantly immersed at the surface of the precipitate of silver halide or crystals, slowing the growth of those crystals. Gelatin's propensity to gel makes it possible to remove undesired soluble components by dialysis and its elevated stickiness makes it easier to coat the support with the emulsion (Park et al. 2001). After coating, the gel that molded keeps the precipitate or crystals of silver salt on the support during dehydrating and development. The gelatin stops the counterreaction of photolysis by fixing the released halogen when it is exposed to light. Gelatin also inhibits declining of the latent image obtained from the photolysis. Reagents can infiltrate through the emulsion layer during development because the additional reagents cause the gelatin to swell. Quick development at elevated temperatures is made possible by the gelatin's ability to tan with numerous substances.

Since bone or skin collagen is used to extract gelatin, most preparations inherently include contaminants. Heavy metals, "fogging agents," dust, and grease are some that must be eliminated since they are harmful to the photographic process. As "restrainers," albumens, polypeptides comprising cystine, and nucleic acids prevent the emergence of reactivity sites or the development of silver halide particles. However, some adulterations have advantageous characteristics that serve as "sensitizers" and aid in the development of silver or silver sulfide centers on the halide particles.

Gelatin in photographic application can be divided into four groups. First one is inert gelatin, which lacks sensitizers and restrainers. Second one is active gelatin, which contains a lot of sensitizers but little restrainer. Third one is retarded gelatin, which contains a lot of restrainers but little sensitizer and the last one is retarded active gelatin, which contains a lot of both.

Finding the best gelatin for a specific application is the responsibility of the manufacturer of photographic emulsion (Gelatin Handbook 2012). In order to preserve quality from batch to batch, the gelatin maker must produce the gelatin according to strict specifications.

Production of Gelatin

The conditions of gelatin extraction determine the attributes of the ultimate product. The liming activity in precise requirements are to be carefully monitored. The triple helix of collagen is broken down at this step due to the hydrolysis of amide groups into carboxylic groups, the removal of numerous impurities, including sulfur, the conversion of the sulfur in cystine to thiosulfate, and the breakdown of RNA into nucleotides. The original material is limed and then treated in aquatic environment to remove as much lime as viable before being "delimed" in a bath of diluted acid. Then, only the first extraction of gelatin is pure enough to meet the stringent standards of photography. By merely reducing the pH, gelatins can be chemically altered to cause flocculation. This type of gelatin is being used more frequently to flocculate emulsions in place of sodium or ammonium sulfate or dialysis-based washing.

Auxiliary Gelatins

Unlike other materials, photographs do not have just one light-sensitive layer. A further auxiliary layer is placed to the support either after the emulsion layer or concurrently. The hydrophilic emulsion has little affinity for the support's surface and is often synthetic. It is vital to have an intermediary layer, or substratum, that contains the components required to create a link between the emulsion and support. Each layer in multiple emulsions is sensitive to a different radiation band which is present in color films or sheets. To stop diffusion from one color layer to another, intermediate layers must be used between the layers.

The emulsion layer's surface needs to be mechanically shielded from outside touch. The supercoat serves this purpose. It must have no photographic impact on the emulsion, like all auxiliary layers. Typically, they are inert gelatines.

To balance off the tension that all the layers place on one side of the support, a backup layer is superimposed on the opposite side. This is frequently colored to elude the halo that the light ray produces when it replicates on the film. Up to a dozen chemical layers may be present in several color movies. At speeds of 100–150 m/min, the sophisticated coating equipment currently in use enables the synchronized coating of the majority of the layers. Since the thickness of individual layer is just about 10 μm , it is simple to see the significance of the gelatin's substantial requirements.

To provide the customer with photographic gelatin that has exactly the attributes they require, the producer must be able to regulate the manufacturing process very accurately and uphold stringent quality regulator. When defining the specifications for an emulsion, it is also helpful for the client to understand the manufacturer's challenges.

Gelatin is used as the dispersion medium for the light-sensitive silver salts in the gelatin process, commonly known as the gelatin dry plate technique. The technique, which was developed around 1880, replaced the wet collodion method, in which a glass plate was coated with nitrocellulose (collodion) solution just before exposure to create a wet negative.

Wherever a photograph was to be taken, a darkroom was required for this chemical process. A method for drying a sensitized gelatin emulsion on a plate and keeping it there for months before use, sheltered from light, revolutionized photography. The standard binding substance for the silver halide crystals used in common photographic film is still gelatin.

In photography, gelatin is frequently employed because, after coating, the gel that is produced holds the silver salt precipitate or crystals on the support while dehydrating and development. Additionally, the gelatin fixes the released halogen when it is exposed to light, preventing the inverse reaction of photolysis. Dichromated gelatin (DCG) is an additional photosensitive material in the physics-optics areas. It has proven useful ever since it was used in the printing business more than a century ago. Making holograms is arguably the most recent successful application. In the table below, gelatin's roles in photographic materials are enumerated (Toda et al. 2002).

Table 3 illustrates the role of gelatin in various photographic materials.

Table 3 The role of gelatin in photographic ingredients

Process		Step	Functions expected from gelatin	Characteristics or properties of gelatin
Production process	AgX emulsions	Nucleation (Tabular)	Encourage the creation of parallel twin planes and discourage random coalescence	Adsorption behavior on AgX crystal surfaces, molecular weight, methionine concentration, and gelation temperature
		Growth	Growth regulation avoids aggregation	Adsorption behavior, inertness, reducing activity, and molecular weight on AgX crystal surfaces
		Demineralization	Bring about permanent flocculation	Adsorption behavior and interactions with flocculants on AgX crystal surfaces
		Chemical maturing	Not obstruct the ripening process Avoid accumulation	Adsorption that is competitive with ripener species, inert, and reducing in nature
		Repository	Refrain from sedimentation	Reversible gelation and viscosity
	O/W emulsions	Emulsification	Mechanical energy propagation and interfacial energy reduction	Viscosity and surfactant interaction
		Repository	Halt emulsion deterioration	Surfactant collaboration, viscosity, and reversible gelation
	Film formation	Coating	Maintain laminar flow while stabilizing a rapidly expanding surface Wet and applied to a specific substrate	Viscosity, interactions with ionic polymers, and interactions with surfactants
		Drying	Keep the layered structure and provide a reliable matrix	Gelation, cross-linker reactivity, and moisture content
	Finishing	Slitting	Protect the system	Gel durability and elasticity
Post-production process	Exposure		Maintain the latent image not to impede the optical process	Transparency, interaction with halide ions, and the rate of expansions and shrinkage as a function of humidity

(continued)

Table 3 (continued)

Process		Step	Functions expected from gelatin	Characteristics or properties of gelatin
	Development		Give the procedure an aqueous medium	Cross-linkability and swelling
	Preservation		Maintain and safeguard the image	Cross-linkability, oxygen (im) permeability, water absorption behavior, and gel strength

Other Applications

Gelatins used for applications other than food and biomedical applications need not have the rigorous specifications meant for human consumption. Gelatin can be used as a mid-IR recording medium. Visible light can pass through gelatin with ease. However, mid-infrared light transmittance for films with a thickness of about 90 m is only about 10% (= 10.6 m). Mid-infrared light is heavily absorbed by thicker layers. Surface relief gratings have been made using this property. Thin gelatin films of thickness ranging from about 10 m to about 50 m were coated and were placed in a two-beam interference pattern. A CO₂ laser (= 10.6 m) was employed and the sinusoidal pattern was captured. The recording region also received light at the same time from a He-Ne laser. It was discovered that relief gratings were captured over the course of exposure time.

Gelatin can be utilized as relative humidity sensor. The thickness of gelatin varies when water vapor is adsorbed by the films. The refractive index of gelatin is 1.5 when it is dry and refractive index gets diminished when water vapor is absorbed. Thus gelatin can be used to make relative humidity sensor. Gelatin is used to make relative humidity sensors by taking into account changes in thickness and refractive index (Calixto et al. 2018).

Gelatin is utilized in paper production, printing, in the manufacture of the coated end of match, abrasives, book bindings, grooved and ribbed cardboard sealings, etc. (Green and Lowell 1957; Gutcho 1976; Wood 1977). Gelatin, along with gum arabic, is used to produce oil-containing microcapsules used in the manufacture of carbonless paper. Biodegradable gelatin adhesives are recently used. They are also used in washing and cleansing agents. Gelatin films with different colors have been used for photographic lighting.

Conclusion

Gelatin is a highly potential functional protein, which finds diverse applications. Extensive research has been carried out to identify newer sources of gelatin ranging from animals to fish and insects. It has multidimensional applications such as in food industry, pharmaceuticals, tissue engineering, controlled, targeted, and sustained

drug delivery, cosmetics, photography, and effluent treatment. It is the characteristic properties of gelatin that makes it a desirable polymer in these applications. Gelatin by itself and in combination with other natural and man-made macromolecules and ceramics have several beneficial properties. The composites of gelatin are often found to possess improved toughness coupled with lightweight and biocompatibility that makes them desirable components as biomaterials. The composites also offer greater flexibility in terms of material degradation. Current research is focused on tailoring the properties of gelatin and its composites to make them suitable for specific needs.

Abstract

One of the most significant polymers for human society is natural rubber (NR), which is made of long isoprene polymer chains. The sole commercial source of natural rubber latex sap is *Hevea brasiliensis*, commonly called the rubber tree, and is an important raw resource that is used to make over 40,000 different goods.

NR-based composites have now widely emerged as a green composite with bio-based properties as an alternative to the rising concern over several environmental issues. Gutta-percha is a natural polymer that has many chemical qualities similar to natural rubber but differs from rubber in terms of its molecular structure. Initially created as a restorative substance, “gutta-percha” has now evolved into a crucial endodontic filling substance. In the process of developing as a specialization, it has evolved into the “soul” of endodontics. The indigenous of the Malaysian archipelago employed gutta-percha in rudimentary form for producing knife handles, walking sticks, and other things long before it was brought to the Western world. Over the years, gutta-percha has undergone a number of modifications to meet changing endodontic trends and fulfill its goals by streamlining the procedures, producing an ideal material. In this chapter, we discuss different applications of the two versatile biopolymers: natural rubber and gutta-percha rubber.

Keywords

Natural rubber · Gutta-percha · Applications · Biopolymer · Green fillers

Introduction

Natural rubber (NR) is a versatile agricultural product and is found to be consumed in nearly 50,000 products worldwide. It is an elastic natural hydrocarbon polymeric product of the addition polymerization of diene monomer isoprene (C_5H_8). The uniqueness of natural rubber is that it is the only biomass among rubbers and the only hydrocarbon among biomasses that consist of carbon and hydrogen only. NR, also known as *cis*-1,4-poly(isoprene) (Fig. 2), is widely found in the milky sap or latex of *Hevea brasiliense* trees (Fig. 1), together with a tiny quantity of nonrubber compounds such as proteins, carbohydrates, lipids, and inorganic salts (Ansari et al. 2021). Natural rubber contains 0.5% water, 2.5% acetone extract, 2.5% proteins, 0.3% minerals, and 94.2% polyisoprene (Feldman 2017). Up to 90% of the world's total production of natural rubber is produced on plantations in South Asia. Due to a lethal fungal illness brought on by an infection with *Microcyclus ulei*, it can be up to 8% in Africa and just 3% in South America.

NR is popular for its flexibility, strength, and elasticity. They are resistant to water as well as certain chemicals. The loosely bounded isoprene chains reattach themselves when pulled apart, giving NR its elasticity (Kurian and Mathew 2011). Natural rubber also has several significant properties like excellent tear and tensile strength, moderate resistance to light, heat, and ozone, and high resistance to tearing, chopping, and cutting. High molecular weight and a defined molecular structure are the prime factors for the enhanced performance which cannot be mimicked by other artificial polymers. Because of its superior structural regularity and capacity to assemble molecular chains along the direction of stretching, NR exhibits strain-induced crystallization during stretching and is one of the most expensive

Fig. 1 Natural rubber tree

Natural Rubber cis-Polyisoprene

Gutta percha trans- Polyisoprene

Fig. 2 Chemical structure of natural rubber and gutta-percha rubber

elastomers and the sole biosynthesized rubber. High tensile strength, abrasion resistance, and tearing resistance are all provided via strain-induced crystallization for the rubber matrix.

Additives like activators, accelerators, and retarders have been utilized since Goodyear introduced the vulcanization to enhance the vulcanization process and mechanical qualities of rubber goods. The vulcanized rubber is far more resistant to abrasion than raw rubber and does not soften much even at very high temperatures or harden with cold water. The introduction of accelerator lends a hand to decrease the vulcanization time, temperature, and quantity of sulfur. The pace of vulcanization as well as the dispersion of created cross-links are significantly influenced by the combined usage of accelerators and zinc oxide as activator. During the vulcanization

process, rubber is heated and combined with various chemicals, such as sulfur, bisphenol, or peroxide; these chemicals are used to increase the durability and elasticity of the material so that it does not decompose too quickly. Vulcanized natural rubber (NR) has exceptional tensile strength and elongation at the break due to the strain-induced crystallization phenomena (Rattanasom and Prasertsri 2009). The homogeneous microstructure of this phenomenon, which can be called a “self-reinforcing effect,” is frequently attributed to it (cis-configuration of the macromolecular chains).

Biopolymers have garnered a lot of attention recently due to their potential to reduce the usage of fossil fuels and nonbiodegradable polymers, hence reducing plastic pollution. The majority of biopolymers are biodegradable, which means that environmental microbes may break them down into CO₂ and water. Improved biopolymer composite qualities, including those of starch-based materials, cellulose-derived polymers, bacterial polyesters, and natural rubber composites, have been the focus of recent times. The majority of current scientific research on fortifying natural rubber and enhancing its physical qualities is a serious area of interest. In order to improve the qualities of rubber and introduce new ones, fillers must be used because the properties of pure rubber are sometimes insufficient for practical applications. The presence of nanofillers in the rubber matrix results in highly effective, lightweight rubber products. Clay, carbon nanotubes, graphene, titanium dioxide, and other nanofillers are contributing significantly to the improvement of the characteristics of rubber nanocomposites. The alteration of filler surface enhances the dispersion of filler particles (hydrophilic) and rubber macromolecules in the matrix and their interfacial adhesion. This is a crucial problem since the straightforward addition of natural-organic fillers to a rubber matrix might result in inferior mechanical capabilities to the neat rubber, this is particularly true when filler particles with low-length-to-diameter ratios are utilized (Chang et al. 2021).

Gutta-percha is a polyisoprene trans-isomer; 1, 4, trans-polyisoprene is its chemical structure (Fig. 2). It has several similarities to natural rubber, which is a cis-isomer of polyisoprene in terms of molecular structure, but a variation in form causes it to act more like crystalline polymers in terms of mechanical qualities. Gutta-percha is a nonconductor that is commonly used to insulate maritime and underground wires. Golf ball covers, surgical appliances, and adhesives are all made out of it (Warneke et al. 2007).

Due to the ability to combine the advantages derived from the bio-based derivatives, NR and GP offer better flexibility and processability and have evolved as perfect polymeric blends or nanocomposites that have recently received a lot of research attention.

Natural Rubber as Biomaterials

It would be fantastic if medical gadgets could be made out of materials with biological qualities. Natural and synthetic rubber are widely employed as materials that are utilized as bodily components or functions in a safe, dependable, cost-effective, and physiologically acceptable way because of their low weight and

biocompatibility. Biocomposites are composite materials that contain one or more biologically derived phases. The use of NR as a biomaterial is rapidly expanding, considering scientific studies and material developments. Different applications of NR as a biomaterial are illustrated in Fig. 3. Both solution cast and latex films of NR have contributed biomaterials owing to their mechanical, biological, chemical, and physical features even after the process of compounding and vulcanization (Anderson 2012). Due to the presence of a double bond in the macromolecular C_5H_8 cis-configured monomer unit, NR is sensitive to oxidation and heat, and it also shows poor hemocompatibility compared to other synthetic rubbers. As it is suitable for effective processing and easy for compounding, grafting of natural rubber with improved hemocompatibility has been an emerging area of research for a long time. Another known disadvantage is that the protein latex component present in the NR system may impart allergy in human bodies. The capability to stimulate the development of new blood vessels (angiogenesis), cellular adhesion, etc. were the reasons for promoting NR as a candidate for tissue regeneration and tissue repair (Phinyocheep 2014).

Various forms of natural rubber latex (NRL)-based biomedical devices have recently been created to improve tissue healing by using the biological features of the latex, and several studies have looked at the biocompatibility of NRL composite materials. In 2021, Barros et al. synthesized NRL-alginate wound dressing materials to cure prolonged diabetic foot ulcers. Exudate release is increased when natural rubber latex dressings are applied to diabetes patients' wounds. The highly absorbent, permeable, alginate-loaded NRL dressing was designed to control humidity in wounds by absorbing excess exudate and increasing water vapor transmission (Barros et al. 2021). For years, researchers have been looking at ways to improve the bone repair process and minimize patient morbidity. GBR (guided bone regeneration) has received a lot of attention, and it was developed to help with bone healing, particularly in major bone lesions. Natural rubber-based latex and restorable membranes are the best options for the GBR approach as it does not recommend the removal and hence avoids another surgery.

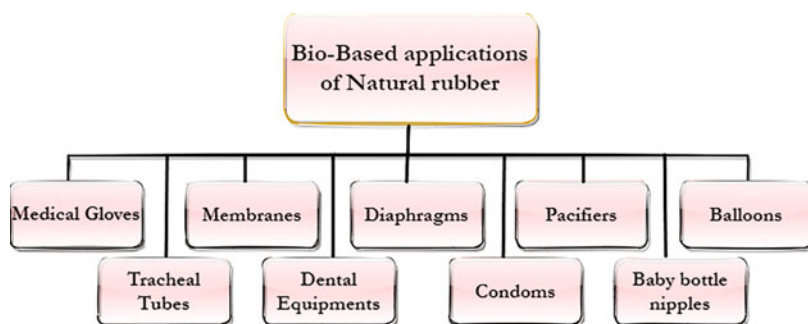

Fig. 3 Bio-based applications of natural rubber

Along with this, NRL membrane offers other advantages for human health, including avoiding bone transplants and grafts, as well as inexpensive cost, easy material accessibility, reduced pathogen transmission risk, and hypoallergenicity (Ciapetti et al. 1994; Barber et al. 2007; Guerra et al. 2021). These advancements, however, faced a variety of challenges, including rubber content and processing, characterization of mechanisms of action, purification and characterization of bio-active molecules, in vivo function, and further transformation to industry and clinical practice after regulatory approval. The application of natural rubber-based wound dressing is illustrated with a detailed mechanism in the below Fig. 4. NR composites with nanocrystalline cellulose reinforcement may soon offer improved performance, sturdiness, value, service life, and usefulness. Around 30–40% of cellulose, of which 50% is crystalline cellulose, is present in natural fibers. Although it may only be a tenth as strong as carbon nanotubes, nanocrystalline cellulose uses 50–1000 times less energy to be made. Although completely bio-based and biodegradable biocomposites can be totally recyclable and are very sensitive to moisture and temperature, they may also be more costly. Biocomposites may be 100% biodegradable if an NR matrix is employed; however, their biodegradation can only be somewhat regulated (Low et al. 2021).

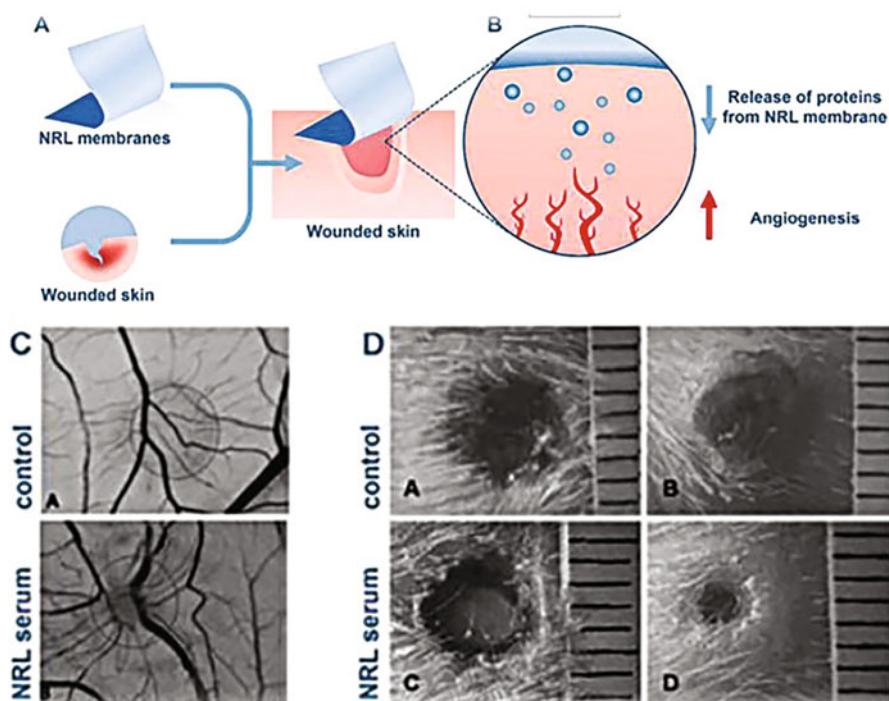

Fig. 4 Application of NR latex for wound dressing. (Adapted from Supanakorn et al. 2021 with permissions)

Regarding the cross-linking of the matrix, Abraham et al. (2012) investigated the biodegradation of NR composites enhanced with nanocellulose using the vermicomposting technique. This was accomplished by using the epigeic vermicompost worm *Eudrilus eugeniae*. The composite's reinforcing material was nanocellulose that was separated from raw jute fiber by steam explosion. A robust cellulose-NR contact is present in the cross-linked samples, according to morphological, X-ray diffraction (XRD) and tensile strength measurements. The NR composites' rate of biodegradation suggests that cellulose must first undergo hydrolysis in order for microorganisms to use it as a source of nutrients. The amount of reinforced nanocellulose in the composite greatly affects how quickly it degrades.

Natural Rubber in Transportation Sector

From ancient Mexican civilizations to modern-day tire manufacturing, the story of vulcanized rubber stretches back thousands of years. Along the way, such notable luminaries as Charles Goodyear and Charles Macintosh played a major role in its development. The majority of the output is utilized to make tires for various automobiles. Rubber production and quality are critical to the transportation and vehicle industries. Millions of automobiles are equipped with vulcanized rubber tires, which are illustrated in Fig. 5. Tire are one of the five rubber-based items that are critical to the advancement of human civilization (Thomas 2017).

Vulcanized rubber is used to manufacture all sorts of products today. Perhaps the best-known and most prevalent use of vulcanized rubber is in vehicle tires, which are commonly combined with the reinforcing agent carbon black for even greater strength. More than a billion tires are manufactured worldwide every year, making the tire industry one of the foremost consumers of vulcanized rubber. Only a small portion of natural rubber may be replaced by synthetic rubber, and the proportion of synthetic to natural rubber has decreased. Natural rubber is a substantial component of automobiles overall, but the more performance is needed, the more natural rubber

Fig. 5 Some of the rubber products used in the automobile industry

is present. About 90–100% of vehicle tires contain NR, but up to 100% of airplane and naval jet tires have NR.

In the example depicted in Fig. 6, natural rubber makes up about 30% of a tire's weight, or slightly less than 60% of the polymer component of a tire. This figure is used to be lower since more SR than NR was formerly utilized for tires. The development of the usage of radial tires and heavy-duty tires are two factors contributing to the recent increase in the percentage of NR in tires. Another significant problem in the production of tires is the unique NR odor that is released into the air during premasticating. The quality of life in neighboring residential communities as well as the job environment at manufacturing facilities may be impacted by this odor. Although the tire industry has been taking steps to deodorize the air, such as utilizing deodorant compounds or installing deodorizing machinery, there are still enough instances to demonstrate that these steps are insufficient.

Ribbed smoke sheet (RSS) and technically specified rubber are the two forms of natural rubber (NR) that the tire industry primarily uses (TSR). According to the International Standards of Quality and Packing for NR Grades, RSS is a form of "sheet rubber." In order to create 5 RSS, NR latex is first coagulated by adding acid, and then water is removed by running a ribbed surface through a mill. TSR was created in Malaysia and has been made for sale in other nations since 1965. It also goes by the name "block rubber." Depending on the grade, multiple processes are used to make TSR. The field latex serves as the only feedstock for the highest

Fig. 6 Weight composition of different constituents in automobile tires

“TSR-L” grade. Other grades employ feedstock like USS, mixes, and cup lump, where the latex is acid-coagulated immediately upon tapping in the tapping cup. Because of the potential variances in feedstock quality, production methods, drying conditions, and inspection, RSS and TSR exhibit varying levels of contamination and performance (Hirata et al. 2014).

In the automobile industry, rubber and rubber products are utilized for several applications. Rubber is used in fluid transfer systems, body sealing systems, transmission systems, automotive antivibration, sealants, adhesives and coatings, O-rings, molded components, flat seals, foam and conversion goods, body parts, spare parts, and other applications in the automobile sector. The rubber sector is inextricably linked to the automotive market. Rubber’s relevance and the industry’s growth are inextricably linked. It is a well-known statistic that tires consume 75% of all the rubber produced on the planet. Both directly and indirectly, the car sector controls the rubber industry. Direct intervention refers to the original equipment tires and many other elastomeric things installed on the automobile during production, whereas indirect intervention refers to replacement items such as tires, wiper blades, and, to a lesser extent, other items (Cadwell et al. 1941).

Natural Rubber in Industrial Sector

Rubber markets have traditionally been centered in the Asia Pacific region, with industry players producing and exporting raw materials or finished goods to other countries. Rubber is utilized in a variety of industrial applications. The rubber products industry is a significant resource-based industry sector. Globally, the rubber sector has had stable and robust expansion. When we talk about the rubber industry, we are talking about a business that makes synthetic rubber and a variety of rubber items, from doormats to rubber bands to industrial rubber products. Rubber has certain distinct characteristics that make it a valuable commodity with applications in transportation, material handling, health care, and sports and leisure activities (Sitepu et al. 2019). The rubber sector provides services to a variety of downstream industries, including manufacturing, construction, and agriculture, due to the diversity of rubber goods created. Conveyor belts, power transmission belts, and other items may all benefit from the cost-effectiveness and value-addedness of isora fiber reinforced natural rubber composites.

Vulcanization paved the way for the contemporary rubber industry by allowing the substance to be used in different equipments. It is used where a high level of wear and heat resistance is required. Also, it is utilized in technical applications such as antivibration mounts, drive couplings, springs, bearings, rubber bands, and adhesives because of its strength and compressibility. However, due to its strength and heat resistance, the bulk of natural rubber (50%) is used in high-performance tires for racing cars, buses, and airplanes. Hoses, automobile components, foam mattresses, and battery boxes all utilize it (Gibbons 1939). For packing, rubberized coir sheet is used to cushion shocks and vibrations during travel. Curled coir is combined with rubber latex to create a premium packaging and upholstery material. Improved load-

bearing capacity and superior resistance to compression set are given to the fibrous constructions when natural rubber latex is used as the binder. Such characteristics guarantee that the structure quickly recovers its original shape following compression of any extent or duration, whether from shock or static stress, which is a need for any high-quality upholstery or packing material. Rubberized coir's key strength is adaptability.

Natural Rubber in Health and Hygiene Sector

Natural rubber is a versatile material that has grown in importance in the medical field in recent years. To meet rising expectations in the health industry, NR is helping to keep health care costs down by giving a cost-effective way to stay up with new advancements. Rubber has become a common base for medical supplies because of its low cost and availability. Initially, natural rubber was used, also the synthetic form of the material, silicone, became widely available, this was a bonus (Mostoni et al. 2019).

Rubber is used in a variety of medical equipments that would not function properly without it. NR-based tubing is widely utilized as a hygienic way of conveying fluids, including blood, due to its unique qualities. Rubber's elasticity makes it the best material for important medical devices like leg straps that secure fluid bags to the patient's body. Surgical gloves are constructed of a variety of natural rubber latex. These gloves have several unique characteristics that are not found in a standard glove. Ultrasensitivity, additional flexibility, maximum strength, more protection, ambidexterity, and sterilizability are some of the qualities. Medical catheters are made of rubber. A catheter is a flexible tube made of latex or silicone that may be placed into the body to allow liquids or medical devices to pass through. NR is also used to produce condoms, diaphragms, and cervical caps, all of which are effective birth control techniques (Millard 2019; de Barros et al. 2018).

Natural Rubber for Earthquake Protection

The idea of rubber mountings for protecting structures from earthquakes has been researched for a very long time. It is crucial for preventing structural damage from vibration, such as that caused by earthquakes. Theoretical studies by Lindley and innovative tests by Payne have had a significant influence on the development of vibration control technology (Pan et al. 2018). Natural rubber's great strength, minimal stiffness, linear elasticity, reversible flexibility, good adherence to metal, wear resistance, and longevity make it a very advantageous material for use in vibration isolation. We may tackle many rubber design issues by utilizing merely the value of the elastic modulus because, like other solids, rubber acts as a linearly elastic substance at small stresses and as a linear viscoelastic material at fairly large strains. Natural rubber's linear elastic properties at static and dynamic loadings, i.e., reversible deformation, are a significant benefit for the system of vibration isolation. This benefit also depends on the rubber's ability to maintain stiffness over a wide

temperature range because crystallization happens less frequently at low temperatures. Because most rubber surfaces are shielded from oxygen by bonded metals, oxygen in the environment is not a significant issue for rubber-metal laminated bearings, but ozone assault severely harms the free surface of rubber. Even at low strain levels, ozone's quick reaction to carbon-carbon double bonds results in the onset and spread of cracks extremely quickly (Kelly and van Engelen 2016; Fukahori 2014). The ideal usage of natural rubber for engineering purposes may involve a compromise between linear elasticity and nonlinear viscoelasticity.

Emerging Trend in Natural Rubber Nanocomposites

Emergence of novel nanocomposites made of natural rubber matrix with organic/inorganic fillers provides enormous opportunities for the synthesis of advanced materials with superior qualities and applications. The peak interaction of the NR matrix and nanosized fillers provides excellent qualities which pave the way for numerous applications. Various nanoparticles based on rubber matrix have been proposed to attain the desired properties like low filler loading and density, and superior chemical resistance and electrical properties. The synergy between the NR and carbon-based fillers such as CB, carbon fiber (CF), carbon nanotubes (CNTs), graphene (G), and other elastomers have been introduced into them, considering the synergistic effect of the conductive fillers and elastomers. Silicon-based nanofillers such as SiO₂, nano-layered silicates, and metal oxides have been incorporated into various polymers to improve electrical, mechanical, and thermal properties. Commercially available NR is widely used in the manufacture of adhesives, surgical gloves, tires, coatings, health care equipments and accessories, coatings, floor covering products, vehicle accessories, etc. (Hema and Sambhudevan 2021; Mahitha et al. 2020).

Inorganic nanoparticles including Si, Ag, Au, TiO₂, and other magnetic nanoparticles were added to natural rubber (NR)-based nanocomposites in order to enhance their inherent functionalities, such as their antibacterial, electrical, thermal, optical, and magnetic capabilities. For the in situ development of an inorganic shell to surround NR particles, the presence of native proteins-lipids stabilizer is advantageous. This reduces inorganic NP bulk aggregation and their incompatibility with nonpolar NR, preventing structural defects in the polymer matrix from affecting the properties of nanocomposites (Wichaita et al. 2021).

Composites' fibrous reinforcing materials might be made up of relatively short fiber segments or thin continuous fibers. Fibers having a high aspect ratio (length to diameter ratio) are used when working with short fiber segments. High-performance structural applications often require continuous fiber-reinforced composites. Continuous carbon fiber-reinforced composites can outperform typical metal fillers in terms of specific strength and stiffness (Bendahou et al. 2010). Depending on the orientation of the fibers inside the matrix, composites may be created with structural characteristics that are especially suited for a certain purpose. The NR matrix among commercial polymers must meet the following criteria, including it must be

flexible and liquid enough to readily penetrate the fabric, moisten all fiber surfaces, and separate them from one another to prevent friction between the fibers. It should also increase the mechanical strength of the finished product. In the case of composites, a chemical reaction or adsorption may be used to attach matrix molecules to the fiber surface. The surface topology of the fiber has a significant impact on the interfacial strength of composite materials (Siqueira et al. 2011). The presence of water adsorbed on the surface of natural fibers, poor wetting of hydrophilic natural fibers with hydrophobic organic polymeric matrices, thermal stresses brought on by an imbalance in the linear thermal expansion coefficients of the fiber and matrix (polymers have relatively high linear thermal expansion coefficients), and the general coating of natural fibers with waxy substances are all factors that can cause composites to delaminate.

Green Fillers for Natural Rubber Composites

Natural rubber (NR) is a versatile bio-based renewable polymer that can be employed in a variety of working environments and applications, from everyday home items to aircraft components because of its attractive properties such as lightweight, toughness, high resilience, high impact strength, tensile strength, low hysteresis, and good formation. The nonrenewable inorganic reinforcing fillers such as SiO_2 , CaCO_3 , clay, etc. are replaced by renewable organic fillers for natural rubber composites often referred to as “green natural rubber” in rubber industries for achieving the appropriate characteristics for the commercial application. The organic fillers include plants and animal remnants such as wood flour, shrimp, straw, crab shell, coconut shell fibers, etc. (Hema et al. 2021)

Plant-based and wood-derived biocomposite materials are used in many product categories including automotive, packaging, furniture, construction, and building materials. Natural fiber–reinforced composites, such as those made from kenaf, flax, jute, hemp, sisal, and henequen, are a desirable research topic because they are environmentally friendly, sustainable, inexpensive, of low density, have good mechanical properties, are simple to separate, sequester carbon dioxide, and are biodegradable. Natural fibers offer certain advantages over synthetic fibers in terms of properties and are therefore a good candidate for development into biocomposites according to their satisfactory properties (Hema et al. 2020). Also, these composites have good impact strength, stiffness, and high strength even though they came from renewable sources and are less expensive than synthetic fibers, also the health risk is low since the emission of toxic vapors during the combustion is low. Production of these fibers requires only low energy and they consume CO_2 and also recycle the O_2 in the environment. But these have some disadvantages such as low durability, high moisture absorption, and lower strength compared with the synthetic one (Masłowski et al. 2019). On the other hand, these drawbacks serve as a drive for scientists to overcome them in creating multifunctional materials.

In terms of rubber chemistry, the filler particles' capacity for dispersion inside the rubber matrix directly affects the characteristics of filler-reinforced rubber

composites. The performance of natural fiber-based rubber compounds is greatly influenced by the hydrophilic character of natural fibers. In a hydrophobic rubber matrix, it can be quite challenging to evenly spread hydrophilic natural fibers. To put it another way, it is difficult to achieve great interfacial contact between the surface of natural fibers and the rubber matrix. The first stage in decreasing the hydroxyl groups on the surface of natural fibers is surface modification, which will also lessen the hydrophilic nature of natural fibers (Ku et al. 2011). The traditional two-roll mixing mill procedure is the method used most frequently to prepare rubber composites loaded with natural fibers. In this procedure, the rubber matrix is gradually supplemented with natural fibers and other curing agents. In some instances, different surface treatments are applied to natural fibers before the mixing process in order to improve the interactions between the rubber and the fiber. From a practical standpoint, the two-rolls mixing mill operation has certain common benefits and drawbacks. Rubber sheets are created after mixing in a hydraulic press with regulated temperature and pressure. The mechanical and thermal characteristics of rubber composites are determined in the next stage.

As nanotechnology advances day by day, nano-sized renewable fillers-reinforced NR composites are becoming an exciting topic in recent trends and opportunities. NR composites having nano-sized fillers with primary particles size having diameters below 100 nm compromise surface area to volume ratios, and has better interfacial and boundary qualities, which enable them to be superior in mechanical, thermal, and barrier properties. The below Table 1 shows the comparison of reinforcing improvement in NR products with various renewable organic reinforcing fillers. There have been several documented ways to alter the surface of natural fibers, such as grafting copolymerized monomers onto the fiber using maleic anhydride copolymers, alkyl succinic anhydride, stearic acid, etc. Additionally, coupling agents including silanes, titanates, zirconates, triazine compounds, etc. are known to enhance fiber-matrix adhesion.

Several research teams have previously looked at the applicability of jute fibers with and without surface modifications as fillers in rubber composites. The inclusion of jute fibers in rubber composites has been theorized as the cause of variance in key cure properties, including the maximum rheometric torque (R_{∞}), ideal cure time (t_{90}), and cure rate index. It was discovered that jute fibers treated with alkali/silane or modified with MWCNTs may both significantly increase the value of R for natural rubber composites. The correct dispersion of jute fibers inside the NR matrix and improved cross-linking in the NR composites are the key causes of this sort of enhancement in the R_{∞} value. The t_{90} and CRI values of composites were not significantly impacted by MWCNTs/jute fiber systems. On the other hand, an NR composite including 10 phr jute fibers and 2.5 phr stearic acid-modified nanoclay hybrid fillers system revealed an improvement in the CRI value, which demonstrated a positive synergism between jute fibers and stearic acid-modified system (Nair and Joseph 2014).

Hemp fibers were also employed as a green filler to strengthen rubber composites due to its high cellulose content (70%). Fiber and seed products made from different cannabis plant species are referred to as hemp. The usage of hemp strains cultivated

Table 1 Comparison of reinforcing improvement in NR products with various renewable organic reinforcing fillers

Reinforcing filler	Content	Tensile strength	Conclusion	Reference
Chitin nanocrystals (CNC)	20 wt%	116.4	The healing process of epoxidized NR/CNS's composites can be carried out in room temperature and can be used for sustainable material since CNS is a renewable material available in large quantity in nature	Nie et al. (2019)
Tunicate cellulose nanocrystals (one pot) Tunicate cellulose nanocrystals (two pot)	10 phr 10 phr	424.3 345.9	On comparing the result, it is seen that in both the composites hydrogen bond is formed and also the mechanical properties were increased	Cao et al. (2018)
Cellulose nanofibers (CNFs)	5 phr	35.4	CNFs are widely used as a reinforcing filler for rubber and resin; however, highly fibrillated CNFs are difficult to handle because it is hard to stop them from spreading. The use of CNFs in NR composites with the effect of their diameter distribution in mind should reduce the cost of production of CNFs, thereby enhancing their applicability	Kumagai et al. (2019)
Chitin nanofibers (ChNFs)	0.3 wt. %	145.3	This filler has high dispersibility and compatibility with natural rubber latex. They can be used for the making of artificial blood vessels, human diaphragm, etc.	Ding et al. (2019)

for low tetrahydrocannabinol (THC) content or with the THC eliminated otherwise is encouraged by legal restrictions for concentrations of the psychoactive drug components in hemp in many countries. Products made from refined hemp include fuel, hemp seed foods, hemp oil, wax, resin, rope, and textiles. The curing qualities of rubber compounds based on hemp fibers have received very little attention in past years. The integration of both surface-unmodified and surface-modified hem fibers resulted in a continuous rise in the magnitude of delta torque, or the difference between maximum and minimum torque. When compared to either unmodified HF's or silane-treated hemp fiber-based NR composites at the same filler loading, the improvement in the delta torque of potassium permanganate-treated hemp fiber-based NR composites was much superior. The way that water absorbs into a hydrophobic natural rubber matrix is less significant. The hydrophilic properties of hemp give its fibers a great propensity to absorb water. As a result, as the amount of fiber in the composites above grew, so did their water uptake percentage.

Additionally, the inclusion of hemp fibers in the composites complicated the process of water absorption in the rubber matrix (John et al. 2008; Krishna et al. 2022).

The seed of cotton plants belonging to the genus *Gossypium* develops in a bowl or protective capsule that is lined with a soft, fluffy staple fiber called cotton. Since this fiber is nearly entirely made of cellulose, cotton balls tend to spread the seeds more widely in their natural environment. The most popular plant fiber is cotton. Softness, good absorbency, color retention, and printability are just a few of cotton's qualities. It can also be machine washed and dry-cleaned, has good strength, drapes well, and is simple to handle and sew. It was effective to use cotton fibers to improve the mechanical qualities of NR composites. The addition of fibers has enhanced shear heating of composites due to the rise in bulk viscosity, which can also increase the rate of vulcanization. The optimal cure time of carbon fiber-reinforced composites decreased with an increase in the fibers loading. To increase the interfacial adhesion between natural rubber matrix and cotton fibers, maleated natural rubber is used as a coupling agent (Meissner and Rzymiski 2013). The amount of cotton used in natural composites consistently increased several significant mechanical parameters like hardness and tensile modulus, whereas the reverse tendency was shown for other mechanical properties like tensile strength and elongation at break. Due to the hydrogen bonding interaction between maleated natural rubber and the surface hydroxyl groups of cotton fibers, the aforementioned approach was able to significantly improve the mechanical characteristics of composites filled with cotton fibers.

Sugarcane bagasse fibers, both untreated and alkali treated, were utilized as filler for reinforcement in natural rubber. To untangle the web of hemicelluloses and lignin on the bagasse surface, alkali treatment proved quite helpful. The alkaline treatment has the potential to significantly shorten the composites' ideal cure period. In other words, as the percentage of alkali-treated sugarcane bagasse fibers used as filler in NR compounds increased, the optimal cure time reduced steadily. Composites made from natural fibers often have a wide range of uses in the building, construction, packaging, and automotive sectors. Natural fiber-based polymer composites have been widely employed by industrial businesses to create lightweight, ecologically friendly materials for the automobile sector. Natural fiber-based rubber composites have just recently begun to be used in the car sector. The fabrication of several interior components, including as seat bottoms, backrests, back cushions, and head restraints, has utilized a combination of natural rubber and coconut fibers. The primary use of natural fiber-based rubber composites in the car sector, however, remains debatable (Roy et al. 2021).

Cellulose Fiber-Reinforced Natural Rubber Composites

One of the most prevalent biomaterials on the planet is cellulose. Most often, plants generate it, but certain bacteria can also do it. Unlike starch, which has β -1,4 connections connecting its monomers, cellulose is a homopolymer of glucose. The sturdy formation of plant cell walls is greatly aided by cellulose, a hard, fibrous, and water-insoluble polysaccharide. The fibrils and microfibrils made up of cellulose

chains make up the plant cell wall. This arrangement shows that cellulose is a biomaterial with outstanding mechanical qualities and great strength, in addition to assisting in the stability of plant structures. Numerous living things, from the bacteria *Acetobacter xylinum* to forest trees, generate cellulose. The bacteria *A. xylinum* generates large amounts of cellulose, and it has been used as a model system for research on the structure of the cellulose product and cellulose production. The enzyme cellulose synthase, a membrane protein, catalyzes the direct polymerization of glucose from the substrate UDP-glucose into a cellulose product, which is how cellulose is produced (Nunes 2014).

These days, there are several techniques to synthesize cellulose at the nanoscale. Such nanofibrillated cellulose is normally quite strong and also possesses a number of intriguing qualities, including superhydrophilicity and intriguing rheological characteristics. Nanocelluloses can also be utilized in food, cosmetics, medicine, packaging, and many other applications. The projected usage is in novel lightweight composite materials for use in transportation and electrical applications. Cellulose-based NR composites demonstrate the combined behavior of the stiff, strong fiber reinforcement and the soft, elastic rubber matrix. The high amount of reinforcing available with long fibers is very difficult to achieve with short strands. However, because of their simple processing, high green strength, and the capacity to create complex-shaped products, short fiber composites are favored in goods like V-belts and hoses. Tensile strength develops a distinctive decline with increasing fiber volume content until a critical fiber level is achieved when fibers are oriented parallel to the stress direction (Phinyocheep 2014).

The maintenance of a high aspect ratio of the fiber, management of the fiber alignment, creation of a solid interface through physical-mechanical bonding, and formation of a high degree of dispersion can all improve the quality of a composite. In short elastomer composites, an aspect ratio of 100–200 is often needed for efficient reinforcing. Venugopal et al. found that adding carbon nanofibers to NR/cellulose nanofibers reduced cure time (t_{90}), but increased minimum and maximum torque (ML and MH) as the amount of added CNF increased. Furthermore, at 3 phr, the NR/CNF biocomposites showed outstanding NR reinforcement in terms of tensile strength, tear strength, hardness, and storage modulus. The diameter of reinforcing CNF affected NR; for example, the lower the diameter of reinforcing CNF, the greater the mechanical qualities of NR (Venugopal and Gopalakrishnan 2018).

Since both cellulose and NR are generated from renewable, biodegradable sources and are low-cost, low-density materials, using them together in composites has several benefits. Because they are simple to manufacture, have a high green strength, and can produce complex-shaped products, such composites are popular in goods like V-belts and hoses. These nanocomposite materials provide improved thermal, mechanical, and barrier capabilities at low reinforcement levels, as well as higher transparency and recyclability as compared to traditional composites. Results for NR/regenerated cellulose nanocomposites point to potential uses in regions where gas impermeability is crucial, as well as anytime the requisite mechanical performance of the article is better than that of a matching carbon black composition. Transparency, affordability, and biodegradability are other qualities that can be

Fig. 7 Illustration of formation of Zn-cellulose complex with CNC in the cross-linked natural rubber matrix (Blanchard et al. 2020)

necessary. Since they may be colored and have a light hue, NR/regenerated cellulose nanocomposites are appealing for industrial usage. Blanchard et al. investigate the addition of cellulose nanocrystals (CNC) to the NR matrix which increase the cross-linking effectiveness of the NR by forming a Zn cellulose complex, which improved ZnO dispersibility in the NR latex. The illustration of formation of Zn-cellulose complex with CNC in the cross-linked natural rubber matrix is illustrated in Fig. 7. The majority of applications are based only on laboratory research because there are few publications in the field of cellulosic nanofibers in NR matrix (Blanchard et al. 2020). Therefore, there is still a need to close the gap between research problems and commercial applications.

Marine-Based Natural Rubber Composites

The three primary physical spheres that make up the planet are air, water, and land. Water is essential for all life. The earth's surface is covered with water to a degree of around 80%. The aquaculture sector is expanding as a result of advances in aquaculture practices and rising human population. Consuming seafood at high and rising rates creates the issue of waste, or the components of marine food items that are not used. Waste from marine food items, particularly aquaculture animals, has been assessed for a variety of purposes because of its copious, affordable, and sustainable supply. Reusing discarded seafood is the most environmentally friendly approach to handle it (Thomas et al. 2021). Based on widely accessible, sustainably renewable agricultural and feedstock waste biomass, biodegradable plastics and bio-based polymer products do not ethically or financially compete with food production. Since marine animal shells cannot be consumed, they are a waste product from the food business and are not in competition with food demand, they are a low-cost commodity with no ethical issues.

The process of composite fabrication is such a way that the waste from acceptable marine products or marine crustaceans is first gathered. Typically, this comes in the

form of waste materials from the various food industries, but it can also take the shape of creatures caught by fishermen or gathered from the sea. The food sector views this as disposed as trash, creating an abundant supply of filler material. These discarded exoskeletons or shells are put through a washing procedure with fresh water for a number of washes before being dried in the sun to get rid of the remaining organic tissue and other impurities as well as the unpleasant smell. If NR is used, mixing the required quantity of marine powder, NR, and curing agent is the next stage in the rubber compounding process. A two-roll mill or internal mixer is used for mixing under previously experimentally adjusted settings (Boonrasri et al. 2020).

Inorganic components (CaCO_3 , SiO_2 , etc.) and biological components make up the majority of marine waste products (chitin, protein, etc.). The organic component of the biofiller acts as a compatibilizer to bind the filler particles to the rubbery matrix and increase the reinforcing mechanism. Due to their exceptional qualities, CaCO_3 -based compounds are now the most common engineering fillers used for industrial, medical, and environmental purposes. As a result, they make up more than half of this mineral's overall consumption. Additionally, using marine-based natural fillers like chitin (or chitosan, a derivative of chitin) from the aquaculture of crustaceans would assist to reduce waste and the need for nonrenewable petroleum and its derivatives. As a result, it will be easier to employ marine items as filler in NR vulcanizates. To determine what type of material may be used for industry, three requirements must first be met. First, the material needs to be able to sustain a supply while maintaining a competitive and steady price, which usually indicates there is not much competition from other uses. The second need is that the preparation procedure be simple, easy to manage, and eco-friendly. The materials must also be promptly available and require little to no modification (Poompradub 2014).

Chitin whiskers were used as the reinforcing phase and latex from both unvulcanized and prevulcanized natural rubber as the matrix to create nanocomposite composites. The chitin whiskers were created by Gopalan et al. (Gopalan Nair et al. 2003) by acid hydrolyzing the chitin from crab shells. Because unvulcanized evaporated samples include a chitin network, it has been found that they are more resistant to swelling tests than freeze-dried samples. Increasing the whisker content was also observed to reduce the level of sample swelling in each approach. The high swelling resistance against organic solvents was made possible by this stiff chitin network. Additionally, the relative weight loss, bound rubber content, and diffusion coefficient data were considered to validate the presence of chitin network. The resultant nanocomposite films' mechanical performance was examined in both the linear and nonlinear ranges. The capacity of chitin whiskers to create a solid three-dimensional network, brought on by strong interactions like hydrogen bonds between the whiskers, was crucial for the reinforcing effect. The findings from the subsequent tensile test studies provide convincing proof that the evaporated samples contain a three-dimensional chitin network.

According to A. Roy et al., the natural rubber/chitin composite's tensile modulus initially fell, then climbed as the chitin percentage rose until it reached its highest point. If more filler content is added after a material reaches its maximum tensile properties, reinforcing results in a reduction in the material's tensile strength. The

filler's inability to support the stresses imposed by the polymer matrix at lower filler levels can be used to explain the initial decline in tensile strength, and further increases can be attributed to the filler's ability to support the stresses imposed by the matrix as the filler quantity increases. The decrease in tensile strength following the ideal filler ratio demonstrates that as a material's reinforcement increases, its tensile strength also increases until more reinforcement is added (Roy [n.d.](#)).

Carbon Allotropes for High-Performance Natural Rubber

Rubbers are widely used in a variety of industries, including civil applications, biomedical applications, aerospace exploration, automotive engineering, and others. Although the unfilled rubbers often exhibit poor mechanical properties. In order to strengthen the rubbers, various fillers like as clay, silica, and carbon black must be used. These fillers make it simple to adjust the rubber's toughness, elongation at break, tensile strength, and modulus for a variety of applications. For the quick development of sophisticated technologies, rubber goods with some increased functionalities and exceptionally high mechanical performances are needed. Numerous interesting uses for 2D carbon-based materials exist, including biosensors, fuel cells, energy storage, and water filtration. New generations of sp² carbon allotropes have been accessible during the past few decades, including graphene, carbon nanotubes (both single- and multiwalled), and graphitic nanofillers consisting of a few layers of graphene. There are still many thrilling obstacles to overcome in the search for the rest of this family. There are many new allotropes to be created, and merging our fundamental low-dimensional forms into more intricate 3D buildings is extremely difficult (Fang et al. [2020](#)).

When contemplating the results of adding nanometer-scale particles, such as different carbon allotropes, to natural rubber, the phrase "reinforcement" can have a number of different interpretations. The element researched the most in the nano-age is carbon. Allotropes of carbon include graphite, diamond, fullerene, carbon nanotubes (CNTs), graphene (GE), and amorphous carbon, among others. These carbon structures have been studied for a number of years and are used in a variety of scientific and technological disciplines, particularly in rubber nanocomposites. A crucial contribution to the mechanical reinforcement is made by the nanostructured fillers CB and silica, whose aggregates include voids that can occlude and immobilize polymeric rubber chains. Cross-linked rubbers are typically brittle materials without additives. Depending on the size, shape, and type of elastomer-filler interactions, reinforcing filler particles can improve rubber's tensile strength, tear resistance, and abrasion resistance to variable degrees. They can also improve rubber's static and dynamic stiffness properties (George et al. [2021](#)). These all constitute enhancement of the mechanical properties.

Due to their improved qualities, carbon nanofillers and their nanohybrids reinforced NR and NR mix nanocomposites may find greater uses in tires, adhesives, surgical gloves, sealing materials, etc. Numerous researchers have examined the mechanical characteristics of various carbon filler-based natural rubber

nanocomposites. Carbon black is the most common type of filler (Robertson and Hardman 2021) used in demanding rubber applications, such as automotive tires and mechanical rubber goods. It comes in a variety of grades with a wide range of particle sizes (surface areas) and aggregate morphologies that are nanostructured to produce different property balances. The 15 million metric tonnes of carbon black produced annually across the world are utilized in rubber applications (73% for automotive tires and 20% for nontire rubber goods), with the remaining 7% going toward compounding paints, coatings, inks, and plastics. Fig. 8 shows the industrial applications of carbon black filler for demanding rubber applications.

The mechanical characteristics of multiwalled carbon nanotube–reinforced thermoplastic natural rubber nanocomposites were studied by Tarawneh et al. (2011). Using melt blending process polypropylene, liquid natural rubber, and natural rubber as compatibilizers with 1–7 wt% MWNTs were incorporated as nanocomposites. At 3 weight percent of MWNTs, the tensile strength and Young's modulus improved by about 39 and 30%, respectively. As the proportion of MWNTs increased, the elongation at break dropped. In comparison to a clean TPNR sample, the highest impact strength was measured at 5 weight percent MWNTs, a 74% increase. Hybrid nanomaterials have also been utilized to reinforce natural rubbers, including MWCNT/silica, MWCNT/CB, CNT-clay, and CNT-graphene. By using melt mixing procedures, Fritzsche et al. (2009). integrated MWCNTs in highly silica-loaded NR. The amount of silica has been sequentially replaced by the same amount of MWCNTs up to 10 phr of MWCNT in order to distinguish between attributes that are based on silica and MWCNT. The resultant samples exhibit improved tensile strength and mechanical stiffness. When a portion of the silica is replaced with 10 phr of MWCNT, the tensile strength rises from 14–17 MPa, however the elongation at break gradually decreases.

Carbon nanotube (CNT) is a nanofiller with considerable potential to enhance the characteristics of rubber composites, both single walled and multiwalled. In general, carbon allotrope's solubility parameter is determined by the functionalizing molecule while constructing the functionalization process. The carbon

Fig. 8 Industrial applications of carbon black filler as represented on the basis of reported data, adapted from reference (Robertson and Hardman 2021)

allotrope may be modified to be more or less compatible with various environments, including rubber phases. Functionalization techniques' major goal is to create dispersible tubes out of CNT bundles that can interact strongly with the matrix. Covalent or noncovalent functionalization, as well as endohedral or exohedral functionalization, are used to complete it. Rubber composites are regularly prepared using functionalized CNT. Utilizing oxidation methods, -OH and -COOH groups are preferentially introduced. Polar rubbers or rubber latexes are preferred when mixing CNT with polar groups. This composite offers higher mechanical and electrical characteristics, better qualities under stretching, decreased permeability to oil, etc. Stronger interfacial contact, also via covalent bonding, with rubber is achieved by using GO derivatives in the manufacture of rubber composites and by adding polar groups to the graphitic layers. Materials that self-assemble and heal self are produced when polar functional molecules, such as antioxidants, are loaded onto the filler (George et al. 2021).

The two techniques that are most frequently utilized to create rubber nanocomposites are melt mixing and solution approaches. Individual carbon-based fillers such CNT, CNF, graphene, expanded graphite, and graphene oxide exhibit improved mechanical and dynamical mechanical capabilities, which are explained by the state of dispersion of the fillers. The hybrid fillers made up of MWCNT or (CNF)-MMT, MWCNT-hectorite, MWCNT-LDH, and MWCNT-graphene in various rubber matrixes also significantly increase performance. These carbon-based fillers are assumed to have significantly increased tensile strength, impact strength, elongation at break, Young's modulus, stand loss modulus, storage modulus, and other properties of NR, SBR, NBR, and SR nanocomposites. However, more recent work must continue to be concentrated on the creation of related EPDM and EVA systems.

Natural Rubber for Asphalt and Bitumen Modification

The addition of polymers can improve asphalt mixtures' elasticity and flexibility, enhancing their resistance to thermal cracking and fatigue. The thermal and binding properties of natural rubber make it used in bitumen modification. It acts as an elastic band in the cold season and on increasing the temperature it functions as a film that improves the fracture toughness, thus preventing the movement of bitumen (Azahar 2016).

Raw NR latex is not utilized directly due to its high water content and sensitivity to bacterial attack. The latex must always be protected as well as concentrated by centrifugation, evaporation, and creaming so that the finished product is stable and includes 60% or more rubber. Usually, ammonia is added during these processes for preventing latex from bacterial attack (Bottier 2020). The introduction of NR to asphalt modification is accidental when there is a fall in concentrated NR latex price which is ready to sell in many top countries and this modification became a winning situation and big relief to the rubber farmers and also can improve the road transit system which are in poor shapes.

During the 1950s and 1960s, the majority of investigations on NR-modified asphalt were undertaken in the UK (United Kingdom). NR power (unvulcanized or moderately vulcanized) and NR latex were studied and compared. Adding NR powder to asphalt pavements had various benefits, along with improved rutting and fatigue resistance. However, it had some downsides, including a high mixing temperature and a long mixing period of up to 2 h (Wen et al. 2017). As the rubber particles in NR latex are well dispersed, they can be used to avoid such drawbacks. As an asphalt binder modifier, NR latex has several advantages, including better resistance to rutting and thermal cracking in asphalt pavements.

Natural Rubber Latex Composites

NR latex is a polymeric substance that is reusable and has outstanding physical characteristics and flexibility. Prevulcanized latex is an easy raw material for the production of thin film goods like gloves, condoms, and other medical items. To boost the film hardness and tensile strength, the rubber chains inside each NR particle must be treated with sulfur or partly cross-linked NR latex has some drawbacks, which includes low chemical resistance and processing capacity. Since prevulcanization causes the first cross-linking to occur within the latex particles, the physical characteristics of the finished product can be efficiently tailored before the articles are made. It is well known that the vulcanization systems affect how quickly the prevulcanization reaction occurs, and that the degree of prevulcanization has a significant impact on how the latex film forms. The cross-links between the rubber chains in the sulfur prevulcanized NR particle may be created by heating the combination of NR latex and the aqueous dispersions of S, ZnO, and accelerator zinc diethyldithiocarbamate. Other than prevulcanization, it has been claimed that chemical modifications of natural rubber latex can be used to get around certain inherent problems with NR vulcanizates caused by high unsaturation and the presence of allylic carbon, which results in changes in molecular structure. The corrosion and flame resistance offered by chlorinated NR latex can be used in coating formulation. Superior thermal stability is achieved by limiting oxidative degradation of NR as a result of hydrogenation and metathesis processes.

For the vast range of potential uses, such as paint, controlled-release medicine delivery systems, and toughening agents for thermoplastics, latex particles must have the appropriate characteristics and attributes. Due to its economic benefits and convenience in formulation, the modification of NR in latex state – a water-based, solvent-free, and low-volatile organic compound system – is preferred. To avoid interfering with their natural stability, creation of NR latex particles demands a deeper knowledge of their colloidal nature. The surface functionalization or hetero-phase radical polymerization process, which permits the insertion of functional groups or polymeric shell, can be used to modify NR particles in a manner similar to that used to modify synthetic polymer colloids. These manufactured particles with planned morphologies can be applied in a variety of contexts. For instance, when utilized as nanofiller, the modified NR particles give the films outstanding mechanical qualities as well as functionality. The presence of extensive double bonds in the

Fig. 9 (a) NR latex particle surrounded by double layer of proteins and phospholipids. (b) Proposed new model comprising a mixed layer of proteins and phospholipids around the latex particle (Nawamawat et al. 2011)

NR chemical structure accounts for the low resistance of NR latex thin films to heat, oxygen, and ozone (Kawahara et al. 2003).

Latex stability is extremely dependent on the pH and ionic environment in the dispersing medium. NR latex is colloidally stable due to the negatively charged phospholipid-protein complexes on its surface. The most abundant phospholipid is strongly attached lecithin on NR latex. Figure 5 shows that the negatively charged phospholipid protein complexes in the surface of rubber particle help in the colloidal stability of NR latex. According to Nawamawat et al., NR latex particle comprises a hydrophobic core of rubber molecules that are surrounded by a double layer of proteins and phospholipids Fig. 9a. The ω - and α -terminal ends of the NR molecule are connected with proteins and phospholipids, hydrophilic endings on the particle surface. The hydrophobic core should subsequently be formed by the polyisoprene molecules, resulting in a core-shell-like particle as shown in Fig. 9b (Nawamawat et al. 2011).

Epoxidized Natural Rubber Composites

Natural rubber can be epoxidized by the conversion of unsaturated linkages in rubber chains to oxiranes. Even though the first report about epoxidized natural rubber (ENR) happened at early 1920s, its commercial exploitation started only at late

1980s. The higher glass transition temperature compared to NR gives ENR some special properties like better damping, higher permeation to air, superior hysteresis, high wet grip, and, moreover, increased polarity. Epoxidation more than 20 mol% will not change the elasticity of original NR, but the presence of oxirane groups opens the possibility of a wide range of chemical reactions involving reinforcement systems and novel cross-linking systems.

Since the NR is nonpolar, the process of epoxidation increases NR's polarity and can also improve its chemical resistance and new properties are given to the polymer, commercially prepared using peracid. This process can elevate the oil resistance by maintaining the dynamic and static mechanical properties of NR. These composites are oil resistant in the same way as polar rubbers like nitrile butadiene rubber are. They have lower permeability toward nitrogen and oxygen and have good wet fraction and modulus compared with the natural rubber. Mainly used in the manufacture of tires and rubber mechanical goods (Gelling and Morrison 1985; Imbernon et al. 2016; Perera 1990), and also in the application of oil and abrasion resistance,

epoxidized natural rubber composites can be chemically modified by partially converting the unsaturated bonds on the backbone of NR to epoxy groups. Carbon black (CB)-filled composites are one such example that was made using epoxidized guayule natural rubber (EGNR)/guayule natural rubber (GNR) blends and GNR. It has been found that addition of ENR will definitely increase the impact strength of the resultant material. The load-bearing capacity was found to increase significantly as a result of rubbery phase morphology and extended chain conformations. Effect of ENR inclusion in varieties of blends and composites are summarized in the following Table 2.

The polar groups present in ENR is the key factor in increasing the toughening property of all these blends/composites as they form good interfacial adhesion. It was also found that the presence of ENR rubber phase is enhancing the uniform distribution of different types of fillers like OMMT and coal gangue powder. Introduction of ENR/LENR into epoxy systems also results in superior mechanical behavior. The toughness of epoxy system is enhanced due to the creation of discrete rubber particles in the precured epoxy mixture. Chemical cross-linking is formed between the two phases which include ring opening of epoxide and glycidyl groups by the carboxylic terminal in the rubber chains.

Applications of Gutta-Percha Rubber

Gutta-percha (GP), a revolutionary material, was first used in the early eighteenth century in several fields. In 1756, Europeans collected water-resistant shoes, textiles, and utensils from the Indian continent. Since working with impermeable, highly elastic gutta-percha is challenging, people began using these rubbers as adhesives at room temperature, especially when two pieces came into contact. When Alexander, Cbriot, and Duclos won the gutta-percha patent in 1864, it became an industrial product. Insulation of underwater cables, stoppers, pipe cement, threads, surgical equipment, clothing, musical instruments, suspenders, shutters, carpets, gloves,

mattresses, pillows, tents, umbrellas, golf balls (gutties), ship sheathing, and boats made entirely of GP has all been successful (Goodman et al. 1974).

Gutta-Percha in Dentistry

In the 2000s, rubber-based dental dams for endodontic applications became increasingly popular. Reamers (hand instruments) were frequent material used for dental dams at that time which has been replaced by rubber, combined with sodium hypochlorite and EDTA as canal irrigants. Rubber-based dental dams and reamers showed no significant differences (Kapitán and Šustová 2011). These rubber-based materials were subsequently replaced by gutta-percha-based materials.

Although there is rigorous endodontic research occurring for better root canal fillers and preventive measures for microbial infections, gutta-percha is still one of the finest materials in dentistry even after 170 years. Gutta-percha has several advantages over other materials like low toxicity, less allergic, ease of use, and the flexibility to use as a matrix for a variety of fillers; also it is used to seal teeth canals. Evolution of gutta-percha in the field of dentistry is illustrated in Fig. 10. Modified gutta-percha based on bioceramic coating was used to enhance the quality of obturation, and reduce the shrinkage which can in turn benefit sealing the canals (Ahmad 2009). According to the adaptability of gutta-percha along with iodoform, calcium hydroxide, and chlorhexidine, chlorhexidine (CHX) and tetracycline enabled it to be applicable in different dentistry therapies which resulted in improved

antimicrobial properties, inhibiting the growth of *Staphylococcus aureus*, *Streptococcus sanguis*, *Actinomyces odontolyticus*, *Fusobacterium nucleatum*, *E. faecalis*, and *Candida albicans*, among other bacteria (Shur et al. 2003; Kim and Kim 2014; Öztan et al. 2006; Bodrumlu et al. 2008).

Evolution of Gutta-Percha in Dentistry

Gutta-percha is a biocompatible material that can be used for drug delivery, endodontic therapy, apical surgery, and rehabilitation. By incorporating nanoparticles into these biocomposites, they may be able to minimize root canal reinfection and improve treatment outcomes. Carbon nanoparticles, nanodiamonds (Lee et al. 2015), and silver nanoparticles (Shantiaee et al. 2011) have been used in the gutta-percha composite. Silver nanoparticles in gutta-percha have great antibacterial activity over a long period, are low in toxicity, have limited bacterial resistance, and are biocompatible with human cells.

The use of hot gutta-percha in thermal stimulation for measuring tooth vitality and intracorneal tooth preparation has become widespread. It can be accurate to 3 mm of the lesion in a diagnostic adjuvant in surgery. On the other hand, cold

flowable gutta-percha root canal obturation after apexification on young permanent teeth can obtain a good obturation outcome. When compared to hot gutta-percha, this cold flowable gutta-percha was found to be more effective in reducing clinical treatment time and improving patient therapy comfort. GP is inexpensive and readily available, its versatility and ease of usage with other materials have made it a popular choice for producing new materials for therapeutic purposes.

Gutta-Percha for Highly Stretchable Films/Membranes

Gutta-percha was started being utilized in the manufacture of coatings, packing materials, and other products replacing old petroleum-based materials, which polluted the environment significantly. It was employed as a biopolymer that is renewable and has good mechanical, thermal, corrosion, and electrical conductivity. It exhibits exceptional flexibility, with a reported elongation at break of 247.7% for the gutta-percha film, and is used as a material to be coated with compounds like zinc oxide and silver nanoparticles to increase the antimicrobial activity of the material (Mohan et al. 2020).

At normal temperature, gutta-percha can crystallize. Novel composites and products can be generated as a result of these individual qualities, or the properties of single-component biopolymers can be improved by mixing gutta-percha with these biopolymers. These biopolymer-based biofilms became very helpful in protecting soil coverings, packing materials, and crops against microbial inflation. Q.Q. Sun et. al found that biopolymers like nanocrystalline cellulose/gutta-percha have improved mechanical and water vapor barrier properties. Biochar was also used to develop GP-based biodegradable composite films that might be useful in a range of industries, including agricultural (mulching and pest protection or treatment), packaging, and electromagnetic interference shielding. This helps to replace potential pollution sources in the environment.

Gutta-Percha for Oil-Water Emulsions Separation

Gutta-percha is an isomer of natural rubber with the molecular structure of trans-1,4-polyisoprene. This structure gave some unique properties like enhanced hydrophobicity and rubber-plastic duality to GP. It is thought to be an excellent candidate for increasing nanofiber membrane flexibility and surface wettability. These renewable biopolymer membranes can be used as an alternative to petroleum-derived membranes.

Oil contamination of water has escalated into a significant environmental problem with long-term consequences for human health. To combat this oil contamination of water, the oil-water emulsifier should disperse. Separation of oil-water emulsions become difficult when the oil droplet diameter is lower to about 10–20 μm as the droplet gets more stabilized at that lower diameter range. Traditional chemical and physical processes such as flotation, absorption, and skimming can be used to

dispose off oily wastewater. However, those approaches are expensive, inefficient, and hard to implement, which is especially unfavorable for oil-water emulsions because the density difference has a significant impact on the separation processes. Thus, an alternative technology based on the wettability difference and sieving effect becomes popular in oil-water emulsions separation. Membranes for oil-water emulsions require these special wettability surfaces with suitable pore sizes allowing the wetting phase to penetrate the membrane. To ensure these requirements, membrane surface modification via an in situ blending or cross-linking can be done. Yichun Yahn et al. synthesized a blend membrane of silylated natural nanofibers and gutta-percha (Ren et al. 2018). This membrane was found to have excellent high hydrophobicity and crystallinity with good mechanical performance, thermal stability as well as water vapor permeability. Especially, the fabricated composite membranes exhibited excellent petroleum ether, dichloromethane, toluene, and cyclohexane in water emulsions separation effects. By integrating gutta-percha into silylated nanofibers from herbal leftovers, renewable hydrophobic membranes for oil wastewater (oil-water emulsion) separation have been successfully constructed. Instead of these silylated nanofibers, Sun. et.al used nanocellulose to improve the tensile characteristics of gutta-percha composite films (Yang et al. 2020).

Gutta-Percha for Electrical Applications

Gutta-percha was made by evaporating the gutta-percha tree's milky fluid and coagulating the latex, yielding an inelastic solid insulator. In hot water, this material softened and gets hardened without becoming brittle after cooling. This is a unique advantage over Indian rubber, which had previously been used in cables. GP was designed to be used underwater, where submersion kept the wire out of sunshine which caused it to deteriorate and the cold and pressure environment enhanced its insulating properties.

Gutta-percha as an insulating material for electrical applications got its start in 1850 when a cable crossing the English Channel to France broke after carrying some signals. That cable was replaced by another cable brought from the Malay Peninsula which was coated with waterproof insulating material. It provided good inelastic, strong insulation that softened when exposed to hot water and cooled hard but not brittle. The main issue they had was that gutta-percha deteriorated in the sunshine (Faraday 1848).

Gutta-percha became an industrially prominent and easily processable low-cost material when it was initially used for electrical and water insulation for telegraph cables; various layers of gutta-percha-coated cables for electrical application are shown in Fig. 11. In the early 1800s, gutta-percha and balata were commonly used as underwater insulating materials. Long deep-sea telegraph cables have too high dielectric losses to suit the demands of underwater communication system cables that must operate over long distances or shorter cables that use carrier currents.

Fig. 11 Various layers of electrical cables coated with gutta-percha. (Adapted Reference Panuganti et al. 2016)

To deal with the mechanical instability of gutta-percha or to adjust its mechanical properties, a new material called paragutta was developed. Pure balata (gutta-percha) hydrocarbons and rubber hybrids make up the majority of it, with a few waxes tossed in for good measure. This commercial method was used to purify rubber, particularly in terms of nitrogenous components, which was necessary for enhanced electrical stability in water. Paragutta had all of the desirable features of thermoplastics and gutta-percha's mechanical properties, as well as improved insulating properties. Its suitability for both long-range transoceanic and shorter-range coastal maritime telephony was improved as a result (Kemp 1931).

Conclusion

After air, water, and petroleum, natural rubber is the fourth most significant natural resource on the modern earth. Due to its distinctive molecular identities, NR is predicted to be used more and in higher-quality products throughout this century. Additionally, the twenty-first-century global environment will require particular types of renewable resources if sustainable development is to be implemented in daily life. The natural rubber-based nanocomposites have a wide variety of application in many fields and the replacement of synthetic filler with bio-based filler increases its application in many areas and also increases fiber content leading to an

increase in the strength and modulus of a fiber-reinforced rubber matrix composites. Although some dentists still use it to create temporary fillings, gutta-percha is rarely utilized any more. It is occasionally combined with balata resin, a very comparable substance used in conveyor belts. To use natural rubber and gutta-percha more methodically and following its characteristics, research- and application-focused initiatives have to be activated.

Government laws, customer preferences, and in certain cases the potential financial benefits that may be gained from the use of these materials and technologies have all contributed to the industry's increasing emphasis on environmentally friendly materials and technology. Bio-based composites have undergone years of development, and they are now getting closer to matching or even surpassing the cost and performance criteria of conventional composites. However, despite these developments, there are still several issues that limit the use of bio-based products in the automobile sector. Automakers are typically hesitant to pay a premium for parts and components due to the fierce pricing competitiveness in this industry. Therefore, suppliers need to overcome this flaw in bio-based products.

Abstract

Albumin is one of the most abundant plasma proteins found in recent times to possess multifunctionality. This chapter reveals the properties and engineering applications of albumin-based hydrogels influenced by chemical crosslinking, drug-coating techniques, pH, and thermal induction. To provide context, we first examine the nanotechnological techniques of developing albumin nanoparticles. Though albumin hydrogels generally find application in tissue engineering, they could also find usefulness for skin and wound healing, as well as toxicological studies involving stem cell-derived nerve cells, disease modeling, and drug delivery, when chemically cross-linked. This is because, cell survival and growth of

chemically cross-linked albumin is possible, rather than when subjected to severe heat and acidic or alkaline conditions. Finally, albumin coatings via linkage engineering, electrostatic interactions, and electrostatic deposition are presented.

Albumin hydrogels · Nanotechnology · Delivery systems · Engineering applications · Properties

Introduction

Albumin is an ubiquitous plasma serum protein presently investigated for several applications, because of its multifunctionality (Ong et al. 2019). Specifically, albumin-based hydrogels are researched for applications in tissue engineering and regenerative medicine since they are inert (Ahmed 2015; Elsadek and Kratz 2012), nonsynthetic, xeno-free, stable, and nontoxic (Das et al. 2012; Yamasaki and Anraku 2016) with a molecular weight of 66.4 KDa, and having about 585 amino acids (Dixon et al. 2020). Albumin-based hydrogel composites are widely explored due to their desirable mechanical and biological properties (Clura et al. 2020). This binding with other composite materials becomes necessary to address the present challenges of poor metabolism, poor immunogenicity, and other limitations associated with albumin protein (Solanki et al. 2021; Haggag et al. 2018).

The improved mechanical properties of albumin when induced thermally and chemically cross-linked include Young's modulus of -46 Kpa, and -34 Kpa for 20 wt% (Amdursky et al. 2018a), and 17 wt%, bovine serum albumin (BSA) (Baler et al. 2014), respectively. Also, tensile strength of -2 – 5 Mpa for 3–9 wt% BSA, and -40 MPa for 10 wt% human serum albumin (HSA) (Zhao et al. 2019; Khairuddin et al. 2018). In addition, most albumin hydrogels are printable under thermal conditions since heat is required to induce gelation (Djoullah et al. 2018). However, the coatings with other materials, particularly drugs, enhance the half-life and treatment efficiency of the drugs (Park et al. 2018) and improve albumin biocompatibility, biodegradability, immunogenicity, metabolism, hydrogel turbidity, storage, and loss modulus, amid others (Naftaly et al. 2021; Arabi et al. 2020).

Presently, more studies are emphasizing novel techniques of enhancing several properties of albumin composites than their applications. Within the last 6 months, numerous studies have emphasized properties improvement. To illustrate, Naser et al. (2022) report on the need to enhance the biodegradable nature of albumin-based composites for suture development in tissue engineering. Also, Wang et al. (2022a) argue that color tunability and self-healing properties of albumin hydrogels should be addressed through a reductant-triggered gelation. They believe that when developed, this protein-based hydrogel could be used to develop optical devices and enhance biomedical applications. Similarly, Sharifi et al. (2022) report that HSA could be a suitable platform for different biomedical applications when the anti-inflammatory properties of the hydrogel are improved through a methacryloylated

synthesis process. Few studies that have considered direct application of albumin-based composites have reported on their use for delamination of MXenes for application in environmental engineering, medicine and biology (Seredych et al. 2022), therapeutic applications with fatty acids interactions (Linciano et al. 2022), and for electrical stimulation of heart cell growth (Gerasimenko et al. 2022).

These applications are possible because albumin binds with other materials including carbon nanotubes (Lu et al. 2018), curcumin-capped mesoporous silica nanoparticles (NPs) (Fu et al. 2022). Research have shown that albumin-based NPs are most commonly used for various applications. In this chapter, we present nanotechnological techniques for producing albumin NPs and consider albumin-based hydrogel applications in drug delivery and clinical conditions.

Albumin-Based Hydrogels for Regenerative Engineering: Synthesis and Properties

For pH-induced albumin hydrogels, it is possible to obtain a clear hydrogel polymer from soluble albumin by altering the pH conditions. Studies have shown that reducing the pH below 2.3 changes albumin structure to an extended form. Similar pH changes between 2.3–4.2, 4.3–8.0, and 8–10 adjust the hydrogel structure to fast migrating, normal, and basic forms, respectively. Albumin could also become aged when pH is adjusted beyond 10 (Ong et al. 2019; Baler et al. 2014). On the mechanical properties, Baler et al. report a Young's modulus of 46 kPa for 20 wt % BSA via indentation. Also, 5–10 and 60–80 kPa storage, G' and loss modulus G'' , respectively, were noted for the 16 and 20 wt% BSA after 2300 and 340 s, respectively. The hydrogels exhibit low immunogenicity, rapid biodegradability, difficult printability, and “clear to translucent hydrogel turbidity.”

Considering thermally induced albumin hydrogels, studies have shown that heat-induced gelation process can be used to ensure stability of albumin hydrogels (Nandlall et al. 2010; Lantigua et al. 2020). Young's modulus of the hydrogels is ranged about 34 and 67 KPa at a pH condition of 3.5 for 17 and 20 wt% BSA hydrogels (Amdursky et al. 2018b). Under conditions of tension and confined compression, the Young's modulus differs even for same weight BSA hydrogels. Though huge amounts of heat are required, printability is possible, low immunogenic effect is observed, and biodegradability occurs over a month. Notably, the storage G' and loss modulus G'' were 120 and 60 KPa for both 16 and 20 wt% hydrogels, respectively. Recently, Lantigua et al. fabricated BSA hydrogels through a photo-cross-linking method with volumes of glycidyl methacrylate in the modification process. Based on the study, the BSA can be used in regenerative medicine and other biomedical applications. The hydrogels resemble those of native tissues due to tissue infiltration in the host tissue, and high binding ability to the native molecules. This illustrates the extent of biocompatibility and integration with the tissue environment. Similarly, the hydrogel materials have desired ranges of mechanically tunable properties including strength of the materials, pore sizes, swelling, and degradation.

More recently, Phan et al. fabricated and applied the triblock copolymer of poly (E-caprolactone-co-lactide)-b-poly(ethylene glycol)-b-poly(E-caprolactone-co-lactide) with BSA bioconjugates for wound healing. Despite the wound healing effects of these injectable hydrogels, they could also be used in regenerative medicine when correctly modified. Biocompatibility of the gels was demonstrated via the fact that “the tissue was intact without any inflammation” according to the study. Also, since improved tissue-like mechanical properties are required for its repair and regeneration (Ebhodaghe 2020, 2021), presence of the “protein-polymer bioconjugates” aided tunability of the mechanical properties of the hydrogels (Chen et al. 2020). Furthermore, Smith et al. (2020) developed the protein constructs of 3D – printable methacrylated BSA through a two-step additive-manufacturing process using a laser-based stereo-lithography printer. These hydrogels can be used for load-bearing in tissue-engineering applications. This is because, cell viability of the hydrogel (>95%) was observed after 3 weeks of culture.

Influence of Cross-Linking and Thermal Induction on Albumin

Amighi et al. (2020) examined the possible use and effect of different cross-linkers (such as tannic acid, glucose, citric acid, ascorbic acid, and sorbitol) on albumin prepared through desolvation process. Overall, the use of glucose cross-linking agent was preferred to toxic glutaraldehyde. This is because, the parameters of size, zeta potential, and FTIR were similar for both cross-linking agents. Moreover, their physical characteristics were same.

On thermal effect, Zhao et al. (2021) prepared doxorubicin (DOX)-based hydrogel through a molecular imprinting method. The DOX imprinted hydrogel exhibited “much higher affinity and selectivity to DOX” than the albumin. This became possible through processes of thermal denaturation, refolding of the thermally denatured BSA, and then polymerization and cross-linking with formaldehyde. Also, Matsarskaia et al. (2020) investigated the influence of common salt on the statics and dynamics of thermally denatured BSA, examined via small-angle neutron scattering and quasi-elastic neutron scattering. While the salt had no obvious effect on the stability and dynamics of the denatured solution, the protein dynamics slowed down in the salty solution. Studies have similarly reported the influence of amino acids (glycine, alanine, proline, and arginine) on the thermal stability and unfolding of BSA (Pal et al. 2020).

Techniques for Albumin Production

Albumin-Bound Technology

Modification of albumin enables its usefulness in specific organ and cancer targeting (Lamichhane and Lee 2020). While a general overview of nanotechnological techniques for albumin modification is presented in Fig. 1, specific modification for target delivery to tumor and cancer sites is shown in Fig. 2. For

Fig. 1 Nanotechnological tools for albumin modification (Reproduced with permission from: Carolina Salvador-Morales, Piotr Grodzinski. *ACS Nano* 2022, 16, 4, 5062–5084)

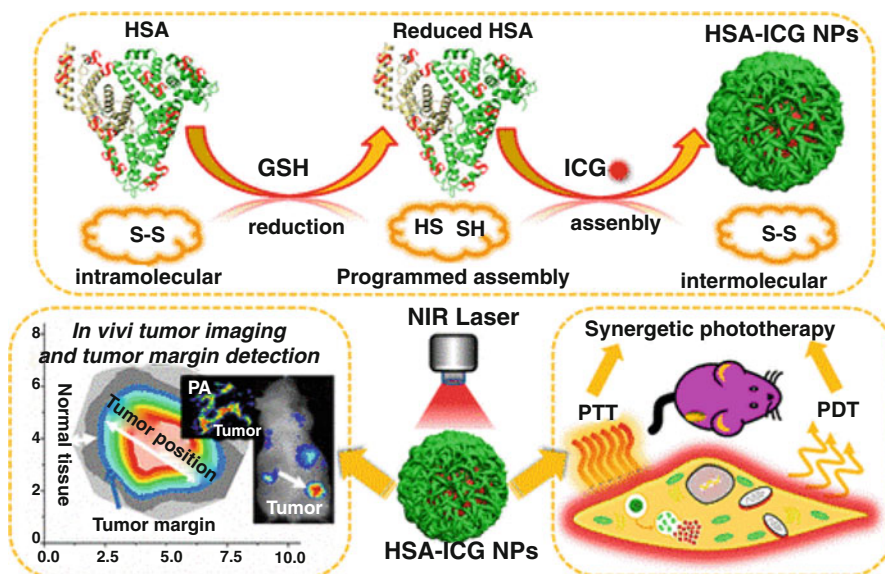

Fig. 2 Albumin nanoparticles for cancer and tumor phototherapy in rodent models (Reproduced with permission from: Zonghai Sheng, Dehong Hu, Mingbin Zheng et al. *ACS Nano* 2014, 8, 12, 12310–12322)

example, several techniques have been developed for liver as a target site which includes targeting asialoglycoprotein receptors (Lamichhane and Lee 2020), targeting mannose-6-phosphate/insulin-like growth factor 11 (Feczko et al.

2019), targeting mannose-6-phosphate receptors (Yang et al. 2018), and targeting glycyrrhetic acid receptor (He et al. 2018). Notably, doxorubicin (DOX) -based recombinant human serum albumin (rHSA) incorporated with glycyrrhetic acid targeted to liver cancer cells. Besides recombinant HSA, DOX could be also loaded with BSA nanoparticles (NPs) with folic acid-modified dextran surface (Lee et al. 2020), BSA/chitosan core (Shen et al. 2018), PLGA NPs (Cao et al. 2019), Fe₃O₄ magnetic NPs (Norouzi et al. 2020), and hyaluronic acid NPs (Tian et al. 2019). Also, the HSA NPs could be loaded into loperamide for targeted delivery to the brain (Harti et al. 2021).

When HSA is compared to Fe and PEG drug delivery vehicles, though these are all very soluble in water, only HSA and Fe are quite biocompatible in their low immunogenicity and toxicity within few weeks, and they are also biodegradable (Juan et al. 2019; Levy et al. 2015). However, only HSA is more suitable for drug delivery. This is because of several reasons. First, it exhibits higher loading efficiency which makes it able to bind metal ions, synthetic drugs, peptide hormones, and proteins (Saleh et al. 2019). Next, the HSA is more stable than the others (Qu et al. 2019). This is due to its ability to resist high temperature conditions as well as low pH (Poureshahi et al. 2017). Finally, it is more tumor specific, which is due to SPARC and gp60 binding capacity (Li et al. 2017). Figure 3 shows how these protein pathways could aid drug delivery to target sites.

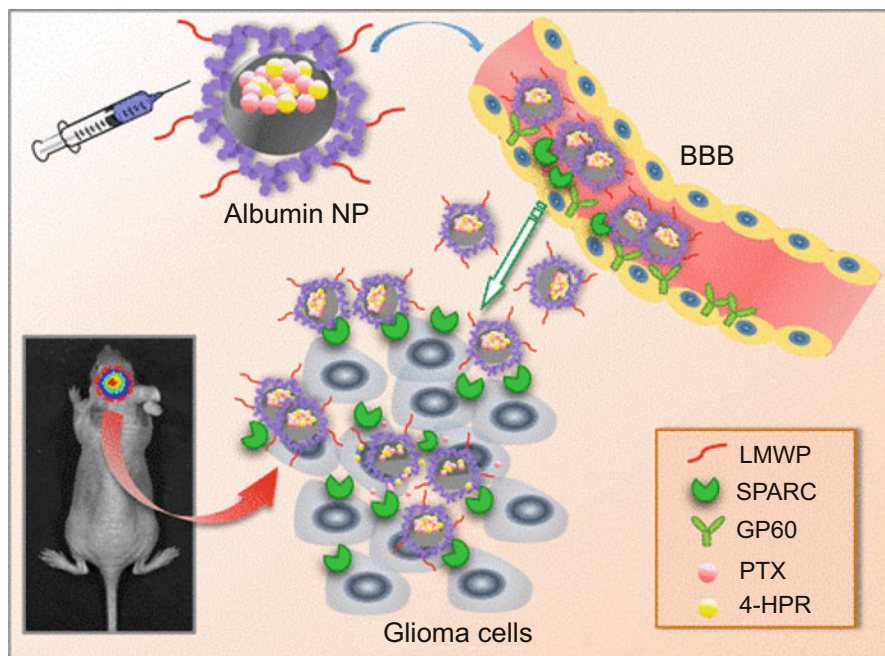

Fig. 3 Albumin-based biopolymers for drug delivery to targeted sites via protein pathways (Reproduced with permission from: Tingting Lin, Pengfei Zhao, Yifan Jiang et al. *ACS Nano* 2016, 10, 11, 9999–10012)

Self-Assembly

Presently, while novel techniques for preparing albumin nanoparticles for enhanced delivery are underway, the need to improve upon their properties of solubility and antimicrobial activities is now investigated. Yu et al. (2022a) prepared albumin NPs using *Camellia* seed cake (CSC) waste via the new technique of Self-Assembly. This method could also be used to develop other NPs, such as those of *Stauntonia brachyanthera* seed albumin, gum Arabic, and carboxymethylcellulose (Poureshahi et al. 2017; Li et al. 2017; Yu et al. 2022a), which are essential to enclose lutein. This is because lutein has enhanced stability and bioaccessibility after loading with the NPs. From the earlier study, the CSC-based albumin incorporated with chitosan was prepared, as the presence of the albumin increased the stable and bioaccessible nature of lutein for its delivery (Yu et al. 2022b). Overall, Self-Assembly could be seen as a simple, easy, and cost-effective means to fabricate the NPs (Li et al. 2021; Lian et al. 2017). Furthermore, Salih et al. (2021) developed polyethylene glycol-fusidic acid for self-assembling into the NPs. This was needed to improve the aqueous solubility, antibacterial action, as well as reduce the serum albumin binding of fusidic acid (Dziwornu et al. 2019). In brief, this PEG-FA made FA more soluble and antibacterial.

Emulsification

The recent study of Yang et al. (2022) shows that emulsion-stabilizing properties of albumin were similar to those of other proteins such as vicilin and legumin, which are present in Bambaran groundnut. The study had several findings about the albumin. First, they could form viscoelastic solid-like air-water interfaces with high dilatational moduli up to 9 N/m. Also, they displayed strong interfaces because of the presence of albumins. So, the albumin-stabilizing foams were almost same as those of whey protein-stabilized foams (Djemaoune et al. 2019; Pycia et al. 2017).

Coacervation

More recently, Zhang et al. (2021) examined the reaction between ovalbumin and pectin, which depends on temperature and pH. This association influenced their complexation, and a rigid layer formed in-between them. The presence of pectin introduced changes into the structure of ovalbumin. Moreover, the ovalbumin was thermally stable in the coacervation. While pH influenced the characterization, pH (12-1) and ratios (Ong et al. 2019; Haggag et al. 2018) have been reported to determine turbidity changes of scallop *Patinoplectin yessoensis* male gonad hydrolysates and k-carrageenan/xanthan gum. As such, they display well-organized and compact networks (Yan et al. 2022). At pH of 6.0–6.5, Kornet et al. (2022) show that solutions of processed pea protein displayed coacervation and the internal protein content of the coacervates was about 45 wt% at pH of 6.25. These findings were reported in absence of albumin.

Albumins are usually more soluble at pH 3–9 with higher foaming capacity (Ajibola et al. 2016) than others such as globulin and protein concentrate.

Thermal-Induced Aggregation

Rondeau et al. (2010) have presented spectroscopic studies on thermal aggregation of native and engineered BSA having different glucose concentrations. Changes in the secondary configuration of the BS aggregates were examined by Fourier Transformed infrared Spectroscopic absorption, while those of its tertiary structure were studied using fluorescence spectroscopy. The study shows that glycation-based changes in BSA affect aggregation process. Notably, the continuous increase of glucose concentration incubated with BSA hinders aggregates formation. More recently, Chandel et al. (2019) investigate the “molecular basis of the inhibition and disaggregation of thermally induced amyloid fibrils of human Serum albumin by an anti-Parkinson’s drug, benserazide hydrochloride.” Also, Zakariya et al. (2022) have shown that Sunset Yellow could restrict the activities of glycated thermally induced HSA aggregates in naturopathy.

Albumin-Based Hydrogel Applications

Albumin in Tissue Engineering

In cardiac tissue engineering, Amdursky et al. (2018b) have developed elastic serum-albumin from low-weight hydrogels as substrates for cardiac cells in vitro. As such, the hydrogel was used as a biomaterial for several other cell types, since elasticity of both BSA and myocardium were similar. A similar study considered the conversion of albumin into an available biomaterial with its cell compatibility (Li et al. 2014). This is important because albumin is a source of autogenic biomaterial for autologous tissue engineering. This tissue scaffold can be used for different tissue engineering applications, and it could also advance artificial fabrication of autogenic tissue substitutes. This is because, the material has a porous structure, and moderate mechanical strength resilience. Also, there is close compatibility with cells, as well as material properties. A more recent study examined the preparation of viable cell clusters of hepatocytes from Hep-G2 in large quantities. This is responsible for the presence of water in water emulsion cell-clustering platform in tissue regeneration (Wang et al. 2022b).

Albumin in Drug Delivery

HSA plays several roles in drug delivery to different sites/systems in the body. Recent studies show that the most common roles of the HSA are in the controlled and sustained release of paclitaxel, docetaxel, and doxorubicin-based drugs for

treatment of sarcoma, Type 2 diabetes, and prostate/breast/lung/ovarian cancers (Gao et al. 2019). The use of exogenous HSA-drug conjugation for these deliveries is commonly reported. Moreover, HSA is similarly used in tumor localization of several drugs including docetaxel N- E-maleimidocaproic acid hydrazide HSA, DOX COL-binding domain HSA, paclitaxel, aldorubicin, and others (Cranmer 2019; Jacob et al. 2018). Other roles of the albumin-based drug delivery systems are in targeted delivery to prostate and colon cancer and types of diabetes through improved PKWY, and higher cellular uptake (National Cancer Institute; De Groot et al. 2019). In brief, albumin binds to drugs through several techniques such as conjugation, in situ binding, genetic fusion, and NPs.

Albumin Coating Techniques for Clinical Applications

Albumin can coat synthetic compounds and NPs through several methods in varied clinical applications. This coating is a process of binding to compounds through several routes, which brings about reduced nonspecific protein adsorption and improved cell adhesion and proliferation (Zink et al. 2016; Kobayashi et al. 2017). Other routes different from protein pathways are shown in Fig. 4.

Albumin binds onto polyethylene and polyethersulfone through a poly dopamine layer which is an antithrombotic coating to resist protein fouling and enhance

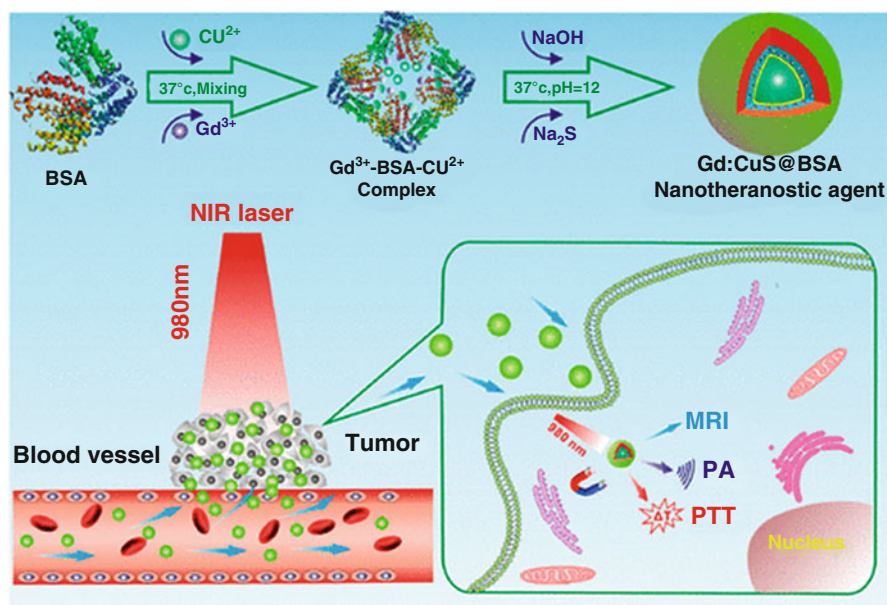

Fig. 4 Albumin nanoparticles for photothermal therapy in rodent models (Reproduced with permission from: Weitao Yang, Weisheng Guo, Wenjun Le et al. *ACS Nano* 2016, 10, 11, 10245–10257)

hemocompatibility (Sandeman et al. 2017). It is possible to reduce the nonspecific adsorption of proteins in albumin when it has been used to coat poly-hydroxyethylmethacrylate, polyurethane, and glass through affinity with octadecyl isocyanate and its reaction with epoxides on epoxysilanated glass (Tao et al. 2019). Improving the proliferation of mesencymal stem cells and antimicrobial action becomes realizable when albumin incubates demineralized bone matrices and polystyrene in protein solution at around 4 °C for an extended length of time (Pinho et al. 2021; Haag et al. 2022).

For albumin coatings on specific NPs such as liposomes, DNA origami, and tobacco mosaic virus, the possibility of attenuating immune response and prolonging blood circulation time becomes real (Achilli et al. 2022; Prabha and Raj 2017). These albumin coatings could be reached via engineering by linkers and reaction between maleimide groups and thiols for the tobacco mosaic virus, cysteine-maleimide bond, and electrostatic interaction for the DNA origami and affinity with ligands for liposomes (dos Santos et al. 2017; Ebhodaghe 2020). Other binding techniques of electrostatic interactions and electrostatic deposition are utilized for synthetic polymers such as poly (hydroxybutyrate-co-hydroxyhexanoate) and poly (methymethacrylate), respectively (Ebhodaghe 2021; Ma et al. 2017).

Conclusion

We have reported the use of albumin-based composites for several drug delivery and clinical applications. Several mechanical and biological properties enhances their disease-targeting “in molecular cancer therapeutics.” Also, we have seen that albumin-based composite coatings could be obtained when they are engineered by linkers, other reactions, and binding techniques.

Abstract

Since the turn of the century, biopolymer uses in the biomedical field have seen a tremendous rise owing to their abundance, biocompatibility, efficacy, minimal immunogenicity, and biodegradability. Biopolymer-based scaffolds - 2D films, hollow fibers, hydrogels, sponge, 2D/3D Electrospun fibers, microcarrier beads are used to produce prototypes to tackle many obstacles in the fields of biotechnology, nanoscience, and in vitro investigations for TE including bone, neuron, muscle, tendon/ligament regeneration. Besides electrospinning nanofibers as well as 3D bioprinting have sparked a lot of consideration as a forthcoming scaffold for the application in the field of TE and wound dressing. Biopolymers have piqued researchers' interest in determining the efficacy of drug delivery to a specific region employing them as a carrier. Wound healing applications are now heavily reliant on biopolymers due to their tunability aiding their employment in production of wide-range of efficient healing-enabling products ranging from woven fibers that expands on exposure to exudate to water-rich hydrogels that prevents drying of wounds. Post-surgical physiological functioning as well as progressive diseases can be monitored using biodegradable biopolymer-based biosensors. The disintegration of the employed biopolymer-based implants reduces the need for a surgical retraction of graft as well as graft rejection. There are an almost endless number of physical behaviors that can be modified for a given purpose due to the large range of biopolymers available and the ability to combine as biopolymers, some of which are discussed later in this chapter.

Bio-polymer · Bio-sensors · Bio-medical implants · 3D-Bioprinting · Hemostatic agents · Hydrogels · Microcarrier beads · Drug-delivery system

Introduction

In the recent years biopolymers have garnered growing importance in our daily life due to the tremendous rise in their applications especially in the field of pharmaceutical and medical sciences. Its abundance, bio-compatibility, effectiveness, relatively economical, low immunogenicity, and bio-degradable properties are the versatile traits which have allowed its wider acceptance and utility in biomedical therapeutics. These polymeric biomolecules are derived from living organisms including plants, animals, and microbes. Compared with their synthetic counterparts, these biopolymers are known to induce less toxicity, antigenicity, and immunological consequences. Biopolymers applied in the field of biomedicines are as follows (Figs. 1–2).

Biopolymers Application in Biomedical Sciences

Biopolymers and Their Attributes

Biopolymers consist of repeated monomeric biomolecule units which in fact define their property. Polynucleotides contain nucleotide repeats, polypeptides are formed of amino acids whereas polysaccharides are formed of repeating monomers of monosaccharides (Glieder et al. 2015). A few of the frequently used bio-polymer having bio-medical application are tabulated as below (Figs. 1–2).

Scaffolds and Matrices Employed in Bio-engineering

Scaffold is basically a material specifically fabricated to provide a platform which may be used in regenerative tissue engineering (TE), drug delivery, and

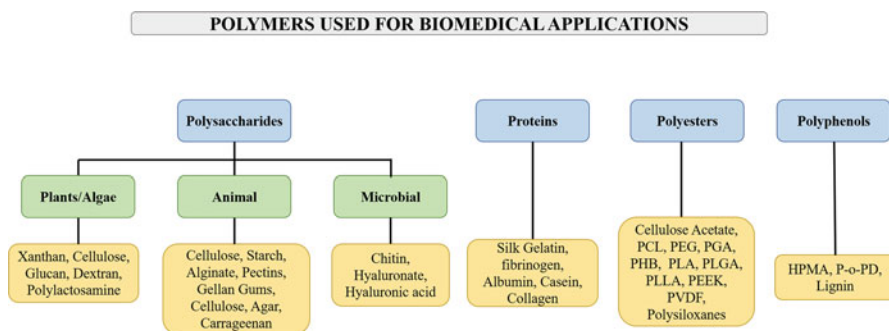

Fig. 1 Biopolymers derived from plant, animal and microbial sources which have applications in bio-medical fields. Polycaprolactone (PCL), Polyethylene glycol (PEG), Poly-Glycolic Acid (PGA), Polyurethanes (PUs), Poly (lactic acid-co-glycolic acid) (PLGA), Polyethylene vinyl acetate (PEVA), N-(2-hydroxypropyl)meth-acrylamide (HPMA) copolymers, Poly(L-lactic acid) (PLLA), Polyvinylidene fluoride (PVDF), Polyetheretherketone (PEEK), Polyhydroxy butyrate (PHB)

Fig. 2 Various geometries of biopolymer scaffolds and matrices employed in biomedical fields

immunomodulation. Scaffolds are known to repair the damaged or lost organ or tissues in TE (Haider et al. 2020). Biopolymer-based scaffolds and matrices are being used in various forms such as 2D films, hollow fibers, hydrogels, sponge, 2D and 3D Electrospun fibers, and solid as well as hollow spheres. TE has been an ever-evolving science which aims to use cells, scaffolds and growth factors under *in-vitro* conditions to generate tissue to replace a damaged or diseased organ/organ part. With an escalating need for organ transplant, TE has become the need of the hour. Successful growth of cells has been achieved *in-vitro* however, its 3D growth calls for appropriate scaffolds which can form the cellular matrix in the tissue. An ideal scaffold should be biocompatible and display biodegradable properties to match the cellular generation *in-vivo/in-vitro*. Its surface geometry must provide a niche for cellular proliferation, homing, and differentiation, while avoiding elements that develop toxicity to growing cells. The biopolymer unit should be malleable enough to be designed into a 3D structure that facilitate the cell bedding and its regulated

proliferation, enables circulation of media containing a cocktail of nutrients, respiratory gases, growth factors, and also facilitates removal of cellular metabolites. It should also display mechanical properties of the *in-vivo* extracellular matrix of the targeted organ to which it is to be grafted. Several biopolymers of cellulose, starch, collagen, silk, lactic acid have been employed to develop films, solid and hollow fibers, gels, sponges, 2D and 3D constructs suitable for *in-vitro* system based on their biocompatible and biodegradable properties (Eltom et al. 2019).

Fabrication Technique

Numerous cell-manipulations for tissue re-generation, polymer-based biomaterials are being used that can be fabricated by various techniques like Leaching, Freeze drying, Solvent casting/leaching, Robotic deposition, Cross-linking, Electrospinning, and 3D bioprinting.

Electrospinning (ES) is one of the most frequent and adaptable technique for producing fibrous materials, both in the laboratory and on a large scale. ES nanofibrous scaffolds is predominantly intriguing owing to the benefits of nanoscale morphology (like high surface to volume ratio (S/V), biomimetic, capacity of molecular level cellular interaction) along with ES technique's great adaptability, cost-efficiency, and simplicity. ES is generally the preferred process for constructing innovative as well as scaffolds with controlled characteristics that bio-mimic ECM for cell culture. In order to improve the process to overcome the issues like low spinnability potential, difficulty with disrupting the biopolymer's original structure, suitable cross-linking can be done to generate a hydrophobic biopolymer. The ES method enables for fine control of physicochemical properties such as fiber shape and diameter, orientation, volume distribution, as well as end product porosity and thickness. Unfortunately, the most significant disadvantage of the ES approach is that it requires meticulous adjustment of production parameters for each polymer-solvent system in order to appropriately manage the process and the resulting end product qualities. Because the viscosity, electrical conductivity, and other essential characteristics of the polymers and their solutions differ, their behavior during ES also vary, even during the identical circumstances. Unwanted materialistic flaws, for instance, formation of droplets and beads, lack of producing consistently similar product as well as absence of solution spinnability, can be a result of unoptimized process. Figure 3 describes the assembly of an ES instrument along with its working (Haider et al. 2020).

Biologically inspired engineering opens new ground for researchers to develop prototypes to overcome various challenges of research in the field of biomedical engineering and regenerative medicine. Multi-cellular tissue and organs, have highly specialized cells each with its own set of biological tasks that must be replicated in transplanted tissue (Fig. 4) which seems achievable through 3D bio-printing of organs involving different primary cell deposition in a pattern that can closely resemble the natural order of the architecture of desired organ to be transplanted. Post-printing, the cells must retain their *in-vivo* activity under optimum conditions.

Fig. 3 Electrospinning (ES) Technique- Polymer filled syringe attached to a syringe pump, a high voltage supplied metal needle as well as a collector are the basic components of ES device. On subsequent exposure to electric field, the surface tension of the polymer solution, at the tip overcomes the electrostatic field produced by the field at the revolving mandril resulting in formation of the Taylor cone. Expanded and elongated jet of charged polymeric solution is deposited on a collector in fibrous manner

Fig. 4 3D Bioprinting technique- Cells are cultured and subjected to printing in combination with growth factors, ECM, biopolymers, conjugated with Bio-ink

Any cell type used during the purpose of 3D-bioprinting should have a higher extent of cell division and precise cell-growth because lower the cell proliferation higher is the rate of loss of cell viability whereas, uncontrolled proliferation can result in apoptosis or hyperplasia. Furthermore, bio-printed tissues must retain cellular

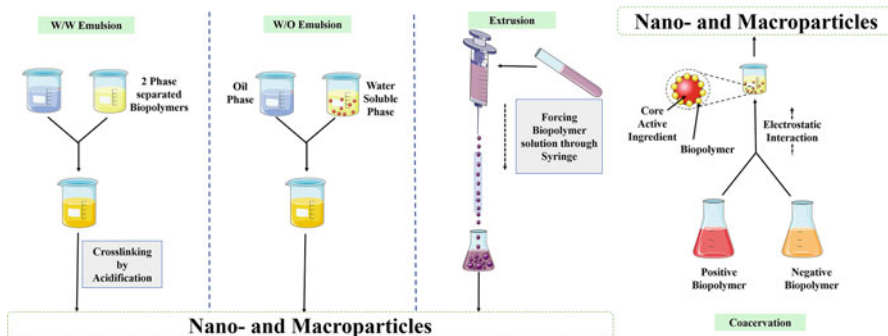

Fig. 5 Fabrication of Nano- and macroparticles (a) Top to Bottom (b) Bottom to Top

homeostasis, self-renewability and react to tissue damage or injury in order to operate long-term after transplantation. Rejection of bio-printed constructs by the host immune system is the major drawback. To overcome this setback, employing an autologous source of cells or through tolerance-induction procedures one can delay graft/ implant rejection.

Nanotechnology has been utilized to fabricate particle-based systems for a wide range of biomedical applications due to its characteristic of encapsulating and releasing active biomedical substances like drugs or therapeutics. Depending on the physiochemical method employed, the fabrication process can be divided into either top-to-down approach or bottom-to-up approach. Milling, shredding, and homogenization are common top-to-down techniques that entail break down of bulk solids or liquids into smaller particles. To break down the particles, these methods typically use three forms of disruptive forces: compression, impact, and shear. Although frequently used in industrial applications to create biopolymer particles, their significant drawbacks include high cost of operation, equipment maintenance, as well as problems in producing particles with well-defined structural features. In contrast, the bottom-to-up methods are characterized as the self-organization of molecules resulting in changes of environmental parameters like concentration, ionic strength, pH, and/or temperature (Joye and McClements 2014). Examples of bottom-to-up method includes coacervation inclusion complexation, liquid ant solvent precipitation and fluid-based gel formation (Fig. 5). Bottom-to-up procedures, on average, have lower energy needs than top-to-down methods. Manufacturing of extremely small particles with better control over particle attributes including size, morphology, and physical state can be achieved by bottom-to-up techniques (Elbert 2011).

Biopolymer and Advancement in Tissue Engineering

In the early 1990s, Langer and Vacanti found “tissue engineering” by application of material science in biology for development of 3D functional scaffolds that can be used to grow cells at the sites of damaged tissue (Langer and Vacanti 1993). This

opened up the new possibilities for regeneration of tissue, with investigators speculating that scaffolds may provide organizational stability and micro-environment conducive for cellular regeneration, emulating the functions of natural tissues. Since then, 3D matrices or scaffolds have been tested for a wide range of applications, including regeneration of tendon/ligament, muscle, neuron, bone, and much more (Eltom et al. 2019).

Specific Properties of Biopolymers Used in Tissue Engineering

Initially natural polymers were employed, owing to their improved overall interactions with numerous cell types without eliciting negative immune response. Synthetic polymers [PLGA, PLLA, and PGA] are frequently combined with natural polymers to enhance the desirable properties such as hydrophilicity, cell adhesion, and biodegradability. Furthermore, specialized ligands, such as protein molecules, are used to boost biological responses on the scaffold surfaces. 3D scaffolds of various consistency like hydrogels, nanofibers, and sintered microparticles have been extensively studied using synthetic and natural biomaterials (Stratton et al. 2016). Post implantation to enhance cellular proliferation and differentiation, these extremely porous 3D scaffolds have proven to be effective. Also the method of fabrication and scaffold geometry may provide the diverse properties-mechanical characteristic, degradation rate besides cellular adherence (Narang and Boddu 2015).

A 3D scaffold can be functionalized in a variety of ways; the majority of which are dependent on the material. A minimum of three functional features are currently regarded to be essential for a 3D scaffold:

- A) Porosity inside a 3D scaffold is a key deciding element for second-generation tissue engineering, which emphasizes the necessity for vascularization and cellular ingression into the scaffold pores. The size and density of the porosity inside a scaffold is one of the determining factors for cellular homing, proliferation and differentiation because cellular networking relies on exchange of nutrients, respiratory gases and metabolites, to ensure adequate cell signaling at various stages of cellular development (Murphy et al. 2013).
- B) Mechanistic property- An ideal scaffold should be tailor-made to maximally mimic the original Extra-Cellular Matrix (ECM) environment, and ensure appropriate surface to volume ratio without compromising its mechanical strength.
- C) Biocompatibility-Scaffold used in TE should be biocompatible and elicit meagre to no immune response. Many different polymeric materials have been surface-modified to add essential molecules for cell growth as per its requirement during various stages of cellular development. To address the constraints of the parent polymer, co-polymerization using the same monomers helps to functionalize the polymeric scaffolds to improve cellular adhesion (Liu et al. 2021).

Applications in Tissue Regeneration

Regeneration of Tendons/Ligaments

Tendons are connective tissue that connects muscle to bone while ligaments connect bones. Tendons do not normally repair effectively after damage, and even mild injuries might end up making the healing process more difficult. Surgical treatments, such as tissue grafts possess inherent complications like graft necrosis, arthrofibrosis, besides failure to restore the mechanical and structural quality of the original tendon. Hence, 3D scaffolds may provide respite to such setback for tendon regeneration to increase the function of de-novo tissue by allowing in-situ restoration (Vasiliadis and Katakalos 2020). Tendon ECM is largely made up of type I collagen and is arranged in a complicated structure that is interwoven, hence making it challenging to recreate 3D biomimetic environment. The Achilles tendon regeneration appears to be a major impediment, attributable due to the persistent mechanical pressure exerted on it (Shearn et al. 2011). Collagen has been used as a scaffold for this regenerative application. Polymeric materials with extraordinarily strong mechanical characteristics, such as silk and PLGA have been used in scaffolds for all tendon regeneration applications (Goh and Sahoo 2010).

Anterior Cruciate Ligament (ACL) plays a strategic role in knee and ligament stability. ACL is mostly formed of collagen types I and III fibers that surrounds the fibroblastic cells. Damage to ACL affects the knee mobility and is now considered a challenging niche in the area of tissue engineering. Polymeric scaffolds like silk fibers and PLLA are being employed for distributing growth factors and imitating the mechanical qualities of the natural environment of tissue since ACL has poor healing capacities and requires outstanding mechanical stability (Laurencin and Freeman 2005). A unique ACL regeneration scaffold has recently been reported, consisting of PLLA nanofibers that are mechanically strong as well as combined with a flexible outer covering of electro-spun PCL nanofibers, allowing for controlled release of growth factors like platelet-derived growth factor (PDGF), fibroblast growth factors (FGF), as well as proliferation of ACL cells (Stratton et al. 2016).

Muscle Regeneration

Muscle tissue regeneration has proven to be a tough task, owing to the fact that scaffolds must maintain integrity of the structure while also being able to generate significant contraction and aid in regeneration.

Muscles are generally classified as smooth, skeletal and cardiac muscle. Smooth muscle tissue is mostly found in the walls of organs, skeletal muscle fibers form unique connections to bones for moment execution while the cardiac muscle tissue is usually forming the heart wall. Cardiac muscle is formed of several cardiomyocytes and has normally very low natural regenerating ability in most mammals. Damage to cardiac muscle cells may result in heart failure. *In-vitro* cardiomyocytes can be nudged to proliferate and differentiate to form cardiac tissue using polymeric scaffolds (Shimizu et al. 2011). Cardiomyocytes are routinely seeded onto alginate, collagen, gelatin, or PGA scaffolds in a 3D structure may lead to higher bioactivity

and cardiomyocyte regeneration. These scaffolds have shown to improve binding to (Arginyl-glycyl-aspartic acid) RGD motifs leading to cellular functioning (Shachar et al. 2011).

Smooth muscle cells develop from quiescent phenotypes to attain adult morphology. This possess barrier for application in engineering tissues, particularly when reverting to a contractile phenotype (Beamish et al. 2010). Nanofibers which are formed of collagen and PCL have been proven to be predominantly beneficial for TE of smooth muscle scaffolds because their orientation guides cell development and allow cells to keep a normal phenotypic shape (Venugopal et al. 2005). Cross-linking, on the other hand, may be used to improve mechanical qualities and promote smooth muscle formation and proliferation required directions.

Skeletal muscle has the ability to substantially regenerate; thus tissue lost during wear and tear is constantly being healed, and replaced without the need for external intervention. However, in the case of a serious damage, its regenerative potential may be reduced or eliminated entirely. Satellite cells play a vital role by migrating to the wound site where it proliferates and differentiates for restoring functional capabilities throughout the repair and regeneration phase (Shearn et al. 2011). Regeneration of muscle is unusual as it encompasses a greater range of tissues. Each tissue comprises of essential components, and there is unlikely to be a single scaffold that can be used to regenerate all tissue types. Myogenic progenitor cells show increased proliferation when subjected to electrical stimuli on a 3D scaffold due to 65% increase in NO(x) which activates satellite cell, suggesting the usefulness of this technique in future (Anderson et al. 2015).

Nerve Regeneration

The Central Nervous System (CNS) and the Peripheral Nervous System (PNS) are the two major parts of the Nervous System (NS). The CNS comprises of the brain and spinal cord, whereas the PNS is formed of the ganglia and nerve tissue located outside the CNS. Both systems have typically been addressed in TE efforts for nerve regeneration. Schwann cells functionally contribute to myelination of axon to provide structural support to the peripheral nerves. These are often targets of grave injury due to diseases or accidents hence, research activities pertaining to Schwann cell regeneration are often at the forefront. For a successful nerve regeneration, the regenerating axons mandate directional cues which are often lost during injury. Hence, bioactive 3D scaffolds are employed to provide axonal guidance and support besides promoting axonal myelination. Nanofibers have specifically aided in nerve guidance conduits, which directs the outgrowth of neuronal axons during the regenerative processes. They are known to have a variety of functions, including their ability to regulate the direction of axonal development, release growth factors that help in tissue regeneration and reduce inhibitory scar tissue. Hydrogels employed in NS regeneration, is reported to promote axonal regrowth via Schwann cell (Y. Y. Tseng and Liu 2015); however the rigidity of the hydrogel scaffold is crucial to its success. Softer hydrogels allow differentiation of neural stem cells into neurons and astrocytes whereas stiffer hydrogels helps them to differentiate into oligodendrocytes (Shoichet 2010).

Regeneration of Skeletal Tissue

Bone grafts, which have historically been utilized for repairing osteogenic deformities, are being phased out in favor of synthetic polymeric scaffolds for TE purposes. Because of their potential to produce reactions at the cellular level, nanostructured materials have become popular for bone regeneration. Due to structural similarities, beta tricalcium phosphate, bioactive glass and hydroxyapatite are commonly employed scaffolds in bone regeneration (Damien and Parsons 1991). The benefits of such inorganic materials appears to have higher potential for osteoconductivity and compressive strength (Schmitz et al. 1999). Mechanical strength that replicates native tissue is a significant element in bone healing. As a result, high-mechanical-strength polymeric materials, such as chitosan nanofibers, PLLA, bioactive glass material and silk protein are frequently employed as scaffolds in bone regeneration. Due to high compressive strength, fatigue resistance and porosity, metallic scaffolds, such as those made of titanium, have become quite popular (Dabrowski et al. 2010). Although this scaffold has been successfully applied in osteogenic regeneration; However, vascularization and mechanical strength remain enigmas in the area of bone regeneration, despite ongoing research to improve these characteristics.

Inadequate vascularization has been shown to result in a severe lack of necessary nutrients for cell survival inside a scaffold, as well as unanticipated and harmful abnormalities in differentiation has been reported. Injecting particular growth agents like VEGF (Wernike et al. 2010) into a scaffold is one way to encourage vascularization. PLGA scaffolds have been recognized to be acceptable options for bone TE owing to their mechanical strength and ability to provide an environment favorable for vascularization, when combined with other bioactive materials for increased cellular adhesion (Ishaug et al. 1997).

Biopolymer Application in Organ Culture

The biomedical cost of treating chronic injuries continue to rise in lockstep with population growth. Clinical results in this area remain unsatisfactory despite cutting-edge medical and surgical treatments because the availability of total number of organ donors do not meet the required need for replacement of biological parts.

In case of burn victims, the decisive goal is to develop materials that endorse efficient skin regeneration simultaneously checking microbial invasion and providing aesthetically acceptable characteristics especially with scar-free results (Venugopal et al. 2005). As a simple, adaptable, and effective approach, electrospun nanofibers have garnered a lot of interest as a possible scaffold for wound dressing as well as bio engineering (Mogoşanu and Grumezescu 2014). Due to their inherent properties, such as high S/V ratio, porosity, permeability tunable mechanical properties, and resembling ECM promoting cellular migration, adhesion, and proliferation, ES nanofibrous scaffolds have many advantages over other types of scaffolds (Venugopal et al. 2005). Skin restoration has been studied using synthetic and natural fibrous membranes made of alginate, collagen, chitosan, cellulose, gelatin,

PVA, PLA, and PVP. Despite having high mechanical qualities, they are usually hydrophobic and have poor cellular adhesive properties, which make them unsuitable for cellular development (Mahmoudi et al. 2017). In contrast, natural polymers are found to have superior biocompatibility and biodegradability than their synthetic counterparts, although their mechanical qualities deteriorate rapidly during decomposition. As a result, the hybrid fibrous scaffolds that combine the benefits of natural polymers with the mechanical robustness of synthetic polymers have made substantial progress in skin TE. Chitosan, possesses biodegradability, biocompatibility, and inherent antibacterial activity making it an ideal candidate for skin grafts as well as its chemical structural resemblance to glycosaminoglycan in the ECM and hemostatic action, make it a suitable for skin replacements (Jafari et al. 2011).

Cornea is the transparent outermost layer protecting eyes from infection and also provides mechanical strength. The transparent stroma which accounts to 90% of the thickness of the corneal layer is essential for vision. Substantial damage to the stromal layer may lead to corneal blindness. This is either treated with a donor cornea transplant or requires an implantation of artificial cornea (Matthyssen et al. 2018). During ocular damage, corneal regeneration mediated by stem cell and TE are now a promising tool to overcome such problems. Numerous research investigations examining the development of tissue-engineered epithelial, stromal, and endothelial replacements have been conducted due to a scarcity of donors and the keratoprotheses' limited application potential (Hollick et al. 2006). The most significant characteristics for corneal scaffolds are biocompatibility, transparency, and strength. Furthermore, scaffold-based techniques focus on the fabrication of a replica that can mimic original tissue architecture and microenvironment that enables cell adhesion, proliferation, differentiation and migration (Kilic Bektas and Hasirci 2018). Due to malleable mechanical properties synthetic polymers stand out, to be suitable for designing corneal stroma. Also these scaffolds have the ability to induce keratinocyte development in human stromal cells. In order to differentiate stromal stem cells to the keratinocyte lineage, polyester urethane has been employed as a scaffold in conjunction with stromal stem cells (Ghezzi et al. 2017). Collagen type I, Chitosan, PLA and PEG have superior biological, mechanical and optical properties in contrast to available synthetic polymers. In order to achieve better optical properties a blend of natural and synthetic polymer is widely employed (Ahearne et al. 2010). Type I collagen, a biopolymer component of stroma, offers advantages of cell encapsulation and corneal stroma regeneration when used as corneal scaffold. However, the major setback is poor mechanical strength. Chemical cross-linkers might help to mitigate the mechanical flaws in collagen type I hydrogels (Kubrak-Kisza et al. 2016).

Nanocellulose is a unique biodegradable polymer that has the potential to revolutionize research and development in a variety of biomedical fields. It encompasses characteristic like toughness, ability to be fabricated into thin films or elastic gels making it an ideal biopolymer for producing wound dressings. Adam and team from Swansea University, Swansea, UK, formulated grid wound dressings with TEMPO (2,2,6,6-tetramethylpiperidine-N-oxyl) and C-Periodate nanocellulose bio-inks, with the deposited components forming a porous structure. They concluded C-Periodate

Fig. 6 (a) TEMPO Nanocellulose. (b) C-Periodate nanocellulose. (Image reprinted with permission -Copyright © 2015 Adam Rees et al. 2015)

nanocellulose which is suitable for use as bio-ink based for the printing of grid structures mostly owing to its consistency and rheology. The nanocellulose produce porous 3D structure having the ability to carry drugs and also checks antibacterial growth which significantly improves wound dressing (Fig. 6) (Rees et al. 2015).

Lab-on-Chip

Biomedical Lab-on-Chip (LOC), is a micro-fabricated device based on Micro-electromechanical Systems, which use a dynamic 3D environment comparable to that of the human body. LOC presents a multitude of opportunity to better understand the etiology of human illnesses and provide a potentially superior model for drug screening. Although organ-on chip models have their limitations, the introduction of new technologies has improved their capabilities for translational research and precision medicine. Microfluidics is the study involving fluidic manipulation at micro/nanoscales as well as the engineering of microfluidic devices, design helping in study of the fluidic model, fabrication of transport and delivery mechanism as fluid movement remains the foundation of Biological or Biomedical Micro-electromechanical Systems and the concept of Lab-on-Chip. Here the biochemical reactions are comparatively faster at lower volume due to lesser but faster utilization of enzyme-substrate and also reduces the experimental cost. LOC gives several advantages like faster diagnosis, cost effectiveness, reduced amount of sample usage, and patient-specific on real time basis. In the revolution of LOC various organ on chips (Fig. 7) have been developed like lung (Artzy-Schnirman et al. 2019), brain (Koo et al. 2018), liver, kidney (Ashammakhi et al. 2018), heart (Ferrari and Rasponi 2021) which it can bio-mimic the functions of organ as well as can serve as a model for diseased condition.

Kimberly and co-workers from Harvard University, (MA), USA, developed a 3D convoluted renal proximal tubule (PT) on a chip. Perfusable PT was designed using

Fig. 7 Organ on chip- This schematic diagram shows the development of organ on chip using human pluripotent cell aggregates (organoids) flowing through microfluidic channel of medium contain growth factors and ECM

fugitive ink which is first printed on to gelatin-fibrinogen ECM followed by ECM casting around the printed bio-structure. Fugitive ink is then retracted to create a hollow tubular structure that resembles normal renal tubule. PTEC-renal proximal tubular epithelial cells are then infused in the tubule and perfused for an extended time period. This 3D PT models was investigated to treat drug induced tubule damage (Homan et al. 2016) (Figure 8).

Microcarrier Beads

For 3D cell culture- solid, porous biodegradable polymer-based scaffolds are developed and tested for cellular adhesion and development. Microcarrier beads comparatively provide greater biocompatibility and porosity imposing efficient 3D cell cultures as it provides efficient cellular adhesion with higher viability, cellular proliferation and ECM remodeling. Technological challenges are imparted in achieving normal cellular cytoarchitecture as well as tissue construct. With a greater surface area to mass ratio, microcarrier beads are preferred as a go to material for cellular adhesion in-consideration with cell density and cellular yields compared to scaffold at macroscopic scale. Porous beads provide a better gaseous and nutrient exchange, also metabolic wastes may be transported more easily within the microcarriers than in cellular spheroids. Due to their benefits such as high specific surface area, suspension culture with homogenous stirring and simple scale-up, it has demonstrated promising ability to grow a wider range of mammalian cells in high yield.

Bioprinting of 3D convoluted renal proximal tubules on perfusable chips. *Sci Rep.* 2016;6:34845. Copyright © Nature Publishing Group. <http://creativecommons.org/licenses/by/4.0/>

Biopolymers and Its Role in Targeted Drug Delivery

Drug Delivery Systems (DDS) are methods for delivering drug candidates to specified region of the body for controlled release. Here the drug particles include beads, bio-composites, dendrimers, films, gels, hydrogels, implants, microparticles, nanoparticles, microcapsules, micelles, nanocapsules, patches, and spheroids scaffolds. Biopolymer carrier intended to carry therapeutics to the targeted site plays an important role in the preservation of drug. Damage and/or degradation of proteins and peptide molecules can affect their chemical structure (Jacob et al. 2018) resulting in the inactivation of drug molecule or may even prevent them from reaching their target sites. A model drug delivery system should ideally be biocompatible, possess high drug carrying capability, should be non-toxic and preferably have simple usage mechanism (Saqib Hasnain and Nayak 2018). While creating a DDS the primary channel lies in selection of polymers which may satisfy the aforementioned properties. Enzymatic or nonenzymatic biodegradation of biodegradable polymers occurs *in-vivo*, yielding biocompatible or nontoxic by-products (Doppalapudi et al. 2016). This polymer ideally enhances medication pharmacokinetics while lowering adverse effects. Recent advances in controlled drug delivery systems (CDDS), sustained release drug delivery systems (SRDDS), anticancer drug delivery, nucleic acid, protein, vaccines as well as TE and regenerative medicine, have focused on

biodegradable biomaterials (Glieder et al. 2015). In the concept of novel macromolecules in targeted drug delivery application, biodegradable polymers have a notable focus on its chemistry. Today various polymers of natural as well as synthetic classes have been utilized for various DDSs.

Hyaluronic Acid

Hyaluronic acid (HA) is a biodegradable natural biopolymer which is highly biocompatible. HA has garnered a lot of interest as a tool for developing DDSs because of its mucoadhesive properties and non-toxic nature. HA and its derivatives are well suited for targeted drug release due to its elasticity along with viscosity, ability to bind to surface receptors of the targeted cells of various organs including kidney, liver as well as tumor cells. It has been employed in administration of various non-invasive and invasive medication administrations. The DDS via nasal as well as ocular routes are examples of non-invasive applications. On the other hand, its usage in invasive treatment methodology includes subcutaneous injection of protein medicines with a sustained drug release (Huang et al. 2020).

Hyaluronic acid (HA) scaffolds are employed in regeneration of both hard and soft tissue. HA hydrogel has been most commonly utilized in TE owing to its capacity to encapsulate cells and other components for distribution purposes, as well as its swelling characteristics. Besides hydrogels, HA scaffolds can be manufactured by electrospinning to build a fibrous scaffold (Séon-Lutz et al. 2019) or by co-polymerizing other biomaterials to manufacture scaffolds that are porous by leaching salt particles (Liu et al. 2021), Rapid Prototyping, Thermal-induced Phase Separation, 3D Printing Phase Separation, Stereolithography, Selective Laser Sintering, Solvent-based extrusion Freeforming and Fused Deposition Modelling (Eltom et al. 2019). Wet spinning, a unique layer-by-layer spray-assisted kind of assembly process is employed to layer different films of polyelectrolyte onto porous HA scaffolds during *in-vitro* culture of human keratinocytes (Montero et al. 2021). Finally, 3D printing seems to be a proven technology for producing HA scaffolds, since it allows microscale reproducibility of scaffold properties, potentially leading to enhanced cellular function as observed in animal models (Gaetani et al. 2015).

Gelatin

It is abundantly present as Type A or B in almost all the animal tissue. Being a natural polymer, gelatin possesses high bio-compatibility as well as low antigenicity. Using a burst or controlled release mechanism, gelatin NPs can offer controlled medication delivery. High solubility as well as poor mechanical strength limits their usage in the field of DDS. To overcome its shortcomings, gelatin can be functionalized by copolymerizing with chitosan composites or by addition of cross-linkers, such as alginates (Sharma et al. 2015) or incorporating it into a synthetic polymer like PVA (Afsana et al. 2019) that enhances its properties as an ideal polymer for DDSs.

Chitosan

3D chitosan scaffolds exhibit functional and structural features identical to glycosaminoglycans, a natural lubricant found in the human body. Previous studies have attested to its bioactivity which stimulate cellular adherence naturally (Candy and Sharma 1990). Therefore, 3D scaffolds of natural polymers combined with chitosan or alone, are utilized in gel, fiber or sponge forms due to its multifunctional structure and capacity to cross-link in TE applications (Azizian et al. 2018). Chitosan has a low solubility at physiological pH, which allows it to be used for elongated period (Albanna et al. 2013).

Polycaprolactone

Polycaprolactone (PCL) first synthesized in 1930s, is a synthetic polymer frequently employed for the fabrication of suitable scaffolds for TE. The PCL structure is formed of five non-polar methylene groups besides one semi-polar ester group. PCL is found in a variety of forms including microparticles, fibers, and films but in order to improve its bioactive properties for various tissue regeneration applications, it is used in the form of composites with co-polymers, like chitosan and gelatin (Arun et al. 2021). In contrast, with other available polyesters, PCL has higher drug permeability, moderate rate of degradation, and fewer acidic by-products, thus making it advantageous in the domains of drug administration and TE. Also, PCL has shown to have higher solubility and blending ability with other biomaterials (Wright et al. 2010). However, PCL possess weak cellular adhesion capabilities, the limitations showcased due to its lower disintegration rate making it an unsuitable scaffold for short term application in TE. To counteract this disadvantage, a variety of techniques have been tried, including- copolymerization and surface functionalization. PCL was initially investigated as a vehicle for constrained medication and vaccine administration due of its low toxicity and high drug permeability. PCL thin film devices are inserted subcutaneously for local or systemic distribution due to its flexibility, biodegradability, and biocompatibility (Narayanan et al. 2016).

Poly-Glycolic Acid

Poly-Glycolic Acid (PGA) was initially found as a biomedical degradable polymer. It has the capacity to increase the efficacy of drug formulation for DDSs while providing a regulated release pattern. PGA is employed in DDS owing to its strength, physiological capability, mechanical properties and non-toxicity. Under physiological settings, polyglycolide degrades due to the non-specific breakdown of esters. Within the body, polyglycolides get either eliminated in urine or gets converted to water and CO₂. However, PGA is found to degrade quickly and remain insoluble in several common solvents, severely inhibiting its application. Yet it offers an arena for discovery of better methods than current protocols (Singh and Tiwari 2010).

Polyurethanes

Polyurethanes (PUs) are flexible polymers with carbamate or urethane($-\text{NH}-\text{COO}-$) linkages in their chains that are biocompatible and physiologically stable. Biodegradable polycaprolactone segments in biodegradable PUs are employed in tissue repair implants and medication delivery systems. To get a favorable drug release profile, physicochemical characteristics of PUs may be adjusted by varying the amount of water sensitivity and crystallinity. The addition of an ionic group promotes electrostatic interface of charged drug molecules with DNA/RNA or proteins. PUs has been investigated for use in biomedical research, however its stability restricts their utility (Cherng et al. 2013).

Polyethylene Glycol

The Poly-Ethylene Glycol (PEG) is the most widely used non-ionic hydrophilic polymer that displays stealth properties which shows reduced agglomeration and enhance stability during storage and application. PEG is used for drug delivery and probably the only polymer having multiple drug approvals. PEG's hydrophilicity, low interaction with blood components, and high biocompatibility all contributes to its success. Yet research findings also warn us about its downsides that includes undesired interaction with the immune system, probable breakdown under stress, and systemic retention beside an unpredicted excretion limit (Knop et al. 2010).

Poly (lactic acid-co-glycolic acid)

The Poly (lactic acid-co-glycolic acid) (PLGA), extensively utilized biodegradable synthetic polymers for TE application is an amalgamation product of PLLA and PGA. The greater the ratio of PGA in a PLGA scaffold, lower is the half-life of PLGA. Benefits of PLGA includes biodegradability, flexibility and fabrication of various types of formulations, and surface modification for DDSs (Gentile et al. 2014). Unfortunately, PLGA also has a significant flaw that limits its bioactivity. It's breakdown firms highly acidic by-products i.e. glycolic acid and lactic acid which can be difficult for the human body to quickly digest in large concentrations. Therefore, in the presence of acid-sensitive pharmaceuticals, this can pose to be a problem in drug delivery applications. Altering the PGA:PLLA ratio such that there is more PGA present, results in a slower degradation rate and has less acidic by-products. However, it is reported that in the presence of certain salts the pH of PLGA by-products may rise, resulting in higher overall bioactivity (Gentile et al. 2014). PLGA has been tagged as "smart polymer" due to its stimuli sensitive properties. PLGA has been utilized for sustained drug release, drug delivery, imaging (Rancan et al. 2009), and protein delivery. It has been extensively used for encapsulating anticancer medicines, quantum dots, and production of magnetic nanoparticles.

Cellulose Acetate

Plant cell wall contains cellulose from which cellulose acetate (CA) is derived. CA is a non-toxic biomaterial that is biocompatible and biodegradable. It has a cheaper production cost, is less hygroscopic and has good chemical and heat resistance. The cellulose derivatives- cellulose triacetate and cellulose diacetate, readily dissolves in organic solvents and can be potentially used in a variety of industrial and biological applications. TE (Rubenstein et al. 2010), antibacterial applications, DDSs and wound dressings (Samadian et al. 2018) are a few of the biomedical application of electrospun CA nanofibers. The use of CA in DDSs is linked to a variety of their features like good electrical conductivity and rapid expulsion from syringe needle under high electrostatic stress and random deposition as nanofibers on a collector. Antioxidants, nonsteroidal anti-inflammatory medications (NSAIDs), and vitamins could all be delivered effectively using electrospun CA nanofibers (Taepaiboon et al. 2006).

Polyanhydrides

Polyanhydrides are a kind of surface eroding hydrophobic polymer that has two carbonyl groups connected by an ether bond. One key benefit of bio-erodible controlled release systems over most other types of delivery systems is that the drug release is potentially regulated mostly by the polymer's characteristics features than the medication itself. This makes biodegradable polymers capable of releasing even macromolecules like proteins. As most of the water molecule cannot permeate till the polymer erodes, the drugs can be preserved when loaded with such biodegradable polymers. Such technology would have a huge influence on the efficacy of protein-based medications. The creation of formulation processes that would keep the protein in its active state during device construction nevertheless remains a major problem. Antineoplastic agents (Eameema et al. 2014), local anesthetics, anticoagulants, neuroactive medicines, antibiotics, vaccinations (Ghadi et al. 2017), and proteins (Sharma et al. 2015) have all been studied for delivery of therapeutics.

Polyethylene Vinyl Acetate

Polyethylene vinyl acetate (PEVA) is a transparent thermoplastic derived from combination of polymer of ethylene and vinyl acetate monomers. PEVA is a well-studied and commercially available excipient for long-acting dosage formulations. It is a preferred and well-studied commercially available biopolymer with proven track records for the formulation of complicated, long-acting dosages and which can be tailor made to deliver different therapeutics using various production methods. A wide range of pharmacological agents, biological molecules including peptides, nucleic acids and proteins, including monoclonal antibodies and growth factors

can be delivered using PEVA-based DDS (Major et al. 2019). PEVA has been reported to be an inert molecule and hence found to be relatively stable in the *in-vivo* system (Externbrink et al. 2013).

Polysiloxanes

Polysiloxanes is a unique polymer which is known to exist in branched, cyclic ring, linear and cross-linked in 3D network. Its unique physicochemical properties rely on its organic nonpolar functional groups and polar inorganic backbone. Silicone fluids of volatile nature which consist of straight linear chain of active or excipient pharmaceuticals on the other hand nonvolatile silicone fluids have shown application in the cosmetic industry (Blanco 2018).

Poly Di-Methyl Siloxane (PDMS) is a good example of this class of polymers. It shows a wide range of applications due to its inertness, biocompatibility, meager toxicity, thermal and oxidative stability, low modulus and antiadhesive properties and good organic solubility. It also displays better potential to form films, adequate adhesion to various substrates, and excellent resistance to chemical degradation both as an active substance (artificial skin, blood pumps, cardiac pacemaker leads, contact lenses, DDSs, denture liners, medical adhesives, and maxillofacial reconstruction) and as an excipient (adhesive pressure-sensitive and skin patches) in medical devices (Abbasi et al. 2001).

N-(2-hydroxypropyl)meth-acrylamide (HPMA) Copolymers

HPMA are non-biodegradable polymers with high biocompatibility. Several functional groups may be added into the polymer backbone such as drug moieties resulting in biologically active HPMA copolymers. Addition of antibody or antibody fragments lowers the immunogenicity of the biopolymer making it more biocompatible. Currently HPMA is one of the most explored platforms for polymer–drug conjugates and its primary application has been heralded to be carrier of anticancer medicines, site-specific DDS to the GI tract antisense oligonucleotides specific to tumor (Jensen et al. 2003).

Application of Biopolymers in Hemostatic Gauge and Dressings

Skin is majorly composed of epidermal layer containing keratinocytes followed by the dermal layer predominantly comprised of high collagen containing dense connective tissue. Skin damage leads to wound formation which triggers a series of complex events to attain the skin integrity as shown in Figure 10. Wound healing (WH) is well-known to contain a series of four overlapping phases via Hemostasis,

Inflammatory, Proliferative and Remodeling phase. The **hemostasis phase** predominantly involves platelet aggregation and series of event required for plugging the damage in blood capillaries to block blood loss from the wound site. This ensures sufficient period for immune cell recruitment and signaling molecules for the commencement of **inflammatory phase** (Chen et al. 2018) much needed to remove tissue debris and invading bacteria by the process of phagocytosis initiated by infiltration of neutrophils as well as monocyte. This is followed by the **proliferative phase** wherein the wound tissue area is diminished by contraction and fibroplasia to result in wound closure. This phase involves important events like angiogenesis, vasculogenesis, fibroplasia, and re-epithelialization. This phase may last from 48 h to 14 days after the wound formation. The final **remodeling phase** successfully generates ECM which helps in restoring the normal skin morphology; this marks the end of remodeling phase anywhere near 14–21 days of WH post wound formation (Gonzalez et al. 2016) (Fig. 9).

Biopolymers are now employed extensively in WH applications. Their multi-functional behavior and physical state tunability allows them to be used in a broader range of wounds; from woven fibers that have an ability to expand when they come in contact with the exudates to water-rich hydrogels that maintains moist environment to avoid wound drying. There is a boundless array of physical characteristics that can be tailored for a given usefulness because of the huge range of biopolymers available and its ability to blend with other biopolymers. Smart biopolymers that are physiologically sensitive can be produced because of their physical compatibility and capacity to load and release drug controllably when exposed to varied biological environments.

Fig. 9 Stages of Wound Healing – During Hemostasis the platelet aggregation checks the blood flow followed by inflammatory phase which is characterized by neutrophil and macrophage filtration at the site of wound. Proliferative phase is marked by cell proliferation, angiogenesis and neurogenesis. Followed by proliferation is the remodeling phase which helps to restore the natural framework of the wounded skin tissue

Biopolymer as Hemostatic and Anti-Inflammatory Agents

The hemostasis has traditionally been the major focus during wound management. Primeval people used herbs, slimy material and most often sand as hemostatic agents to stop bleeding. Advancement in the sector of biotechnology has introduced applications of various natural and synthetic polymer based hemostatic agents.

Alginate

Alginate based wound dressing has known its way into the biomedical science as wound healing material since 1980s. In its native form, alginate is a heteropolysaccharide made of uronic acid residues of 1 \rightarrow 4-linked β -D-mannuronic (1 \rightarrow 4 M) and 1 \rightarrow 4-linked α -L-guluronic acid (1 \rightarrow 4GA). But during biosynthesis, the polymer chains consist of only residues of 1 \rightarrow 4 M which are converted 1 \rightarrow 4GA; this epimerization is catalyzed by the enzyme C5 epimerase. Epimerization results in a conformational change which in turn enhances physical properties of the polymer. Uronic acid present in alginate-based biopolymer dressing has the ability to bind to metal ions like Na^+ and Ca^{2+} . Calcium salt-based alginates are in-soluble in water and hence can be interlaced into fibers and used as dressing patches or cavity fillers.

Wound exudation is the major problem that needs to be accounted while designing a biopolymer-based dressing. The ability of alginates to absorb 15–20-fold higher volumes of fluids compared to its weight makes it well suited as dressing material (Jones 1999). The proportion of guluronate groups and mannuronate groups tend to determine the swelling. Calcium when comes in contact with wounded area, there is an exchange between Na^+ ions from the exudated wound and Ca^{+2} rich alginate, resulting in solubilization. Since Ca^+ can readily exchange only when loosely bound to mannuronate guluronate, hence higher the guluronate group lower is the swelling (Yimin Qin 2008).

Chitosan

Chitin is a highly available natural biopolymer formed of poly-N-acetyl-d-glucosamine present in exoskeleton of crustaceans and in fungi and bacterial cell wall. Deacetylation of chitin forms chitosan, which is known to possess improved solubility, bioavailability, biocompatibility, and biodegradability. The N-acetyl group is either fully or partially replaced by NH_2 , and these acetylated or deacetylated groups can be distributed randomly or block-wise in chitosan (Vårum et al. 1991). The physicochemical and biological properties of the biopolymer is determined by the composition and distribution of these two units. Previously, chitin-based polymer dressings are well-thought-out to be effective for the hemostasis. Chitosan is currently preferred for developing dressings to control post-surgical bleeding in patients. Chitosan contains positively charged amino group which can readily interact with negatively charged membrane of RBCs (red blood cells) and hence serves as a good anticoagulative agent. Its higher porosity aids in-sufficient gaseous exchange essential for WH. It is argued that chitosan in solid state and solution state have different hemostatic activity (Yang et al. 2008) due to the varying degree of

acetylation (DA). The rate of degradation of chitosan is directly proportional to the DA and inversely proportional to its molecular weight and degree of crystallinity. To overcome this, increased degree of deacetylation (DD) has proven to be an effective strategy. However, it is noted that increased DD causes decrease in its degradation (Islam et al. 2019). Amalgamation of carrageenan in chitosan by carboxymethylation and cross-linking modifications have resulted in dressing with increased hemostatic competence (Pippi et al. 2017).

Chitosan can be processed into many forms like membranes /sponges, hydrogels, beads, films, microgels/ nanogels, nanofibers, micro/nanoparticles or scaffold /bandages. Both biological and mechanical properties of chitosan make it suitable for use as biomaterial. Chitosan based 3D hydrogels are used in tissue regeneration and targeted DDSs due to its soft, flexible and non-toxic properties. However its instability results in dissolution beyond control and despite shows low mechanical resistance. Chemically cross-linked chitosan-based 3D hydrogels have more stability and smaller pore size. Chitosan-based sponges are free standing highly porous and soft material but may shrivel. It is most commonly used as filling material in treating wounds. Chitosan based 2D films used as coating materials but has high production charges and is labor intense. It finds its way into biomedicine as scaffold coating material or wound dressing substitute for skin. 2D porous nanofibred membrane which mimics skin ECM. They are highly porous but during production, electrospinning of chitosan is the major hurdle. Such membranes are used for wound dressing and scaffold coating material (Croisier and Jérôme 2013).

Pectin

Dicotyledon cell-wall constitutes of a large proportion of pectins, heteropolysaccharides which plays an important role in cellular growth and development (Willats et al. 2006). Pectin polysaccharides are structurally composed of regions of rhamnogalacturonan type I (RG-I) and homogalacturonan (HG). Pectin has several recomences as wound dressing materials mainly due to hydrophilicity, which aids in the wound exudate removal (Munarin et al. 2012). Traditionally, pectin-based materials seemed to have been used in wound healing since they maintain an acidic pH that acts as antimicrobial barrier. Pectin potentially binds to bioactive molecules and prevents degradation (Jáuregui et al. 2009). The amount of pectin in the dressing varies depending on the phase of WH $\sim 40\%$ in hemostasis phase and during the inflammatory phase less than 10% pectin is suitable (Alvarez and Lechuga 2010).

Gelatin

Gelatin is abundantly present in mammalian tissue and is generally produced from collagen type I present in skin and bone. Gelatin depending on its isoelectric point are characterized into type A(~ 8.0) and gelatin type B(~ 4.9) (Poppe 1992) and hence contributes to different total charge of the gelatin, at physiological pH. Hence selecting the gelatin material based on the exudate pH is important when used in WH dressing material. High-molecular-weight gelatins which are produced first during extraction of gelatins have higher viscosity along with a greater gel strength compared to lower molecular weight gelatins which are produced later in the extraction process. The

strength of gelatin-based hydrogels is measured in terms of “bloom value,” example commercially gelatins range from 50 to 300 Bloom value. “Bloom value” is directly proportional to strength of the hydrogels. Gelatins serves as wound dressing for a various type of wound starting from partial to chronic wounds. Due to its hemostatic properties and its ability to get easily incorporated with other biopolymers it acts as a promising candidate for wound dressing material. Gelatin based hydrocolloid dressings that containing pectin and carboxymethylcellulose; sterile compressed gelatin-based sponge absorbs 45-folds more blood compared to its weight (Council on Pharmacy and Chemistry, 1947). The limitation to using mammalian origin gelatin despite having attractive wound healing properties is due to ethical factors and religious obligations. Hence, producing gelatin-free hydrocolloid dressings is the only suitable alternative. Targeted growth factor, antimicrobial drug delivery to wound using gelatin is widely studied (Kawai et al. 2000; Rattananuengsrikul et al. 2009; Tanaka et al. 2005).

Hyaluronan

Hyaluronic acid is an important constituent of ECM and found in animal tissues. It is also a constituent of connective tissues like vitreous humor, synovial fluid, as well as dermis and epidermis of skin. It hence plays an important role in various phases of WH.

During the WH, in inflammatory phase, high-molecular-weight HA is seen to be functional and has antiangiogenic and immunosuppressive activity (Delmage et al. 1986), and it also functions to aid granulocytes infiltration for checking bacterial growth and debris of damaged tissues. High-molecular-weight HA molecules occupies a large hydrodynamic volume physiologically also it randomly stiffens when hydrated. This significantly aids to trapping large volumes of aqueous fluid, making it an ideal hydrogel (Gandhi and Mancera 2008). Chitosan based dressings due to the degree of acetylation and molar mass of chitosan impact biological features such as antibacterial, analgesic and enhances permeation, albeit the mechanism of these influences is not apparent and frequently conflicting (Holme et al. 2008).

Agents for Regulation of Angiogenesis, Tissue Regeneration, and Remodeling

Hyaluronic Acid

In biomedical sciences Hyaluronic Acid (HA) was initially used for treatment of corneal wounds, viewing the positive outcomes it was then that commercialization for repairing corneal damage. HAs' have been also used for managing chronic diabetic, leg, and pressure ulcers. HA has emerged as a promising scaffold for skin tissue engineering. Addition of HA benzyl ester in the co-cultured human fibroblasts and keratinocytes shows expression of normal skin molecules in both dermis and epidermis (Gandhi and Mancera 2008). In contrast, with higher-molecular-weight HA the low-molecular-weight HA dominates in remodeling as it stimulates fibroblast proliferation and collagen synthesis (Rooney et al. 1995).

Gellan Gum

It is not seemed to be widely used in WH dressings. Gellan is bacterial origin biopolymer, produced as a product of aerobic fermentation by the bacterium *Sphingomonas paucimobilis* (Gibson and Sanderson 1997). Endotoxin free gellan is a promising material for bio-engineering (Smith et al. 2007). Gellan is composed of a linear tetra saccharide repeating unit of glucose, glucuronic acid and rhamnose. High acyl gellan, the native form, glyceryl and acetyl substituents are linked to the 1 \rightarrow 3-linked glucose residue. In contrast, the low acyl gellan, produced by removing glyceryl and acetyl substituents, can be used for application in WH due to its physical properties. On dissolution in water at around 80 °C gellan forms randomly coiled structure which transit to double-helix structure during temperature drop. This coil-helix transition in conformation is concentration dependent (Miyoshi and Nishinari 1999). In this well-organized state its viscosity increases in to exhibit “weak gel” properties. Gellan with divalent cations like Ca^{+2} forms hydrogels due formation of linkage between double helical pairs (Morris et al. 2010). In contrast, gellan also forms hydrogels with monovalent metal ions such as Na^+ and K^+ . In order to form a cross-linking similar to wound fluid physiology concentrations, of 5 mM Ca^{2+} and Mg^{2+} and 100 mM Na^+ and K^+ is reported to be ideal.

Gellan gum hydrogels are transparent hence serve the purpose of inspecting the wound bed during the healing very well. In addition, gellan gum can potentially be applied as in situ gelling liquid or as a hydrogel sheet. Gellan is required in comparatively very low concentrations, strong hydrogels can be easily formed at polymer concentrations <1% (w/w). Gellan gum is a non-toxic biopolymer and also serves to deliver antimicrobial drugs at wound site (Cencetti et al. 2012).

Collagen

Most of the connective tissues show an inherent presence of collagen structurally and hence justify abundance of collagen protein in the mammals. Along with profuse commercial use of collagen as strings for instruments, glues and pharmaceutical capsules, collagen is also being progressively used for WH and TE in biomedical fields. Collagen in nature has many different structural confirmations (Kadler et al. 2008). Fibrous collagens (Collagen Type I, II, III, IV and V) have the ability to form collagen based fibrillar packing molecules together side by side ECM. Owing to its natural origin collagen is the ideal material for WH application. During wound treatment the immune system does not consider it as foreign entity thus drastically reducing chances of rejection in patient (Ruszczak 2003). Collagen fibrils promote cell proliferation and differentiation. High porosity collagen sponges with when used as wound dressing material provide a base during WH. Collagen sponge when applied to burnt area adheres to the skin and provides moist environment. It prevents bacterial infection by cutting the contact between wounded area and external environment. Scaffold is loaded with fibroblasts, which migrates into the wound and proliferates. The sponge, due to its porosity allows invasion of inflammatory cells aiding to faster healing and regeneration of skin tissues. Collagen sponges are

ideal for implantation because they subsequently start degrading, depending upon the cross-linking level, they degrade in an average 3–6 weeks' time period allowing space for replacement with native fibroblast synthesized from type I collagen (Chattopadhyay and Raines 2014). Hydrogels that are collagen-based are used in delivering wound healing agents such as growth factors, anesthetics, various drugs and cells (e.g., fibroblasts). Collagen-based hydrogels loaded with mesenchymal stem cells enhances WH (Rustad et al. 2012). Besides an important wound dressing's material, collagen can be an ideal material for developing tissue engineered substitute for skin. Type I collagen with its biocompatibility shows promising strength to substitute skin directly. Currently, collagen has wide application in WH but it has much more potential to be developed as tissue damage repair material as well as for tissue replacement.

With an ageing population and ever-increasing diabetes propensity within the population, demand for innovative wound healing treatments is expected to skyrocket in the coming times. An increase in demand for a more biologically driven, regenerative medicinal approach in WH, in particular, opens the door to the development of complex biopolymer products that combine medicines, proteins, and cells.

Biopolymers Used in Biomedical Sensors and Implants

Nowadays, Biopolymer based implants and sensors (Fig. 10) are being utilized majorly due to their flexibility, biocompatibility, conductivity, and cost-effective fabrication processes. Biosensors are designed to monitor physiological functioning post-surgery or progressive diseases on the basis of altered homeostatic mechanisms (Alvarez and Lechuga 2010). On the other hand, for restoring and mimicking a damaged organ or organ-part, diagnosis, screening, and treatment of various medical conditions, implants are introduced into the body entirely or partially (Rebelo et al. 2017).

Biopolymer-Based Biosensors

Biosensor is an analytical device which converts the biological signals into electrical/electronic signals. Biosensor contains bio-sensing element as shown in Fig. 11, which senses or detects the concentration or presence of target analyte. This sensing element passes the biological signal to the transducer element which further converts the signal into quantifiable as well as measurable signals such as electrochemical, electrical, electronic, optical, and piezoelectric signals. Appropriate sensors should have certain requirements for instance: (1) Functional and structural stability of the device, (2) Biocompatibility, and (3) Cytocompatibility. Sensing element is usually made up of metal nanoparticle, biopolymers, and carbon-based nanomaterials; among which biopolymers are proven to be the most suitable material till date (Ashammakhi et al. 2021).

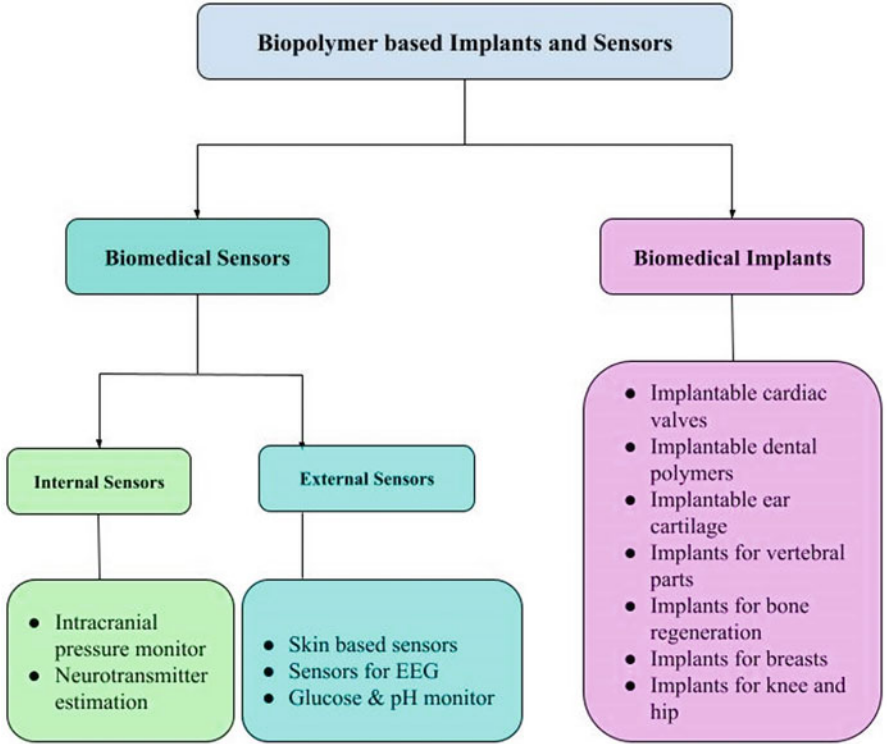

Fig. 10 Flow chart showing biopolymer-based implants and sensors for biomedical applications

Fig. 11 Basic elements of a Biosensor

Internal Biosensors

Internal biosensors reside within the body for monitoring various physiological conditions. But removal of such internal sensors can be painful, toxic, and expensive procedure. Biopolymers are of exceptional interest for fabricating internal sensors due to their swelling and shrinking capacity, degradability, elasticity, biocompatibility, and their ion exchange capacity than the other materials. It is important for biodegradable sensors to have a protective layer to isolate the internal components of the device from body fluids as they are readily dissolvable (Korostynska et al. 2010).

Biosensors to Monitor Intracranial Pressure

It is extremely important to monitor intracranial pressure for the treatment of stroke, traumatic brain injury, and high blood pressure. A biodegradable sensor, made up of silicon nanomembrane embedded on PLGA was designed to monitor intracranial pressure which progressively disappears as a result of metabolic processes and hydrolysis. This sensor can successfully sense pH, fluid flow, thermal characteristics, and motion (Kang et al. 2016). Apart from that, conductive silk fibroin hydrogel (CSFH) based wearable sensors are fabricated for sensing pressure as well as strain. Through the remotely triggered decomposition mechanism, CSFH based sensors can be degraded. These sensors are reported for having an excellent biocompatibility, mechanical robustness, controlled degradation, and outstanding sensing performance (Zhang et al. 2020).

Biosensors to Detect Neurotransmitter Levels

Neurotransmitters are known to transport chemical signals inside the entire nervous system (NS). Disruption in neurotransmitter signals is detected during neurodegenerative diseases like Parkinson's disease, Alzheimer's disease, schizophrenia, and so on. Monitoring of neurotransmitter level during such neurological condition remains extremely important. Earlier researchers fabricated Poly (o-phenylenediamine) based device to monitor dopamine levels. Since it is a synthetic non-biodegradable polymer-based device, its removal is mandated post-implantation surgeries (Chauhan et al. 2017). Thereafter, PCL based biodegradable biosensors were devised to electrochemically detect dopamine levels patient affected with schizophrenia, Parkinsonism and Attention-deficit/hyperactivity disorder (ADHD) (Leone et al. 2021). Moreover, micro-sensors that can detect glutamate and dopamine levels was fabricated using over oxidized polypyrrole (OPPy) (T. T. C. Tseng and Monbouquette 2012).

External Biosensors

Such biosensors are attached to the body surface externally to sense the physiological and homeostatic information; this information is being sent to the transducer and then to the display. These non-invasive sensors are widely being used for real time

monitoring of wearer's physiological parameters such as pressure, tactile senses, electrical impulses, pH, and glucose levels. For fabricating external biosensors, biopolymers are of major interest due to their ion exchange capacity, durability, biocompatibility, high conductivity, good sensitivity, and stability.

Skin-Based Sensors

It is important to measure pressure, pain and tactile senses in severe medical conditions such as paralysis. Polyvinylidene fluoride (PVDF) based sensors detect pressure and tactile senses as well as blood flow (Fig. 12). Such sensors can work piezoelectrically, i.e., can interchange mechanical energy and electrical energy. Anyhow, PVDF sensors are complex to be fabricated, have low thermal stability as well as expensive. However, further research can be done to avoid such shortcomings (Yiheng Qin et al. 2014).

Sensors for Electroencephalography

Electroencephalogram (EEG) is used in diagnosing altered brain activity in brain related disorders especially in epilepsy. Standard EEG electrodes can detect the signals for an hour. Hence, sensors that can continuously monitor the signals are more appropriate. Alginate based hydrogel sensors are being used for rapid EEG monitoring. Such hydrogel enhances the electrode sensitivity and remains easy to apply and cleanse post-recording. However, hydrogel-based sensors require pre-preparation of hydrogel application over the scalp skin for its usage and it remains the major impediment to the usage of this devise (Cui et al. 2021). Apart from hydrogel, biopolymer based dry electrodes are also designed for the application of EEG. In the dry electrodes (Fig. 13) the hydrating solution loaded in polyurethane foam passes through the Polycarbonate wick. The hydrating solution contains normal saline (for electrical conductivity), tween 80 (for improving permeation of skin), propylene glycol (interacts with lipid layer) and skin irritation avoiding solution. Polycarbonate wick aids to deliver a controlled amount of hydrating solution at the scalp site. Whereas, the silver wire is a signal transduction element, which is directly in contact with the hydrating solution. The whole structure containing Polycarbonate wick as well as PU is encased into a silicone tube from

Fig. 12 Schematic image of tactile and pressure sensor

Fig. 13 Schematic image of dry electrode fabricated using biopolymers for EEG applications

which the silver wire exits from the rear end. As compared to our preliminary EEG electrodes, dry electrodes are more comfortable and less time consuming. Moreover, since no post examination cleaning is required, due to which the chances of skin allergies get minimized (Pedrosa et al. 2018).

Sensors for Glucose and pH Monitoring

Glycemic fluctuations, as a part of severe health conditions like diabetes and hypoglycemia needs to be monitored. An implication of such instability becomes critical when the fluctuations are more frequent and usually goes un-noticed especially during pancreatitis, stroke, severe microbial infections, and pregnancy. Currently glucose-based sensors are available in the market. This biosensor includes sensing elements made-up of Glucose oxidase incorporated with P-o-PD which is a semi-conductive polymer, over the electrodes. Between glucose present in the body and glucose oxidase, catalytic enzymatic reaction takes place which produce hydrogen peroxide. Hence, its response depends on the hydrogen peroxide's electrochemical oxidation. Sensing elements detect glucose concentrations which are displayed on the monitor as result of an enzymatic reaction (Korostynska et al. 2010). Kownacka and team designed a tear-based biosensors which can accurately measure glucose concentration using tear. This polysaccharide-based hydrogel coated device can be worn beneath the inferior conjunctival fornix (lower eyelid) which has been proven to be non-painful and non-invasive (Kownacka et al. 2018).

The pH monitoring gains importance in medical condition that requires frequent pH monitoring, such as in deep wound healing. For monitoring pH, biopolymeric polyaniline film (PANI) based pH sensor is devised. Here pencil graphite electrode (PGE) coated with PANI is being used. This pH biosensor has shown high stability, sensitivity, reproducibility with precision (Alam et al. 2018). Recently in 2021 attempts were made to monitor pH and neurometabolic lactate alterations. Here

potentiometric biosensors respond to pH while amperometric biosensors are lactate detectors. Potentiometric biosensors use 5% graphite into conductive polyethylene and micro-fluidic channels whereas lactate-based electrode sensors were able to detect neuro-metabolic transient changes in lactate concentrations in the injured brain mouse model. These sensors are under clinical trials (Booth et al. 2021).

Biopolymer-Based Implants

At the end of the 1950s, implantable medical devices came into the picture. By the early 1960s, active radio transmitting units coated with metal, glass, or ceramic were developed for body cavities such as gastrointestinal tract as well as electronically implantable heart valves were available. Anyhow, removal of such implants requires another surgery. Nowadays biopolymer-based implants are available since they degrade in the presence of oxygen and nitrogen atoms which further lowers the requirement which does away for the need of secondary surgery (Rebelo et al. 2017).

Cardiac Valves

It is reported that nearly 1.3 million individuals suffer from faulty or diseased heart valves globally (Fig. 14). Such dysfunctional valves can cause stenosis (hindrance in the blood flow), blood leakage, or both and are in dire need for replacement. In the 1960s mechanical and bioprosthetic valves were invented to address these

Fig. 14 Silicone based heart valves- with permission © 2019 Elsevier Inc. (Coulter et al. 2019)

osteolysis and high biocompatibility. Furthermore, PEEK implants showed no reported cytotoxicity or carcinogenicity is yet to be reported (Al-Rabab'ah et al. 2019). PEG-like coating has been used on the titanium dental implant to reduce the chances of bacterial adhesion due to their antifouling properties (Buxadera-Palomero et al. 2020).

Implantable Ear Cartilage

Congenital anomalies or traumatic injuries are often the causes of cartilage damage, which may be surgically repairable. Autologous costal cartilage as a graft material is being used for the reconstruction yet, it is limitedly available and gives insufficient measurements. To overcome such limitations biopolymers such as hyaluronic acid, fibrin, silk, collagen is being used. Promising results were seen using benzyl ester of hyaluronic acid in auricular implant, which aids in tissue regeneration like hyaline cartilage within a month period (Aigner et al. 1998). Fibrin-based hydrogel assistance improves the formation of tissue along with cartilaginous microscopic appearance. Injectable scaffold can be created using fibrin-based hydrogel which are less invasive (Balakrishnan and Banerjee 2011). Study conducted at Imperial College London could successfully form cochlear implants using an array of electrode made up of shape memory polymer (SMP) which is fabricated using polylactide (PLA), polytetrafluoroethylene (PFTE), and ethylene-vinyl acetate (EVA) (Fig. 16). SMP uses body temperature for curling up inside the cochlea. The implant converts sounds into the electrical impulses which are further sent to the vestibulocochlear nerve inside the damaged ear. However, inability to absorb moisture inside the ear is sited to be a disadvantage for which further research can be taken up to address this challenge (Bautista-Salinas et al. 2022).

Fig. 16 Schematic image of SMP based ear implants

Biopolymers for Treating Vertebral Parts

The spinal cord is an essential part of our NS which assists in conduction of somatic activities. Its weight bearing capacity and flexibility is often compromised due to age or injury. This calls in for medical implants which can treat the spinal injuries or help to recover the fractured spine. Fibronectin is made of three different folded molecules: Type I, Type II, and Type III. These fibronectin bio materials in the form of cables or mats have been developed to treat injured spinal cord and to repair peripheral nerves. Collagen coated implants and gel matrices are found to be highly permeable, promote glial migration, and help in spinal regeneration (Tabesh et al. 2009). PEEK has become a popular biomaterial for fabricating spinal implants. The *in vivo* studies involving PEEK rod (Fig. 17) demonstrates its excellence as resistor in implant degradation procedure. Currently, such rods are available commercially for lumbar fusion. The radiolucent property of PEEK rods though prevents its observation by x-ray detection (Kurtz 2012). PEEK based implants are widely accepted for fusing the vertebrae together as it provides a significant relief to the patient. PEEK cages (interbody fusion cages) are used for bone fusion, these cages though biocompatible and flexible, can cause mild inflammation in implanted tissue (Kersten et al. 2015).

Implants for Bone Repair and Regeneration

Severe accidents often lead to irreparable bone damage. In such grave conditions, medical practitioners often resort to implant materials which can aid in bone repair. Silk fibroin bone implants provides flexibility, high mechanical support, thermal stability and can be subjected to chemical modification easily. However, their biocompatibility is yet to be tested in humans (Meinel et al. 2005). Use of natural polymeric materials like chitosan, collagen often leads to early polymeric degradation to the bones, which may need 4–6 months of healing period (Wu et al. 2018). In 2014, Chitosan/alginate/hydroxyapatite (CAH/ B2) scaffolds were used as implants for bone regeneration, the in-vivo study demonstrated enhanced bone healing in rats and thereby concluded that CAH/B2 scaffolds could enhance osteogenic bone morphogenetic protein-2 delivery (He et al. 2014). PLA-based screws (Fig. 18) are now available for graft, bone, tissue, vertebral fixation, and ligament reconstruction. Unlike titanium screws, PLA-based screws reduces the need for subsequent operation for its removal. However, it is noted that bones and tissues often takes time to fill up the hole formed by polymer degeneration (Tappa et al. 2019).

Breast Implants

By the end of 2020, WHO reported approximately 7.8 million women were suffering from breast cancer, of which majority of them undergo mastectomy. Cosmetic surgery using breast implants can bring aesthetic relief to such patients (Fig. 19). Polyurethane foam-based breast implants are reported to cause to less irritation,

Fig. 19 Schematic image of implanted breast

sensitization, and toxicity with almost meager to no immunological complications. These implants have inherent limitations of untimely implant rupture resulting in sticky sensation and skin rashes (Handel and Gutierrez 2006). Currently, silicone based pre-filled silicone gel breasts are widely preferred. However, cases of breast pain, infection as well as implant rupture have been reported. Nevertheless, most importantly such implants mimic human fat accurately, thus they feel more natural in morphology (Balk et al. 2016).

Knee and Hip Implants

To relieve the severe osteoarthritic pain, patients often undergo knee replacement surgery. Standard knee replacement surgery includes metals such as titanium or cobalt based prosthetics. However biopolymer-based implants are now designed and claimed to be more convenient. PEEK-based knee implants are reported to be most reliable due to their better mechanical support and biocompatibility. Recent studies claim PEEK to be more efficient than Ultra High Molecular Weight Polyethylene (UHMWPE) for overall knee replacement surgery (Sandeep Kumar et al. 2020). UHMWPE has high impact strength, low friction quality, and excellently wear resistance. Similarly, hip implants offer relief from arthritis, necrosis, and hip joint damage. Currently, UHMWPE cobalt-based alloys are commonly used for production of hip joint implant, especially for overweight patients (Merola and Affatato 2019).

Conclusion

The need for breakthrough biomedical applications and treatments is predicted to grow in the coming decade as the population ages. The demand for a more biologically driven, regenerative medicinal approach in the field of TE, drug delivery,

wound healing, biomedical implants, as well as sensors in particular has surged. This provides excellent opportunities for biopolymer research to unravel beneficial properties which may help in the development and delivery of treatments in the coming future.

Abstract

Cellulose is a unique biopolymer having distinctive structure and exceptional qualities beneficial for numerous industrial, environmental, medicinal, and pharmaceutical applications. *Cladophora* nanocellulose, extracted from *Cladophora* green algae, has unmatched advantages over those celluloses derived from other plant sources. Unique features of *Cladophora*-derived cellulose include excellent crystallinity (>95%), low moisture adsorption capacity, better solution processability, high porosity in the mesoporous range, and larger specific surface area. Due to its rich surface functionality, it can be easily modified by simple chemical reactions. Numerous *Cladophora* nanocellulose derivatives and composites have been reported, and their applications have been explored in diverse fields, including biomedical, environmental remediation, energy storage, batteries, etc. The pore size's tenability could be applied as an immunosorbent, hemodialysis, and

Introduction

Cellulose is one of the most promising green materials for a bio-based future and sustainable economy due to its natural abundance, fibrous structure, mechanical flexibility, ease of chemical modification, biocompatibility, and renewability. Cellulose made from wood or bacteria has dominated the industrial cellulose market and has been developed to provide various innovative materials for energy storage, environmental, and biotechnology applications (Lavanya et al. 2015).

Marine algal biomass is rich in biopolymers like cellulose. In 1885, algal cellulose was extracted and described for the first time, and later, cellulose was extracted from numerous algal species. Cellulose can conveniently be extracted from marine algal biomass and used to prepare composites or support matrices for various applications and new industries. As a renewable energy source, using cellulose-based products as an alternative makes use of synthetic polymers or materials, which may conserve energy and foster economy while addressing environmental issues. Cellulose isolated from Cladophora, a green alga designated as Cladophora cellulose, has unmatched benefits over cellulose obtained from other methods like wood or bacterial celluloses due to its high crystallinity (>95%), low moisture absorption capacity, superior solution processability, high porosity especially in the mesoporous region, and larger specific surface area (Baghel et al. 2021; Lavanya et al. 2015; Romruen et al. 2022; Siddhanta et al. 2011; Zhou et al. 2019). This chapter comprehensively describes the unique physicochemical features of Cladophora nanocellulose-based materials and their applications in diverse fields.

Nanocellulose from Cladophora: Extraction and Properties

Cellulose is the most prevalent biopolymer found in the cell walls of all plant cells. Apart from plants, cellulose can be obtained from algae, certain bacteria, and fungi. The chemical formula of cellulose is $(C_6H_{10}O_5)_n$. There are thousands of D-glucose subunits in cellulose. The D-glucopyranose units are held together by a covalent bond between the OH group of C-4 and C-1 carbon atoms (Fig. 1). Unlike other polysaccharides, the D-glucose molecules in cellulose have a beta orientation, with the anomeric carbon's hydroxyl group pointed above the plane of the glucose ring. The hydroxyl groups of the remaining carbon atoms are pointed below the ring plane. Thus, in cellulose chains, every alternate glucose molecule is reversed. Unlike

Fig. 1 Chemical structure of cellulose

starch or glycogen, the polymeric chains of glucose are organized linearly and do not undergo coiling, helix formation, or branching. Instead, these chains are parallel to one another. These chains are stacked in parallel to produce microfibrils. The tensile strength of cellulose microfibrils is due to the strong hydrogen bonds between the individual chains in cellulose microfibrils. The shape, length, and diameter of cellulose structures in nature vary depending on the source and process through which they are extracted. The donor group, OH, is responsible for chirality, hydrophilicity, degradability, and chemical flexibility – crystallinity in cellulose results from its strong hydrogen bonding. Cellulose's unique structural features come from the fact that, unlike most polysaccharides, it can maintain a semi-crystalline state of aggregation even in water (Baghel et al. 2021; Mihranyan 2011; Steven et al. 2021).

Most of the cellulose used in the industry comes from wood pulp and cotton. To get cellulose out of such lignocellulosic feedstock as wood or cotton, lignin needs to be removed, and the lignin removing process requires necessary chemical treatment and may cause partial cellulose degradation. Delignification is an energy-consuming process, and cellulose thus obtained may be contaminated with chemicals or by-products (Mihranyan 2011).

In addition to lignocellulosic biomass, cellulose is present in the cell walls of marine biomass, including macroalgae. Cellulose derived from macroalgae has attracted considerable interest recently due to its several advantages over cellulose derived from terrestrial biomass. The lack of lignin in macroalgae results in purer cellulose fractions that may be more appropriate for biomedical applications than lignocellulose. Additionally, the absence of lignin enables cellulose extraction under milder conditions, resulting in less degraded cellulose segments.

Macroalgae is a low-cost source of biomass, which multiplies, and cultivation does not require irrigation or arable land areas. Furthermore, macroalgae farming does not necessitate the use of fertilizers, hence preventing coastal eutrophication. It has been demonstrated that cellulose can be successfully extracted from brown, green, and even red macroalgae. The total amount of cellulose that makes up a plant's dry weight can range from around 1% to 15% (w/weight), depending on the species. The amount of cellulose present is prone to seasonal shifts and is extremely sensitive to the degree to which the biomass has matured (Mihranyan 2011; Zhou et al. 2019).

Cladophora is a filamentous green alga that belongs to Chlorophyta, commonly known as Mekong Weed (Fig. 2). It is a large genus and includes 183 taxonomically

Fig. 2 Photograph of *Cladophora* green alga. (Inset: Magnified image)

accepted algal species. It possesses thick walls without a mucilaginous sheath, dichotomously branched thallus with narrow tips and rough texture. Cells are large, cylindrical, multinucleated with reticulate chloroplast and numerous pyrenoids. The bright green color of *Cladophora* reflects the presence of pigment chlorophyll a, b, β -carotene, and xanthophylls. It contains chlorophyll a and b in the same ratio as in higher plants. *Cladophora* naturally grows on surfaces of substrates using hold fast. It often detaches from substrates and accumulates along shores, forming thick mats. High light intensity and nutrient-rich neutral or slightly alkaline water are needed for their growth. Their metabolism and morphologies are significantly affected by temperature, water currents, and wave action. *Cladophora* usually exhibits an isomorphic diplohaplontic type of life cycle and reproduces by vegetative, asexual, and sexual modes of reproduction. *Cladophora* can grow in single, bi-, and polyculture systems for biomass production (Munir et al. 2019; Stabili et al. 2014; Steven et al. 2021).

Cellulose is present in the cell walls of *Cladophora* green algae, and the properties and content of cellulose obtained may vary according to species. The cellulose content of several *Cladophora* species was analyzed, and the studies revealed that the cellulose content varied from 5% to 34% by dry weight. However, it was possible to recover cellulose as high as 45% on a dry weight from residual seaweed biomass, comparable to the cellulose content of higher plants. The findings suggested that biomass from *Cladophora* algae could be employed in industrial cellulose production. The cellulose fibers were conveniently extracted from the fresh *Cladophora* biomass and dried residual biomass. In addition to its economic benefit, the extraction of cellulose fibers from *Cladophora* algal sources can be treated as a method of environmental restoration. Using algal biomass to extract cellulose fibers helps reduce the damage caused by these algae's excessive and undesirable growth to the marine ecology (Brett 2000; Imai and Sugiyama 1998; Mihranyan 2011).

Primarily cellulose is taken from the dry biomass of entire seaweed. The extraction procedure is analogous to that used in the timber industry, although under milder conditions. Mihranyan et al. prepared exceptionally crystalline *Cladophora* cellulose by exposing bleached *Cladophora* green algae to acid hydrolysis and keeping it overnight (Ek et al. 1998; Mihranyan 2011). The typical cellulose extraction process from residual biomass consists of a series of steps and is illustrated in Fig. 3. The initial step involves bleaching dried seaweed biomass with sodium chlorite (NaClO_2) in an acetate buffer at 60 °C for about 3–6 h, then neutralizing the material by washing it with distilled water. Then, it was treated with 0.5 M NaOH at 60 °C for 6–12 h, followed by washing till pH became 7. The alkali-treated material was then boiled in 5% HCl (v/v), followed by room-temperature incubation. It was then

Fig. 3 Flow chart showing extraction of cellulose from *Cladophora* biomass

washed till the filtrate became neutral and dried to obtain the cellulose. The cellulose thus obtained is usually mesoporous or microporous and amorphous (Romruen et al. 2022).

Nanocelluloses are exceptional and promising natural materials among cellulose-derived goods. Based on structural features and origin, nanocellulose is classified into three types: (1) nanocrystalline cellulose, (2) cellulose nanofiber, and (3) bacterial cellulose. The size and crystallinity of nanocellulose are the most prominent properties. Nanocellulose's lateral dimensions range from 5 to 20 nm, and its longitudinal dimensions are a few microns. Nanocellulose is a light solid made of nanosized cellulose fibrils. This pseudo-plastic substance has the properties of thick fluids or gels. Due to its larger surface area and nanoscale size, the nanoform of cellulose is superior to cellulosic microfibrils (Mihiranyan 2011; Zhou et al. 2019).

Cladophora nanocellulose was obtained by hydrolyzing the chemical-sensitive amorphous portion of cellulose microfibrils in a controlled manner. A strong acid like sulfuric acid is often used for the hydrolysis process that breaks down amorphous cellulose to get nanocellulose (Steven et al. 2021). Siddhant et al. presented an alternative approach in which *Cladophora* green algae was defatted by repeated extraction in methanol for a longer time at room temperature, followed by treatment with NaOH. The defatted dried algae are further bleached by soaking in an acetate buffer, and the defatted dried algae are resuspended in HCl and cooked. This cellulose could be spread using a variety of techniques (Baghel et al. 2021; Romruen et al. 2022; Siddhanta et al. 2009, 2011; Zhou et al. 2019). Cladophora nanocellulose can be stored as a powder easily dispersed in water to produce a homogeneous hydrogel or suspension, which is attributed to its increased crystallinity and nanofibrous shape. Cladophora nanocellulose is strong, flexible, and light. It is biocompatible, bio-expandable, and has a low toxicity level. The cellulose surface can easily be modified because of many hydroxyl groups (Igor et al. 2016; Mihiranyan 2011).

The structure of Cladophora nanocellulose is more similar to nanocellulose produced by bacteria than to the corresponding nanocellulose from wood or cotton. Cellulose derived from Cladophora mostly belongs to polymorph I, characterized by parallel strands rather than intersheet hydrogen bonding. Crystal structural changes induce differences in cellulose I and II. Cellulose I is a mix of two different types of cellulose, called cellulose I α and cellulose I β . Like bacterial cellulose, Cladophora algal celluloses have many triclinic I α allomorphs, while wood-derived celluloses mainly comprise I β allomorphs. The cellulose I α allomorph is more likely to be broken down by enzymes, while cellulose found in cotton, which is high in the I β allomorph of cellulose, has a lot of disordered and is prone to chemical reactions. The presence of an amorphous fraction mainly decides the overall reactivity of the cellulose substrate. However, for nanocellulose obtained by the hydrolysis of Cladophora cellulose, the crystallinity is typical >95%, which is higher than that of bacterial cellulose and significantly higher than that of cellulose derived from wood or cotton. Because of this unique structure and high crystallinity, Cladophora nanocellulose is less hygroscopic than cellulose derived from other sources. The available surface area for water molecules in cellulose decreases steadily with increasing crystallinity (Mihiranyan 2011).

Cladophora nanocellulose retains its capacity to disperse in water and create stable dispersions through ultrasonication due to its nanoscale properties and low hornification level. These dispersions offer an efficient method for organizing and processing nanocellulose into a wide range of bulk products (Suciyati et al. 2021; Xiang et al. 2016).

Rheological qualities reveal a material's microstructure and the degree and pattern of material deformation under stress. Rheology analyzes fluid mechanics of a sample like stress, relaxation, viscosity etc. Recently, Mihranyan et al. examined that *Cladophora* cellulose powder could be a viable alternative to dispersible cellulose grades. They dispersed *Cladophora* cellulose in the liquid phase via high-frequency sonication to give complex, semisolid products with viscoelastic qualities based on oscillating frequency. According to the study, a 0.2% dispersion of *Cladophora* cellulose exhibits the properties of a fluid dispersion ($\tan \delta \gg 0.176$) rather than a true gel (Mihranyan et al. 2007).

Furthermore, it was shown that the material's elastic and viscous modulus improved with increasing cellulose concentration, and the gel strength declined as the concentration of carboxymethylcellulose increased. This study provides evidence that *Cladophora* cellulose powder may be a suitable replacement for commercially available dispersible cellulose grades. Its utilization may even provide benefits over already utilized solutions in circumstances where a more potent gelling action is required and when adding a minor solid phase into the central dispersive system is mandated (Mihranyan et al. 2007).

By accumulating interfiber gaps, *Cladophora* cellulose is highly porous (pore volume $0.55 \text{ m}^3 \text{ g}^{-1}$) and has a high specific surface area ($95 \text{ m}^2 \text{ g}^{-1}$) which was corroborated by BET surface area measurements. Good mesoporosity and non-swelling upon contact with water are advantageous for battery separator or water purification applications. Due to the abundance of hydroxy groups on the surface of cellulose nanofibrils, their surface can be easily modifiable to produce functional cellulose derivatives. Due to the ease of chemical modification, *Cladophora* nanocellulose offers other choices for less commonly utilized reactions, such as aldehydes by periodate oxidation, diamines via reductive amination of 2,3-dialdehydes, and sulfonyl via a sulfonation reaction, while maintaining the original nanofiber morphology. Being highly crystalline, *Cladophora* nanocellulose can withstand strong reaction conditions like high temperature and pressure (Rocha, Hattori, et al. 2018; Steven et al. 2021).

Mihranyan et al. coated *Cladophora* cellulose and prepared two different routes with conducting PPy via oxidative chemical polymerization. They could observe that coating pure *Cladophora* cellulose nanofibers with PPy shifted the pore size distribution to higher, resulting in composites with an open, loosely packed structure with a large surface area. The composites' electroactivity depended on the composite's total porosity. Compared to clean nanocellulose samples, the composites' mechanical strength has been reduced due to the breakdown in H-bonding between neighboring cellulose fibers. However, the nanocellulose-PPy nanocomposites obtained by adding bare nanocellulose fibers to PPy showed improved mechanical properties (Mihranyan et al. 2012).

Cellulose is a good choice for electrical insulator applications due to its unique properties such as low resistance, wide availability, low cost, high mechanical strength, and thermal stability. However, due to the presence of hydroxyl groups, cellulose can absorb water, and hygroscopicity is the most significant barrier to its utilization in electrical insulator applications. For electrical insulator application, the moisture content of cellulose should be 0.5% or less. Otherwise, the paper must be treated and kept dry, which is an extensive, time-consuming, and costly procedure. According to the results of He pycnometry, N₂ sorption, and SEM studies reported by le Bras and coworkers, the overall porosity of Cladophora cellulose is around 44%, which is much higher than that of wood-derived cellulose. They could also observe that Cladophora cellulose sheets are substantially more permeable. The high porosity and residual air in Cladophora cellulose paper result in increased dielectric loss. The Cladophora cellulose exhibited a moisture sorption pattern that was characteristic of that of non-hygroscopic mesoporous materials. Water sorption studies confirmed that Cladophora cellulose has a limited moisture sorption capability at low to moderate vapor pressures, while at high relative vapor pressures, condensation in numerous pores causes a fast surge in adsorbed water. The specific surface area values determined via N₂ and water sorption studies for Cladophora cellulose are similar, while that for wood cellulose was different. This finding suggests that, unlike wood, in which cellulose penetrates the solid mass in the disordered regions, the water sorption in Cladophora cellulose takes place only on the surface of fibrils due to the high crystallinity of the cellulose. It was observed that porosity influences mechanical properties, and Cladophora cellulose has lower tensile strength, tensile index, Young's modulus, and yield stress compared to wood-derived cellulose. However, the tensile strength per relative density was the same in both samples, indicating that the inherent strength of cellulose fibers is stable. Based on the studies on dielectric behavior, it was proposed that the increase in conductivity and dielectric loss increased with an increase in moisture content. The adsorbed water molecules on the nanofibrils' surface of Cladophora cellulose are less tightly bonded and can create a channel for ions and increase ionic mobility. The low moisture sorption properties, conductivity, and dielectric parameters of Cladophora cellulose are very suitable for developing novel high-power paper insulators (le Bras et al. 2015).

Mihranyan et al. established that incorporating nanocellulose could improve the mechanical properties of conductive paper electrodes. They studied the effect of incorporating nanocellulose having different porosity, density, and tensile strength obtained from three Cladophora cellulose sources. Interestingly the tensile strength observed for the composites was much lower than pristine nanocellulose. The low tensile strength of nanocellulose cannot be accounted for by the large pore sizes and higher porosity. Mihranyan et al. argued that the declining mechanical capabilities could be due to H-bond shielding between O-H groups on cellulose nanofiber surfaces. In order to achieve good electrical conductivity, continual polypyrrole (PPy) coating on nanocellulose fibers is needed. Incorporation of PPy via in situ polymerization weakens H-bonding between ordinarily robust nanocellulose sheets within the composite. The study adopted post-synthetic routes for incorporating PPy,

and the mechanical characteristics of nanocellulose-PPy composites were improved to a great extent (Mihrianyan et al. 2008, 2012). The unique physical and chemical properties of *Cladophora* nanocellulose can add new features and improve the performance of nanocellulose-based materials, and these characteristics have garnered significant scientific interest over the past decade. Due to its unique physico-chemical properties, it can be used in many different areas, including composite reinforcement, scaffolds for tissue engineering, biosensors, drug delivery, and electronics.

Applications of *Cladophora* Nanocellulose

Cladophora nanocellulose is particularly valuable because of its unique structure, lightweight, excellent mechanical performance, large surface area, aspect ratio, biocompatibility, wide availability, and the ability to change its surface to increase nano-reinforcement compatibility with other polymers. Both academia and industries are looking into new ways to produce and use nanocellulose, a vital material in developing commercial nanostructured materials. In comparison to carbon fiber and glass fiber, nanocellulose is more economical. There are a wide variety of applications for *Cladophora* nanocellulose. However, most of these applications are in the mechanical, medical, and industrial sectors. Degradable polymer composites often use cellulose as a matrix filler in their composition. Additionally, applications for cellulose can be found in the fields of packaging, tissue engineering, sensors, pharmaceuticals, electronic materials, water filtration, and viral filters. Moreover, cellulose has been utilized in conjunction with carbon nanotubes and conducting polymers as current collectors in Li-ion battery applications and electrode material for supercapacitors. Therefore by using nontoxic, recyclable, carbon neutral, and sustainable *Cladophora* nanocellulose based goods as an alternative for synthetic or petrochemical-based components, most of these industries can lessen their environmental impact.

Environmental Pollution Remediation Applications

Many environmental issues have arisen because of the rapid development of industrialization and urbanization worldwide in recent decades. Water pollution from large-scale industrial production has raised serious concerns about water scarcity and safety. Burning large amounts of fossil fuels have resulted in a significant increase in carbon dioxide emissions, resulting in apparent global warming due to the greenhouse effect. Poisonous gases (SO₂, NO_x, volatile organic compounds (VOCs), and other pollutants in the air) are significant causes of respiratory diseases (Yoon et al. 2008). Despite developing numerous materials and technologies to address these environmental issues, more effective and environmentally sustainable strategies are still required. *Cladophora* nanocellulose can be effectively used for water purification, heavy metal ion adsorption, CO₂ absorption, organic gas

adsorption, and separation as a naturally abundant, sustainable nanomaterial with inherent mesoporosity.

Cladophora Cellulose for Water Purification

Water purification necessitates the rapid and efficient filtration and adsorption of impurities in the water to make it safe to drink. Synthetic polymers (e.g., polyamides) with micro- or mesopores (pore diameter of <2 nm or 2–50 nm, respectively) are the most common materials used in commercial water filtration membranes. Cellulose is a standard and inexpensive filter with a long history. However, when large amounts of water need to be filtered for nanoscale contaminants, ordinary filter paper with micrometer-sized pores is unmanageable (nanoparticles, viruses, etc.) (Thomas et al. 2018). The limited processability of bacterial cellulose nanofibers and the low porosity of wood cellulose limit their use as water filtration membranes. On the other hand, *Cladophora* cellulose membranes with high porosity are promising for water purification (Fig. 4a) (Gustafsson et al. 2018). A simulation of wastewater filtration revealed that *Cladophora* cellulose-based papers could remove nano pollutants (100 nm) with up to 99.99% efficiency at industrial flow rates ($60\text{--}500\text{ L m}^{-2}\text{ h}^{-1}$) (Fig. 4b, c). Furthermore, the study reported that chemically altering *Cladophora* cellulose produces a new class of high-performance adsorbents: surface-functionalized *Cladophora* cellulose beads (Fig. 4d, e) can be used to effectively adsorb metal ions and small organic molecules from water (Fig. 4f) (Ruan et al. 2016).

The cellulose obtained from the cell walls of *Cladophora* algae is insoluble in water; it does not swell as much as cellulose from other familiar sources, suggesting that it has a lower capacity to absorb water (Xiang et al. 2016). This observation points to the highly crystalline nature of the lake-derived *Cladophora* cellulose. If the cellulose has a high degree of crystallinity, water cannot easily pass through the chains despite numerous hydroxyl groups. This finding backs up a study by Mihranyan et al. that claims cellulose absorbs less moisture as its degree of crystallinity rises (Mihranyan, Llagostera, et al. 2004). The quantity of available hydroxyl groups, or in other words, the degree of crystallinity, plays a significant role in how easily water can permeate the structure and cause swelling. Compared to wood cellulose, the *Cladophora* sample's high degree of crystallinity suggests a higher order of the polymer chains and, consequently, a higher surface area. The native cellulose found in terrestrial plants, known as type I cellulose, frequently used in the paper industry, has a relatively small specific area of $1\text{ m}^2/\text{g}$. On the other hand, the cellulose obtained from the cell walls of *Cladophora* sp. green algae is highly crystalline and has a distinctively high surface texture made of numerous intertwined strings, resulting in an aggregate web-like structure with high porosity and a large surface area. It is well known that polymers like polypyrrole (PPy) can effectively wet cellulose fibers, which makes it possible to coat each fiber uniformly. Composites made of cellulose and conductive polymers are desirable because they are entirely recyclable, light in weight, mechanically robust, and quickly produced.

They allow the aniline monomers to adsorb onto the surface of the cellulose fibers before allowing the polymerization agent to pass through, resulting in the polymerization of aniline with the formation of a thin coating on cellulose fibers. By forming an H-bond between the oxygen moieties in cellulose and the aniline N-H groups, cellulose fiber that meets the reaction mixture is coated with a thin layer of PANI. In contrast to the micro- and milli-layers that can be formed by combining the monomer, polymerization agent, and cellulose in a single pot, a nanolayer of polyaniline (PANI) is developed on the cellulose fibers using this method. A PANI coating nanolayer will maintain the cellulose's high surface area. An effective polymerization can be seen from the blue coloration that develops after allowing the polymerization agent to pass through the cellulose with adsorbed aniline. The obtained

Fig. 5 SEM image of pure Cladophora nanocellulose (a) and PANI-coated Cladophora nanocellulose (b) (Tan et al. 2018)

cellulose-PANI composite is still blue in color, indicating that PANI is still locked in the cellulose fibers, even after washing several times in acetone and sonicating the residue to remove the free PANI. While the SEM images of Cladophora cellulose coated with PANI show all fiber surfaces coated with an amorphous/granular-like coating, indicating uniform morphological modification, the SEM images of pure Cladophora cellulose (Fig. 5a) show intertwining fibers with smooth surfaces. It was confirmed that the cellulose fibers are coated with PANI nano-layers (50 nm) while maintaining their high surface area (Fig. 5b) (Tan et al. 2018).

By comparing the electrical conductivity and resistivity of the composite to those of pure Cladophora cellulose, it is possible to confirm the presence of PANI coating on the cellulose fibers. Using the four-probe conductivity meter, the electrical conductivity of the composite was measured and found to be significantly higher (0.670 S/cm) than that of pure cellulose (0.091 S/cm). The conductive polymer coating's presence is what causes the conductivity to improve. The higher surface area of PANI on Cladophora cellulose can be attributed to the conductivity measured in this study's better performance. This implies that highly conducting composites can be created using conducting component nanolayers. The manufactured cellulose/PANI composite was used to remove toxic environmental metals. Chromium is used in industry, especially in the tanning and plating sectors. Chromium ions are frequently dumped into the river system with wastewater after being used. There are two oxidation states of chromium: Cr (VI) and Cr (III). Due to their unusual redox activity, conducting polymers provide an alternative method for the remediation of Cr(VI). It has been reported that pure PANI films were used before pure PPy films to reduce highly toxic hexavalent chromium ions to less toxic trivalent chromium ions utilizing conducting polymers. When PANI is exposed to hexavalent chromium, the PANI in its reduced form (emeraldine base, EB) will function as a reducing agent. When the Cr (VI) is reduced to Cr, the PANI will subsequently be oxidized to pernigraniline. Redox activity and surface adsorption may work together to remove chromium in the presence of cellulose/PANI composite. The reduction of hexavalent

chromium ion to trivalent chromium by *Cladophora* nanocellulose-PANI composite caused the emeraldine form of PANI to get oxidized to pernigraniline form change in acidic pH. Although PANI (emeraldine form) is not a metal, its reduction potential is comparable to silver's, making it effective at reducing chromium. Surface adsorption may also be a viable alternative mechanism. Positively charged chromium ion gets coordinated through the lone pair electron of nitrogen in the *Cladophora* cellulose-PANI composite. Additionally, electrostatic attraction may happen under acidic conditions between solution anions (chromate and dichromate) and the protonated form of nitrogen atoms in PANI. The study established that using low-cost *Cladophora* cellulose coated with nano-layers of PANI, toxic hexavalent chromium can be removed from wastewater regardless of the mechanism (Camacho et al. 2013; Mhraryan et al. 2012; Razaq et al. 2012). 2,3-Dialdehyde cellulose (DAC) prepared from the *Cladophora* nanocellulose via chemical modification acts as an excellent adsorbent for the metal Pd (II). DAC can be prepared as the first *Cladophora* nanocellulose in water mixed with sodium meta periodate. The periodate-containing reaction mixture was meticulously covered in aluminum foil to protect it from light. For 13 days, the reaction mixture was stirred briskly at room temperature in the dark. After that, ethanol was added, and the DAC was repeatedly washed with water to produce pure DAC. The adsorbent was produced by reductive amination, which functionalized the DAC with natural amino acid cysteine. Plenty of coordination in the functionalized DACs sites makes palladium adsorption effective. The DAC materials with L-cysteine functionalization were then put through Pd(II) ion adsorption and provided a large adsorption capacity (Ruan et al. 2016).

The adsorption of Congo red is a fascinating subject that has received much research. Congo red aqueous solutions turn red above a pH of 5 and blue below that. When the Congo red dye solution of a definite pH is shaken well with the DAC, it was observed that the intensity of the dye is decreased, indicating its adsorption by DAC. The dye can be removed from the solution by penetrating the voids of this nanocrystalline particle derived from *Cladophora*. Similarly, nicotine is also adsorbed into the vacant space of the DAC (C. Q. Ruan et al. 2018).

Remediation of Air Pollution

Selectively adsorption of noxious gases from the air is essential for air purification. The adsorption process requires materials with high specific surface areas and interconnected nanopore structures. Nanopore structure is practically unattainable for pure *Cladophora* cellulose. Studies demonstrated that the pore structures could be tuned by combining metalorganic frameworks with *Cladophora* nanocellulose, and novel crystalline nanoporous materials that can function as efficient adsorbents for removing noxious gases from the polluted air can be developed. It was observed that the natural blending of metal-organic framework particles with *Cladophora* nanocellulose into a composite paper was inefficient due to the poor gas flow between metal-organic framework particles. Using a new nanostructure in which metal-organic frameworks are assembled into continuous nanolayers on *Cladophora*

nanocellulose to form hybrid nanofibers, the effective contact area for the gas can be improved (Zhou et al. 2019). Thus, the prepared hybrid nanofiller achieved high efficiency in VOC separation (air purification). A pyrolysis process involving sodium oxidation, carbonization, and activation was used to convert *Cladophora* nanocellulose into sustainable activated carbons. High surface areas (up to $1241 \text{ m}^2\text{g}^{-1}$) and tunable micropore sizes (pore diameter $<0.8 \text{ nm}$) were found in the activated carbon (Xu et al. 2018). The activated carbon had a high capacity for CO_2 uptake ($5.52 \text{ m mol g}^{-1}$ at 1 bar and 273 K) and high CO_2 -over- N_2 selectivity (Pan et al. 2018).

Biomedical Applications

Biomedical applications of algal cellulose and its derivatives are gaining popularity. The physical, mechanical, chemical, and biological properties of *Cladophora* cellulose are unrivalled by those of synthetic polymers. Hence these biocompatible, nontoxic *Cladophora* cellulose could replace synthetic polymers in several biomedical applications, including tissue engineering and drug delivery. Due to their biocompatibility, biodegradability, low cytotoxicity, high crystallinity, tunable porosity, and rich surface functionality, *Cladophora* cellulose has proved a cost-effective future material for biomedical applications. Recent discoveries have shown that due to excellent chemical functionality, *Cladophora* cellulosic materials could be easily modified to produce valuable products that are useful for various biomedical applications like immunosorbents, hemodialysis, medicine administration, and viral filtration (Asper et al. 2015; Ferraz et al. 2013; Ferraz and Mihranyan 2014; Metreveli et al. 2014; Wu et al. 2019).

It has been claimed that strategies based on *Cladophora* nanocellulose successfully achieved sustained drug release, which has considerable potential in biomedical applications. Mihranyan et al. demonstrated the effectiveness of *Cladophora* nanocellulose as a sorbent for nicotine. It has been reported that nicotine-containing dosage forms are an effective treatment for minimizing withdrawal effects from nicotine depletion. Even though nicotine can be used in various forms, the free base form is more effective in nicotine replacement therapies and quitting aids. Mihranyan et al. observed that *Cladophora* cellulose powders are suitable nicotine carriers due to the additional advantages of being colorless, tasteless, stable, biocompatible, and somewhat adsorptive. Due to the large surface area and pore volume, the free nicotine was efficiently stabilized on *Cladophora* nanocellulose powder. The study established that nicotine was occupied on open pore surfaces nanocellulose matrices but not in disordered cellulose. High loading capacity, extended-release, and protection from oxidative degradation were accomplished by loading nicotine in porous *Cladophora* cellulose. They found that the crystalline nature of the cellulose powder did not affect nicotine loading or release. However, a large surface area and pore volume could hold more nicotine. They could observe that all nicotine samples were quickly released into water, and the study established

that highly porous *Cladophora* nanocellulose could stabilize and handle liquid drugs (Mihiranyan, Andersson, et al. 2004).

Traditional paper filters have larger pore sizes. Hence cellulose derivatives having smaller pores obtained by the chemical processing of cellulose are used in sterile filtration. However, the functionalization of cellulose is time-consuming since it involves dissolving, derivatizing, and precipitating cellulose, and the final pore size distribution is subject to processing. Besides, most viruses are 20–250 nm, and the filters designed to remove viruses must have a narrow pore size distribution in the 20 nm range. Metreveli et al. examined a *Cladophora* nanocellulose-based membrane filter that can remove virus particles exclusively based on the size-exclusion principle, and their efficacy is comparable to the commercial synthetic and semi-synthetic polymeric counterparts. Their work suggested that using naturally occurring crystalline and porous *Cladophora* nanocellulose-based filters is desirable and economical. The researchers claimed to be the first to show that an unmodified nanofibrous polymer-based membrane could remove virus particles using the size-exclusion principle, producing performance comparable to commercial synthetic polymer-based filters (Metreveli et al. 2014). The cellulose nanofibers used were 30 nm thick and possessed a high level of crystallinity. Comparatively better performance of *Cladophora* nanocellulose-based filter than wood-derived cellulose filters was credited to the better porosity and large specific surface area (about 100 times larger than cellulose made from wood). Using N₂ gas adsorption experiments, they found that *Cladophora* nanocellulose filter paper with an average pore size of 19 nm and a surface area of 88 m²/g can be made by drying wet pulp in a conventional household heat-press. Most of the *Cladophora* nanocellulose membrane pores were smaller than 30 nm. The cellulose membrane had about 35% porosity and was 70 μm thick. Polystyrene latex containing beads of varying sizes (300 nm, 100 nm, 30 nm) were allowed to pass through the cellulose membrane, and SEM images of the filter taken after filtration show that the beads are retained on the membrane surface, demonstrating that the manufactured membrane was capable of filtering particles and viruses via size exclusion strategy. By examining the membrane's ability to retain the 80–100 nm-sized swine flu virus, it was further established that the fabricated *Cladophora* nanocellulose filter could filter out particles of a specific size. According to them, the better performance of the demonstrated filter is because in comparison to other wood-derived nano cellulose, *Cladophora* nanocellulose could keep its large surface area and porosity during conventional drying. After all, their primary nanofibrils are highly crystalline, stiff, and have a large thickness.

Paper filters are fragile when subjected to pressures above a specific threshold, so their industrial application is constrained. In order to use cellulose-based filters at higher pressures, their wet strength must be enhanced, and different methods have been tried to enhance the wet strength of nanocellulose paper. Quellmalz and Mihiranyan developed an entirely nature-derived polymer filter that can remove particles as small as 20 nm, having improved wet strength than pristine *Cladophora* nanocellulose. The wet strength was improved by crosslinking cellulose fibrils with citric acid of the *Cladophora* cellulose filter by crosslinking with citric acid. The

average pore size was 15 nm for the crosslinked *Cladophora* nanocellulose. In order to evaluate the size exclusion filtering potential, tracer retentions tests were carried out with AuNPs having an average size of 20 nm. They performed SEM analysis of the modified and unmodified *Cladophora* cellulose membrane after retention studies, and it was apparent in the SEM images that only a few AuNPs are retained in the unmodified cellulose filter (Fig. 6a), suggesting that majority of tracer particles are escaped through the membrane while, while the surface of the crosslinked nanocellulose paper filter is abundantly covered with Au nanoparticle clusters (Fig. 6b). Therefore they could confirm that crosslinking has drastically improved the filtration capabilities of the cellulose-based paper filter. The crosslinked *Cladophora* nanocellulose membrane could effectively filter Au nanoparticles at a pressure gradient of 37 k Pa without cracking the filter membrane confirming its enhanced wet strength. This team was the first to describe a 100% cellulose-based paper filter capable of removing tracer particles with a particle size of 20 nm, which has tremendous potential for developing a network of nanofiltration devices, such as sterile virus elimination filters (Quellmalz and Mihranyan 2015).

Due to the possibility of retrovirus contamination of therapeutic protein products, the biopharmaceutical industry demands economic and efficient virus removal

Fig. 6 SEM images of the unmodified and cross-linked nanocellulose-based paper filter samples following tracer retention tests (Quellmalz and Mihranyan 2015)

filters, especially for generic therapeutic biologicals. The utilization of cellulose-based filter paper for virus elimination is beneficial due to its cost-effectiveness and ease of preparation. Asper et al. demonstrated that the size-exclusion filter paper made from pure *Cladophora* nanocellulose removes xenotropic murine leukemia virus. Investigations using atomic force microscopic images (Fig. 7a) and pore size calculation based on gas adsorption studies confirmed that the prepared filter paper has an average pore size of 16 nm, which is significantly smaller than the nominal size of xenotropic murine leukemia virus (size range of 100–120 nm). This was further corroborated by SEM studies (Fig. 7b, c). In particular, the ability of the filter paper to hold particles were tested by filtering 100 nm latex beads and 50 nm gold nanoparticles and it was clear from the corresponding SEM images that the latex beads (Fig. 6c) and gold nanoparticles (Fig. 7c) are retained on the surface of the *Cladophora* nanocellulose filter (Asper et al. 2015).

Rocha et al. demonstrated that the hemodialysis potential of the *Cladophora* cellulose could be enhanced by chemical modification of the cellulose nanofibers. Spherical beads composed of sulfonated Cellulose were produced by first oxidizing *Cladophora* nanocellulose to produce DAC, then subjecting the resulting Cellulose to sulfonation with bisulfite (Rocha, Ferraz, et al. 2018). Due to the high surface area, high degree of oxidation, spherical shape, and the ability to tailor the porosity of the sulfonated beads make them exciting candidates for the development of immunosorbent platforms, including their application in extracorporeal blood treatments.

IVIG, which stands for intravenous immunoglobulin, is a valuable plasma-derived biotherapeutic with ample clinical indications in primary and chronic immunodeficiencies and autoimmune disorders, especially neuropathies. Human IVIG and other plasma-derived products must be virus-safe. Viral filtration is used to remove viruses in plasma products. Viral filtering of large amounts of IVIG feed solution can take a long time and be expensive. Therefore, high-capacity filters that can process large volumes of plasma-derived biotherapeutic compounds quickly and cheaply are needed. For the first time, Wu et al. detailed the effectiveness of a virus-removal filter paper made from *Cladophora* nanocellulose in processing human IVIG (Wu et al. 2019).

Fig. 7 (a) Atomic force microscopic image of nanocellulose filter paper, (b) SEM images of 100 nm latex beads and (c) 50 nm gold nanoparticle retained over *Cladophora* nanocellulose filter paper (d). (Published with permission (Ref: Asper et al. 2015))

The solute diffusion properties of the materials can be further tuned by incorporating suitable fillers. Ferraz et al. developed an electroactive membrane composed of Cladophora nanocellulose PPy composite for blood purification. They could observe that upon the incorporation of PPy, the average pore size has increased to 53 nm compared to 21 nm of the pure Cellulose. It was observed that the diffusion of tested uremic toxins across the composite membrane was faster since the composite membrane could provide an open structure with a larger pore that facilitates more accessible transport across the membrane (Ferraz et al. 2013).

Due to its high stability, versatility, biocompatibility, adhesive, and therapeutic properties, Cladophora nanocellulose has a wide range of biomedical applications. Hua et al. prepared carboxyl and hydroxy- propyltrimethylammonium functionalized Cladophora nanocellulose derivatives and demonstrated that prepared derivatives are effective as a potential anti-inflammatory agents. *Inflammation* is a localized physical condition when an injury or infection causes the affected body area to swell, turn red, or hurt. The restoration of tissue structure and function, as well as cellular homeostasis, is ultimately caused by the positive host response. Without an inflammatory response, infections, wounds, and tissue damage cannot heal. Cladophora nanocellulose are more effective at blocking inflammation-enhancers like cytokines and inflammation-assisting enzymes than their bulk counterparts because they have a higher surface area-to-volume ratio. Due to their diminutive size, Cladophora nanocellulose may readily pass through most biological barriers, including mucous linings, and even reach the sense organs. The circulatory system receives the Cladophora nanocellulose as soon as they enter the body. The proteins in the blood plasma interact with the nanocellulose inevitably. Despite being less prevalent in blood plasma, serum proteins have a high affinity for binding to Cladophora nanocellulose. Without the use of membrane receptors, based on the location of the Cladophora nanocellulose within the cell, which again depends on its size, different cellular actions are triggered. Some tiny Cladophora nanocellulose are easily endocytosed by most cellular vesicles at greater concentration levels. Neutrophils and macrophages both engage in phagocytosis and macro-pinocytosis. The protein corona that surrounds the nanoparticles makes initial contact with the cell surface receptors when the protein-coated Cladophora nanocellulose interact with macrophages or neutrophils in areas of inflammation and thus reduce the effect (Hua et al. 2015; Patel et al. 2019).

Cladophora nanocellulose-based material is promising for developing affordable and efficient electrochemically controlled ion exchange membranes for batch-wise biomolecule separation demonstrated that Cladophora nanocellulose-PPy composite is used for the electrochemically controlled solid-phase microextraction charged biomolecules like DNA. It is reported that upon oxidation or reduction of electroactive polymers, the ion can be extracted or released when it is kept in contact with the solution. The ions enter or leave the matrix to compensate for the charges during the oxidation/reduction of the conducting polymer matrix. The release and intake of ions depend on the size and nature of the ion. Several research groups have examined the adsorption of DNA on PPy. DNA adsorption on partially oxidized conducting polymers includes diffusion-controlled replenishment of the polymer's counteranions. Some adsorbed DNA can be released by adding additional anions,

albeit at slower rates. This observation suggested that DNA-trapped PPy films can act as cation exchangers for solid phase microextraction (SPME). SPME under electrochemically controlled conditions is more effective than conventional SPME methods since the number and nature of active sites in the electrode membrane and the extraction rate can be readily controlled by adjusting the external current or applied potential.

However, the extraction using pristine conducting polymer alone is not so effective since the outer layer alone is electroactive and can take part in ion extraction. Increasing the polymer layer thickness makes mass transport difficult, further reducing the ion exchange capacity. Razaq et al. found that the ion extraction efficiency can be improved by increasing the surface area of the active PPy layer by coating PPy over high surface area *Cladophora* nanocellulose support. The porous structure of *Cladophora* nanocellulose provided a large surface area for incorporating PPy layers. Electron microscopic studies confirmed that the PPy coating over the Cellulose is only 30–50 nm thick, and the composite could retain the fibrous structure and specific surface area of pure Cellulose. TEM results also revealed that during the extraction, DNA could access the whole volume of the PPy coatings within the composite matrix. The porous structure of the composite and the thin layers of PPy on the high-surface-area cellulose matrix is responsible for the composite's relatively quick adsorption activity. Using the composite material, DNA oligomers of 6, 20, and 40 bases can be extracted, and the amount removed is proportional to the oxidation charge applied in the extraction stage. The conducting paper sheets of PPy-*Cladophora* nanocellulose composite exhibited excellent ion exchange capacities, low internal resistances, and better stabilities. The study demonstrated that the proposed composite material is a good option for batch-wise electrochemically controlled DNA extractions. According to the findings of their research, the developed composite membrane was able to extract all tested DNA oligomers; however, the smallest oligomer was preferentially released during the reduction of the PPy layer, which indicates that the present PPy-cellulose composite may be utilized to separate small DNA oligomers from larger ones (Razaq et al. 2011).

The *Cladophora* cellulose has blood anticoagulant activity which may be due to the inhibition of thrombin, and novel anticoagulants can be derived from *Cladophora* nanocellulose by chemical modification of the surface hydroxyl groups. Scientists have reported that large surface area sulfonated *Cladophora* nanocellulose with a pore diameter ranging from 1 to 100 m could be used instead of heparin as a nontoxic anticoagulant during blood purification (Igor et al. 2016; Majdoub et al. 2009).

Cladophora Nanocellulose as Electrode Material

Cellulose-based paper electrodes have gained much attention compared to traditional metal-based electrodes. Since it is cheap, readily available, biodegradable, flexible, lightweight, and recyclable, the paper makes for a fantastic substrate for electronic devices. To compensate for the poor electrical conductivity of untreated

paper, most paper-based electronics need the deposition or growth of electro-active components onto the cellulose fibers during the manufacturing process. Alternatively, films can be made from electrically conductive materials by assembling components such as carbon nanotubes, graphene, and carbon fibers. Paper-based electronics have exceptional electrochemical performance while retaining considerable flexibility in these approaches. These paper-based electronics achieve significantly high power and energy density because of the cellulosic material's low electrical resistance and compact size (Nyström et al. 2009; Olsson et al. 2012; Wang et al. 2014).

Many applications exploiting the property of conducting polymers to incorporate and exclude ions when they undergo oxidation and reduction have been explored. Using voltammetry and chronoamperometry, several scientists have investigated the relative impact of anion and cation mobility during the oxidation and reduction of conducting polymers. Anions enter oxidized polymers as charge-balancing ions if they are tiny and mobile enough. Since cations migrate to compensate large anions, a high ion absorption capacity is maintained. Charge adjustment by anions and cations is significant in electrochemically regulated solid phase microextraction applications. The ion exchange properties are highly dependent on several factors, including electrochemical properties of the polymer, morphology, pore structure, charge of ions, size of ions, etc. Novel hybrid materials can be developed by combining conducting polymers with high surface area fibers like cellulose, and composites can be used as the economic and environmentally benign alternative for the conventional water softening technique.

Mihiranyan et al. recently established that thin PPy coatings on *Cladophora* cellulose nanofibers are more promising as an ion exchange material. The composite was prepared by incorporating conducting PPy into *Cladophora* cellulose nanofibers by polymerizing pyrrole with ferric chloride oxidatively. The novel conductive paper material, which has a large specific surface area, can be easily molded into paper sheets and bent, twisted, or folded without losing mechanical integrity. It was employed as an ion-exchange membrane and can be immersed in the solution under investigation.

Mihiranyan et al. have demonstrated that by electrochemically switching the polymer between its oxidized and reduced states, these composites can be readily employed for the extraction and desorption of small anions such as chloride ions. The doped composite paper demonstrated excellent chloride ion exchanging capacity (370 °C per g of composite) and cyclic stability when employed as a working electrode in a chloride-containing solution because of the high surface area of the nanofibrous *Cladophora* cellulose and unique electrochemical properties of PPy (Mihiranyan et al. 2008).

Actual water samples generally have a mix of anions and cations, and the presence of another ion also interferes with the ion exchange capacity of the hybrid membrane. Gelin et al. investigated how this PPy-*Cladophora* nanocellulose composite material behaves in water samples containing mixtures of ions since other ions will influence the amount of a specific ion that can be extracted. In order to study the effect of concentration and size of other ions on the ion exchange capacity of a

specific ion, they examined the effects of varying concentrations of nitrate, chloride, and p-toluene sulfonate on the electrochemical characteristics of a novel composite paper material consisting of PPy supported on *Cladophora* cellulose. It can also be seen that the oxidation current was much lower when the experiments were done in an electrolyte containing p-toluene sulfonate instead of electrolytes with smaller anions. This means that the diffusion coefficient of the larger ions is much lower than that of the smaller ions, both in the bulk electrolyte and the composite material. For all three types of electrolytes studied, the current went down as the electrolyte concentration went down. This is because it takes less time for the electrolyte layer next to the composite surface to run out of ions as the electrolyte concentration goes down. It was discovered that nitrate ions are slightly more easily absorbed into the composite than chloride ions. However, the composite's capacity to host major p-toluene sulfonate ions is approximately 50% lower than the smaller ions under the oxidation conditions used in this work. At sufficiently high electrolyte concentrations, most of the composite surface was physisorbed by the anions before they diffused into the bulk of the polymer, and the distance between surface sites roughly matched the sizes of the anions. In a solution containing both p-toluene sulfonate ions and chloride ions, it was revealed that high concentrations of the more significant p-toluene sulfonate anion might inhibit the transit of chloride ions into the composite, whereas low quantities may promote the transport. Even for large anions, the present results demonstrate that the combination of the thin polymer covering and the large specific surface area of the composite results in a high ion absorption capacity (Gelin et al. 2009).

Razaq et al. prepared chopped carbon filaments that reinforced PPy–*Cladophora* cellulose composites and symmetrical supercapacitor systems containing paper-based composite electrodes with high charge capacities owing to the fabrication of lower resistance. The excellent cyclic stability exhibited by these electrodes demonstrated inexpensive and ecologically acceptable paper-based energy storage devices (Razaq et al. 2012).

Tan et al. prepared *Cladophora* cellulose coated with PANI nanocomposite to create a paper-based electrode for lead detection. Polymerization was done in the dispersion of threads of *Cladophora* cellulose, which resulted in the formation of thin layers of PANI over cellulose while keeping the highly crystalline structure of cellulose intact. The composite was formed into a working electrode, and the cyclic voltammetry (CV) profile displayed characteristic peaks of PANI, and the peak current was significantly higher than the corresponding cellulose electrode. PANI-cellulose modified electrodes exhibited quasi reversible redox processes and good cyclic stability. The PANI-cellulose composite was used to fabricate a low-cost electrochemical sensor for lead ions, and sensing parameters were determined employing stripping voltammetric techniques. It was reported that the developed sensor could show a linear working range of 0.2–1.0 ppm and a low detection limit of 0.0721 ppm for Pb^{2+} . This work high lightened the potential of cellulose-based electrochemical sensors for rapid water pollution monitoring since there was no significant difference in the quantity of lead from that estimated by conventional atomic absorption spectroscopy techniques (Tan et al. 2018).

Wang et al. also prepared a conductive composite of Cladophora cellulose with PPy by chemical polymerization of pyrrole in the presence of dispersed cellulose nanofibers, and the resulting composite was employed as binder-free electrodes. The prepared composite was compressed by applying external pressure, and it was observed that the density and porosity of the electrode material thus obtained were influenced by the pressure applied. As the applied pressure increased, the electrodes became thinner and denser. Electron micrographs indicated that the compressed sample had a more compact structure and flat surface. The uniform coating of PPy on Cladophora cellulose resulted in uniform interweaved PPy@nanocellulose fibers with a 90 nm average diameter. Entangled nanofibers form voids with tens-of-nanometer pores. For the sample exposed to higher compression pressure, the material displayed small voids that suggest the material remained porous, and the interconnected pore structure was well preserved throughout the material. N₂ sorption studies revealed that mesoporous microstructures were retained in the uncompressed and compressed samples, while specific surface area measurements suggested that compression has reduced the effective surface area. They could observe that the electrochemical performance of the nanocellulose-PPy was not hindered by the reduction in the surface area since energy storage occurs mainly through oxidation and reduction of the PPy layer rather than charging the double layer. It is suggested that cellulose-incorporated porous material could allow the PPy layer to rapidly oxidize and reduce throughout the material and enhance energy storage. Their findings suggested that the compacted materials have well-maintained mesoporous structures, and the PPy layer on the cellulose fibers should give rise to a suitable surface wettability concerning the aqueous electrolyte, suggesting that these compact materials should serve as all polymer-based electrodes with higher energy densities than their new counterparts. Remarkably, they could find that when the electrodes were compressed, it was discovered that their volumetric capacitance increased, but their gravimetric capacitance decreased. The compact composite sample has far higher volumetric capacitance than compact porous carbon. It has been found that prepared electrodes had significantly higher areal capacitances than carbon and polymer-based electrodes, reaching values as high as 5.66 F cm⁻². This is a significant finding since it suggests that the energy density of electrodes can be enhanced simply by compressing them, whereas earlier efforts to reduce porosity tend to lower capacities due to changes in mesopore distribution. While pressing in water, the polar environment surrounding the fiber screens the surface charges, resulting in an altered fiber alignment (Wang et al. 2014).

Due to better crystallinity, high thermal stability, and ease of manufacture, Cladophora cellulose is considered an excellent candidate as an alternative for conventional polyolefin separators in lithium-ion batteries. Pan et al. have demonstrated that the renewable and inexpensive Cladophora cellulose is highly crystalline and porous, so it is suggested to be easier for lithium ions and electrolytes to move through Cladophora cellulose-based separators. Due to high wettability, Cladophora cellulose separators are anticipated to rapidly absorb electrolytes generally used in lithium-ion batteries, hence facilitating the electrolyte filling process. They could observe that Cladophora nanocellulose was stable without any visible deformation

even at temperatures as high as 150 °C; it could be considered a safer choice, especially for high power/temperature battery applications. The lithium-ion batteries with *Cladophora* cellulose separators with good cyclic stability were obtained with 99.5% capacity retention after 50 cycles (Pan et al. 2016).

Recent studies reported that silicon-based anodes are appropriate for lithium-ion batteries due to their cost-effectiveness and high theoretical specific capacity. However, silicon undergoes enormous volume changes during charging/discharging, causing the anode to break up and lose contact with the current collector, causing the battery's capacity to drop quickly. It is reported that such issues can be resolved by incorporating polymers, nitrocellulose, or carbon nanomaterials with silicon. Wang et al. demonstrated that lightweight, flexible *Cladophora* nanocellulose-based silicon paper electrodes could be made without post-treatment. Due to the silicon nanoparticles' uniform distribution and strong adhesion to the 3D conductive flexible CNT-*Cladophora* nanocellulose cellulose network, these electrodes exhibit high areal capacities (2.5 mAh cm⁻²) and specific capacities (3200 mAh g⁻¹). The better electrochemical performance and industrially scalable preparation method are promising for developing lightweight, cost-effective, high-energy anodes for lithium-ion batteries (Wang et al. 2015).

Olsson and colleagues explored the root cause of self-discharge in positively charged PPy. Consequently, they assessed the potential loss under open circuit conditions in a three-electrode configuration with PPy/cellulose composites as the working electrode. *Cladophora* nanocellulose-PPy composites were fabricated by combining pyrrole solution (in 0.5 M HCl) and FeCl₃ solution with *Cladophora* nanocellulose dispersion. The self-discharge of PPy was measured by charging the composite with a potential step to 0.53 V for 600 s, followed by monitoring the open circuit potential decay. They hypothesized that the self-discharge of the positive PPy electrode is caused by an activation-controlled Faradaic reaction that results in the partial degradation of the polymer. They proposed that self-discharge in PPy is caused by a range of degradation products, including maleimide, derived from a common intermediate generated in a polymer-intrinsic and rate-limiting Faradaic process. Due to the exponential dependency of the self-discharge rate, the primary source of self-discharge becomes insignificant at potentials below 0.25 V vs Ag/AgCl; hence, PPy composites can be operated under stable conditions below this potential limit in applications involving electrical energy storage (Olsson et al. 2014).

Tammela and his co-workers investigated the effect of cell design on cell resistance in symmetric PPy and cellulose-based electric energy storage devices utilizing chronopotentiometry and ac impedance measurements with various separator and electrode thicknesses. With SEM micrographs of PPy/cellulose and PPy/cellulose/carbon chopped fiber composites, the morphologies of the composites were analyzed. Both samples displayed the characteristic fine fibrillar structure of PPy-coated *Cladophora* cellulose samples. Based on constant current and ac impedance measurements, it has been demonstrated that the cell resistance of symmetric PPy/cellulose composite-based energy storage devices is primarily governed by the resistance of the current collectors and the contact resistances between the electrodes and the current collectors. They discovered that the resistance of the

PPy and cellulose composite electrodes was insignificant. However, the resistance of the separator soaked in electrolyte increased linearly as the thickness of the separator increased. In the absence of sufficient external pressure on the cell, it was determined that the employment of platinum foils (with negligible resistance) as current collectors led to significantly higher contact resistances than graphite foils. Platinum current collectors are not feasible alternatives to graphite foils for enhancing the performance of energy storage devices due to their high cost. Also, the incorporation of chopped carbon fibers into the electrode material and the application of external pressure across the cells were found to reduce the charge transfer resistance as determined by ac impedance measurements due to decreased contact resistances between the electrodes and the current graphite collectors. It is also evident from their study that the separator should be as thin as feasible in order to reduce cell resistance and that the porosity of the electrodes guarantees that sufficient electrolyte is maintained within the cell. These findings enable the creation of energy storage devices based on the current type of affordable PPy and cellulose composite electrodes (Tammela et al. 2014).

Etman et al. demonstrated that electrode materials having high charge/discharge rates for flexible charge storage devices could be derived from *Cladophora* cellulose by incorporating electroactive fillers. The ternary composite of nanostructured molybdenum oxide (MoO_{3-x}), carbon nanotube, and *Cladophora* cellulose obtained via a one-step route have resulted in a uniform distribution of molybdenum oxide within the *Cladophora* cellulose-carbon nanotube (CNT) matrix confirmed by the electron microscopic and energy dispersive X-ray spectroscopic studies. The MoO_{3-x} -CNTs-*Cladophora* cellulose-based electrode delivered a reversible capacity of 30 Cg^{-1} at current densities between 0.78 and 78 Ag^{-1} . The observed low capacity suggested that only the surface layer of the oxide was electroactive. Also, electrodes can be cycled for more than 30,000 cycles without a significant reduction in capacity loss and severe structural change in the active electrode material. Based on the peak current and potential redox analysis, it is established that the electrode kinetics were fast and that the polarization was caused primarily by the iR fall. The developed MoO_{3-x} -CNTs-*Cladophora* cellulose electrodes demonstrated excellent cyclability and rate capability, ascribed to the redox reaction's surface-confined nature, the absence of diffusion limitations, the electrodes' high electrical conductivity and flexibility, and the reasonably moderate rise in iR drop (Etman et al. 2019).

Keskinen et al. prepared symmetric and asymmetric supercapacitors using either two PPy composite electrodes, one PPy composite, or one activated carbon electrode, respectively. The fabricated PPy composite electrodes utilized *Cladophora* nanocellulose as the substrate or binder. The electrochemical characteristics of the symmetric and asymmetric supercapacitors containing cellulose, PPy composite electrodes, and activated carbon were investigated. Capacitance is better for symmetric composite-based devices over asymmetric supercapacitors, while an asymmetric supercapacitor combining PPy and activated carbon electrodes seems to have a longer lifetime. The specific capacitance of PPy electrodes was roughly 200 F g^{-1} depending on the manufacturing method, generating supercapacitors with capacitances between 0.45 and 3.8 F and above 90% energy efficiency. An asymmetric

device with activated carbon positive and PPy negative electrodes lost 5% capacitance after 14,300 cycles, whereas the PPy sheet component's efficiency did not change. By using *Cladophora* nanocellulose, the study showed that the printing techniques they demonstrated could be used to make many supercapacitors that are cheap and safe for the environment (Keskinen et al. 2015).

Liu et al. fabricated a novel binder-free nitrogen-doped carbon paper electrode derived from a nitrogen-rich PPy/cellulose-chopped carbon filaments (CCFs) composite for Li-O₂ batteries. The preparation of electrode material is economical and environmentally friendly as the composite is obtained by in situ polymerization of pyrrole in *Cladophora* cellulose. The composite of nitrogen-rich PPy and cellulose-CCFs had a bird's nest microstructure capable of providing the free-standing electrode with mechanical durability, rapid O₂ diffusion, and sufficient space for discharge product deposition. N-doping could promote electrochemical reactions. The discharge capacity of 8040 mAh.g⁻¹ was observed for a nitrogen-doped carbon paper electrode Li-O₂ cell, along with satisfactory cyclic stability and good coulombic efficiency (81% at the current density of 0.2 mA cm⁻²). These studies established that by using *Cladophora* nanocellulose as the support matrix for incorporating active fillers, novel non-metallic, binder-free electrode materials have improved energy density for the Li-O₂ batteries can be developed (Liu et al. 2016).

Using PPy-coated *Cladophora* nanocellulose composites and highly porous carbon nanofibers-based materials that can be easily obtained from the PPy-cellulose composite itself, Tammela et al. demonstrated that all-organic material-based asymmetric energy storage devices could be manufactured. The PPy-cellulose was subjected to a heat treatment in the presence of nitrogen, which resulted in the production of the porous carbon nanofiber-based material. Studies using electron microscopy and x-ray photoelectron spectroscopy demonstrated that the heat treatment results in forming a porous carbon nanofiber material were almost topologically identical to the PPy-cellulose composite used originally. Additionally, it was shown that the electrochemical performances of PPy-cellulose and carbon nanofiber materials varied greatly from one another and that the combination of these materials in asymmetric supercapacitor cells is favorable. Asymmetric supercapacitor performance was evaluated using galvanostatic charge, discharge, and electrochemical impedance spectroscopy. With a current density of 156 mA/cm², the asymmetric devices had a capacitance of 11 F/g, and the capacity dropped by about 23% after 1000 cycles with a current density of 20 mA/cm². The supercapacitor could undergo galvanostatic charge and discharge for 1000 cycles at 20 mA/cm² with acceptable stability in 0.2% NaCl. This work is a massive step toward all-organic, renewable energy storage devices with commercially viable mass loadings, capacitances, and energy densities (Tammela et al. 2015).

Nystrom et al. produced a robust, lightweight, flexible PPy-cellulose composite that can be molded and rolled to construct miniature energy storage devices and paper-based batteries. Cost-effective, recyclable paper batteries require abundant cellulose and simple composite construction. The composite material was created readily by oxidizing pyrrole on *Cladophora* cellulose with Fe(III) chloride. The method they describe has limited cell potential compared to Li-ion batteries. However, it offers

significant promise for applications where Li-ion batteries are difficult to employ, such as affordable large-scale or flexible energy storage devices integrated into textiles or packaging materials. Cladophora nanocellulose composite conductive paper material has a specific surface area of $80 \text{ m}^2 \text{ g}^{-1}$, and its batteries lose only 6% of their capacity over 100 charge and discharge cycles. The cellulose and PPy-based batteries have charge capacities between 25 and 33 mAh g^{-1} or 38–50 mAh g^{-1} , opening new opportunities for environmentally friendly, cost-efficient, up-scalable, and lightweight energy storage systems (Nyström et al. 2009). This paper-based battery technology is compatible with fast charging rates and has good cycling stability, making it ideal for future high-performance energy storage systems.

Cladophora Cellulose as Eco-Friendly Packaging Material

The primary contributor to plastic pollution in the environment is using plastic for packaging. Therefore, it is desirable to employ readily available, biodegradable cellulose as an environmentally friendly packaging material. Despite its excellent tensile strength and water resistance, cellulose is difficult to process due to its fragility. The processability can be improved by introducing materials like starch which is also environmentally friendly. Steve and his coworkers studied the usefulness of Cladophora nanocellulose-starch-based bio-composite as an alternative eco-friendly packaging. Starch has poor mechanical strength and water-resistant properties, but blending starch with Cladophora cellulose which has excellent mechanical strength and good water-resistant properties has resulted in the composite material having desired properties. The Cladophora cellulose microfibrils are much broader than that derived from wood, so the Cladophora cellulose has superior crystallinity.

Additionally, the distinctive web-like structure of Cladophora cellulose resulted in improved mechanical strength. Steve et al. made bio-composite film from cellulose and starch by adding glycerol as a plasticizer to improve processability and flexibility. They found that the developed bio-composite film had greater tensile strength and elongation than the new components – the bio-composite film comprised 70% starch and achieved a tensile strength of 80.16 MPa. The study revealed that the water resistance properties of the starch film were improved during the composite formation since cellulose inhibits interactions between starch and water. The bio-composite films exhibited superior biodegradability than new cellulose film. According to the results of the study, it is established that Cladophora cellulose has the potential to be used as a green packaging material that is both eco-friendly and long-lasting (Steven et al. 2020; Sucaldito and Camacho 2017).

Conclusion

This chapter presents a comprehensive discussion on the extraction, unique characteristics, and applications of the Cladophora-derived nanocrystalline cellulose. It is demonstrated that the unique properties like tunable porosity, larger surface area,

biocompatibility, and rich surface functionality could find excellent applications in exciting fields like hemodialysis, virus filtration, environment pollution remediation, energy storage, and electronics. Notably, utilizing *Cladophora* biomass to extract cellulose offers a remedy for biowaste accumulation and is economically viable. The review revealed that intensive research is needed in academia and industry to develop innovative extraction processes that would result in efficient processes for getting high-quality cellulose in good yield. This research was required in order to develop novel industrial extraction processes. To improve the properties of nanocellulose and expand the application sphere of nanocellulose, especially in medical and industrial technologies, additional work must be done to modify the current material. We anticipate that the structure, biochemistry, and electrochemistry of *Cladophora* nanocellulose, detailed here, can further enhance and expand the exploration, application, and future development of various cellulosic materials from numerous marine and agricultural biomass.

Abstract

The nanoscale version of cellulose, known as nanocellulose (NC), has emerged as a promising green material thanks to its distinct properties, including its renewability, biodegradability, ecologically benign nature, and abundant natural occurrence. Many of the beneficial qualities of cellulose are also present in NC, such as their low density, nontoxicity, biodegradability, thermal stability, mechanical properties, reinforcing capabilities, and tunable self-assembly in aqueous conditions. The surface of NC is one of their most interesting features since it may be altered in a wide variety of ways by adding functionalizing chemicals. Esterification, etherification, amidation, and urethanization (all hydrophobic decorations), phosphorylation, sulfonation, TEMPO-oxidation, and carboxymethylation (all hydrophilic surface modifications) are just some of the ways documented for surface functionalization of NC. It is possible to create NC/inorganic composite materials by functionalizing the NC surface with inorganic metal ions, complexes, or compounds. The catalytic transformation of organic molecules is one area where such inorganically modified NC finds use. An in-depth analysis of how cellulose nanocrystals (CNCs) can be inorganically functionalized for use in catalysis has been done. Using CNCs to facilitate the catalytic transformation of organic compounds through oxidation, reduction, coupling, and electrocatalytic reactions has environmental benefits.

Introduction

Since the dawn of civilization, humans have used various forms of written and visual communication to convey meaning and information to one another. In the past, humans have used everything from rocks and wooden pieces to leaves to write down their thoughts and pass on their knowledge to future generations. These days, most people use wood pulp paper since it is both affordable and widely available. The main chemical components of wood pulp are cellulose, lignin, and pectin. Scientific advances have allowed researchers to isolate or synthesize cellulose from a wide variety of sources, including wood, leaves, algae, fungi, bacteria, fibers, grasses, husk, and marine animals. Payen discovered cellulose's fibrillar arrangement, which makes a significant contribution to plants' mechanical strength. It is a staple of plant life and one of the most common organic substances. Each year, between 1010 and 1011 metric tons of cellulose biopolymer are produced. Cellulose polymers are formed when D-glucopyranose (glucose) molecules are bonded to one another via 1,4-C–O–C-glucosidic linkages. Cellulose molecules have the chemical formula (C₆H₁₀O₅)_n, where n is the number of repeating sugar units, and their degree of

polymerization (DP) has a major impact on the properties of cellulose-containing materials. The cellulose repeating unit, known as anhydrocellobiose, consists of two glucose molecules. The DP of native cellulose can be anywhere from 1500 to 3500, depending on its source and degree of processing. Cellulose, hemicellulose, lignin (Fig. 1), waxes, etc., form a traditional hierarchical structure in plants that gives them their strength and other special features. Cellulose, a biopolymer made from the α -D-glucose monomer, is the primary component of plants that provides structural support and reinforcement along with hemicellulose and lignin. It has been identified as the most abundant biopolymer with specific properties such as hydrophilicity, hydrophobicity [and thus a typical hydrophilic to lyophilic balance (HLB)], biodegradability, nontoxicity, good mechanical strength, etc. Nanocrystalline particles, which are renewable, biodegradable, and nontoxic, can be synthesized using cellulose because of the material's semi-crystalline structure. Isolating the nanoparticles of this substance from the biomass requires a top-down mechanically or chemically induced deconstruction technique (Dufresne 2013).

The wide spectrum of possible uses and low manufacturing cost of cellulose make it a material of particular interest for its positive impact on the environment. Due to its singular form, size, surface chemistry, and high degree of crystallinity, it possesses great mechanical strength, reinforcing capabilities, and tunable self-assembly in aqueous mediums. Cellulose nanocrystals (CNC), cellulose nanofibers (CNF), and bacterial nanocellulose are the three most common types of nanocellulose used in nanotechnology due to their distinct origins (or more precisely, due to the extraction protocol or synthetic approaches), morphology, particle size/shape, crystallinity, etc. (BNC). It is possible to extract CNCs and CNFs using either direct chemical procedures or a mix of chemical and mechanical channels, such as enzyme-chemical or mechano-enzymatic hydrolysis approaches, whereas BNC is obtained through bio-formation utilizing

Fig. 1 A diagram demonstrating the hierarchical structure of nanocellulose from the top down. (Permission granted to reproduce BNC and CNC photos from Fan Li et al. *Holzforschung* doi:10.1515/hf-2018-0251 and Nirmal N et al. *RSC Adv.* DOI: 10.1039/D0RA04649C)

bacterial cultures. These are utilized in many different industries, including those dealing with food, textiles, autos, study aids, kitchen aids, polymers, paints, chemical manufacturing, fuel generation, etc. Modifications to the surface of nanocellulose produced from waste biomass or bacterial cultures activate the catalyst's broad activity in organic transformations and biofuel production. In this review, we discussed about the structure, modification of cellulose using metal based catalysts and its applications, especially towards diverse types of organic transformations.

Catalysis is employed in roughly 80% of all manufacturing processes, including the production of anything from sulfuric acid to acetone to phenol, etc. These three considerations highlight the critical nature of this physical process. The production of chemicals has become more sustainable, which has three benefits: (1) it protects the environment, (2) it helps produce things that people need in the twenty-first century, and (3) it aids the world's major economies in their quest for growth in a sustainable way. Homogenous catalysts, heterogeneous (solid) catalysts, heterogenized homogeneous catalysts, and biocatalysts are the four primary types of catalysts. It is easier to handle, store, recycle, and separate the catalyst from the product, among other benefits, when using a heterogeneous catalyst as opposed to a homogeneous or heterogenized homogeneous catalyst, which is an important consideration when designing eco-friendly technologies. Several materials are used as commercial catalysts, including vanadium oxides, iron and manganese oxides, platinum and rhodium gauze, zeolites, clays, alumina, zirconia, and others. Exploring nanocellulose's potential as a catalyst support for various reactions has witnessed a spike in research in recent decades. Nanocelluloses, or nanomaterials based on cellulose, are currently the focus of extensive research. Thanks to its enhanced chemical, colloidal, optical, and mechanical capabilities, bacterial nanocellulose has been selected as a promising catalytic support among the numerous nanocelluloses (CNC, CNF, and BNC). So, although these sustainable heterogeneous catalysts have not yet been deployed in a commercial setting, a lot of work has gone into their creation and usage.

This chapter details the state-of-the-art extraction techniques used to create metal/CNC nanocomposites with excellent metal dispersion, high surface area, and high catalytic activity. To enhance its physicochemical properties and aid in efficient metal stabilization, synthetic procedures were devised to modify the morphological/chemical functionality of CNC. This resulted in enhanced catalytic activity. The organic reactions that can be catalyzed by catalysts based on CNC are then illustrated graphically. A perspective for the future of the discipline is provided, as are developments in the study of materials based on CNCs for (nano)catalysis that are expected to occur in the near future.

Hierarchical Structure and Source of Cellulose

The composition of lignocellulose biomass varies depending on its source, but it always includes the three structural components cellulose, hemicellulose, and lignin (Fig. 1). Lignin and hemicellulose form a matrix around the cellulose fibrils in a lignocellulosic composite. Hydrogen bonds hold cellulose to hemicellulose within

the biocomposite system, and covalent bonds hold it to the lignin framework outside of the biocomposite. Hemicellulose is assembled both inside of the cellulose and between the cellulose and lignin (Klemm et al. 2005; Moon et al. 2011; Thomas et al. 2018).

Significant portions of the plant cell wall are made up of hemicellulose group of materials. Hemicelluloses are heteropolysaccharides with a diverse range of chemical compositions, including pentoses (xylose and arabinose), hexoses (glucose, mannose, galactose, and fructose), and sugar acids (glucuronic acid and galacturonic acid). Although having a lower DP value than cellulose, hemicellulose is highly chemically soluble, making its extraction from lignocellulosic biomass a simple and straightforward process (Klemm et al. 2005; Moon et al. 2011; Thomas et al. 2018). The physical properties of hemicelluloses contribute to make up the bulk of the fiber; they are white solid solids that are rarely crystalline or fibrous in character. By interacting with cellulose and, in some walls, with lignin as a lignocellulosic biomass composite, hemicelluloses play their most essential biological role as a component of the cell wall (Fig. 1).

Lignin, a phenolic (phenolics – having a -OH group attached to an aromatic ring) polymer, is found in all land plants and possibly some marine ones as well (Fig. 1). To sum up, they are plant polymers made up of phenylpropanoid building blocks and accounting for the vast bulk of wood's methoxyl content. Lignin is made up of a collection of irregular propyl phenol units, some of which are coniferyl alcohol, sinapyl alcohol, and p-coumaryl alcohol. Ether, ester, and carbon-carbon bonds are used to bring these subunits together. Plants get their tensile strength from lignin because it fills the voids between cellulose, hemicellulose, and other cell components. Lignin is a natural substance found in plants that improves the tensile and compressive strength of the cell wall (Klemm et al. 2005; Moon et al. 2011). It is believed that it helps terrestrial plants evolve by making them more resistant to the weight of the Earth's atmosphere. Water can more easily travel up the xylem tissues of a plant thanks to the lignin's waterproofing qualities. Lignin's carbolic composition gives it powerful antifungal properties, and it is often rapidly deposited in response to fungi attack or other injury, shielding the plant from potentially fatal infections.

Cellulose is a linear-chain polymer with a greater number of hydroxyl groups in the thermodynamically preferred C4 and C1 conformation (Klemm et al. 2005). It is a carbohydrate polymer composed of repeating -D-glucopyranose molecules covalently linked through acetal functions between the equatorial OH group of C4 and the C1 carbon atom (Fig. 2). With each consecutive glucose residue rotated over an angle of 180 degrees about the molecular axis, the anhydroglucose units adopt a chair configuration (Eichhorn et al. 2001). Cellulose's strong axial stiffness and linear structure come from the intrachain hydrogen bonding between the hydroxyl groups and oxygens of the neighboring ring molecules. This, together with the action of Van der Waals forces, promotes the parallel stacking of numerous cellulose chains, which results in elementary fibrils that eventually aggregate into bigger microfibrils (Moon et al. 2011).

Fig. 2 Cellulose, shown in simplified form, is a linear polymer composed of β -D-glucopyranose units that are covalently bonded by (C1–C4) C–O–C glycosidic bonds and characterized by intramolecular hydrogen bonding between units as well as intermolecular H-bonding between chains

Cellulose's numerous crystalline forms, or polymorphs, result from subtle shifts in the packing and molecular orientation of its chains as a result of the complicated intra- and intermolecular hydrogen-bonding (Fig. 2) arrangements. According to the literature (Nishiyama et al. 2003; Nishiyama et al. 2002; O'sullivan 1997), cellulose can be found in six distinct polymorphs: cellulose I, II, III, IIII, IVI, and IVII. Crystalline cellulose I is composed of two sub-polymorphs: cellulose I, which is found mostly in algal and bacterial cellulose, and cellulose I, which is found primarily in the cell wall of higher plants (Imai et al. 1999). The percentages of cellulose I and cellulose I within the cellulose are different depending on the source of the cellulose; cellulose I contains a cellulose chain in a triclinic unit cell, whereas cellulose I unit cells contain two chains with a monoclinic structure. Cellulose II, produced through regeneration or mercerization, has a monoclinic structure and an antiparallel configuration of chains grouped in a 3D hydrogen-bonded network, rendering it more thermodynamically stable than cellulose I. Cellulose's crystalline structure can be altered into cellulose III by treating it with amine-containing substances like ammonia or ethylenediamine; cellulose III has two sub-polymorphs, IIII and IIII, which are distinguished by the orientation of their cellulose chains (Wada et al. 2004). Cellulose III's crystalline structure changes into cellulose IV (Zeronian and Ryu 1987), which has two sub-polymorphs, IVI and IVII, when heated in water, glycerol, or formamide to temperatures up to 180 °C.

Plants benefit from the structural support, reinforcement, and other special features provided by cellulose, which has β -D-glucose as its monomer, hemicellulose, and lignin. By synthesizing nanocrystalline particles, this most abundant biopolymer can be put to use since its features, such as hydrophilicity, hydrophobicity, biodegradability, non-toxicity, good mechanical strength, etc., can be exploited. As a result, research into the synthesis of nanocrystalline cellulose, its inorganic functionalization, and applications in

Fig. 3 Schematic representation of the extraction of cellulose from different plant sources

the field of catalysis, with a focus on using renewable resources rather than petroleum-based sources, is now a hot topic. A linear homopolymer of glucose (Pacsu 1947), insoluble in water, cellulose with a β -1,4-C-O-C glycosidic linkage consists of crystalline and semi-crystalline or amorphous areas connected by inter- and intramolecular hydrogen bonding. Hydrogen bonds unite cellulose and hemicellulose in lignocellulosic biomass, and lignin is covalently bound to cellulose (Li et al. 2019) (Fig. 2). Xylans, a uronic acid, and arabinose are all examples of the class of complex carbohydrates known as hemicellulose. Lignin is a naturally occurring, irregular phenolic polymer made up of propyl phenol units such as coniferyl alcohol and sinapyl alcohol, as well as a small amount of p-coumaryl alcohol, which are cross-linked using carbon-carbon, ester, and ether links.

Cellulose can be extracted from a wide variety of plant and animal sources, including algae, fungi, bacteria, invertebrates, and amoeba (protozoa), and every plant and animal from the lowest to the highest trophic levels (Habibi et al. 2010). Cellulose can be made both from the ground up (from trees, cotton, and crop waste) and from the top down (through bacterial fermentation of glucose) (Trache et al. 2016) (Fig. 3).

Nomenclature and Types of Nanocellulose

In the 1950s, Ranby was the first to discover that colloidal suspensions of cellulose could be generated through the controlled sulfuric acid-catalyzed breakdown of cellulose fibers (Habibi et al. 2010). Nanocellulose refers to materials whose lateral dimensions fall between 5 nm and 20 nm and whose lengths range from a few tens of nanometers to several microns. Renewal, hydrophilicity, high mechanical qualities, biocompatibility, broad chemical-modification capacity, and the generation of various semicrystalline fiber morphologies were augmented with characteristics,

including transparency, electrical conductivity, strength, and lightweight (Klemm et al. 2011).

Cellulose nanocrystals (CNC), cellulose nanofibers (CNF), and bacterial nanocellulose are the three primary categories of nanocellulose (Fig. 4), each with its own unique origin, morphology, particle size/shape, crystallinity, etc. (BNC). Highly crystalline cellulose nanocrystals are obtained using a multistep chemical process that includes alkali treatment, bleaching, and acid hydrolysis to eliminate the amorphous portions of lignocellulosic material (Gupta and Shukla 2020). Cellulose nanofibers are produced by mechanically disintegrating cellulose or by subjecting it to controlled acid hydrolysis, both of which result in the breaking of the long, thick fibers. Bacterial nanocellulose, also known as high-purity cellulose, can be synthesized by microorganisms such as *Gluconacetobacter* bacterial strains such as *G. xylinus* in aqueous culture conditions in a matter of days to weeks (Abol-Fotouh et al. 2020).

Cellulose nanocrystals (CNCs) are rod-like cellulose crystals that are formed by the removal of amorphous parts of cellulose. Their widths and lengths range from 5 to 70 nanometers and 100 nanometers to several micrometers, respectively. Cellulose nanocrystals are also known as CNCs. The crystallinity of cellulose can range from 54 to 88% depending on its origin and isolation technique (Moon et al. 2011). For the purpose of CNC extraction, many different types of biomass were used, including wood, cotton, and agricultural wastes like wheat straws or rice, garlic, tomato, kenaf, coir, sugarcane bagasse, and algae (Thomas et al. 2018). Traditional chemical methods for isolating cellulose nanocrystals used pretreatments

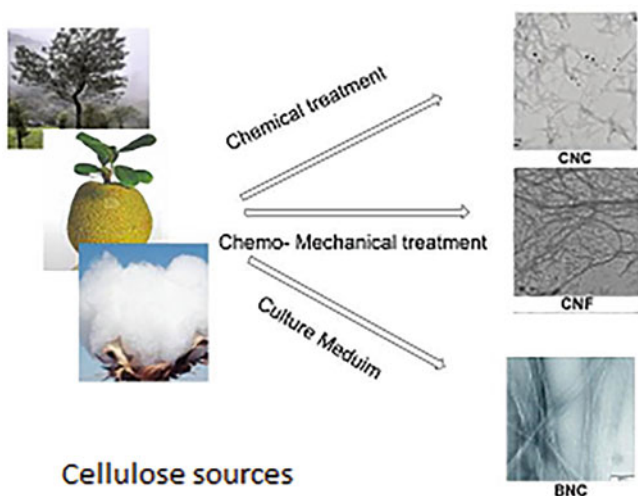

Fig. 4 The hierarchical structure of nanocellulose from the top down, together with the many forms of cellulose, depicted schematically. (Permission granted to reprint BNC and CNC photos from Fan Li et al. *Holzforschung* doi:10.1515/hf-2018-0251 and Nirmal N et al. *RSC Adv.* DOI: 10.1039/D0RA04649C)

with alkali and bleaching, followed by acid hydrolysis of lignocellulosic biomass. The pretreatment phase involves the elimination of non-cellulosic substances such as waxes, lignin, pectin, and hemicellulose. To get rid of lignin, several cellulose sources have been subjected to alkali treatment using a 2–18 wt% NaOH solution at 30–70 °C for 1–2 hours. In addition to the use of sodium chlorite in a variety of concentrations in an acidic medium, alkaline medium bleaching using hydrogen peroxide/acetic acid was also utilized. Typically, CNCs are prepared by acid hydrolysis with sulfuric acid (64 wt% at 45–60 °C for 30–120 minutes). A variety of acids, including nitric acid, hydrochloric acid, phosphoric acid, and a combination of sulfuric acid and hydrochloric acid, were employed. When isolating nanocrystals, other organic acids and a combination of organic and inorganic acids were also used (Lin et al. 2021). The use of cation exchange resins for solid acid hydrolysis acetic acid/phosphotungstic acid (H3PW12O40)/octanol catalyzed hydrolysis and phosphotungstic acid (H3PW12O40) catalyzed solvolysis (Liu et al. 2015; Torlopov et al. 2019). Considering the organic transformations, some researchers, including (Liu et al. 2015) have modified CNCs with precious metals including rhodium. For the model reaction studies of the cyclopropanation of styrene with ethyl diazoacetate, heterogeneous dirhodium(II) (Rh₂) catalysts based on environmentally friendly and sustainable cellulose nanocrystals (CNC) as support material were obtained by ligand exchange between carboxyl groups on the CNC surface and Rh₂(OOCF₃)₄. In a study (Liu et al. 2015), traditional chemical approaches were followed by ultrasonication, cryocrushing, magnetic stirring, etc. (Liu et al. 2015), and other chemo-mechanical techniques (Kaur et al. 2018; Kaur and Singh 2020). Researchers have reported and on different types of mechanical treatment approaches including ultrasound-assisted methods, including high-intensity ultrasonication (Pandi et al., 2021), combination enzymatic treatment/acid hydrolysis, high pressure homogenization, and cooking with active oxygen and solid alkali (CAOSA) (Wang et al., 2019), and others for the extraction of nanocellulose.

Properties and Surface Modification of CNCs

The adaptability of cellulose nanocrystals is attributed to their functionalization, which can be accomplished in a number of ways. Sulfates, phosphates, and acetates can all be made through straightforward functionalization utilizing sulfuric, phosphoric, and acetic acids. The ammonium persulfate synthesis of recycled medium density fiberboard fibers into carboxylated rod-like cellulose nanocrystals yielded nanoparticles with average dimensions of 170–365 nm and 13–17 nm, and an aspect ratio of 13–21 (Khanjanzadeh and Park 2021). The synthesis of the rod-like acetylated cellulose nanocrystals with diameter and length of 12–18 and 191–234 nm was achieved in a single step by hydrolyzing a mixture of sulfuric acid and acetic acid, which resulted in the esterification of surface hydroxyl groups and the simultaneous hydrolysis of amorphous regions of cellulose. High-crystallinity, rod-shaped, bifunctional CNCs were produced in a mixed acid system containing sulfuric and formic acids (Wang et al. 2021) Applications in composite manufacturing use

3-aminopropyltriethoxysilane (APTES)-functionalized CNC tools as reinforcing elements (Khanjanzadeh et al. 2018). As a result of a condensation reaction between hydroxyl and silanol groups, APTES was adsorbed onto CNC following hydrolysis in water via hydrogen bonds and to the surface of CNC via Si–OC interactions, all without disrupting the crystalline structure of either material. Functionalized cellulose nanocrystals (CNCs) were grafted onto 3-methacryloxypropyl-trimethoxysilane (-MPS) (fCNC). As reported by Yu et al. (2019), fCNC/acrylic PSA films were synthesized via in situ semi-continuous seeding emulsion polymerization by incorporating acrylic pressure-sensitive adhesive (PSA) with varying contents of CNC or fCNC, which improved the compatibility and dispersion of fCNC in the acrylic copolymer and allowed for its use in adhesives and coatings. Some most common functionalization approaches are depicted in Scheme 1.

The production of highly efficient functionalized CNCs by using p-toluenesulfonic acid-catalyzed deep eutectic solvent and a microwave-solvothermal technique resulted in a high yield of 87.6% and provided a high charge density, crystallinity, improved thermostability, and dispersibility (Lu et al. 2021). Improving energy efficiency in the mass production of FCNs allowed for the creation of FCNCs with reinforcing potential on gelatin for nanocomposite application; PDES could be reused, and PTSA and formic acid could be efficiently recovered through recrystallization and evaporation. Phosphoric acid hydrolysis, both heterogeneous and homogeneous, yielded ester derivatives bearing phosphoryl side groups via phosphorylation (Kokol et al. 2015). CNC-based nanosystems with a chitosan (CS) derivative (CNCs/FA-CS-FITC) were found to have high affinity toward folate receptor-positive cancer cells with improved cellular internalization (Pinto et al. 2021). This means that they can be used as nanocarriers with imaging properties for active targeted therapy. Cellulose

Scheme 1 A schematic representation of the numerous functionalization approaches that have been employed in order to manipulate the surface characteristics of cellulose nanocrystals

nanocrystals (CNCs) can have their hydrophilic groups converted to alkyl groups through a nucleophilic substitution process with an alkyl bromide. This change improved dispersion in a nonpolar environment and increased hydrophobicity, both of which have uses in food packaging, and strengthened the PLA's thermal stability, mechanical, and gas barrier qualities (Lee et al. 2020). Esterification of cellulose nanofilms with salicylic acid and p-aminobenzoic acid yielded UV-shielding materials with UVB-shielding characteristics of 99.7% and an ordered cholesteric organization displaying birefringence following evaporation-induced self-assembly (Ling et al. 2020). CNC was dialdehyde and dicarboxylated functionalized at the C-2 and C-3 locations of the glucose using a selective chemical oxidation procedure (Chen et al. 2016). The surface of the sulfated CNC is modified in aqueous media by acrylonitrile, which is then followed by the hydrolysis of grafted nitrile groups. These groups are able to undergo additional directional alterations and can take part in a wide variety of processes (Torlopov et al. 2019).

Inorganic Functionalization of CNCs and Catalytic Applications

Thermal stability, regulated miscibility, and low volatility are just a few of the physical and chemical characteristics of heterogeneous catalysts that contribute to their ease of recovery and recycling. Better selectivity, high conversion, easier synthesis procedures, and low cost have all piqued the attention of researchers in heterogeneous catalysts. Nanocellulose allows for a versatile production platform for these catalysts. Because of their remarkable stability in water, CNCs are particularly suited for catalysis. Catalytic conversions of substrates soluble in solvents that result in a biphasic liquid–liquid system with water are considerably simplified as a result. Since the catalyst is no longer considered a solid support, recycling it requires far less work when using this method.

Because CNCs have hydroxyl groups and sulfonate half ester functions on their surfaces, they make good substrates for the direct deposition and attachment of metal nanoparticles. This is because metal nanoparticles are very small. To create NPs, metal salts are typically fused with a colloidal aqueous solution of CNCs. The material's reactivity can be reduced with the help of various chemical reductants. Silver (Lokanathan et al. 2014), gold (Chen et al. 2015), and platinum (Zhou et al. 2012) nanoparticles can be extracted from CNCs using sodium borohydride as a common reagent. It has been proven that dihydrogen and hydrazine hydrate work effectively. It is fascinating that CNCs can transform metal salts into NPs. The CNC's surface primary hydroxyl functionalities acted as a reducing agent for H₂PtCl₆ in a mixture of water and supercritical CO₂ (100 °C, 100 pressures), resulting in the formation of Pt NPs with diameters ranging from 5 to 30 nm during a procedure in which ultrasmall Ag NPs (1.3–0.3 nm) were created in situ from the oxidation of bulk Ag wire.

Given that water being the most common solvent and the best solvent for suspending CNCs, functionalization techniques based on aqueous solutions have proven to be the most popular. Many approaches are being taken to the study of

functionalization. Reports of CNC functionalization in an organic media have also been made (Lam et al. 2012). It has been suggested that mechanically forcing the composite mixture (which typically takes place in the solid phase) can activate or maintain chemical reactions that functionalize the surface of CNCs. The integration of metal nanoparticles (NPs) is made possible by dry milling CNCs in the presence of ascorbic acid, which dissolves the Ag and Au salts on the surface of the CNCs in the solid phase. NPs with diameters of 6–35 nm and 18–24 nm, respectively, create strong hydrogen bonds with the surface hydroxyl groups (Eisa et al. 2018).

A heterogeneous catalyst made of nanocellulose and hydroxyapatite may catalyze the cyclocondensation reaction between semicarbazide and an aromatic aldehyde at room temperature. Pseudo wet impregnation technique was used in the manufacture of this catalyst. The reaction conditions generated by the NCC/HAp composite catalyst are both cost-effective and low-impact because of the catalyst's recyclable nature (Moodley et al. 2020).

Acetylation with anhydrous acetate yielded the functionalized (acetylated) nanocellulose with an increase in the number of active groups, surface area, and catalytic efficiency. This was achieved through the generation of the nanocellulose-utilizing acetylation. This procedure was performed so that nanocellulose might be created. Acetylated nanocellulose was impregnated with 30-nm-sized nanomagnetite Fe_3O_4 to produce a robust base. Using the produced nanocellulose Fe_3O_4 nanocomposites as a catalyst for the oleic acid to methyl ester synthesis resulted in a conversion yield of 89.21% and a low activation energy of 16.56 kJ/mol. Vegetable oil and other oils rich in fatty acids can be converted into biodiesel with the help of this catalyst (Helmiyati and Anggraini 2019).

2-Aminopyrimidine nanocellulose-supported palladium nanoparticles (CNC AMPDPd) were synthesized as an efficient and reusable heterogeneous bio supported nanocatalyst for the production of coumarin derivatives, a class of antioxidants with a long history of use (Miroosanloo et al. 2018). To obtain the CNCAMPDPd nanocatalyst, nanocellulose crystals were first tosylated (CNC-Tos), then reacted with 2'-amino pyrimidine (AMPD), and finally PdCl_2 solution was added. This process is useful in the production of coumarins, which have unique applications in the pharmacological, pharmaceutical, agricultural, and perfume industries.

In order to achieve covalent enzyme immobilization, dopamine was utilized as a nanocarrier in conjunction with magnetite nanoparticles ($\text{DA/Fe}_3\text{O}_4\text{NPs@CNCs}$). Nanobiocatalysts that combine oxygen/amine functionalities with a high magnetization value and a high specific surface area have been created to increase biomass conversion yield by 20–76% (Ariaenejad et al. 2021). The dopamine-induced polyethylene glycol functionalization of cellulose nanocrystals enhanced their mechanical, barrier, and poly(poly (L-lactic acid) crystallization properties (PLLA). Balanced strength, 168% improvement in ductility, and a 66.4% reduction in the oxygen permeability coefficient were all achieved when CNCs were functionalized with PEG with a lower molecular weight, which was established previously by various studies (Li et al. 2019).

Nanocrystalline cellulose sulfuric acid (s-NCC), a bio-based solid acid catalyst, was synthesized by reacting rod-shaped nanocrystalline cellulose with chlorosulfonic acid. In order to synthesize polyhydroxy pyrimidine-fused heterocycles (PPFHs), this catalyst has been utilized in a pseudo-four-component condensation process of barbituric acid, carbohydrates, and (hetero)aromatic amines in refluxing ethanol (Nikoofar et al. 2018).

Silver NP catalysts were stabilized by using nanocellulose as a support/carrier in combination with hexadecyl-trimethylammonium bromide (CTAB) surfactant. In comparison to the control Ag NPs and CNC/Ag samples, the CNC/CTAB/Ag nanohybrid composite, in which the Ag NPs are immobilized on CTAB-adsorbed CNC, was found to be more effective in converting 4-nitrophenol to 4-aminophenol. This points to the possibility of its catalytic use in wastewater treatment (An et al. 2017).

A one-pot solvothermal approach was utilized in order to create magnetic hollow CuFe_2O_4 nanoparticles (H- CuFe_2O_4 NPs) in situ on the surface of CNC. These nanoparticles had consistent sizes and were hollow. As compared to CNC-based ferrite catalysts, H- CuFe_2O_4 /CNC has demonstrated stronger catalytic activity in the reduction of 4-nitrophenol in aqueous solution, with a higher rate constant of 3.24 $\text{s}^{-1}\text{g}^{-1}$ (0.50 $\text{s}^{-1}\text{g}^{-1}$). With their one-of-a-kind hollow mesostructure and CNC introduction, H- CuFe_2O_4 NPs show promise as a catalyst thanks to their high conversion efficiency (even after 10 cycles), low environmental effect, and good magnetic separability (Zhang et al. 2018).

Composites of manganese dioxide (MnFe_2O_4) and cellulose nanocrystals (MnFe_2O_4 /CNC) were developed, and they exhibited desirable qualities such as a high specific surface area, a minuscule particle size, and a narrow band gap. These properties might be used in a variety of applications. More than 60% quicker breakdown of methylene blue (MB) pollutants was catalyzed compared to MnFe_2O_4 . The high magnetic properties and robust catalytic activity of MnFe_2O_4 /CNC composites during recycling may make them beneficial in the clean-up of polluted areas (Zhan et al. 2018). A zerovalent iron (ZVI) nanocatalyst supported on bamboo pulp cellulose nanocrystals (CNCs) was able to degrade methylene blue in a single step. A component of next-generation nanomachines for sensing, imaging, and drug delivery, it has been shown to be active in the hydrogenation of 4-nitrophenol into 4-aminophenol. CNC-supported ZVIs are a viable option for next-generation nanomachines utilized in sensing, imaging, and drug delivery since they can move independently in the presence of peroxide fuel and their speed and trajectory may be modified remotely (Dhar et al. 2015).

The C–N coupling reactions of open-chained and cyclic secondary amines and electron-deficient vinylic compounds can benefit from copper nanoparticles supported on nanocellulose that have an average size of 7 nm, and this size range was achieved through a simple chemical reduction process. There was a wide range of yields, from 82% to 95%, and the heterogeneous catalysts could be recycled up to six times without losing much of their catalytic activity (Goswami and Das 2018). Producing and using copper nanoparticle catalysts based on extremely crystalline nanocellulose allowed for the regioselective synthesis of 1,4-disubstituted 1,2,3-

triazole from the 1,3-dipolar cycloaddition of various azides and alkynes. The returns were anywhere from 68.0% to 99.0%. Through five iterations, its catalytic efficiency remained at roughly 90%. Several researchers (Chetia et al. 2017) came to this conclusion.

Adsorption of iron oxide nanoparticles can be accomplished using microcrystalline cellulose that has been functionalized with chlorosulfonic acid and cellulose using the co-precipitation technique developed by Massart. Magnetite-decorated sulfate cellulose nanoparticles (MDSCNs) are a biocompatible magnetic composite with high adsorption efficiencies (up to 90%) in water filtration (De Nino et al. 2020). Controlled and selective room temperature conversions of sulfides to sulfoxides and primary alcohols to aldehydes were achieved using copper nanoparticles immobilized on nanocellulose. High yields of sulfoxides were produced from aromatic, aliphatic, and heterocyclic sulfides, while no over-oxidized sulfones were formed during the oxidation of alcohols to aldehydes (Dutta et al. 2019). By reacting 1,8-diaminonaphthalene with various aldehydes at room temperature in the absence of solvents, a green, bio-based, eco-friendly, and recyclable catalyst, $\text{Fe}_3\text{O}_4@\text{NCs}/\text{BF}0.2$ (BF is BF_3OET_2), was used to synthesize 2,3-dihydro-1H-perimidine derivatives. The reaction proceeded quickly, yielded high-purity products, and had minimal environmental impact (Mirjalili and Imani 2019). Heterogeneous dirhodium(II) catalysts based on cellulose nanocrystals (CNC-Rh_2) were produced through ligand interaction between carboxyl groups on the CNC surface and $\text{Rh}_2(\text{OOCF}_3)_4$. Immobilization of CNC-Rh_2 catalysts via covalent bonding, in combination with the separation of binding positions and active sites of CNC-Rh_2 , provides a high stability against leaching and permits the recovery and reuse of the catalyst during the cyclopropanation reaction, where it was found to perform well in a model reaction (Liu et al. 2015).

Catalytic Transformation of Organic Compounds for Environmental Purposes

The unique properties of nanocellulose, such as its bioavailability and ability to dissolve in water, have been the subject of a great deal of research and development over the past few years. Recent studies have also shed light on how these state-of-the-art materials perform as catalysts for a wide variety of reactions, such as reduction, oxidation, coupling, and electrocatalytic reactions. These complex nanocomposites are built for a wide variety of uses, one of which is safeguarding the natural world. It has been shown that sulfonates, carboxylates, and hydroxyls frequently serve as binding sites for metal catalysts. The nanocelluloses are considered a support platform upon which the metal catalyst can be immobilized.

Research into the use of nanometer-sized cellulose materials functionalized with metallic systems in catalytic transformations of organic compounds is a hot topic in the field of sustainable and environmentally friendly products made from natural resources like cellulose. CNC-based materials have been used in a variety of cutting-edge applications, including as adsorbents, catalysts, photocatalysts, flocculants, and

membranes for environmental remediation, in addition to more traditional uses like reinforcing plastics and papers.

Reduction Reactions

In an aqueous solution, hexachloroplatinic acid was reduced by cellulose nanocrystals, resulting in platinum nanoparticles with a mean diameter of 2 nm. Reduction reaction in a carbon-black support (Vulcan XC-72R), followed by removal of the cellulosic material by heating in air, led to the formation of carbon-black-supported Pt nanoparticles that were highly active toward electrocatalysis of the oxygen reduction reaction (Johnson et al. 2011).

Over a new Pd catalyst that has been chemically bonded to the surfaces of cellulose nanocrystals, Ullmann reactions have been carried out (CNC-BIA-Pd). The catalyst's TON (490) and TOF (1960) values were exceptional, and they displayed high levels of selectivity and activity in a brief reaction time. It was determined that the nanocatalyst was sustainable as a green catalyst because it could be reused for at least eight cycles. The new catalyst was synthesized using 2-(1H-Benzo[d]imidazol-2-yl) aniline (BIA), tosylated cellulose nanocrystals (CNC-TOS), and PdCl₂. When compared to commercial palladium catalysts, the CNC-BIA-Pd catalyst showed superior catalytic efficiency for the Ullmann C–O reaction (Seyednejhad et al. 2019).

In order to reduce 4-nitrophenol, a simple and easy synthesis method was utilized. This method was based on the solid-state production of silver and gold nanoparticles supported on CNC. These nanoparticles have been referred to as Ag@CNC and Au@CNC. This method was used as a sustainable heterogeneous catalyst. Because of its nanoscale nature and its amenability to functionalization via its abundant surface hydroxyl and sulfate groups, CNC is an excellent support. These hybrid CNCs, which can function as heterogeneous catalysts, were synthesized by milling freeze-dried CNC in ambient conditions with the appropriate precursor salt and a simple organic-reducing agent, ascorbic acid. Standalone films of Ag@CNC and Au@CNC were used as a solid catalyst for the reduction of 4-nitrophenol (4-NP) (Eisa et al. 2018).

Reduction of 4-nitrophenol to 4-aminophenol has been reported using a wide variety of metal-decorated CNC catalysts. These include a CNC/CTAB/Ag nanohybrid composite, H-CuFe₂O₄ Nps supported in the presence of CNC, CNC-supported zerovalent iron nanoparticles (ZVIs), etc. (Scheme 2). Reduction of 4-nitrophenol was accomplished with NPs made of Au, Ag, Pd, Au–Pd, Pt, Cu, Ni, and CuO that were supported on CNCs or CNFs. Compared to metal NPs supported by mesoporous silica or other polymers like poly(methyl methacrylate), metal NPs supported by CNC are often more efficient and offer superior TOFs (PMMA). This is because CNCs have the ability to suspend and facilitate diffusion, unlike porous supports, and because of their intrinsically small nanodimensions, CNCs are able to stabilize extremely small metal NPs (5–10 nm in width). Tam and coworkers published the highest TOF for agricultural NPs among Au, Pd, and Cu NPs.

Scheme 2 Catalytic reduction of 4-nitrophenol to 4-aminophenol over various CNC-functionalized catalysts: (a) CNC/CTAB/Ag nanohybrid composite, (b) $\text{H-CuFe}_2\text{O}_4$ Nps supported in the presence of CNC, and (c) $\text{CNC-supported ZVIs}$

Higher TOF values were observed for Pt NPs around 2 nm (2 nm) compared to Pt NPs around 21 nm (21 nm), demonstrating that NP size has an impact on the TOF due to the higher specific surface area and defect content of the smaller NPs (Xiong et al. 2011).

For the catalytic decomposition of methylene blue, a magnetic composite of MnFe_2O_4 and cellulose nanocrystal ($\text{MnFe}_2\text{O}_4/\text{CNC}$) was synthesized. CNC/inorganic nanocatalyst demonstrated enhanced catalytic activity for MB decomposition in H_2O_2 solution compared to that of pure MnFe_2O_4 . In addition, $\text{MnFe}_2\text{O}_4/\text{CNC}$ showed excellent recovery after incorporating a magnet into the reaction system; this bodes well for its application in wastewater treatment. Similarly, zero-valent iron nanoparticles (CNC/ZVI) supported by a CNC have found use in a wide range of settings. Decomposing MB is one application of CNC/ZVI catalyst in wastewater treatment (Dhar et al. 2015). Through the use of UV-visible absorbance analysis, the decomposition was shown to be quantitative. The GC-MS-suggested hypothesized decomposition products are shown in Scheme 3.

It is important to reduce olefins, carbonyls, alcohols, and arenes in academic as well as industrial laboratories in order to increase the atom economy by moving away from stoichiometric quantities of reductant and to find “greener” reaction conditions (according to the 12 principles of green chemistry). In order to do this,

Scheme 3 A general hypothesized decomposition pathways of methylene blue over CNC-supported ZVI nanocatalysts

it is necessary to move away from stoichiometric quantities of reductant (Elsevier and de Vries 2007). Employing a metal catalyst and hydrogen gas as a reductant offers a solution to address these challenges and allows recyclability over many cycles of the reaction and, in some situations, greater enantioselectivity with the possible aid of CNC. Pd NPs supported onto CNCs were found to be very effective for the hydrogenation of phenols under simple conditions (4 bar H₂, room temperature, and two hours), with up to 90% yield in 24 hours (Cirtiu et al. 2011). The necessary efficiency of CNCs' support could be determined by comparing the collected data to those of other supported Pd NP catalysts, such as Pd NPs/Al₂O₃ or carbonaceous supports. Comparing the two showed that high yields could be obtained with a Pd loading of only 50%. As platinum is a precious metal, this is crucial information. Two hours of enantioselective reduction of prochiral aromatic ketones in water at 4 bar H₂ pressure was reported in subsequent studies (Kaushik et al. 2015a). Cryo-transmission electron microscopy and tomography revealed that the CNCs were a malicious support that acted as chiral inducers, creating a local chiral environment around the active catalytic centers that allowed for enantiomeric excess (ee) yields of up to 65%. Although this result for enantioselectivity was lower than that achieved with grafted chiral inducers, it was the highest ee ever achieved when using a biomass-based support as the sole chiral source (Yasukawa et al. 2015). For the reduction of aromatic aldehydes, alkenes, and alkynes, CNC-supported Ag NPs have been shown to be effective alongside Pd NP-based catalysts, albeit under more extreme conditions, such as under 40 bar of H₂ and at 100°C for 24 hours (Kaushik et al. 2016). Furthermore, Ru NPs were used for the extremely unfavorable hydrogenation of arenes with H₂ under mild circumstances (4 bar of H₂, ambient temperature, and 24 hours) to achieve full conversion into the saturated ring product (Kaushik et al. 2015b). Styrene and acetophenone were also investigated under the same conditions, with yields toward the fully reduced ethylcyclohexane product being 96% and 76%, respectively, expanding the applicability of the reduction reactions of metals supported on CNC supports. Interestingly, 2-acetylfuran, a heterocyclic aromatic compound, yielded a superb 90% in tests.

Oxidation Reactions

Oxidation processes are fundamental to the functioning of the entire natural world and are necessary for the production of organic compounds. Oxidation reactions are commonly used in the petrochemical industry. Molecular oxygen, hydrogen peroxide, osmium tetroxide, and other oxidizers are used. By eliminating the excess gas produced during a reaction, using traceless gaseous reagents instead of chemicals allows for the creation of greener processes by reducing the amount of waste generated during the purification process. The synthesis of organic compounds relies heavily on oxidation processes, which add new functional groups to molecules or modify existing ones. Metal stoichiometric oxidants are widely used in processes, but they go against the 12 principles of green chemistry because they create massive amounts of waste (Védrine 2019). In a similar fashion, many conventional techniques for oxidizing alcohols and sulfoxides with toxic and environmentally harmful stoichiometric oxidants like hypochlorite, permanganates, chromium oxides, and others are already available (R O C Norman and Coxon 1993). Catalysts are absolutely vital for activating these oxidants, but non-waste-producing oxidants like air, O₂, or H₂O₂ provide support for environmentally acceptable and moderately cheap systems (Noyori et al. 2003). Heterogeneously catalyzing oxidation processes can be done with any number of different types of metals and metal oxides, including those of common metals, noble metals, and mixed metals. It is impossible to overstate the significance of these supported metal catalyst-catalyzed reactions. The fact that these are heterogeneous catalysts for oxidation processes does not change the fact that they are cumbersome and have a weak support system. As a biodegradable, nontoxic, renewable, and compact support for disseminating metal-based oxidation catalysts, CNC presents significant opportunities.

For instance, CuNP/CNC catalytic material was studied as a heterogeneous catalyst for the oxidation of sulfides under mild reaction conditions, with good yields and in a controlled amount of time. There were CuNPs-immobilized on nanocellulose. Sulfides are versatile substances with significant pharmacological activity that can be found in nature (Paonessa et al. 2018). There is little difficulty involved in making them. Using the nitroxyl radical TEMPO (2,2,6,6-tetramethyl-1-piperidinyloxy), the CuNP/CNC catalyst facilitated the oxidation of a range of alcohols (Scheme 4). The high potential of copper is likely responsible for the high yield (82–95%) achieved by the

Scheme 4 On op, CuNP/CNC oxidizes sulfides in ethanol medium, while on the bottom, CuNP/CNC and TEMPO-mixed composite system oxidize a variety of alcohols – both R1 and R2 can be aryl or alkyl systems

heterogeneous catalyst, which can be easily recovered from the reaction mixture and reused multiple times with little to no loss of activity. Catalyst was recovered by filtration, washed with water and acetone, and then reused in subsequent runs with identical conditions and a new supply of substrates.

Grafting copper-tetrasulfonate phthalocyanine onto cellulose nanocrystals made them a high-yield, heterogeneous, and selective catalyst for the aerobic oxidation of alcohols and alkyl arenes to the corresponding aldehydes and ketones in *o*-xylene at room temperature with good yields and recyclability in an aqueous green solvent. Both the cationic CNC and the anionic sulfonate Cu-PC make extensive electrostatic contact with one another and form strong H-bonds within the catalytic system. To our knowledge, no Cu was lost during the catalytic reaction, and the system was recyclable up to seven times (Chauhan and Yan 2015). For the aerobic oxidation of primary and secondary benzylic alcohols to aldehydes and ketones at room temperature, it was found that cobalt(II) complexed with functionalized nanocellulose crystals made of ethylenediamine was a highly efficient heterogeneous catalyst. This heterogeneous catalyst was stable enough to be recycled more than five times. It was possible to achieve good catalytic activity with a low loading of Co (II) (1.04 wt%) because of the way cobalt was distributed on the high surface area nanocelluloses (Shaabani et al. 2014).

Coupling Reactions

C–C- coupling reactions have been a mainstay in conventional pharmaceutical procedures for a very long time. These reactions are used to synthesize active pharmaceutical ingredients (APIs) and drug molecules. As a consequence of these and other early successes with Pd-catalyzed cross-coupling reactions, Suzuki, Negishi, and Heck were awarded the 2010 Nobel Prize in Chemistry. From the early works of Tsuji and the formation of allylmalonate via an allylpalladium analog (Tsuji et al. 1965) to the studies of Heck (1968a, b) and Mizoroki (1971) demonstrating carbon–carbon bond formation with palladium catalysts in the late 1960s, these reactions have a long and illustrious history.

Nanocellulose is useful for binding not only nanoparticles but also metal ions. This principle is illustrated by the synthesis of a heterogeneous nanocellulose–palladium nanoparticle catalyst for Suzuki cross-coupling reactions in water. Chemically modifying cellulose with coupling agents enabled an interface to create a chemical bridge between the reinforcement and matrix, which can be used for chelating or adsorbing heavy metal ions. Dehydrated cellulose with surface hydroxyl groups and amino groups that bind heavy metal anions improves the adsorption capacity, as does aminopropyltriethoxysilane (APS), a silane coupling agent bearing one amino group in one molecule that can be hydrolyzed to the silanol group. Cd(II), Cu(II), and Ni(II) were removed from polluted aqueous solutions using aminosilane (APS)-modified nanostructured microfibrillated cellulose (MFC) with experimental maximum adsorption capacities ranging from 2.72 to 4.20 mmol/g and an optimal pH value of 5 (Hokkanen et al. 2014). A variety of organic coupling

reactions, such as the Heck coupling, Ullmann coupling, Suzuki coupling, and A3 coupling (Scheme 3), have been successfully carried out over metal-stabilized nanocellulose nanocomposites. Numerous recycling experiments have been performed in these studies to effectively prove the advantage of CNCs as a support for the recovery of the catalytic species, and they have been used in a wide range of different coupling reactions involving Pd NPs. Examples of coupling reactions include the multicomponent coupling reaction of aldehyde, amine, and alkyne (A3). Using benzaldehyde, piperidine, and phenylacetylene as model substrates and 80 °C and 24 hours with 4.4 mol% catalyst loading, Huang et al. conducted the A3 coupling to high yield (Huang et al. 2013).

In organic transformations, multicomponent coupling reactions are given special consideration. High yields can be obtained after 24 hours of treatment at 80 °C with Au NPs supported on thiol-functionalized CNCs in a conventional aldehyde-amine-alkyne (A3) coupling. Benzaldehyde, piperidine, and phenylacetylene were used as model substrates, with a catalyst loading of 4.4 mol%. Although the maximum yield was achieved in sterile conditions, there are reports of lower yields when using solvents like water (87%), toluene (92%), and ethanol (56%).

The A3-coupling reaction was carried out by Huang et al. using AuNPs supported on thiol-functionalized CNCs catalysts (coupling of aldehyde-alkyne-amine). The system showed remarkable activity in water and without a solvent, as well as strong promiscuity toward a variety of reactants, when heated to 80 °C for 24 hours. One of the catalyst's best qualities was its high recycling rate (up to 11 times) (Huang et al. 2013).

Electrocatalysis

Shen et al. 2022 introduced a sustainable synthesis route that modified the carbon aerogel's (CA) intrinsic chemical nature and produced a hierarchically porous microstructure, making CA a promising new material platform for electrocatalysis. A thermally sacrificial template Cd metal with a low boiling point (767 °C) and TEMPO-mediated oxidized cellulose nanofibers (TOCNFs) was used to assemble a TOCNFs-Cd²⁺ hydrogel/aerogel, which upon pyrolysis at a moderate temperature was converted to ultralight N-doped carbon nanofiber aerogel (N-CNA-Cd). Due to their abundant interior micro- and mesoporous, rich defects, enormous BET-specific surface area (1782 m² g⁻¹), and interconnected fibrous network, N-CNA-Cd samples have shown electrocatalytic efficacy toward oxygen reduction reaction, a large electrochemical active surface area, and considerable stability under both alkaline and acidic conditions (Shen et al. 2022). Using electrostatic interaction and a specific Co–N interaction, a uniform coating of the cobalt–adenine coordination polymer (CoA) complex was achieved on a hydroxyl-rich and negatively charged CNC self-template. Due to CNC's role in facilitating the well-dispersed Co nanoparticles and the formation of the unique bimodal micro-/mesoporous structured carbon, the carbonized CoA@CNC exhibits appealing bifunctional electrocatalytic activity for both the oxygen reduction reaction (ORR) and the oxygen evolution reaction (OER).

The CoA@CNC-700 air cathode was used to create a rechargeable Zn–air battery with high-power density (187 mW cm^{-2}), specific capacity (782 mA h g^{-1}), and cycle life (50 h) (Shen et al. 2020). Immobilized powder catalyst nitrogen-doped molybdenum carbide nanobelts (N-Mo₂C NBs)(N-Mo₂C@NCs) exhibit good performance toward the hydrogen evolution reaction. Nanocellulose, which exhibits excellent dispersibility and multiple exposed catalytically active sites, was used in place of Nafion (HER). N-Mo₂C NBs, graphene nanosheets, and nanocellulose (N-Mo₂C/G@NCs) formed a conductive film that could be bent and reshaped while still maintaining its high performance in HER applications (Li et al. 2019).

The production of nanostructured silver has been shown to benefit from the use of reducing agents that are derived from nanocellulose crystals derived from cotton. As part of the procedure, cellulose nanocrystals were suspended in an aqueous solution of AgNO₃ and heated for two hours at 80 °C. Metallic silver was confirmed to have been produced via transmission electron microscopy, UV/Vis, and X-ray diffraction (TEM). The product suspension was used to develop nanocomposite films on a smooth surface. The films' textures changed depending on the ratio of cellulose. Analyzing the electrochemical and electrocatalytic activity of these films with cyclic voltammetry and rotating-disk electrode voltammetry revealed that the nanocomposite films were very efficient electrocatalysts for the reduction of oxygen in alkaline media (Johnson et al. 2010). Since silver's activity is nearly as high as platinum's while being substantially less expensive, it is a superior cathode material for alkaline fuel cells, which use the electrocatalytic oxygen reduction reaction.

Pt nanoparticles were synthesized using hexachloroplatinic acid and subsequently reduced using cellulose nanocrystals derived from cotton in an aqueous solution at mild temperatures. Pt/CNC catalytic systems were characterized by transmission electron microscopy (TEM), X-ray photoelectron spectroscopy (XPS), and thermogravimetric analyses (TGA). Physical and chemical analysis of nanoparticles 2 nm in size showed that they consisted of an oxidized surface layer over a Pt metal core. Producing carbon-black-supported Pt nanocatalyst was doable by carrying out the reaction on a carbon-black support (Vulcan XC-72R) and then burning off the cellulosic material in air. Since electrochemical measurement shows that Pt/C electrocatalysts are very active, especially for the oxygen reduction reaction, this strategy seems like it could be very useful in the production of Pt/C electrocatalysts (Johnson et al. 2011).

Other Types of Catalytic Transformation

The formation of tetra-sulfonated porphyrin, which was introduced in the subphase as an anionic competitor, strongly inhibited the binding of CNCs to the floating fullerene layer using Langmuir hybrid films that were based on the electrostatic interaction between cationic fulleropyrrolidines deposited at the air/water interface and anionic CNCs dispersed in the subphase. Sturdy hybrid films were assembled thanks to the interfacial interaction between fulleropyrrolidines and CNCs, and these films were then transferred to solid substrates. Anodic photocurrents at 0.4 V vs.

Ag/AgCl were generated by ITO-electrodes modified with five-layer hybrid films, and their intensity (230 nA/cm^2) was four times higher than that observed with the sole fullerene derivative (60 nA/cm^2). Using chronoamperometry, we observed the photo-electrochemical behavior of ITO electrodes coated with five layers of FP or FP/CNCs in a neutral aqueous environment. This behavior included alternating dark and light periods and a significant increase in the light-induced current increment.

Solid-state ^{19}F and ^{13}C NMR spectroscopy confirmed the formation of heterogeneous dirhodium(II) (Rh_2) catalysts using environmentally friendly and sustainable cellulose nanocrystals (CNC) as the support material. Surface carboxyl groups on CNC interact with $\text{Rh}_2(\text{OOCCH}_3)_4$ to form a ligand exchange complex. This CNC–dirhodium catalyst performed admirably in a model cyclopropanation reaction (Scheme 5), even at extremely low dirhodium(II) surface concentrations (0.2 mmol g^{-1}). CNC-covalent Rh_2 is immobilized through covalent bonding, ensuring a high level of stability against leaching and allowing for the recovery and reuse of the catalyst during the cyclopropanation reaction due to the specific locations of its binding positions and active sites (Liu et al. 2015).

Through an azide–alkyne cycloaddition that was catalyzed by copper (I), Thielemans and colleagues were able to graft an imidazolium salt onto the surface of CNCs. Following this, the feasibility of employing the modified CNCs in ion-exchange processes was investigated. The ion-exchange capacity of modified CNCs was determined by soaking them in a solution of lithium bis(trifluoromethanesulfonyl)imide for an entire night. By using a heterogeneous method to immobilize imidazolium salts, this study paves the way for the development of a variety of catalytic and ion-exchange systems.

Aerogels made from cellulose nanoparticles and membranes made from cellulose nanoparticles are just two examples of the many cellulose nanocomposites that have found successful use in environmental contexts. Zhu and colleagues made nanocellulose aerogels with varying amounts of metal-organic framework (MOF) particles. The CNCs provide structural support for the functional MOFs in a networked material that is both three-dimensionally flexible and lightweight. Changing the proportion of ingredients in the beginning allows for a wide variety of MOF loadings. The ability to incorporate three distinct MOFs into CNC-based aerogels showed not only the versatility of the processing technology and materials, but also

Scheme 5 A simplified model of the heterogeneous catalyst CNC-Rh_2 at work in a cyclopropanation reaction

Scheme 6 Schematic representation of the CNC/HAp-catalyzed synthesis of triazolidine-3-ones via the reaction of aromatic aldehydes and semicarbazide

that the MOFs maintained their crystallinity and functional properties during the incorporation process. The hybrid material was effective in removing Cr(VI) from water that had been contaminated with the heavy metal. When the composite system is in the aerogel form, its crystallinity, porosity, and accessibility are all maintained, making it an excellent adsorbent for research into the purification of water. Aerogels lacking metal-organic frameworks (MOF; controls) were unable to remove Cr after 24 hours (VI). Approximately 85% of Cr was absorbed by the aerogel containing 50% MOF after 24 hours (VI). Cr(VI)abilityability's ability to adsorb material was drastically reduced along with the decrease in MOF concentration. Aerogels with a lower MOF loading (33.3% and 20 wt% of MOF) are able to absorb 67% and 51% of the Cr(VI), respectively (Yuan et al. 2020; Zhu et al. 2016).

Nanocellulose (CNC)/hydroxyapatite (HAp) has been used as a catalyst in the reaction of aromatic aldehydes with semicarbazide, and Moodley and coworkers have achieved excellent yields in this synthesis (Scheme 6). All three types of electron-donating and -withdrawing substitutes (ortho, meta, and para) performed admirably under the reaction conditions and produced the expected products. The mechanism of this reaction is completely understood when the CNC catalyst is taken into account. In the first stage, the carbonyl group of the aldehyde is attacked by the acidic CNC/HAp-protic solvent mixture, which may produce a transient zwitterionic intermediate. Restarting the catalytic cycle requires the removal of water. There was no noticeable degradation of the catalyst after five reuses, indicating the system's stability under reaction conditions (Moodley et al. 2020).

Photocatalytic Transformation of Organics for Environmental Remediation

An increasing number of water pollution remediation projects are employing nanocomposites based on nanocellulose for the catalytic breakdown of organic contaminants. The two most common types of guest NPs used in catalytic applications are precious metals and photocatalysts like TiO₂ (Au, Ag, Pt, etc.). In order to keep nanoparticles from clumping together, catalytic supports like nanocellulose are frequently used. When used in mild reaction conditions, photocatalysis efficiently transforms solar energy into chemical energy for the elimination of pollutants (Shayegan et al. 2018; Anise et al. 2020). The S-doped carbon nanosheet (SCN)/ZnO composite photocatalyst synthesized using the freeze-dried cellulose

nanocrystals (CNCs) as the carbon precursor has a regular nanosheet-like morphology, integrated graphitic structures (ID/IG of 0.692), rich surface heteroatoms (14.62 at% for O, 1.93 at% for S), and increased surface reactive site with specific surface area of 45.55 m² g. In addition to its excellent photocatalytic performance for methylene blue (99%), the SCN/ZnO composite has potential for use in the removal of other organic pollutants from the environment, such as phenol (91%), formaldehyde (92%), acetone (79%), and methyl alcohol (84%). After four cycles, the composite remains stable and reliable. CNCs are able to function as carbon nanosheets because they self-organize into a 2D nanosheet structure during freeze drying due to electrostatic repulsion (Han et al. 2013; Zhang et al. 2021).

Eosin yellow (EY) is a carcinogenic dye that was successfully removed and photocatalytically degraded from aqueous solutions using a conductive conjugated polymer/semiconductor system, poly(pyrroleco-aniline)-coated TiO₂/nanocellulose composite (P(Py-coAn)-TiO₂/NCC) (Fig. 5a) (Anirudhan and Rejeena 2015). Pseudo-second-order kinetics and the Langmuir and Fritz–Schlunder isotherm models indicated that 91.7% of the dye was adsorbed within 90 minutes at a pH of 4.5, and a dose of 3.5 g/L was required for the complete adsorption of EY from aqueous solutions. Polypyrrole and polyaniline were coated onto TiO₂/NCC by chemical oxidation polymerization of pyrrole and aniline with FeCl₃, and TiO₂/NCC was prepared from NC and the precursor Ti(OiPr)₄ via chemical precipitation methods. The adsorption capacity of 3.39 10⁵ mol/g and the degradation of 92.3% of the dye in 90 min under sunlight (Fig. 5b) are indicative of the photocatalytic degradation of adsorbed dye.

In addition, a composite of Ag₃PO₄ and nanocellulose was synthesized with a photocatalytic degradation rate of methyl orange of 90% in DI and 70% in wastewater after the same amount of time under solar irradiation (Lebogang et al. 2019). Adsorption of methylene blue from model water using a CNC/ZnO nanocomposite prepared from sawdust followed the Langmuir isotherm model (Fig. 6) (Oyewo et al. 2020).

TiO₂ nanorods were grown in situ on cellulose nanocrystals, and then decorated with Au nanocrystals to serve as a functional template. To degrade RhB dyes via

Fig. 5 (a) SEM photographs of (a) cellulose, (b) NC, (c) TiO₂/NCC, and (d) P(Py-co-An)-TiO₂/NCC; (b) kinetic data for the photodegradation of EY onto P(Pyco-An)-TiO₂/NCC

photocatalysis in sunlight, a nanostructured hybrid of biological and inorganic NR photocatalyst decorated with Au NCs is employed (Nair et al. 2020). Surface-functionalized cellulose nanocrystals were used to achieve selective adsorption and separation of organic dye mixtures (methylene blue, with either methyl orange or rhodamine b or crystal violet) (Mohammed et al. 2021). In the adsorption experiment, both bare and polydopamine (PD) and melamine-formaldehyde (MF)-coated CNCs were used. Adsorption efficiency for MB on pure CNCs with anionic sulfate ester groups was 85.78%, while adsorption selectivity for MO was 100% on PD-CNCs and MF-CNCs with cationic amine groups. Pesticide contaminants in organic and aqueous media were removed using amine-functionalized cellulose nanocrystals (Swasy et al. 2020). For example, 100% degradation of malathion in organic systems was achieved by using a poly(ethylenimine) cellulose nanocrystal (CNC-PEI), and 95% and 78% degradation of deltamethrin and permethrin were achieved in aqueous systems, respectively (Fig. 7). Therefore, amine-modified cellulose nanocrystals can be a low-cost, high-efficiency material for cleaning up water tainted with pesticides.

C-doped graphitic carbon nitride/tungsten oxide (C-doped $g\text{-C}_3\text{N}_4/\text{WO}_3$) was synthesized by hydrothermal impregnation with cellulose nanocrystal, high-temperature calcination, and electrostatic self-assembly with WO_3 nanocuboids, resulting in a ternary Z-scheme (Zhao et al. 2021). The photocatalytic degradation of 75.0% of tetracycline was achieved in 60 minutes thanks to the high specific areas ($57.20 \text{ m}^2 \text{ g}^{-1}$), C-substitution, and formation of Z scheme heterojunction, all of which resulted in a narrower bandgap, enhanced visible-methyl light absorption and separation of charge carrier, faster interfacial charge transfer, good oxidation/reduction capacities, and the like. Photocatalytic activity was demonstrated in the removal of organic pollutants from wastewater using a nanocomposite film of carboxymethyl cellulose reinforced with cellulose nanocrystals in the presence of bismuth ferrite (BFO)/poly-o-phenylenediamine (PoPD). This included the removal of methyl orange by 94% at 20% wt CNC (Nazri et al. 2021).

Recent research has also concentrated on the reductive environmental remediation of pollutant dyes like methylene blue by using Pd and Fe NPs immobilized on

Fig. 7 (a) Degradation of malathion, (b) deltamethrin, and (c) permethrin with CNC-PEI. Untreated samples contain only pesticide solution and serve as controls at $t = 0$ h and $t = 24$ h. Malathion and deltamethrin were conducted at RT while permethrin was conducted at 35°C

CNCs. These NPs have been shown to be an effective catalyst toward this goal. Using CNC-supported metal NPs as a catalyst, NaBH 4 as a reducer, and UV-Vis monitoring, this model reaction has been investigated. The latter case demonstrated CNC-stabilized Fe Nps's possible utility in addressing water pollution.

Mesoporous Fe_2O_3 has been manufactured using sol-gel techniques and used as a catalyst in photocatalytic processes, with CNCs serving as a template. Pore sizes in mesoporous $-\text{Fe}_2\text{O}_3$ varied from 4 to 42 nm. For $-\text{Fe}_2\text{O}_3$, the crystalline size was around 57 nm, and the specific surface area was $47.26\text{ m}^2\text{ g}^{-1}$. Methylene blue was photodegraded with the help of an $-\text{Fe}_2\text{O}_3$ catalyst that was synthesized in the lab. The results demonstrated that the photocatalytic activity of $-\text{Fe}_2\text{O}_3$ on CNC templates was superior to that of the samples prepared without CNCs (Liang et al. 2015).

Conclusions and Future Perspectives

As the study of nanocellulose-supported catalysis progresses, it is becoming clear that there is the potential for the field to become a source of solutions to societal problems that are more easily accessible, reasonably priced, environmentally friendly, dynamic, selective, and harmless. Nanocellulose (NC) is rapidly gaining attention in the fields of nanocomposites and sustainable materials. NC has many applications outside of the medical industry, including biodegradable materials, reinforcing agents, packaging films, permeable membranes, and even biodegradable packaging. NC functionalized with organic and inorganic groups has proven useful in a wide variety of applications, including as a catalyst in chemical reactions. By mimicking the structure of a conventional heterogeneous catalyst, nanocellulose allows for the development of soluble and suspendable catalytic systems, typically for use in water. Even though prefunctionalization to provide anchoring groups has also been extensively discussed over the years, direct functionalization with metal nanoparticles is ideally suited to the surface chemistry of nanocellulose. It is argued that the resulting catalytic systems are powerful catalysts for a range of processes.

The Heck, Ullmann, Suzuki, and A3 couplings are examples of significant reactions that proceed with high yields. Other significant reactions include reduction

reactions that have been accomplished with catalysts such as Au, Ag, Pd, Au–Pd, Pt, Cu, Ni, and CuO NPs supported onto CNCs or composite catalysts such as CNC/CTAB/Ag nanohybrid composite, H-CuFe₂O₄ Nps supported in the presence of CNC or CNC-supported zero environmental remediation, electrocatalysis, oxidation reactions, photocatalytic transformation of organics, etc. The efficiency of nanocellulose-based catalysts relies on the ability of such support to retain very small metal NPs while promoting good mass diffusion through the catalyst. These advancements have allowed for high TOFs and even enantioselective induction. Therefore, many methods of inorganic functionalization of nanocellulose can be used in various types of catalysis. Electrocatalytic reactions, oxidation, reduction coupling, and other processes are all possible with these CNCs-based nanocatalytic systems. These reactions have applications in catalysis, particularly electro- and photocatalysis.

Emerging nanoparticles of a wide variety of other polysaccharides are expected to be taken into consideration as potential support for novel catalysts in the not too distant future. In particular, nanocrystalline chitin, chitosan, and starch nanoparticles (SNPs) provide access to the amiable nitrogen manifold and present an opportunity to supplement the chemistry of cellulose. The development of such nanocatalysts has been facilitated by recent examples. It is concluded that the utilization of nanocelluloses in catalytic applications has resulted in the development of novel, intriguing, and environmentally friendly catalytic systems. We hope that new uses will emerge as a result of these discoveries.

For catalytic purposes, smaller metal NPs are preferable, while larger NPs are required for SERS. The loading of NPs is also important for the practical application of nanocomposites. It is important to learn how much different NPs can weigh down a nanocellulose matrix. Nanocellulose's long-term viability could be jeopardized by the presence of inorganic components in the matrix. It is important for scientists to work on rejuvenating or extending the life span of nanocomposites to ensure their continued usefulness. Nanocellulose-based nanocomposites may be an option when looking for a low-cost, eco-friendly material to combat growing environmental concerns.

Aerogels, membranes, and other composite materials based on nanocellulose have been utilized in the treatment of wastewater and waste oil, respectively. The primary applications of such functionalized CNC materials included oil–water separation, catalytic degradation of organic contaminants, adsorption of heavy metal ions, and adsorption of colors. While the results of many scientific experiments have been encouraging, the difficulty of scaling up for industrial applications remains a major issue.

Aggregation or agglomeration of CNC is a common problem in any types of nanocomposite systems, making it difficult to achieve uniform dispersion and distribution of inorganic system in to CNC matrix. Incorporating inorganic system into CNC efficiently requires a unique chemical modification process. It is expected that advances in nanotechnology involving renewable nanomaterials like CNC will yield technologically advanced, non-polluting, and above all biodegradable catalytic materials.

Acknowledgments We thank the University Grants Commission, Government of India, for the financial support of the UGC Major Research Project (No. F. No. 42-300/2013(SR)). Dr. Bejoy expresses gratitude to the Department of Science and Technology for supporting the college's Fund for Improvement of S&T Infrastructure (FIST) program.

Abstract

There is an increasing interest in the field of nanocomposites and sustainable materials, namely, for catalytic and biomedical applications, and bacterial nanocellulose (BNC) is an interesting and renewable natural nano-biomaterial that could play a role in these areas. The exceptional crystallinity, mechanical strength, purity, porosity, moldability, water-holding capacity, biodegradability, and biological affinity of BNC are only a few of its remarkable physical features. These properties distinguish BNC as an excellent substrate/matrix for customizing with metals, metal oxides, or metal compounds/complexes, as opposed to plant-based nanocellulose. The low rate of catalyst leaching from the catalyst support and the simplicity of separating the catalyst from the reaction medium provide cellulose-supported catalysts a high recycling potential. These bio nanocomposites based on BNCs have many uses, one of which is in catalysis. These BNC-supported metal based catalysts have a wider range of applications, including, environmental purification, bioremediation, the treatment of wastewater, photocatalysis, electrocatalysis, various organic transformations including coupling processes, reduction and oxidation reactions, and a great deal more. Novel catalytic applications based on the insights on metal supported BNC systems are expected to emerge eventually.

Introduction

Microorganisms are essential for the naturally occurring production of a wide variety of biopolymers, including polysaccharides, polyesters, and polyamides. These biopolymers can take the form of viscous liquids or materials that are similar to plastic. Similar to their petroleum analogues, the physical properties of these materials change with both molecular weight (the degree of polymerization) and composition (the nature of the monomeric units). Biopolymers, also known as cellular polymers, are organic compounds synthesized by cells. The monomeric building blocks of these molecules establish covalent connections to form polymers. Microbial production of custom biopolymers with physico-chemical properties suitable for high-value medical application, including occlusion, suturing, covering, fixing, isolating, adhering, tissue engineering, cellular proliferation, contact inhibition, tissue guide, soft-tissue replacement vascular grafts, and breast implants, has enormous potentials and a completely benign pathway thanks to advances in genetic manipulation of microorganisms with cutting-edge biotechnological methods. Xanthan, alginate, cellulose, cyanophycin, poly(γ -glutamic acid), levan, hyaluronic acid, organic acids,

oligosaccharides, polysaccharides, and polyhydroxyalkanoates are only a few of the many important molecules in this large family.

Biopolymers can be broken down further into subcategories based on the monomers used and the overall structure of the biopolymer; for example, polynucleotides, polypeptides, and polysaccharides. Polynucleotides, such as deoxyribonucleic acid (DNA) and ribonucleic acid (RNA), are long polymers composed of 13 or more nucleotide monomers. Collagen, actin, and fibrin are just a few examples of the proteins and polypeptides that are made up of chains of amino acids. Starch, cellulose, glycogen, alginate, heparin, and a number of other substances are all examples of polysaccharides, which are linear or branched polymeric carbohydrates. Natural rubber (isoprene polymers), chitin (the second most abundant natural polysaccharide after cellulose), and gamma globulins (N-acetyl-hexosamine, D-mannose, D-galactose), a class of globulins, identifiable by their location after serum protein electrophoresis are also examples of biopolymers. Complex polyphenolic polymers like suberin and lignin, complex polymers of long-chain fatty acids like cutin and cutan, and the pigment melanin, responsible for the coloration of hair, eyes, skin, and other body parts.

Naturally produced molecules/materials from substantially hierarchical structure are promising possibilities for high-performance and functional advanced materials due to their renewability, non-toxicity, biocompatibility, biodegradability, flexibility, increased availability, cost-effectiveness, and eco-friendliness compared to non-biodegradable petroleum-based polymers. Along with these inherent properties, (bio) enabled nanocomposites based on biopolymers and materials from chemical sources can benefit greatly from the synergistic combination of biological and synthetic elements made possible by powerful interfacial interactions or surface modifications, leading to enhanced structural performance and the introduction of novel functions/applications. Consequently, these natural materials have several benefits in comparison to synthetic polymers, especially in the areas of society, the economy, and the environment. In addition, when compared to biopolymers, the use of polymeric materials derived from petroleum has a far more detrimental effect on the long-term viability of the ecosystem.

The term “BNC” was not used publicly for the first time until 1886, when Adrian Brown did so. Studies of the chemical processes of *Bacterium aceti* also revealed the presence of an acetic ferment, or “mother of vinegar,” which is well-known for its ability to create acetic acid. The resulting coating on the medium’s surface was not as permeable as that produced by *Bacterium acetiana* and had some tactile similarities to an animal membrane. As a consequence of testing this film with various chemical solutions, Brown was able to conclude that the “vinegar plant” indeed did exhibit all the properties of cellulose. Bacterial nano-cellulose (BNC), or microbial cellulose, can be manufactured from microbial cultures in the same way as other biopolymers can. The material is novel in its structure and characteristics, making it an intriguing pioneering biomaterial. Advantages over plant-derived cellulose include higher purity (free of lignin, hemicellulose, and pectin) (Reiniati et al. 2017), higher crystallinity, higher elasticity and con-formability, lower density, higher strength, and greater biodegradability and biodegradability than conventional synthetic fibers

(Bäckdahl et al. 2006). Biologically-fabricated nanocrystalline (BNC) cellulose is generated from well-defined carbon sources by biochemical pathways and the self-assembly of secreted cellulose fibrils in the culture medium. Unlike plant celluloses, which contain functional groups like sulfates, acetates, carbonyl, and carboxyl, BNC contains no such contaminants and is also free of other veg-polymers including lignin, hemicelluloses, and pectin. BNCs, which are synthesized from pure cellulose, have micrometer-scale lengths and average diameters of 20–100 nm, and their network architectures are highly stable. The bacterial nanocellulose was produced through communication between various Gram-negative bacteria, including *Rhizobium*, *Xanthococcus*, *Pseudomonas*, *Azotobacter*, *Aerobacter*, and *Alcaligenes* (Table 1). The improved water-holding capacity and hydrophilicity of BNC in contrast to cellulose obtained from plants have made it possible for enhanced and

wider applications of nanocellulose, particularly in the fields of biotechnology, medicine, pharmaceuticals, and the food industry.

In the manufacturing of more than 80% of all goods derived from sulfuric acid acetone, catalysis is used at some stage as a technique that is involved in the processing of the product. Therefore, there are three reasons why this physical process is so crucial: (a) It helps the world's largest economies succeed economically. (b) It makes possible the production of things necessary for the upkeep of modern society. Thirdly, it has made chemical production far more eco-friendly and sustainable as a whole. There are four main types of catalysts: (1) the homogeneous catalyst, (2) the heterogeneous (solid) catalyst, (3) the heterogenized homogeneous catalyst, and (4) the biocatalyst. When compared to homogeneous catalysts/heterogenized homogeneous catalyst, heterogeneous catalysts have various benefits in terms of sustainable technology. These include being easy to handle, store, recycle, and separate the catalyst and product. Vanadium oxides, Fe-Mo, Pt-Rh gauze, zeolites, clays, alumina, zirconia, etc. are all examples of commercial catalysts. Nanocelluloses, or cellulose-based nanomaterials, are currently the focus of much research. In particular, the use of nanocellulose as a catalyst support in various catalytic reactions has garnered a lot of attention over the past few decades. Bacterial nanocellulose is a suitable catalyst support because it has superior chemical, colloidal, optical, and mechanical properties compared to other nanocelluloses (CNC, CNF, and BNC). So, there has been a lot of time and effort put into studying and potentially using these sustainable heterogeneous catalysts, but they have not yet been put to use in a commercial setting.

In this chapter, we provide an overview of recent synthetic methods for the production of metal/BNC composites with high metal disparity and large surface areas, and therefore superior catalytic activities. These composites can be used in a variety of applications, including catalysis, chemical synthesis, and fuel cell applications. Synthetic methods that altered the morphological and chemical functionality of BNC in order to improve its physicochemical qualities as a substrate for more effective metal stabilization, which led to an increase in the catalytic activity of the material. After that, the existing organic transformations that can be accelerated by such BNC-based catalysts are shown. In this chapter, a prospective outlook on the topic is discussed, and anticipated future developments in research on BNC-based materials in (nano) catalysis are broken down in depth.

Synthetic Approaches Towards Bacterial Nanocelluloses (BNCs)

The chapter provides a brief overview of the many synthetic methods that have been applied to the production of bacterial cellulose. As a potential carbon source, agro-industrial waste from a variety of sources has been employed in cultivation. Production of BNC from agro-industrial by-products and cellulosic residues has been the subject of previous research. These materials have included konjacglucomannan (Hong and Qiu 2008), wheat straw (Hong et al. 2011), waste fiber sludge (Cavka et al. 2013), waste cotton textile (Hong et al. 2012), and sweet sorghum bagasse

(Wang et al. 2021). Using naphthalene crystals as its only carbon source, the *Xanthobacter* sp. strain *Starkeya* sp. strain N1 was able to produce cellulose nanofibrils (Marín et al. 2019). This process is more socially responsible because it recycles hazardous polycyclic aromatic hydrocarbons like naphthalene. The discovery of a nanocellulose network with a diameter of 33 nm paves the path for a valuable polymer with broad biotechnological applications.

Enzymatic hydrolysis of the oat husks pulp to furnish a solution of reducing sugars, principally glucose, followed by creation of a nutritional broth based on the enzymatic hydrolysate and biosynthesis of nanocellulose microfibrils by the symbiotic *Medusomyces gisevii* Sa-12 culture and purification of BNC employs an appropriate approach for the chemical transformation of the feedstock (Sakovich et al. 2017). Bacterial nanocellulose (BNC) was produced using *Gluconacetobacter xylinus* and waste colored cotton fabrics (Guo et al. 2016). Through static fermentation, the BNC-producing *Komagataeibacter medellinensis* ID13488 strain was able to extract BNC from sugars produced from grass biomass at yields of up to 6 g L⁻¹ (Jeremic et al. 2019). Purified, separated, and mechanically treated Kombucha membrane, produced by fermenting tea broth with a symbiotic culture of bacteria and yeasts, yields bacterial cellulose nanofibrils (Dima et al. 2017). Under static conditions, *Gluconacetobacter xylinus* used grape pomace extract (a wine industry byproduct) as a carbon source and maize steep liquor (a byproduct of corn wet milling) as a nitrogen source to create bacterial nanocellulose (BNC) (Cerrutti et al. 2016). Recently published works explain a comprehensive study on the influence of the BNC production parameters and its use in transition metal nanocomposites for the catalysis of cross-coupling reactions, and provide a detailed discussion on the influence of the single parameters, such as pH, glucose concentration, and day of incubation, for the optimization of BNC production. The treatment of grass biomass yields a sugar combination that can be used as a carbon source for BNC production, leading to the valorization of non-food renewable biomass. As of Thiruvengadam and Vitta (2017).

Carbon nanotubes were added to the synthetic media in a select number among these studies. Structure study performed after 2 weeks of incubation showed that bacterial cellulose fibrils had coiled around the carbon nanotubes (Yan et al. 2008). As a composite synthesis technique, in situ poly-3-hydroxybutyrate was used by Ruka et al. (2013) to alter the shape and crystallinity of bacterial cellulose (Ruka et al. 2013). Serafica et al. (2002) developed bacterial cellulose composites by feeding shake cultures with metals including aluminum and iron. It was observed that the concentration, spin speed, and particle size of a suspension all play a role in how easily the particles in that suspension can pass through a membrane (Serafica et al. 2002). Ex-situ synthesis can occur by either a physical interaction (such as OH-binding) or a chemical interaction (also possible). The matrix of bacterial cellulose is porous, thus it may physically absorb or let through liquids and small solid particles. With this synthesis technique, the polymer structure is kept relatively intact. The production of composites for applications in the biomedical and industrial sectors makes extensive use of nanocelluloses grown in static culture (Maneerung et al. 2008). In addition, a sizeable number of researchers have made

important contributions to the production of a large number of compounds that can be made from polymers, inorganic materials, metals, metal oxides, and bacterial cellulose. These compounds have been manufactured in a laboratory setting (Evans et al. 2003).

Synthesized polymer compounds are in two fundamental forms, in-situ and ex-situ, depending on the nature of the combination agents and the method to composite development, In-situ synthesis and ex-situ synthesis. The in-situ approach uses the addition of material during its synthesis, which then becomes part of the polymer. In the ex situ approach, the polymer matrix is impregnated with reinforcing elements to generate the composites (Saibuatong and Phisalaphong 2010). In addition, many researchers have worked to perfect and perfect new compounds made from polymers, inorganic materials, metals, metal oxides, and even bacterial cellulose for use in a wide range of fields.

Properties and Surface Modification of BNCs

The building blocks of cellulose are D-glucose monomers linked together by β -1, 4-C-O-C- glycosidic bonds (Ross et al. 1991). The most important characteristics of bacterial cellulose are its high levels of mechanical strength, purity, crystallinity, and water content. Bacterial cellulose also has a high degree of crystallinity (Klemm et al. 2005). Structure that is thin, extremely hydrophilic, and porous that is produced from bacterial cellulose microfibrils that are arranged in a nanofibrillar network in three dimensions. Because of its porous structure, nanobacterial cellulose is useful in many contexts, whether it is wet or dry.

Its resistance to enzymatic and chemical hydrolysis is due to the fact that bacterial cellulose is insoluble in water and other common organic solvents. Additionally, its supramolecular organization, which stabilizes the glucan chains via inter-chain and intra-chain hydrogen bonds, also contributes to its resistance. Because of its linear cellulose chains and strong cohesion between macromolecules, bacterial cellulose exhibits remarkable mechanical strength (Klemm et al. 2006). Young's modulus of bacterial cellulose fibers ranges from 78 GPa (Guhados et al. 2005) to 114 GPa (Raman spectroscopy) (Hsieh et al. 2008). There is no difference in terms of their mechanical properties between filaments of bacterial cellulose that vary in diameter (Guhados et al. 2005). When bacterial cellulose membranes are exposed to air, the Young's modulus increases to around 9.7 GPa, the stress and strain at break increases to over 240 MPa, and the strain at break increases to around 2.6%. Rheological investigations of bacterial nanocellulose fibers exhibit stress-softening behavior due to the destruction of physical cross-links and bending of fibers, followed by a rearrangement of the network due to the synthesis of new cross-links. The loss modulus also decreases after a specific stress level is attained. Bacterial cellulose can have a crystallinity level of around 80%; however, this varies greatly depending on factors like the composition of the medium and whether or not the product is formed in a static or agitated environment during cultivation (Jung et al. 2010; Trovatti et al. 2011).

Inorganic Functionalization of BNCs and Catalytic Applications

Numerous inorganic substances, including as metal oxides, metal sulfides, silica, or metal nanoparticles, have been integrated into BNC by taking advantage of its isotropic three-dimensional nanostructure in order to generate flexible heterogeneous catalysts. These catalysts can be used in a variety of different reactions. Synthetic methods can be used to incorporate these inorganic components into nanocomposites for the purpose of boosting their activity.

Reduction using an external reducing agent is most common approach is to use an external reducing agent to reduce a metal precursor into metal NP on the nanocellulose surface. For example, AgNPs have been synthesized on various types of nanocelluloses by reducing AgNO_3 with NaBH_4 (Ramaraju et al. 2015). Other methods, which have been utilized the most and have been reported in the scientific literature: (i) the mixing under conditions of simple agitation or ultrasound-assisted conditions; (ii) the absorption through solvothermal processes; and (iii) the in situ incorporation in the growth medium. The subsequent sections categorize and discuss the catalytic applications of these novel materials.

Immersing the bacterial nanoellulose in this metal salt solution allowed for the imbuing of metal nanoparticles, which led to the desired catalytic, energy storage, food packing, antibacterial, and piezoelectric activity features. Through a reduction process involving sodium borohydride or ascorbic acid, metal nanoparticles were incorporated into bacterial cellulose. The silver ions were found to be released immediately from the freeze-dried silver nanoparticle-impregnated BC produced with NaBH_4 : AgNO_3 at a molar ratio of 1:1 (silver nanoparticles impregnated on the surface) and gradually when the molar ratio was increased to 10:1 and 100: 1 (deeply impregnate) (deeply impregnate). The freeze-dried BC loaded with silver nanoparticles was effective against both Gram-negative *Escherichia coli* and Gram-positive *Staphylococcus aureus* (Maneerung et al. 2008).

In 2017, Chen et al. used the 2,2,6,6-tetramethylpiperidine-1-oxyl radical (TEMPO)- mediated oxidation reaction to take advantage of this capability in order to get a BNC with carboxyl groups on the glucose moieties (TOBNC), which have been subsequently used as a support for gold nanoparticles (Au-TOBNC). This was accomplished in order to obtain a BNC with carboxyl groups on the glucose moieties in Chen et al. (2017). Mild aqueous conditions were used to initiate the oxidation reaction, which was subsequently carried out on slurry of fibrillated BNC treated with TEMPO, NaBr, and NaClO. In the presence of sodium borohydride, TOBNC was mixed with a HAuCl_4 solution to create the Au-TOBNC catalyst. Particle size distribution is more uniform for AuNP-TOBNC than for unsupported AuNPs because the carboxyl groups, in their dissociation form, are able to immobilize the AuNP more tightly. The effect of pH on the number of AuNPs that might be loaded onto a particle has been studied. When the pH was adjusted to a range between 3.2 and 11.3, researchers saw a shift in the suspension's hue that corresponded with the observable increase in AuNPs concentration. There is a good chance that the dissociated or associate form of the carboxyl groups is to blame (Sen et al. 2013). Copper nanoparticles (CuNPs) loaded bacterial cellulose

membranes were fabricated by using an in situ chemical reduction method, which gave sustained release of copper ions. This may contribute to the long-term antibacterial activity and with controlled Cu concentration, and most importantly, the membranes were not cytotoxic to normal human dermal fibroblasts, which allowed them to be used as wound dressings (He et al. 2018). After being soaked in CuCl₂ solutions, BC/Cu membranes were reduced with NaBH₄, resulting in excellent long-term antibacterial activities against both Gram-positive and Gram-negative bacteria (*S. aureus* and *E. coli*). Antibacterial activity against *Staphylococcus aureus* and *Escherichia coli* was demonstrated by ZnO-deposited bacterial cellulose composites in the absence of a photocatalytic reaction, suggesting their potential use as a wound dressing and water disinfectant (Janpetch et al. 2016). An amidation reaction between carboxylated bacterial cellulose and dopamine was used to modify the bacterial cellulose that was isolated from *Gluconacetobacter xylinus* (MTCC7795). This reaction was then used to prepare BC-DOPA/rGO/Ag NPs, a composite film that demonstrates antimicrobial activity against Gram-positive (*Staphylococcus aureus* and *Lysinibacillus fusiformis*) and Gram-negative bacterial strains (Khamrai et al. 2019). By fusing dioxyphenyl amine (DOPA) onto bacterial cellulose, a green reduction of Ag⁺ and GO led to the fabrication of a composite transdermal patch containing AgNPs/ rGO. Accelerating wound healing, Ag NPs have been demonstrated to do so by stimulating the growth and migration of fibroblast cells (such as those found in NIH 3T3) and lung epithelial cells (such as those found in A549).

The excellent biocompatibility and bioactivity of hydroxyapatite-bacterial nanocellulose composite materials makes them suitable for use in medicine (Silva-Holguín and Reyes-López 2020). This is made possible by the antibacterial properties of silver nanoparticles. With a turbidimetry-determined 52.99% inhibition of *Pseudomonas aeruginosa* at a 5mM AgNPs concentration, HAp-AgNPs dust was found to have a potent antibacterial effect. As a result of the thinner peptidoglycan layer (20–80 nm) of Gram positive bacteria, AgNPs typically show greater antibacterial activity against Gram negative bacteria (10 nm thick cell wall). Therefore, HAp-AgNPs may be useful in a variety of medical settings. To enhance the colloidal stability of HA nanoparticles, an in situ BNC/hydroxyapatite/cellulose nanocrystal (BHC) composite was synthesized with the aid of CNCs (Niamsap et al. 2019). BHC composite had no cytotoxic potential, as evidenced by the fact that cell viability was 99.20.08% in the negative control and 83.43.6% in cells treated with BHC-0.5 wt% HA and HC (Hydroxyapatite/ cellulose nanocrystals).

The strength-to-weight ratio of BC sponges cross-linked with glucose and citric acid was 150% and 120% higher compared to that of unmodified BC sponge, and such modified BC sponges are non-cytotoxic and do not trigger an inflammatory response in macrophages. Highly porous 3D structures with multi-hierarchical organization were created using bacterial cellulose (Frone et al. 2010). In cases of retinal degeneration, a novel substrate was developed using bacterial cellulose (Gonçalves et al. 2015). Increasing cell-material interactions, RPE cells adhere to and grow on BC-modified surfaces. The hydrophilicity of BC's surface was reduced through acetylation and polysaccharide adsorption using chitosan or carboxymethyl cellulose, while amine or carboxymethyl groups were incorporated into BC via

protein adsorption. Acetylation of BC reduced swelling and the amount of endotoxins and decreased elastic modulus due to the moderately hydrophilic surface after acetylation, but these surface-modified BC substrates exhibited similar permeation coefficients with solutes, stress-strain behavior, and enhancement of adhesion and proliferation of RPE cells.

The bacteria *Gluconacetobacter xylinus* create the bacterial nanocellulose, and a precise and carefully developed multi-step procedure is used to fabricate the magnetic MBNC material (BNC). To sum it up, BNC pellicles are made out of frozen *G. xylinus* strain to meet the specific size and morphological needs of our experiments. Preparing a 2:1 molar ratio solution of iron (III) chloride hexahydrate ($\text{FeCl}_3 \cdot 6\text{H}_2\text{O}$) and iron (II) chloride tetrahydrate ($\text{FeCl}_2 \cdot 4\text{H}_2\text{O}$) in deoxygenated high purity water. After the reactants have been placed in the vessel, a BNC pellicle is added. For the purpose of precipitating the ferrous ions into the BNC mesh, this mixture is heated to 80°C in a silicon oil bath while being agitated, and then ammonium hydroxide (14% by weight) is dropped into the pot (Fig. 1). This final step allows for the formation of in situ magnetite nanoparticles (Fe_3O_4) inside the bacterial nanocellulose mesh in order to confer magnetic characteristics onto the BNC pellicle. The biocompatibility of the BNC-IONP (iron oxide nanoparticles) pellicle was determined using a toxicological experiment. To increase their biocompatibility, IONPs were coated with polyethylene glycol (PEG). The magnetic properties of the MBNC pellicle were confirmed by magnetic force microscope (MFM) measurements, which revealed the presence of magnetic domains with both strong

Fig. 1 Schematic representation of the fabrication of magnetically functionalized bacterial nanocellulose. Iron oxide nanoparticles (IONPs) are assembled and incorporated in situ within the BNC, yielding a MBNC. (Adopted from Arias et al. (2016). Copyright@ MyJove Corp; 2022)

and weak intensity magnetic field. The results of this work on Young's modulus are similarly consistent with those reported for a variety of blood arteries in other investigations (Arias et al. 2016).

In this study, we created novel BNC one-dimensional hybrid nanofibers by combining hydrated bacterial cellulose nanofibers with Cu-Pd NPs (Pd = 3.7; Cu = 4.0). To make palladium-copper nanoparticles, potassium borohydride was used to reduce metallic ions absorbed by the BCF during immersion in a solution of palladium chloride (PdCl₂) and copper chloride (CuCl₂) in water. Pd-Cu nanoparticles precipitated uniformly on the BCF surface, as shown by physicochemical characterization of mixed metal/BNC nanocomposites (Sun et al. 2010a).

Very recently, the research group of Kamal et al. proposed several different examples in which BNC was used as a high surface area support for transition metal nanoparticles that were stabilized with carboxymethyl cellulose (CMC), such as cobalt (CMC-Co-BNC) (Kamal et al. 2019a), copper (CMC-Cu-BNC) (Kamal et al. 2019) and nickel (CMC-Ni-BNC) (Kamal et al. 2019b). In these works, a mixture of metal chloride and CMC (1 wt%) solutions was combined, and then hydrazine hydrate and ascorbic acid were added in a slow, controlled fashion. The resultant solution was heated in a microwave, which resulted in the formation of carboxymethyl cellulose-metal nanoparticles (also known as CMC-M). Last but not least, the CMC-M-BNC dip-catalyst was made by spreading a CMC-M suspension on BNC sheets obtained from a *Gluconacetobacterxylinum* culture.

The comparatively low cost of manufacture of ZnO-NPs, antibacterial characteristics, chemical stability, reactive oxygen species (ROS), and photo-catalytic abilities are all factors that contribute to the great features that these nanoparticles exhibit. Zinc oxides were said to be widely employed in the paper, paint, and plastics sectors due to their generally equal absorption of ultraviolet (UV) and visible light (Wang et al. 2019). Excellent catalytic performance, high antibacterial activity, and improved electrical conductivity were observed in a composite of nanocellulose and zinc oxide NPs, and the NPs were also reported to improve the UV-barrier properties, thermal stability values, and antibacterial activities of biopolymer films (Farooq et al. 2020).

Catalytic Transformation of Organic Compounds for Environmental Purposes

Numerous attempts have been made in order to make use of the one-of-a-kind features that bacterial nanocellulose possesses, such as its bioavailability and aqueous solubility, which brings in some very interesting advantages towards the application of bacterial nanocellulose in catalysis. These additions have been brought about as a result of the numerous efforts that have been made. Recent research has also shown how these state-of-the-art compounds perform as catalysts for reactions like electrocatalysis, reduction, oxidation, and coupling. In this case, BNCs can serve as a platform or support material for the active metal catalyst, helping to keep it stable. The catalytic transformation of organic compounds is an area of active

research, and nanoscale cellulose materials functionalized with metallic systems are of particular interest. Renewable natural resources, such as microbial cellulose, can be used to create these goods. Conventional uses for CNC-based materials include reinforcement in the plastics and paper industries, but these materials have also been put to work in a wide range of cutting-edge applications for environmental remediation, including as adsorbents, catalysts, photocatalysts, flocculants, and membranes. Such applications are typical. Catalysts based on BNCs are highly active and selective for a wide range of organic transformations, while retaining a key advantage of heterogeneous catalysis – the ability to separate products with relative simplicity.

Reduction Reactions

In commercial settings, the reduction reaction is typically carried out in a blast furnace. A blast furnace is a specific kind of furnace that is utilized during the smelting process that is necessary for the production of iron. The method of making iron involves chemically reducing iron oxide to a liquid state. The zinc case of a dry cell serves as the anode, and the reduction of MnO_2 takes place at this site; this reaction has various applications in industry, including those involving batteries and cells.

The conversion of 4-nitrophenol to 4-aminophenol has seen extensive use of hybrid nano-composites comprised of metal nanoparticles and nanocellulose. Tests of this reaction have been performed on a variety of other NPs, including gold (Au), silver (Ag), platinum (Pt), and gold (Au-Pd) NPs. Metal NPs supported on nanocelluloses undergo a reduction reaction in the presence of NaBH_4 at room temperature, with the reaction being completed between 15 and 30 min and yielding excellent conversions of 95–100%. Metal NPs supported on nanocelluloses reduced 4-nitrophenol to 4-aminophenol at various turnover frequencies (TOFs). An Au-TOBNC catalyst was tested to see if it could reduce 4-nitrophenol (4-NP) using NaBH_4 . 4-NP was used as a model reaction. Support from TOBNC increases the rate at which 4-nitrophenol (2-NP) is converted to 4-aminophenol (6-AP) by about 20-fold compared to AuNP alone. Since the TOBNC increased the amount of reagent exposed to each nanofiber, it is likely that the Au reagent was more evenly distributed. After examining how different temperatures affected the reduction reaction, scientists settled on 65 °C as the sweet spot for maximizing the efficiency of both the substrate and the products. There has been no other work that has produced such a high level of catalytic efficiency for an analogous catalyst (Sen et al. 2013).

The nitro group in biphenyl-4-amine (4) and 4'-fluorobiphenyl-4-amine (5) was efficiently reduced using Pd/BNC in the corresponding process. Pd/BNC was typically added to the chemical in ethanol and hexane before the reaction mixture was purged with hydrogen. Thus formed amalgam was swirled at constant rate in a 3 h long hydrogen-filled environment. After filtering the reaction mixture and evaporating the solvent at low pressure, 4.32 mg (99%) of a white solid was

Scheme 1 Reduction reactions by metal NPs-(bacterial) nanocellulose hybrid composites, the reduction of 4-nitrophenol to 4-aminophenol (top) and para-nitro-biphenyl derivative in to para-amino biphenyl (b), which is considered as a model reaction in heterogeneous catalytic reactions

obtained. Pd/BNC catalyst has been used for nitro group reduction to amino group hydride reduction (Scheme 1). It is important to note that quantifiable yields of amines were produced even though no additional purification procedures were utilized. When the eco-friendly catalyst was used, it was easily recovered and put to use in two separate reactions of a different type.

Oxidation Reactions

Oxidation reactions are not only extremely important in the natural world, but they also play a significant role in the process of organic synthesis as critical transformations. Utilizing oxidizers such as molecular oxygen, hydrogen peroxide, and osmium tetroxide, the chemical industry makes substantial use of oxidation reactions. Due to the ease with which excess gas may be evacuated from the reaction, the development of greener processes is facilitated when traceless gaseous reagents are used in place of chemicals. Organic synthesis is mostly dependent on oxidation processes, which modify or add functional groups to molecules. Chemoselectivity and regioselectivity, on the other hand, are frequently low in autooxidations and other processes involving radical intermediates. Large amounts of waste are produced when stoichiometric metal oxidants are used, such as KMnO_4 or K_2CrO_4 , and they are not always environmentally sustainable.

Biocatalytic oxidations that are mediated by laccases are becoming increasingly significant as a result of their adaptability as well as the good impacts that they have on the environment that they are surrounded by. Several bacterial laccase-based

catalysts have been employed for the oxidation of 1,4-dihydropyridines. These are BNC supported BliLacc catalysts, whole *Escherichia coli* cells expressing this laccase, and pure laccase from *Bacillus licheniformis* ATCC 9945a (BliLacc). Catalysts based on bacterial laccase were compared to the commercially available *Trametes versicolor* laccase (TvLacc). Good yields (70–99%) of the 2,6-dimethyl-1,4-dihydropyridine-3,5-dicarboxylate oxidation product were achieved with all three biocatalysts in as little as 7–24 h. Regarding substrate diversity, five more 1,4-dihydropyridines were investigated (Scheme 2). Whole-cell biocatalysts were shown to be relatively stable for up to one month of storage at 4 °C. And there's more evidence that the *E. coli* multicopperoxidase CuO is effective. It has been demonstrated that the *E. coli* expression host enhanced the whole-cell biocatalyst's oxidation efficiency. Reusing previously used *E. coli* (BliLacc) could grow on BNC, however the reaction yield dropped nearly linearly after three rounds of growth. In addition, after three biotransformation cycles, the immobilized whole-cell biocatalyst retained 37% of its initial activity. Several of the biocatalytic systems

Scheme 2 Schematic representation of the chemical structure and the biocatalytic oxidation of Hantzsch 1,4-dihydropyridines by employing biocatalysts based on bacterial laccase. Diethyl-2,6-dimethyl-1,4-dihydropyridine-3,5-dicarboxylate (DHPy1) was converted to diethyl-2,6-dimethylpyridine-3,5-dicarboxylate (Py1) and 1,4-dihydropyridine (DHPy2–DHPy6) substrates for this work (b). Except for DHPy6, all substrates produced the matching pyridines

developed in this study can be applied to additional laccase-mediated processes (Simić et al. 2020).

Coupling Reactions

There is a high demand for heterogeneous catalysts to be used in organic synthesis as well, and BNC meets this need thanks to its unique properties, such as its high functionalization selectivity. There is a wide variety of applications for BNC, but one of the most common is as a support for the synthesis of heterogeneous catalysts through the use of straightforward metal loading on the BNC surface. Metals such as Pt(II), Pd(II), or Cu(I), Cu(II) salts in sodium borohydride solution in water under mild reaction conditions are used to load onto BNC. Surface metal dispersion on catalysts has been found to vary, indicating varying degrees of affinity with the BNC. Using quadrupole inductively coupled plasma mass spectrometry (ICP-QMS), researchers found that the amount of Cu on Cu/BNC was tenfold lower than Pd on Pd/BNC, indicating more efficient incorporation for the Pd catalyst than the Cu catalyst. Also, Cu formed spheres on the surface, while Pd nanoparticles were embedded in the BNC structure. The eco-friendliness of the Pd/BNC grafted catalyst is highlighted by its use as catalysts for the Suzuki-Miyaura reaction in mild reaction conditions with water as the solvent. Using bromobenzene with various arylboronic acids resulted in increased yields during the coupling reaction (Scheme 3a).

Pd/BNC was also utilized in the process of obtaining 4-methoxybiphenyl in water using a method that did not involve the use of ligands. A colorless solid was obtained

Scheme 3 Pd/BNC catalyzed Suzuki–Miyaura reaction of aryl halogenides with arylboronic acid in water, where TON: Turnover number and TOF: Turnover frequency (**a**), reduction of nitro-group catalyzed by Pd/BNC catalyst, which demonstrates the potential of the catalyst towards reuse under the experimental conditions (**b**), where X can be H or F

as a byproduct of the standard Suzuki reaction protocol. To obtain 4-nitrobiphenyl without the use of ligands, Pd/BNC was also used (Zhang 2005). In accordance with the procedure that is considered standard operating procedure for the Suzuki reaction, the compound was successfully obtained as a solid yellow substance. 4-Fluoro-4'-nitrobiphenyl: Using ligand-free methodology, Pd/BNC was also used to obtain 4-fluoro-4'-nitrobiphenyl in water (Scheme 1) (Samarasimhareddy et al. 2013). In accordance with the standard operating procedure for the Suzuki reaction, a yellow solid form of the compound comprising approximately 91% was obtained. Throughout the course of the catalytic recycling experiments, they have used inductively coupled plasma (ICP) emission spectroscopy to examine the products and found that there was no Pd contamination to be found in any of them. SEM analysis further confirms the stable morphology during recycling of Pd/BNC catalyst after 4 reaction cycles.

Both from an economic and an environmental point of view, the recovery and reuse of a spent catalyst is important. Both of these factors contribute to the importance of this practice. After a catalyst has served its purpose, it is considered “spent,” and poses a danger to the environment because of the metals that can be leached from its surface. Consequently, a catalyst’s usefulness depends largely on its resistance to extreme reaction conditions and its potential for recycling. The reduced nitro to amino group using hydrogen gas was catalyzed by the recovered catalyst with a 99% yield for both compounds (Scheme 3b). With a yield of 99%, the ability of the BNC-based catalyst to be reused is demonstrated in a clear and convincing manner.

When an aryl boronic acid is mixed with either an alcohol or an amine, a sort of cross-coupling reaction known as the Chan–Evans–Lam coupling takes place. This reaction is a type of cross-coupling reaction. Secondary aryl amine or aryl ether is formed during this process, depending on the molecule being linked. However, using copper complexes to catalyze the reaction raises concerns about the process’s repeatability and, by extension, its environmental sustainability. The Cu/BNC nanocatalyst has been employed as a heterogeneous catalyst for the Chan–Lam coupling reaction between benzylamine and phenylboronic acid (Scheme 4). The authors speculated that low Cu incorporation on BNC may have caused the modest output. The effectiveness of these materials as heterogeneous catalysts was, however, shown by the low amount of metal leaching and the straightforward recovery techniques.

Scheme 4 BNC grafted with copper nanoparticles as a sustainable green catalyst for the coupling of benzylamine and phenylboronic acid

Electrocatalytic Applications

Ozone has a wide variety of applications that go well beyond the realm of environmental science. One of the most powerful oxidants is O_3 , which has an oxidation potential of 2.07 V. Because of its potent oxidative property, ozone is an effective chemical for sanitizing and disinfecting environments (Beltrán 2004; Cheremisinoff 2001). In the process of disinfecting water systems, microorganisms are eradicated, organic molecules are decomposed, and cyanide, phenols, manganese, detergents, and colors are removed. It is used to purify drinking water, food, and surgical tools, in addition to the purification of wastewater and the water in swimming pools. This is also brought to use in a broad variety of other contexts, such as those listed above. It is a raw ingredient in the production of several organic compounds like oleic acid and peroxyacetic acid. Ozone is a great option for water purification because it does not leave behind any toxic byproducts. (Han et al. 2004). However, ozone is extremely volatile, with a half-life of only 30 min in water. Therefore, it is widely employed by technologies for production in situ. In comparison to other methods of production, electrocatalytic ozone generation technology is viewed as a more environmentally friendly chemical process. In-situ sterilization and decolourization applications can benefit greatly from eco-friendly electrochemical ozone production (EOP). Ozone can be synthesized electrochemically using a nanocatalyst composed of Pt single atoms (SAs) embedded in BNC nanotubes (Pt-Sas/BNC). The enhanced performance of the EOP in neutral media can be attributed to the process, which creates a local environment abundant in oxygen intermediates and thus modifies the EOP's thermodynamics and kinetics. At a current density of 50 mA cm^{-2} , the Pt-SAs/BNC catalyst displays excellent EOP performance, with a Faraday efficiency of 21%, nearly double that of commercial $-PbO_2$. The significant performance of the Pt-SAs/BNC nanocatalyst material in electrodegradation of various pesticides and antibiotics is further evidence of the potential environmental application capabilities of Pt-SAs/BNC, in addition to its use in O_3 (Gu et al. 2021).

The utilization of environmentally friendly components in the production of renewable energy technologies that are predicated on the production of electrode materials that are based on BNC for the purpose of electrocatalytic hydrogen production that is both effective and efficient. Conductive flexible substrates made from BNC isolated from *Komagataeibactersucrofermentans* were used in electrocatalytic experiments. Electrodeposition in a Ni and Mo solution (Fig. 2) transformed the conductive BNC substrate into an active electrode for the hydrogen evolution reaction (HER) under basic conditions. Since the BNC electrode is binder-free and has a highly nano-porous structure, the surface active sites are amplified, and the electrolyte shows remarkable catalytic hydrogen production under basic conditions. According to the results of the electrochemical studies, the $NiMoO_4$ /BNC electrode needs an overpotential of 109 mV with a Tafel slope of 170 mV dec^{-1} in 1 M KOH to produce a current density of 10 mA cm^2 . And after 48 h of electrolysis in an alkaline medium, the electrode stands up well (Abraham et al. 2020).

By employing an in-situ chemical reduction method, a membrane made of BC that supports CuO/Cu nanocomposites and is relatively inexpensive to produce was created. Electroactive nanocomposite electrodes were grown in situ using CuO/Cu with bacterial cellulose as support. The electrocatalyst (CuO/Cu₄:3@BC) has been used successfully for the electroreduction of CO₂ to CO. As prepared, the CuO/Cu₄:3@BC electrode exhibits superior charge transport property and higher current density for CO₂ reduction in comparison to carbon paper-supported CuO/Cu composite catalysts. This is because the web-like porous structure of the BC substrate provides easier access to active sites to electrolytes and faster transfer of reactants and products. Therefore, the CuO/Cu₄:3@BC electrode's architecturally arranged CuO/Cu composite catalysts offer unique structural advantages of good ion and charge transport, thereby promoting the catalytic kinetics for the conversion of CO₂ to CO. The resulting electrode is capable of producing CO with a Faradaic efficiency (which is also called *coulombic efficiency* or *current efficiency* describes the

efficiency with which charge (electrons) is transferred in a system facilitating an electrochemical reaction) of 53% at a modest over-potential of 490 mV, and it maintains its activity for a period of over 40 h (Zhou et al. 2020). On a platform that is very similar to this one, Gao and his colleagues have reported that a CNT/Bacterial Cellulose (BC) nanocomposite with conductive properties and a large surface area was in-situ cultivated in order to preserve the native 3D nanofibril network. Electrodes effective at reducing carbon dioxide (CO_2) were fabricated in situ using a Cu-Cu_xO/CNT/BC nanocomposite electrode as a support and either potassium dihydrogen phosphate (KBH_4) or sodium hydrogen phosphate (NaBH_4) as a reducing agent (ECR- CO_2). For the purpose of converting ECR- CO_2 into CO and C_2H_4 (Fig. 3), the performance of both electrodes was superior to that of the conventional carbon cloth or pure BC supported Cu-based catalysts. The current density in the double layer increased to 33.3 mA cm^{-2} , and the capacitance increased to 11.8 mF cm^{-2} . The Faraday efficiency ($\text{FECO} + \text{FEC}_2\text{H}_4$) was 66% at a potential of 1.5 VRHE. The Cu-Cu_xO/CNT/BC nanocomposite electrode also showed remarkable stability, remaining functional in ECR- CO_2 for over 20 h (Gao et al. 2022).

Silva and colleagues have reported on the development of skin-adherent biosensors that are based on the use of pure microbial nanocellulose fibers as the substrate (Silva et al. 2020). Screen-printed carbon electrodes (SPCEs) on bare-nylon-coated (BNC) substrates have been reported as a flexible strategy for engineering wearable sensing platforms, as they integrate well with human skin. The use of SPCEs on MNC makes it possible to determine whether or not sweat contains uric acid, 17-estradiol, Pb^{2+} , or Cd^{2+} . The as-prepared SPCEs were able to detect the toxic metals cadmium (Cd^{2+}) and lead (Pb^{2+}) in human sweat and urine at limits of detection of 1.01 and 0.43 M, respectively. The detection limits for uric acid and 17-estradiol in synthetic sweat were 1.8 M and 0.58 M, respectively, when using SPCEs functionalized via anodic pre-treatments. The electrochemical treatment increased wettability and hydrophilicity by adding oxygen groups to the carbon

surfaces. In this work, BNC was used as an adhesive-free, yet highly skin-adherent platform for wearable sensing devices, taking advantage of BNC's semi-permeable, non-allergenic, and renewable properties, which set it apart from other materials that have been used for the whole purpose. These findings may pave the way for combining immunosensing devices and have clear ramifications for the development of greener, more biocompatible, and more efficient substrates. Moreover, these findings may pave the way for the combination of immunosensing devices (Silva et al. 2020).

Studies have been conducted on the in situ deposition of platinum (Pt) nanoparticles on bacterial nanocellulose membranes (BNC) for the application of fuel cells. The results of morphological (TEM) and crystallographic (XRD) examinations reveal that the BNC fibrils are well impregnated with spherical metallic platinum nanoparticles with a mean diameter of 3–4 nm. The Pt/BC composite materials have extremely high thermal stability, according to TG's thermal analysis. CV looked into the electrosorption of hydrogen (cyclic voltammetry). The electrocatalytic activity of Pt/BC catalysts in the hydrogen oxidation reaction was found to be quite high. Under non-humidified conditions, the single cell performance of Pt/BC was tested at 20 °C, 30 °C, and 40 °C. Renewable BC is a promising material to be investigated as a membrane in the field of fuel cells, according to preliminary testing on a single cell (Evans et al. 2003; Yang et al. 2009).

Other Types of Catalytic Transformation

The membranes made of bacterial nanocellulose/spiropyran nanofibrous have a photochromic effect (Hu et al., 2011). When exposed to ultraviolet light (UV), BNC/spiropyran photochromic membranes turn pink (merocyanine structure), but when exposed to visible light (spiropyran structure), they revert to their original color (colorless). In a comparable pattern, Gutierrez et al. demonstrated the fabrication of photochromic vanadium nanopapers by using BNC templates and the sol-gel process. Polyoxometalates, also known as POMs, are complex molecules that are composed of highly symmetrical metal clusters that are formed by a number of different metallic ions that are coordinated by shared oxide ions. Because of their structures and properties, they could be used as functional molecules in organic-inorganic matrices. Due to the formation of mixed valence cations, the metallic ions in the POM structure are able to undergo reversible redox process, resulting in the appearance of colored species (heteropolyblues and heteropolybrowns). In photo and electrochromic applications, its redox property and high electron density are highly desirable. Phosphotungstic acid (PWA), with the molecular formula $\text{H}_3\text{PW}_{12}\text{O}_{40}$, is one of the most significant POM that has been investigated in the preparation of new OINs due to its good solubility in water-based and polar solvents. Additionally, the structure of size Keggin has been defined by PWA, where the photoreduction of its W^{6+} sites in response to ultraviolet irradiation is responsible for the majority of the color change. The color shift is due to the photoreduction of $\text{H}_3\text{PW}_{12}\text{O}_{40}$, which is triggered by ultraviolet light. At room temperature, Santos

and colleagues soaked H3PW12O40 in BNC membrane mats made from the *Gluconacetobacter xylinus* (ATCC 23760) bacterium to create photochromic organic-inorganic nanocomposites. It was possible to create a paper-like, semitransparent BNC/PWA nanocomposite. Spectral studies showed that the primary Keggin structure was maintained in the nanocomposites, and exposing a colorless BNC/PWA nanocomposite to UV light caused a change from a bluish semitransparent color sheet to a bluish opaque one. The degree of blueness is proportional to the amount of ultraviolet radiation, and the color returned to normal after the nanocomposites were exposed to air (Santos et al. 2021).

(Photo)Catalytic Transformation of Organics for Environmental Remediation

In recent years, a significant amount of work has been made into the treatment of wastewater coming from industrial sources, with the intention of lowering or getting rid of pollutant levels. Azoic dye usage in the textile sector is a significant contributor to water contamination. Since transition metal-based nanoparticles are less expensive to manufacture than noble metal nanoparticles, we investigated their potential to degrade these pollutants. Thiruvengadam and Vitta (2017) advocated the use of BNC as a flexible and multifunctional Ni-based nanocomposite. They did this by employing methyl orange (MO) as a model dye pollutant (Thiruvengadam and Vitta 2017). The authors generated Nickel-Bacterial Nanocellulose (NiBNC) nanocomposites with varied amounts of nickel by employing a method referred to as “inverse chemical reduction.” Method: Sodium borohydride (NaBH_4) and nickel chloride (NiCl_2) solutions were applied to a BNC hydrogel (NiCl_2). After being hot-pressed at 70 °C and 4 megapascals, the resulting black NiBNC sheet formed a BNC network of strongly linked metal nanoparticles that displayed magnetic and electrical capabilities. NiBNC was also examined for its reduction catalytic activity, and it was discovered to be more effective than pure BNC in reducing the amount of UV-absorption that a methyl orange solution had. Researchers looked into this catalyst’s reusability and found that it could be reused with good results even if it weren’t stored in an aqueous solution between uses.

Hexagonal phase CdS nanoparticles with outstanding photocatalytic activity were homogeneously coated onto the hydrated BNC nanofibers by a simple hydrothermal reaction at a temperature that was relatively low, and they were stabilized by means of the coordination effect. This reaction took place at a temperature that was in the range of around 100–200 °C. The CdS/BNC hybrid nanofibers demonstrated high efficiency photocatalysis, with 82% methyl orange breakdown after 90 min of irradiation and strong recyclability. According to the findings, it would appear that the CdS/BNC hybrid nanofibers are a good choice for application as highly stable photocatalysts that are responsive to visible light (Yang et al. 2011).

Synthesized through the decomposition of BC that was then infiltrated with an aqueous solution of zinc acetate while the process was carried out at a high temperature. In addition, using BC or Am-BC as a template, the photocatalytic

ZnO/BC and ZnO/Am-BC nanocomposite membranes can be synthesized using a simple polyol method. The resulting nanocomposites exhibit high photocatalytic activity in the degradation of methyl orange and good mechanical properties thanks to the inclusion of ZnO nanoparticles with a uniform distribution and an average diameter of 50 nm. ZnO/Am-BC nanocomposites with a high loading content of ZnO nanoparticles showed a higher decolorization efficiency of 91% at 120 min, making them a promising photocatalyst candidate.

A membrane technique referred to as superhydrophilic/underwater superoleophobic (SUS), which is used for the purpose of water filtration, has attracted a considerable amount of interest in recent years. Still, there is a major challenge to be met in the production of multifunctional membranes to meet the complex wastewater treatment requirements. The use of BNC-based multifunctional membranes for wastewater treatment is widespread. One type of nanocellulose employed in the creation of these multipurpose SUS membranes is bacterial nanocellulose (BNC). BC nanofibers and TiO₂ nanoparticles (NPs) were combined in order to produce membranes, and these membranes were further changed by the in situ growth of ZnO-Nps. Oil/water (o/w) separation has been demonstrated by the composite membranes at a flux rate of 8232.81212 L m²h⁻¹ and a high separation efficiency (>99.9%) under a low driving pressure (0.2–0.3 bar). Membranes, with a separation flux of 1498 74 L m²h⁻¹ and a high efficiency (99.25%), could also separate oil-in-water emulsion. To top it all off, the composite membrane displayed potent photocatalytic activity (>92%) when exposed to visible light. Inspiring the fabrication of next-generation multifunctional membranes for wastewater treatment, especially oily wastewater, dyes, and microbial contaminated water, is the high efficiency of the BNC based membranes (Wahid et al. 2022).

The use of novel photoactive membranes in treatment of wastewater and the elimination of microorganisms or organic pollutants from wastewater has drawn the attention of those working in the field of environmental protection. In addition to enhancing the adsorption and photocatalytic capabilities of such membranes, the concurrent application of BC with two distinct metal oxides or metal oxide-MWCNT nanocomposites could offer a promising alternative that could lengthen the lifetime of such membranes. Increasing the capacity for absorption is the strategy that would be used to bring about the desired outcome of achieving this goal. For example, BC-Fe₂O₃-ZrO₂ nanocomposites have been reported for the adsorptive removal of organic dyes and anti-pathogenic agents from contaminated water (Siddiqui and Chaudhry 2019) and BC-Fe₂O₃-SnO₂ nanocomposites have been reported for the same purpose (Siddiqui et al. 2019). The inorganic composite was manufactured using impregnation and solvothermal processes. Composite materials had 10 w/w% CTAB modified MWCNT added to them before use. The composites that resulted were given the names ZnO-MWCNT-IMP and ZnO-MWCNT-SOLVO to reflect the respective manufacturing processes. Methylene blue (MB) adsorption and photocatalytic degradation by bacterial nanocellulose-zinc oxide (ZnO)-multi walled carbon nanotube (MWCNT) hybrid membranes exposed to UV light. The photocatalytic performance of hybrid membranes is highly sensitive to both the preparation method and the amount of ZnO-MWCNT additives loaded into the

membranes. Under UV-irradiation and in filtration experiments, the SOLVO membranes exhibited significantly greater mechanical stability. In contrast, IMP membranes' lower tensile strength parameter led to failures in both photocatalysis and filtration experiments. Micrometer-sized ZnO particles in BC-ZnO-MWCNT-SOLVO membranes may therefore provide additional benefits and potential application alternatives, such as in the area of photocatalyst-based water treatment technology (El Mrabate et al. 2021).

In the past year, research into the removal of dyes and pollutants from water using heterogeneous catalysis led to the discovery of advanced oxidation processes, also known as AOPs. These processes are an additional method for cleaning water. Because of its distinct properties, the BNC is a promising substrate for developing a Fenton-type catalyst. To study the catalytic degradation of methylene blue (MB), a model dye pollutant, a Fenton-BNC hydrogel was freeze-dried to produce a Fenton-BNC aerogel. Its catalytic activity was higher than that of the bare Fenton catalyst made in the absence of BNC, suggesting that the heterogeneous Fenton catalyst supported by BNC is the superior catalyst. As an added bonus, Fenton-magnetic BNC's properties make it easy to recover with a magnet or magnetic field (Wibowo et al. 2018).

Owing to the fact that BC possesses both hydrophilic and oleophobic properties. Oil remains on the surface of the membrane during filtration of oily effluents or emulsions because only water droplets pass through the nanometric pores of the membrane at the pressure used in the process. Some research suggests that certain modifying agents can turn BC membranes hydrophobic, improving their oil/water selectivity for emulsions containing both oil and water (Sai et al. 2015). This is an effort to improve the filtration yield so that it conforms more closely to the specifications for the filtrate. Furthermore, BC is suitable for the removal of heavy metal ions from aqueous solution due to its nanoporous structure and its receptivity to chemical derivatization (Jin et al. 2017). To this end, it has been proposed to improve the adsorption capacity of cellulose-based materials by grafting them with functional groups like amino, carboxyl, and thiol (He et al. 2014). However, other reports have demonstrated that the ability of these modified materials to adsorb metal ions, as well as their mechanical properties, still require further improvement through new derivatization strategies. For this reason, research has been directed toward making these materials more flexible and mechanically strong than simple BC, the latter of which is crucial when these materials are used to create reusable membranes. The dense nanofibrillar structure of BC can hinder the performance of the separation process due to liquid infiltration, which can be mitigated by preparing composite materials with larger pore sizes. Because gravity alone is used for the separation process, no additional pressure is required, which means that less energy is used (Wang et al. 2021) (Fig. 4).

It is important to note that each of these alterations to the polymer can be carried out either independently or in conjunction with other systems. The few studies that have been done so far using BC as a filter membrane suggest that it has enormous unexplored potential, with particular reference to its low sensitivity to water, so that it does not decompose in contact with substances that are in liquid state, high degree

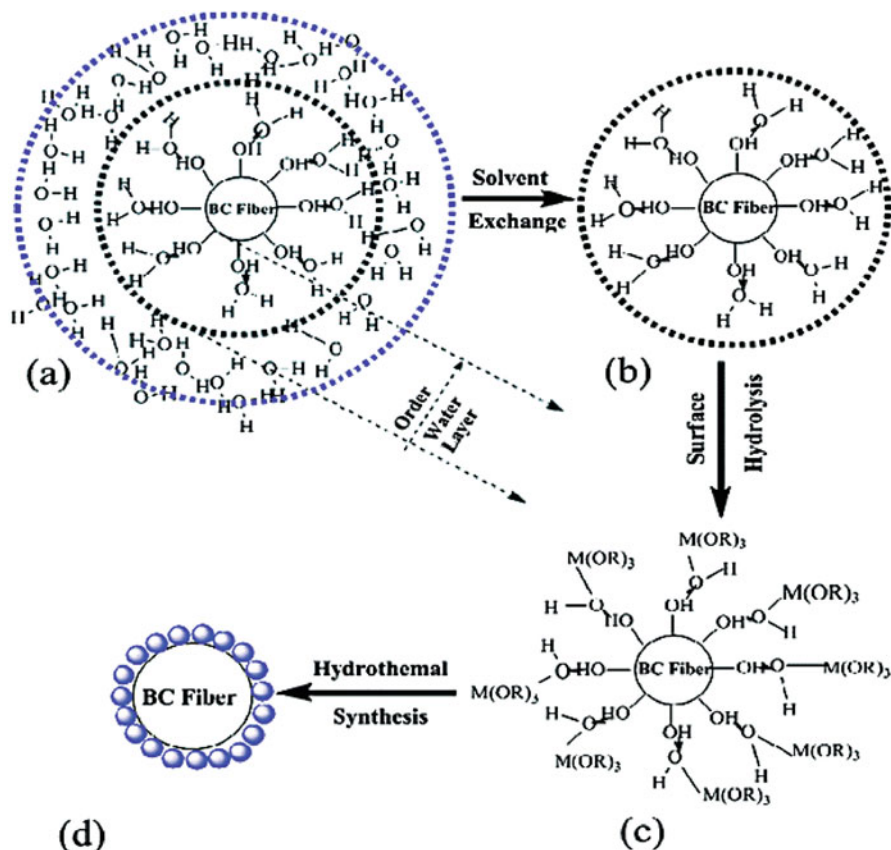

Fig. 4 Schematic illustration of the preparation of BC/TiO₂ hybrid nanofibers for the photo-degradation of model pollutant, methyl orange (MO) under UV irradiation (Sun et al. 2010b). Copyright@American Chemical Society, 2022)

of porosity, low density, and nanofiber structure that allow nanoscale filtration. In addition, its low sensitivity to water means that it does not decompose in contact with substances that are solid (Hungund and Gupta 2010).

A surprising level of efficacy in the orientation of TiO₂ nanoparticle arrays was demonstrated by bacterial nanocellulose (BNC) nanofibers. These nanofibers were biosynthesized by *Acetobacter xylinum* NUST5.2. We used a solvent exchange technique to gradually increase the ethanol concentration to up to 99%, which effectively removed the disordered water from the BNC solution. The BC fibers that had been treated were separated by centrifugation and then put into a 200 mL ethanolic solution of Ti(OBu)₄. The mixture was autoclaved in a stainless steel autoclave with a Teflon tube attached for 5 h at 150 °C (Fig. 5). The N-doped TiO₂/BC fiber composite underwent the same preparation method as the unmodified composite, except urea was added (Schaaff and Blom 2002).

Fig. 5 Schematic illustration of the various steps involved in the fabrication of Pd/graphene oxide (GO)/bacterial nanocellulose (BNC) and its use towards remediation of water. (Reproduced from Xu et al. (2018)) Copyright@ Wiley-VCH, 2022)

By performing surface hydrolysis with molecular precision, it is possible to efficiently create large amounts of uniform BC nanofibers coated with TiO_2 nanoparticles. This process results in the development of uniform and well-defined hybrid nanofiber structures. Methyl orange (MO), employed as a model pollutant, was degraded using this TiO_2 /BNC hybrid nanocatalytic system as a photocatalyst, and it performed more effectively than the widely available P25 photocatalyst. The process for a series of photocatalytic degradation studies was as follows: materials were suspended (200 mg) in a MO solution (20 ppm) and put in a 200 mL quartz reactor with a 300 W UV light. In addition to the commercial P25, the findings of comparing BNC/ TiO_2 hybrid nanofibers with BC/ TiO_2 hybrid nanofibers doped with nitrogen have been compared (Sun et al. 2010b).

In situ reduction of Ag^+ by $\text{Na}_3\text{citrate}$ on the BC matrix was used by Marques et al. to create an AgNP/BNC nanocomposite. Thiosalicylic acid and 2,2'-dithiodipyridine can both be detected using the resulting AgNP/BNC substrate at concentrations as low as 104 M. Additionally, this substrate has been used to acquire the SERS spectra of three amino acids: L-phenylalanine, L-glutamate, and L-histidine. The hydroxyl groups of BC reduced HAuCl_4 in situ at 373 K to create AuNPs in the interstitial space of the layer of BC hydrogen, resulting in an Au/BNC nanocatalyst (Marques et al. 2008). For the SERS detection of trace organic compounds such as phenylacetic acid and 4-fluorobenzenethiol (4-FBT), Park et al. created AuNP/BC substrates (PAA). SERS hot spots were produced as the hydrogel dried and the space between its surrounding layers and the attached AuNPs significantly shrunk. This method allowed for the detection of PAA at low concentrations (107 M). It is noteworthy to note that the minimum concentration detected for 4-FBT, which has a high affinity for AuNPs, was much higher (105 M). This strategy profited from BC's three-dimensional structure. Drying-mediated deformation of the three-dimensional AuNP/BC nanocomposites produced hot spots in the vertical direction that resulted in significantly stronger Raman signals than standard two-dimensional SERS substrates (Park et al. 2013).

Ferreira-Neto and colleagues developed self-supported hybrid aerogel membranes of bacterial nanocellulose/MoS₂ nanocomposite systems, which combine the mechanical stability and remarkable textural properties of bacterial nanocellulose (BNC)-based organic macro/mesoporous scaffolds with the superior adsorption-cum-photocatalytic capabilities and high pollutant removal performance of MoS₂

nanostructures. Coating quantum-confined photocatalytic MoS₂ nanostructures (2–4 nm crystallite size) on BC nanofibrils through controlled hydrothermal growth and exact adjustment of the synthetic parameters allowed us to construct BC/MoS₂-based porous, self-supported, and stable hybrid aerogels with a distinctive shape. These BC/MoS₂ samples feature significant surface area (97–137 m²g⁻¹), small pore volume (0.28–0.36 cm³ g⁻¹), and short interlayer distances (0.62–1.05 nm). Researchers found that by modifying BC with nanostructured MoS₂, the hybrid aerogels' efficiency at removing pollutants via adsorptive and photocatalytic mechanisms was greatly improved. This was demonstrated in a comprehensive study using a membrane photoreactor specifically designed to house the developed photo-active/adsorptive BC/MoS₂ hybrid membranes. Both organic dye (methylene blue (MB)) molecules (96% removal within 120 min, $K_{\text{obs}} = 0.0267 \text{ min}^{-1}$) and heavy metal ions (88% removal within 120 min, $K_{\text{obs}} = 0.0012 \text{ min}^{-1}$) were efficiently removed via photoassisted in-flow removal using the prepared BC/MoS₂ aerogel membranes, demonstrating excellent recyclability and photo-stability. According to extensive environmental studies, the interlayer expanded MoS₂ nanostructures were much more successful in the removal of smaller species (CrO₄²⁻) as compared to larger (MB) dye molecules. This was the case in both cases when comparing the two different sizes of dye molecules. The created hybrid aerogel membranes display promising behavior for use in in-flow water purification, representing a significant advance over the use of self-supported aerogel membranes for photocatalytic applications in liquid media (Ferreira-Neto et al. 2020).

Synthetic Applications of BNCs Grafted with Inorganic Catalysts

Because of its desirable features, such as great mechanical strength and toughness, rich chemical functionality, and high specific surface area in aerogel state, bacterial nanocellulose (BNC) serves as an appropriate material for realizing functional composites by adding functional nanomaterials inside BNC matrix. These properties include: outstanding mechanical strength and toughness, rich chemical functionality, and high specific surface area in aerogel state. The aerogel state exhibits several ideal qualities, including a large specific surface area, great mechanical strength and toughness, and a rich chemical functionality. Graphene oxide (GO) sheets and other 2D materials can be efficiently included into the growing matrix of BNCs. Durable membranes, like those made possible by the efficient intercalation of GO flakes within the layered BNC matrix, are crucial for efficient, large-scale water treatment. Accordingly, Jiang et al. have demonstrated a simple and repeatable procedure for constructing Pd/GO/BNC membrane for very effective dye degradation. A Pd/GO/BNC membrane is made by first growing a BNC matrix with GO flakes inserted into the matrix, and then growing PdNPs directly on top of the GO flakes. The layered structure of Pd/GO/BNC produces nanocapillaries throughout the membrane, bringing organic dye pollutants closer to the PdNPs anchored on the GO flakes. These innovative membranes show promise for use in wastewater treatment and separation due to their efficiency in degrading organic dyes.

Realization of this Pd/GO/BNC membrane is made possible by in situ incorporation of GO flakes into the BNC matrix during its growth, followed by in situ formation of palladium nanoparticles (Fig. 5). This membrane exhibits extremely efficient methylene orange (MO) degradation during filtration (up to 99.3%) over a broad range of MO concentrations, pH, and multiple cycles of reuse. Pd/GO/BNC membrane has proven successful in treating numerous pollutants at once (a cocktail of 4-nitrophenol, methylene blue, and rhodamine 6G). The new and strong membrane developed in the paper shows promising results in wastewater treatment. The efficiency of degradation remained stable at 99.3% throughout a broad range of pH values encountered in both natural and manufactured aquatic systems. The Pd/GO/BNC membrane suffered just a minor performance loss (to 99.2%) after being filtered and regenerated six times (Xu et al. 2018).

Porous crystalline materials called metal organic frameworks (MOFs) can be designed to act as selective adsorbents. Because of their great porosity, they can absorb a lot of liquid. However, the brittleness of these crystalline materials presents problems for many commercial applications. Liquid phase separation techniques can benefit from the usage of MOFs that have been immobilized on solid supports and scaled up for commercial application. Nanocellulose is a promising candidate for use in this context due to its excellent flexibility and biocompatibility. The Fe(III) 1,3,5-benzenetricarboxylate-containing MIL-100(Fe) from the Material Institute de Lavoisier was immobilized onto bacterial nanocellulose (BNC) nanofibers to create a new BNF-MOF nanocomposite. The nanofibrils of bacterial cellulose were extracted from a pellicle of uniformly developed bacteria using 30 vol% reagent grade acid (Merck KGaA, Stockholm, Sweden) in 1 L of aqueous sulfuric acid solution with stirring at 60 0.5 °C. (300 rpm). When using the new nanocomposite material for efficient arsenic and Rhodamine B separation from aqueous solution, adsorption capacities of 4.81 and 2.77 mg g⁻¹, respectively, were achieved. In order to conduct adsorption studies, 0.18 grammes of MIL-100(Fe)@BC was dissolved in aqueous solutions containing various pollutants at concentrations ranging from 20 mg L⁻¹ of As(III) (50 mL) to 10 mg L⁻¹ of Rhodamine B (40 mL) for a set amount of time. Following the extraction of the MIL-100(Fe)@BC nanocomposite from the aqueous solution, a UV-vis examination of the dye concentration was carried out in accordance with a calibration curve. Nonlinear pseudo-second-order fitting provided a good model for the adsorption process. Meanwhile, inductively coupled plasma atomic emission spectroscopy was used to quantify the amount of As(III) in the supernatant (ICP-OES) (Ashour et al. 2020).

Conclusions and Future Prospects

Concerns for the environment, sustainability, reusability, and renewability of conventionally utilized materials have led to a greater focus on the development of novel materials for cutting-edge applications in the research of nanomaterials. Based on these features, BNC is a suitable construction component for the manufacture of emerging materials. Researchers are increasingly interested in BNC-supported

catalysts due to its many desirable properties, including low toxicity, excellent catalytic holding power, and, most crucially, ease of manufacture in comparison to plant-based nanocellulose. The mechanical, chemical, porous, water-absorbing, moldable, biodegradable, excellent, and biological affinity properties of BNC are unparalleled. These characteristics, in particular when applied to inorganic systems, give rise to a broad spectrum of possibilities for the functional alteration of the system. Production, physical-chemical characteristics, functionalization, especially with inorganic nanosystems, and new developments in BNC-based catalysis are discussed in this chapter. Topics covered include reduction, oxidation, coupling, electrocatalysis, and photochemical reactions. Recent research is capitalizing on the superior performance of BNC-based nanocatalysts in a variety of applications, including reduction reactions, oxidation reactions, photocatalysis, electrocatalysis, wastewater remediation treatments, and environmental bioremediation reactions. Inorganic nanoparticle-modified BNCs are highly effective catalysts for a wide variety of processes. The Heck, Ullmann, Suzuki, and A3 couplings are examples of important coupling reactions; (b) reduction reactions using Au, Ag, Pd, Au-Pd, Pt, Cu, Ni, and CuO NPs supported onto BNCs or composite catalysts have been successfully studied over the past few decades; and (c) oxidation reactions using Pd-based catalysts are examples of important oxidation reactions.

In light of the many advantages associated with bacterial nanocellulose, it is essential to acquire more information regarding the ideal loading levels of the numerous NPs that comprise this matrix. Nanocellulose's support from the matrix can be short-circuited over the long haul if it contains inorganic ingredients. If nanocomposites are to be used indefinitely, researchers will need to find ways to either lengthen their service life or replenish them. Nanocomposites based on nanocellulose can be an attractive alternative when seeking for a low-cost, eco-friendly material to address growing environmental concerns. Furthermore, it is difficult to avoid its disintegration because it is utilized as reinforcing filler and has poor compatibility with other hydrophobic polymers. It has a high production cost and a lower yield compared to the extraction method used to generate nanocellulose from other sources, and its high hydrophilicity reduces cellular adhesion and proliferation compared to other protein-based materials.

In the not-too-distant future, it is possible that surface functionalization utilizing cutting-edge technologies may be able to improve and enhance the nature of BNC while simultaneously fixing its limitations. This would be a significant step forward. More and more studies are using BNC-based products as stabilisers, polymer additives, functional catalysts, elements of energy storage materials, medication administration, self-healing, and stimulus sensitive materials. In the field of medicine, the application of BNC and materials based on BNC has led to significant shifts as a result of the modifications. In recent years, scientists have used genetic engineering to develop a wide variety of bacteria with novel properties. The special capacities of these bacteria will soon allow for the production of BNC with better properties, which should match the needs of producing cutting-edge bio-based functional materials for novel applications.

In conclusion, water-based nanocellulose suspensions offer a stable system in which biphasic catalysis can be investigated. The metal NPs and salts in these suspensions are exposed to conditions similar to those seen in ionic liquids. Based on it, another significant approach to follow would be to investigate the ligand exchange processes employing organometallic precursors in the CNC-water solution. The resulting system could be tested for catalysis in several processes of interest, such as C-H activations, C-C coupling reactions, redox reactions, etc. To sum up, we find that the usage of nanocelluloses in catalytic applications has led to the development of intriguing new catalytic systems over the past few years. New and valuable applications based on these insights are expected to emerge eventually.

Acknowledgments We thank the University Grants Commission, Government of India, for the financial support of the UGC Major Research Project (No. F. No. 42-300/2013(SR)). Dr. Bejoy expresses gratitude to the Department of Science and Technology for supporting the college's Fund for Improvement of S&T Infrastructure (FIST) program.

Abstract

Nanocellulose already proved to be a highly relevant material for biomedical applications, ensued by its outstanding mechanical properties and, more importantly, its biocompatibility. Nevertheless, despite their previous intensive research, a notable number of emerging applications are still being developed. Interestingly, this drive is not solely based on the nanocellulose features, but also heavily dependent on sustainability. The three core nanocelluloses encompass cellulose nanocrystals (CNCs), cellulose nanofibrils (CNFs), and bacterial nanocellulose (BNC). All these different types of nanocellulose display highly interesting biomedical properties per se, after modification and when used in composite formulations. Novel applications that use nanocellulose include

well-known areas, namely, wound dressings, implants, indwelling medical devices, scaffolds, and novel printed scaffolds. Their cytotoxicity and biocompatibility using recent methodologies are thoroughly analyzed to reinforce their near future applicability. By analyzing the pristine core nanocellulose, none display cytotoxicity. However, CNF has the highest potential to fail long-term biocompatibility since it tends to trigger inflammation. On the other hand, never-dried BNC displays a remarkable biocompatibility. Despite this, all nanocelluloses clearly represent a flag bearer of future superior biomaterials, being elite materials in the urgent replacement of our petrochemical dependence.

Introduction

Fortunately, the amount of research focused on the use of nature-based substrates in wound dressings, indwelling devices, and other medical textiles has been subject to an impressive exponential growth. Nevertheless, in recent years due to the COVID-19 pandemic, there is an unprecedented boom in demand for petrochemical-based medical textiles to produce a staggering amount of personal protective equipment, in particular masks and respirators. With the deceleration of the pandemic allied to the ever more evident climate change-driven phenomena, the sustainability concerns are becoming an essential feature of every material or textile (Padrão et al. 2022). Furthermore, in biomedical applications the use of biopolymers is not only due to sustainability concerns, but majorly due to their biocompatibility. Biocompatibility may be briefly summarized as the impact of a medical application on the host. If it triggers an adequate or benefic response by the host, it is considered biocompatible. However, if it cascades into an ominous reaction, such as necrotic foreign body granulomas, the application or material is classified as nonbiocompatible (Barrère et al. 2008). Therefore, relevant biocompatibility properties include the assessment of the cytotoxicity of the novel applications developed *in vitro*, prior to experiment *in vivo*. Cytotoxicity may simplistically be regarded as how the materials will impact the living cells in terms of viability, proliferation, metabolism, adhesion, morphology, expression of key metabolites or signals, among others. If the material has a clear negative impact on one or several of these parameters, it will be classified as cytotoxic (Ramakrishna et al. 2015). The established threshold for acceptable loss of viability is 30% (Montanaro et al. 2000). If a material is considered cytotoxic, then it will most likely fail to exert an adequate or beneficial host response, thus failing to be biocompatible. If the material is considered noncytotoxic, it will possess a higher probability to trigger a suitable response by the host. However, a noncytotoxic material may still fail to be biocompatible (Fig. 1). In addition, hemocompatibility is a key parameter for medical applications. Hemocompatibility of a material is

defined by its propensity to lyse erythrocytes, as well as by its level of adsorption of coagulating agents and other signaling molecules that interact with the complement activation pathway. Cellulose is understandably one of the most common biopolymer substrates for biomedical applications and medical textiles due to its ubiquitous availability and remarkable properties. Cellulose has been used since the beginning of human history; however, cellulose and cellulose-based materials underwent an important revolution with the advent of nanotechnology. Nanotechnology was defined by the scientist Norio Taniguchi in 1974, which ensued the thriving development of nanoscale materials, which depict 1–100 nm in at least one of their

dimensions (Bayda et al. 2020). Nanocellulose encompasses five main types: cellulose nanocrystals (CNCs), cellulose nanofibrils (CNFs), bacterial nanocellulose (BNC), electrospun nanocellulose (ESNC), and wet-spun nanocellulose (WSNC). In brief, CNCs are generated through the chemical hydrolysis of the amorphous regions of cellulose. The crystalline cellulose, which is able to withstand the aggressive chemical hydrolysis, is collected and purified. Commonly, the smallest size of CNCs is approximately 3 nm wide and 70 nm long, and the largest reported size is nearly 25 nm wide and 150 nm long. Due to their needle shape, allied to this size ratio, CNCs are also named whiskers. CNFs are obtained from mechanical degradation of the amorphous regions, and this process may be aided by the presence of enzymes or chemicals. Unlike CNC, CNF in scanning electron microscopy (SEM) images depicts a “spaghetti”-like appearance due to their fairly higher length ranging from approximately 500 nm to over than 1 μ m. CNF width is encompassed between 20 and 60 nm. Both CNC and CNF may be obtained from a plethora of origins, encompassing nearly all sources of cellulose (including BNC). The BNC is mainly synthesized from bacteria. BNC nanofibers are excreted by bacteria. During incubation, the buildup of generated fibrils originates in a three-dimensional matrix. The BNC fibril size is influenced by several parameters, namely, bacteria strain, dissolved oxygen concentration, type of culture (static or dynamic), incubation time, reactor layout, culture media, among other parameters. BNC crystallinity is fairly superior to plant cellulose. Furthermore, it is solely composed of cellulose, thus to obtain a 100% nanocellulose material, the only purification procedure required is to remove bacteria, bacteria debris, and culture media constituents from the collected BNC (Padrão and Zille 2021). The most common purification consists of a maceration procedure. This purification procedure reduces the liposaccharide concentration values considerably below the threshold defined by the Food and Drug Administration (Gonçalves et al. 2015). Therefore, the size of BNC fibers and their concentration (which influences pore size) is highly variable: width between 10 to 100 nm and 50 nm up to 100 μ m in length. CNC, CNF, and BNC may be regarded as core nanocellulose materials since the ESNC and WSNC are obtained from them. In brief, electrospinning consists of the production of a fiber (usually at nanoscale) that is extruded through the generation of a potent electrical field between the spinneret and a grounded collector. During their flight, the fibers crosslink. For ESNC, one or a combination of the previously mentioned nanocelluloses is present in the dope solutions. Similarly, WSNC uses one or a combination of the above-described nanocelluloses as one of the components added to a mixture that is extruded (usually using mild conditions) into a coagulation bath where the components crosslink. The nanosize of nanocellulose greatly enhances the availability of the hydroxyl groups that populate their surface. Fibrinogen, a glycoprotein present in blood, may be cleaved in an array of different peptides that regulate cell adhesion, cell migration, and may work as chemotactic for key angiogenesis cells such as fibroblasts, keratinocytes, macrophages, myocytes, and endothelial cells. Fibrinogen bonds tightly to -OH groups (Thevenot et al. 2008). Thus, the outstanding -OH availability in nanocellulose may result in a favorable promotion of angiogenesis. In

addition, the impressive nanocellulose crystallinity may be explored in the development of chemically and mechanically sturdier materials for non-host-degradable applications. These features will be critically analyzed in this chapter. Furthermore, the emerging applications of nanocellulose in the medical field will be discussed according to its enhanced biocompatibility.

Cellulose Nanocrystals and Cellulose Nanofibrils

Nanosized cellulose has been widely studied due to the unique properties, namely, its surface chemistry, mechanical properties, biocompatibility, biodegradability, and wide availability. CNC and CNF present similar chemical composition but different morphologies owing to the differences in their manufacturing procedures. CNCs are short, rod-like cellulose nanocrystals, whereas CNFs are long entangled cellulose crystalline fibrils. CNFs exhibit remarkable gelling properties in water. Furthermore, CNF displays superior reinforcing properties in polymer nanocomposites in comparison to CNC (Ghafari et al. 2019; Svagan et al. 2014). CNCs were proved to be noncytotoxic to a plethora of cell lines, despite the high concentrations tested ($50 \mu\text{g mL}^{-1}$) (Dong et al. 2012). Cytotoxicity of CNF was investigated using human monocytic (THP-1) cells, without any signs of cytotoxicity even using high doses ($100 \mu\text{g mL}^{-1}$). However, its exposure did trigger a higher release of growth factors and relevant pro-inflammatory cytokines, which may induce a problematic inflammatory event (Bhattacharya et al. 2017). Ho et al. studied the long-term in vivo biocompatibility of CNC and CNF through their subcutaneous implantation in Sprague–Dawley rats. No foreign body reaction was observed up to 2 weeks after implantation. No indication of implant rejection was observed in rats that were observed for CNC or CNF materials. Histologically, CNC exhibited an active cell migration; however, some acute inflammatory effects were also noticed. CNF subcutaneously implanted denoted the presence of fibrotic capsule, indicating chronic inflammation signs after 3 months. These findings were corroborated by the thickness of fibrous tissue formed around the injected nanocellulose materials. The thickness of fibrous tissue in CNC increased within the first 2 weeks and subsequently declined. Whereas CNF showed an increasing thickness of the fibrous tissue unfolded during the first month and remained stable afterward. The increase of fibrous tissue in CNF could lead to granulation, which may elicit a long-term foreign body response, due to CNF slow degradation (Ho et al. 2020). Therefore, in comparison, CNC displays a higher potential for biomedical applications than CNF. Nevertheless, and as an example, the same study describes superior biocompatibility once CNF is oxidized using 2,2,6,6-tetramethylpiperidinyloxy (TEMPO) (Ho et al. 2020). Thus, both CNC and CNF remain landmark materials for the development of emerging biomedical applications, per se, modified or as part of a composite formulation. These applications include tissue engineering and wound dressing (Table 1).

Table 1 CNC and CNF emerging biomedical applications properties

CNC/CNF source	Functionalized nanocellulose/ "composite"	Adequacy	Assays	Cell/animal	Application	References
CNF, bleached softwood kraft pulp (a mixture of pine (25%) and spruce (75%))	TEMPO-oxidation and carboxymethylation of CNF	(a) In vitro – cytotoxicity (b) In vivo – biocompatibility	(a) Cell viability, proliferation, and morphology on scaffolds (live/dead staining, DNA assay); inflammatory cytokine measurement (Bio-Plex Human 27-plex kit) (b) Cytokine measurements (BCA Protein Assay Kit)	(a) Immortal human monocyte/macrophage (U937 cells) (b) Rats	Drug delivery and tissue engineering	Rashad et al. Tissue Engineering

Tissue engineering was defined over 30 years ago and has been evolving to describe multidisciplinary approaches in the development of materials that are able to recuperate, maintain, or enhance the tissue or organs' healthy operation (Chapekar 2000). A research work developed by Rashad et al. investigated the inflammatory response of porous hydrogel scaffolds made of CNF oxidized by TEMPO or by CNC carboxymethylation. The biocompatibility and inflammatory response of the hydrogels were assessed *in vitro* using immortal human monocyte and macrophage U937 cells, and *in vivo* using rats. Host responses to the hydrogel scaffolds were evaluated within a 1-month period. Furthermore, the foreign body reaction was evaluated through histological analysis for half a year. Tissue plate culture (TCP) and gelatin scaffolds were employed as controls. After 3 days, no significant differences were observed in the production of chemokines growth factors and pro-inflammatory cytokines between the CNF scaffolds and TCP. These important signals were quantified through polymerase chain reaction (PCR) and Bioplex bead arrays. However, on the fourth day *in vivo*, a significantly higher gene expression of the anti-inflammatory interleukin (IL)-1Ra in the modified CNF scaffolds was clearly seen when compared to the gelatin scaffold. After 1 month, CNF scaffolds clearly stimulated the production of IL-10, an anti-inflammatory cytokine. Unlike gelatin, both CNF scaffolds had not degraded after 6 months. The slow degradation (or even absent degradation) of the modified CNF scaffolds triggered a foreign body reaction. CNF scaffold surface chemistry promptly triggered cytokine production and did not modify the inflammatory profile *in vitro* or *in vivo*. Clearly, both modified CNF scaffolds did not display any cytotoxicity *in vitro* or *in vivo*. Moreover, they induced repair processes, an important feature for patients that display impaired wound healing. Nevertheless, to promote a transition from reparative to regenerative properties, further functionalizations of CNF materials are required. The authors suggested an accelerated degradation of the scaffolds to prevent the foreign body reactions (Rashad et al. 2019). Pereira et al. proposed a methacrylated gellan gum-based scaffold reinforced with CNC as a self-gelling fibrous that may be used as an injectable. The hydrogels were characterized regarding the swelling capacity, degradation rate *in vitro*, and mechanical properties. Rheological evaluation of the nanocomposites demonstrated that the gellan–gum reinforcement with CNC promoted matrix entanglement with higher scaffold stiffness due to ionic crosslinking. Mechanical tests demonstrated a compressive modulus value close to those of the human annulus fibrosus tissue. Furthermore, cell culture studies with encapsulated bovine annulus fibrosus cells indicated that the developed nanocomposite promoted cell viability and maintained adequate cell morphology for up to 14 days *in vitro* (Pereira et al. 2018). Vega-Figueroa et al. assessed a CNC–nanodiamond composite as eclectic application for the regeneration of bone tissue. The authors assessed surface functionalization, biocompatibility, and impact on human fetal osteoblastic cell (hFOB) proliferation and differentiation. CNC was functionalized via a 3-aminopropyltriethoxysilane silylation. Afterward, a strong acid oxidation was used to generate carboxyl groups on the surface of the

nanodiamonds. Then, an amide linkage promoted to covalently bound the two. The nanocomposite was tested for its suitability as a material interface for cell growth, in particular its chemical compatibility. hFOB cell morphology, adhesion, differentiation, and expression of osteocalcin and sialoprotein were evaluated. Each component used in the fabrication of the nanocomposite was tested. No striking differences were observed between the material and their combinations. The immunocytochemical analysis showed no detrimental morphological differences of hFOB cells (which are commonly elongated and polygonal), in the expression of osteocalcin and sialoprotein or cell viability. The results reinforced the concept that micro-/nanotopography may considerably improve the osteoblast adhesion, avoid unfavorable differentiation, and promote bone formation. This may be due to the micro-/nanotopography structure that has the potential mimic the topography of the extracellular matrix (Vega-Figueroa et al. 2017). Baniasadi et al. developed new viscoelastic bioinks composed of quince seed mucilage and CNF, which were extruded by direct ink writing into three-dimensional (3D) lattice scaffolds. The scaffolds denoted suitable porosity, water uptake capacity, and mechanical strength for tissue engineering, in particular scaffolds for soft tissues and wound dressings. All samples exhibited a rapid water uptake during 2 h, and dramatically diminished up to 24 h. They presented high swelling ratio, similar to the values reported for hydrogels used in biomedical applications. The scaffolds' high porous structure may have favored water diffusion within the homogeneously porous internal structure. By increasing CNF content, the scaffolds displayed a denser and tightly organized network, with smaller pore size and higher surface area. Moreover, CNF slowed the degradation rate, due to its high crystallinity. Several tissues require a longer period of time for re-epithelialization, namely, the skin. Thus, hydrogels that denote lower degradation rate and higher physical stability could be an important asset for this organ. The incorporation of CNF increased the compressive modulus and ultimate strength by approximately 50% and 70%, respectively, indicating a stiffer hydrogel and a reinforcing function of CNF. The obtained hydrogels displayed mechanical properties comparable to the skin and soft tissues. Human liver cancer (HepG2) cells were used to assess the biocompatibility of the printed samples. The results showed no cytotoxicity and suitability to promote attachment and proliferation of the cells. CNF loading and cell viability increased proportionally, which can be explained by the higher porosity, swelling ratio, and physical integrity of the structures with higher CNF concentration. Enhancing the surface area available for cell proliferation by the presence of CNF was found to be essential for filament self-supporting and shape retention after deposition (Baniasadi et al. 2021). Most of the printed nanocellulose scaffolds still exhibit limited resolution and mechanical properties due to the lack of CNF curing properties or thermoplasticity to form shape. Therefore, the development of 3D nanocellulose natural polymer with desired precision and mechanical strength for tissue engineering remains a challenge. Blending CNFs with photocurable resins is a strategy to solve their compatibility to obtain a stable and uniform suspension with proper rheology and photocuring properties. Tang et al. mixed cellulose nanofibers and polyethylene glycol diacrylate. The CNF with a waterborne photopolymerizable acrylic resin was used to fabricate 3D cytocompatibility

hydrogel scaffold by stereolithography process. CNFs were prepared by TEMPO-oxidation combined with mechanical treatment to disperse uniformly the CNF in water forming a transparent suspension due to the electrostatic repulsion of carboxyl groups. The excellent mechanical reinforcement of CNF with other matrixes results from their high specific surface area and numerous hydrogen and carboxyl groups. The produced hydrogels were all transparent and homogeneous. The hydrogel scaffolds possess high and tunable compressive modulus and high porosity of approximately 90%. The CNF content exhibited a significant role in structural shape integrity, porous structure, and mechanical strength. The biocompatibility tests using mouse fibroblasts (NIH3T3) showed a tight adherence to the composite, adequate differentiation, and viability. The scaffolds containing CNF showed an obvious increment of NIH3T3 cells, which was not observed on the scaffolds without CNF. This difference may be related to the porous networks of the CNF-containing scaffold, which provide more anchor points for the cells. Whereas pure polyethylene glycol diacrylate scaffolds due to their flat surface did not favor as much the cell adhesion. These results have revealed a superior method to prepare tissue engineering scaffolds that possesses suitable mechanical strength and biocompatibility for 3D cell cultivation (Tang et al. 2019). Zhao et al. prepared CNC from Whatman® filters, which were activated by thiolation, and then end-grafted with polyethylene oxide (PEO), to form a composite. Pristine CNC and the developed composites were redispersed in aqueous solution for 20 days. The thiolated CNC-containing polyethylene oxide composite exhibited a high dispersion stability without forming any sedimentation. The cytotoxicity of the modified CNC was estimated by the viability of human foreskin fibroblasts (HFF) and human tongue squamous carcinoma (CAL-27) cells. No statistical difference in viability was detected between the control group and modified CNC composites. These results reflected the low cytotoxicity of these CNC composites, indicating their potential as carriers of bioactive agents (Zhao et al. 2021). Sunasee et al. also produced CNC from Whatman® filters, which were functionalized with β -cyclodextrins (B-CD) to study their immunological and antioxidant response in (THP-1) and mouse macrophage-like cells. Furthermore, an immunological study was performed by tracking the secretion of inflammatory cytokine interleukin-1 β (IL-1 β) in myeloid cell lines. It was observed that the obtained CNC composites did not induce a strong immunological response in either THP-1 or J774A.1 cells. However, the CNC containing β -cyclodextrins showed a slight propensity to enhance IL-1 β secretion in human cells at higher concentrations. In addition, no major oxidative stress was observed (Sunasee et al. 2019). Zhang et al. used electrospinning to generate aligned and unaligned/random cellulose and CNC-based ESNs, to be used as scaffolds. These ESNs were coated with recombinant human bone morphogenetic protein-2 (rhBMP-2). Bone marrow-derived stem cells (BMSCs) were isolated from Wistar rats and cultured, firstly by themselves and then with the CNC-based ESN scaffold. Cell growth, viability, and distribution among the scaffolds were assessed, which exhibited no significant difference in proliferation between the control, aligned or random ESN, and aligned or random ESN functionalized with rhBMP-2. However, BMSC depicted a distinct morphology according to the

scaffolds. BMSCs were spindle in aligned scaffolds and polygonal when incubated in random scaffolds. In vitro osteogenic mineralization was examined using alkaline phosphatase (ALP) activity and calcium content measurement. Overall, aligned ESNC presented better results than random ESNC. Furthermore, the calcium content was significantly increased in the ESNC functionalized with rhBMP-2, regardless of fiber orientation. As for in vivo bone regeneration, scaffolds were implanted into a rabbit cranial defect. After 3 months, only scaffolds loaded with rhBMP-2 showed some spongy bone formation, where the newly formed bone volume and bone mineral density were significantly higher, nearly fivefold and threefold respectively. These results state that ESCN orientation is considerably less relevant than rhBMP-2 functionalization (Zhang et al. 2019). Zhao et al. prepared lignin-carbohydrate complexes from poplar tree with different ball milling times (48 and 72 h), which were combined with commercial CNF to form tubular biocarriers. CNFs were casted into a polytetrafluoroethylene plate, followed by LCC coating onto the CNF-formed film. The CNF-LCC composite was crimped into a tube (blood vessel-like). Specific surface area of the composite was approximately $3.7 \text{ m}^2 \text{ g}^{-1}$, and the average pore size was nearly 9 nm. The prepared scaffolds presented good pH stability from 4.5 to 9.5. Human coronary artery endothelial cells (HCAECs) were used to assess cell proliferation with CNF-LCC scaffolds in vitro. Overall, CNF-LCC composites that contained an LCC content lower than 60% presented a superior number of cells. Within this range, the number of cells increased with increasing amount of LCC. Above 60% of LCC content, there was no impact on cell proliferation. CNF-LCC composites presented promising scaffold features for biomedical carriers for heart stent tissue since they provide good environment for the growth of human coronary endothelial cells (Zhao et al. 2019).

Wound Dressing

Bacterial infections are responsible for massive worldwide grievous health complications. Due to the loss of antibiotic efficacy, this problem is becoming increasingly a case of concern, as mortality, morbidity, and healthcare costs grow exponentially. Infections that unfold in pressure ulcers, prosthetics, and reconstructive surgeries are particularly worrisome (Hassan et al. 2020). Several emerging applications are under development to cope with this urgent global issue. Poonguzhali et al. prepared biocompatible composites comprising chitosan, poly(vinyl pyrrolidone), and CNC through casting. Thermogravimetric analysis denoted a loss in thermal stability of the composites decreasing proportionally to the increasing content of CNC. Composite thickness, barrier, mechanical, water vapor, and oxygen permeability properties were evaluated. It was determined that the composite was able to maintain an adequate moist environment over a wound. Furthermore, the composite exhibited swelling, blood compatibility (less than 2% of hemolysis), and moderate antibacterial activity against *Staphylococcus aureus* and *Pseudomonas aeruginosa*. The cytotoxicity of the composite was above the acceptable threshold of 70%, when tested using normal mouse embryonic fibroblast cells (Poonguzhali et al.

2017). Silva et al. designed a fibrous patch by combining two bio-based nanofibrous polymers, CNF, and lysozyme nanofibers. The singular properties of the mechanically robust CNF and the bioactive lysozyme nanofibers represented an interesting strategy to engineer advanced functional patches with enhanced mechanical performance, UV-light barrier properties, antioxidant, and antimicrobial activities. Biocompatibility, comprising cytotoxicity, cell adhesion and proliferation, and wound healing activity are also key features of these composites. The antioxidant activity of the composites was determined by the 1,1-diphenyl-2-picrylhydrazyl (DPPH) radical-scavenging method. The pristine CNF presented nearly negligible antioxidant potential (nearly 7% and 17% after 2 h and 24 h, respectively). CNF does not contain any functional groups capable of behaving as free-radical scavengers, which easily donate hydrogen to reactive free radicals. Pristine lysozyme nanofibers exhibited an elevated radical-scavenging activity (approximately 59% and 85% after 2 h and 24 h, respectively). The combination of CNF with lysozyme nanofibers created a free-standing patch with good antioxidant activity (76–79.5 after 24 h). The DPPH radical-scavenging activity of both patches is comparable to that reported for anti-inflammatory nanocellulose patches loaded with phenolic-based ionic liquids, vitamin B-based ionic liquids, and bromelain. Clearly, this is an important concept when dealing with the excess generation of reactive oxygen species (ROS), which curiously is closely associated with inflammatory processes in wounds. CNF patch per se did not avoid the growth of the pathogenic microorganism. The combination of CNF with lysozyme nanofibers generated patches with antimicrobial activity against *S. aureus*, suggesting that the higher contact availability of the lysozyme nanofibers in the patch results in a higher antimicrobial capacity. Moreover, the developed patches showed to be biocompatible toward L929 fibroblast cells according to ISO 10993-5. The in vitro wound healing assay showed adequate cell migration. The degree of cell adhesion of L929 fibroblast cells on the patches was assessed through SEM for short-term adhesion (up to 72 h) and by live/dead assay for long-term adhesion (up to 21 days). The L929 fibroblast cells' metabolic activity was normal (approximately 100%) for all the investigated patches. However, the SEM micrographs showed that the L929 fibroblast cells adhered differently to the surface of the patches. Poor cell adhesion was observed in pristine CNF patch with no observable confluence. Moreover, after 72 h the cells started to detach. On the other hand, patches encompassing CNF and lysosome nanofibers exhibited a great cell adhesion as a cell monolayer covers throughout the entire surface of the samples (Silva et al. 2020). Yin et al. obtained CNC from commercial microcrystalline cellulose, which was incorporated into the formulation of a gelatin and hyaluronic acid hydrogel. NIH3T3 cell viability and proliferation on the hydrogels was estimated. This study showed that the composite hydrogels lead to an increase in metabolic activity of NIH3T3 cells throughout the incubation period. However, no significant differences in cell viability were observed for the different hydrogel formulations. Furthermore, in live/dead analysis it was possible to observe that most live cells looked like spindles (their healthy morphology) and there were no dead cells in CNC gelatin hyaluronic acid hydrogel. On the other hand, hyaluronic acid and CNC gelatin groups showed few dead cells, whereas the other combinations

presented a cell viability similar to the tissue plate culture. The gelatin, hyaluronic acid, and CNC hydrogels also demonstrated an improvement in mechanical and physicochemical properties, thus making this nontoxic hydrogel a promising applicant for skin wound repair (Yin et al. 2019). Nonleaching antimicrobial surfaces offer great promise for the design of bioactive coatings to be used in medical devices. However, their vast majority are cationic, which usually implies an undesirable toxicity. Thus, Hassan et al. developed an antimicrobial composite that encompassed CNF obtained using a high-pressure fluidizer (raw material: never-dried birch kraft pulp), carboxymethyl cellulose, and through direct functionalization of the surface with dehydroabietic acid derivatives to generate nonleaching anionic surfaces. Interestingly, the wettability of the CNF in comparison to the composites was very distinct. As expected, CNF wettability was high (approximately 30° of contact angle), whereas the composite was nearly hydrophobic (approximately 80°). The composites were able to reduce the concentration of planktonic viable Gram-positive bacteria, including multi-drug-resistant *S. aureus*. The antibacterial surface showed a log reduction from 4 to 5 upon contact. Anti-biofouling properties were also assessed using a clinical isolate *S. aureus* UAMS-1. The composite was able to withstand fouling in a model mimicking the physiological environment in chronic wounds and still exerts a log reduction of 2.5, proving the feasibility of an approach fully based on renewable polymers, as well as a suitable alternative to silver and cationic antimicrobials. Human skin fibroblasts proliferated to a larger extent at the surface of the composite than they did at the surface of CNF. Furthermore, only a minor hemolysis (1.8%) was induced by the best-performing composites. Overall surface is likely to be perceived by bacteria as a complex anionic sugar-based polymeric matrix unevenly branched with the compound, where hydrophilic and hydrophobic regions are not clearly separated but instead have a mosaic distribution of polarity; the films reveal an “imperfect amphipathicity.” The negative surfaces and corresponding mosaic distribution of polarity cannot bind so strongly to positively charged groups in proteins and do not solubilize membranes, and this may help to explain why fibroblasts grow well at its surface and why it does not induce significant hemolysis of red blood cells (Hassan et al. 2020).

Bacterial Nanocellulose

Macroscopically, BNC may be regarded as a 3D or two-dimensional material. If the BNC is not dried, hereby defined as never-dried, then it will display a “wet spongy” macroscopic 3D appearance. The same occurs in the case of freeze-dried BNC, an aerogel with a “frosty” appearance. However, if the BNC is dried (independently if it is dried in an oven or at room temperature) due to the evaporation of the water present within BNC nanofibrils, these tend to collapse by forming additional hydrogen bonds, becoming “paper-like” (Fig. 2). The freedom of the nanofibrils to rearrange is drastically reduced, which considerably reduces stretch ability (Anton-Sales et al. 2021). Furthermore, this event is irreversible despite the swelling degrees achieved by dried BNC (approximately 200%) (Padrão et al. 2016). BNC has been

Fig. 2 (a) Dried BNC;
(b) freeze-dried BNC;
(c) never-dried BNC

used in biomedical applications for at least two decades. In particular, BNC was especially effective per se (when never-dried) as a dressing for burn wounds. BNC offered a sterilized, comfortable, protective, and adequately moist environment for clean burn wounds, which accelerated wound healing (Muangman et al. 2011). Furthermore, never-dried BNC is highly moldable, tightly adapting to the wound site. Never-dried BNC is more stretchable; however, it is less resistant to tear than dried BNC (Anton-Sales et al. 2021). One of the most important BNC limitations is its absence of antimicrobial activity, which greatly limits its application as an active wound dressing and other application prone to infection, such as urinary catheters (Zmejkoski et al. 2021). Therefore, several researchers focused on further enhancing the properties and/or adding functions to this outstanding material. However, in specific applications, BNC per se still possesses highly relevant features. Furthermore, another distinguishing feature of BNC is that its macroscopic shape adjusts to the shape of the area where it is being synthesized by the bacteria (in static culture). Therefore, some studies were focused on the design of BNC conduits to be potentially used as blood vessels or catheters. Some of the recent biomedical applications using BNC are present in Table 2.

Tissue Engineering

Angiogenesis is a key feature of biocompatibility, thus the biocompatibility of the BNC was assessed using shell-less hen's egg model. This model allows the evaluation of the gene activation matrix for regenerative processes on a genetic level, as well as the monitor the embryonic angiogenesis of the area vasculosa. Never-dried BNC and rehydrated freeze-dried BNC did not exhibit any occurrence of hemorrhage, vascular lysis, thrombosis, hemolysis, or death during the entire experiment (24 h). Thus, all BNCs demonstrated the high biocompatibility of BNC and gene-activated matrix since all eggs developed a highly vascularized blood vessel system without changes in the chick area vasculosa. In the same study, the high

n.d., not defined.

loading capabilities of BNC were used to evaluate it as a candidate for carrying DNA. BNC loaded with DNA exhibited good and prolonged transfection efficacy without hindering BNC mechanical properties (Pöttinger et al. 2019). Osorio et al. developed 3D BNC extracellular matrix-like scaffolds for tissue engineering and cell regeneration of soft tissues by cultivation of BNC on a mold containing paraffin microspheres that generate interconnected micropores after leaching. The solvent-exchange method using xylene as dewaxing agent for paraffin microspheres was less time consuming and more suitable for preserving BNC crystal size, resulting in scaffolds with regular porosity and good mechanical behavior. Murine fibroblast NIH3T3 cells could adhere and proliferate, without overcrowding, in scaffolds with small pores and highly interconnected surface area. The scaffolds with extra small pores (approximately 60 μm) presented the highest number of cells on the 16th day (Osorio et al. 2019b). In another study, the microporous 3D BNC surface was populated with fibronectin and collagen type produced by a culture of NIH3T3 fibroblasts. Once confluence reached 90%, the cells were lysed by a mechanical-ionic stress cycle. The presence of collagen type I and fibronectin contributed to a stronger cell adhesion and higher mitochondrial activity (Osorio et al. 2019c). Reis et al. immobilized the pentapeptide Iso-Lys-Val-Ala-Val (IKVAV) in never-dried BNC through carbodiimide chemistry. The envisaged objective was to mimic the microenvironment for human melanoma cells (SKMEL-28). In vitro cytotoxicity tests showed that BNC and BNC-IKVAV did not hinder the metabolism of mouse fibroblast (L929) cells after 7 days of culture. Furthermore, IKVAV improved the adhesion, proliferation, and organization of SKMEL-28 cells, allowing a better in vitro model to screen antitumor drugs (Reis et al. 2018). Autier and coworkers developed a BNC membrane that was used as a scaffold applied to the brain parenchyma after resection of a glioblastoma (Autier et al. 2019). Due to its high flexibility and conformability, the BNC scaffold could be easily introduced into the surgical resection cavity of glioblastoma. Furthermore, the random fibrous nature of BNC is ideal for trapping tumor cells, preventing their movement once attached, thus facilitating targeted treatment and avoiding recurrence. The latter is particularly important since glioblastoma is a highly infiltrative tumor, with a recurrence percentage of 90% within centimeters of the surgical resection cavity. Due to BNC visibility on magnetic resonance imaging, stereotactic radiosurgery may be facilitated during targeted treatment. The trapping capacity of BNC membranes was analyzed by SEM that showed that seeded rat brain glial cells (F98) were able to grow with a spheroid morphology on BNC membranes. In addition, by using transwell migration assay it was verified that F98 cells were exclusively located in the vicinity of inset when the BNC membrane was present. This suggests that these cells permeated at the edge of the insert; however, they were not able to permeate through BNC membrane. Magnetic resonance imaging results showed an edema around the BNC implantation within 24 h. This signal decreased after 21 days and was absent after 3 months. The biocompatibility of BNC was shown by the unaffected brain microenvironment after BNC membrane implantation in the brain parenchyma. Furthermore, after 12 months brain cells were present on the BNC membrane, demonstrating the noncytotoxicity of BNC to normal cells (Autier et al.

2019). Ul-Islam et al. dip-coated BNC in chitosan that was then freeze-dried to obtain a scaffold. The cell–scaffold interaction was analyzed using human ovarian cancer cell lines (A2780). Human ovarian cancer cell lines were found on the surface as well as deeply infiltrated into the scaffold matrix. The incorporation of chitosan greatly improved the probability of enhanced biocompatibility of BNC by promoting cell adhesion, proliferation, and differentiation. Regarding the pristine freeze-dried BNC, cell adhesion was observed. Nevertheless, proliferation was clearly hindered, observed by the presence of larger cell aggregates, when compared to the scaffold. The cell aggregates' sizes on BNC and composite scaffolds were 281 and 133 μm , respectively. Moreover, real-time-polymerase chain reaction (RT-PCR) analysis denoted a decreased mRNA level of Notch receptors in BNC chitosan scaffold, indicating a strong cell–scaffold interaction (Ul-Islam et al. 2019). BNC can be used as a corneal bandage and alternative to amniotic membrane whose availability is highly limited and tissue donor dependent. Essential requirements of ocular surface bandage are their easy application and durable suturing. BNC membrane showed higher suture resistance than amniotic membrane offering good conformability to the eye shape. Furthermore, both materials exhibit low visible light absorbance. In vitro and ex vivo-simulated physiological conditions were performed to assess the durability and stability of the BNC membrane. No significant changes in diameter or thickness as inferred by visual observation and superficial mass measurements were detected (Anton-Sales et al. 2020). Zhang et al. studied the biocompatibility of BNC as a scaffold for corneal stroma replacement using rabbit corneal epithelial and stroma cells. In vitro tests showed a nearly 100% survival rate, good adhesion, and proliferation of the epithelial and stroma cells on BNC. In vivo experiments confirmed the adequate biocompatibility and stability of BNC in rabbit cornea. The optical transparency of BNC was maintained, and no obvious edema or inflammation around the BNC was detected over a period of 90 days (Zhang et al. 2020). Printable scaffolds for bone regeneration were prepared through modification of BNC with (i) TEMPO-mediated oxidation and (ii) maleic acid. After each modification, BNC was hybridized with gelatin (Wang et al. 2021). Both modifications generated a significant change in the nanofiber morphology. In particular, the width was reduced (approximately fivefold), which created a looser fiber network. This proved beneficial for the homogeneous dispersions, consequently improving its printability. The mechanical properties and wetting capability of BNC modified with maleic acid proved superior to the TEMPO-oxidized BNC. The osteogenic marker genes expression of mouse osteoblasts (MC3T3-E1) was also much higher for maleic acid BNC, even though both modified BNC dispersions showed good cell viability for pre-osteoblast. In vivo bone regeneration was assessed using the Sprague–Dawley rat defect model, showing that both BNC composite scaffolds were able to form a larger amount of bone in the skull-defect area. Dispersions demonstrated to be noncytotoxic to MC3T3-E1 cells between 10 and 200 $\mu\text{g/mL}^{-1}$, seemingly promoting cellular viability (114–143%) at 100 $\mu\text{g mL}^{-1}$. According to cell differentiation assays, the BNC dispersion showed slight cytotoxicity after 5 days of incubation, resulting in a decrease in cell viability of 5.4%. In contrast, an obvious increase in cell proliferation was observed in TEMPO-oxidized BNC and

maleic acid BNC groups, with increase in cell viability of 33% and 30%, respectively. Similar results were observed with the staining of live and dead cells. Composite scaffolds for bone tissue were fabricated by Noh and co-workers, containing in their composition BNC and collagen (Noh et al. 2019). Different ratios (1:1, 3:1, 5:1) of BNC:collagen were evaluated. The composite containing the highest BNC content displayed the most organized interconnected porous structure, with improved physical stability and water uptake. Mouse fibroblast and human umbilical cord blood-derived mesenchymal stem cell attachment and growth was favored by the increasing concentration of BNC in the scaffolds. This interesting result was attributed to the higher stability provided by the BNC in comparison to the pristine collagen. Hobzova et al. prepared composites comprising BNC and poly (2-hydroxyethyl methacrylate) composite hydrogels, using UV light to perform in situ radical polymerization. The mechanical properties of the scaffolds containing 10 wt% of BNC were improved, presenting an increase in tensile strength and Young's modulus of 80- and 120-fold, respectively. Moreover, composites were nontoxic, providing a favorable environment for mouse mesenchymal stem cell (rMSC) proliferation. The morphology of the cells was not affected, and the number of viable cells after 72 h of BNC and BNC composites was similar to the tissue plate culture (Hobzova et al. 2018). In another work, Silva et al. studied the in vitro interaction between rabbit bone marrow mesenchymal stem cells and BNC for tissue engineering and regenerative medicine. Cells anchored into the BNC matrix in the first 24 h were fully integrated after 14 days. It was also found the multipotentiality of the cells to differentiate into three lineages, chondrogenic, osteogenic, and adipogenic. Moreover, BNC presented a high cellular viability (approximately 94%) and adequate macrophage activation rate (Silva et al. 2018). An additional, bone tissue-based scaffold was developed by Torgbo and Sukyai, containing magnetite (Fe_3O_4) and hydroxyapatite nanoparticles synthesized by in situ co-precipitation on BNC under ultrasounds (Torgbo and Sukyai 2019). The metabolism of mouse fibroblast L929 cells in contact with the freeze-dried composite scaffold and freeze-dried BNC was evaluated. Results showed a cell viability percentage of nearly 85% for pristine BNC and 74% for the composite. The decrease in cell viability of the scaffold could be the result of the restrictive effects of bonding between phosphate and iron ions. Nonetheless, the scaffold presents great potential in promoting osteoconduction and osteointegration of cells. Furthermore, human fibroblast cell (MC3T3-E1) adhesion on the surface of the scaffold was observed using SEM. On the pristine, BNC exhibited few and sparse cells attached on the surface, likely due to the compact structure, and the absence of osteoconductive and osteoinductive factors. On the contrary, the composite presented a completely covered surface with a healthy and subconfluent monolayer of osteoblast cells. The rougher surface and higher microporosity may have eased the transport and permeation of nutrients and oxygen. Urbina et al. took advantage of the hydrophilic nature of BNC to embed waterborne polyurethane within the never-dried BNC matrix through immersion to obtain a shape memory biomedical application. The obtained composite displayed good water-activated shape memory, flexibility, and transparency. The presence of BNC in these composites contributed to increasing the

shape fixity ability and recovery. The recovery was found to be 92.8% and 33.4% after 3 min for the composite and pristine waterborne polyurethane, respectively. Cytotoxicity tests using murine fibroblasts (L929) showed that both BNC and BNC containing waterborne polyurethane did not hinder cell growth and cell adhesion. Cell viability was significantly higher than the established viability threshold of 70% (Urbina et al. 2019). Dydak et al. immersed titanium–aluminum niobium bone scaffold implants into BNC cell cultures. The implants were fully covered by BNC. Subsequently, the antibiotic gentamycin was incorporated by saturation of the BNC. The BNC-coated scaffolds exhibited a considerably lower cytotoxicity against human osteoblasts (U2-OS) and mouse fibroblasts (L929) cell cultures in comparison to noncoated implants. Furthermore, the incorporated gentamicin exhibited a moderate activity against the proliferation of the bone pathogen *S. aureus*. The zone of inhibition (ZoI) ranged between strong to medium antibacterial activity depending on the gentamycin concentration used for the saturation. However, coated and noncoated did not exhibit striking differences in the generated ZoI. The presence of gentamicin may prevent infections, thus accelerating the recovery process (Dydak et al. 2018). The regenerative capacity of BNC implants was evaluated using a standardized bovine cartilage punch model (Horbert et al. 2019). The host cartilage cylinders were derived from the bovine femoral trochlea using a standardized punch system into which BNC implants were inserted. Progressive colonization was observed for the BNC implants, in concomitance to signs of chondrocyte migration, in particular from the surface of the host cartilage. Such results evidence the high cytocompatibility of the BNC implant in the current in vitro model. The initially cell-free BNC implants presented deposition of the matrix proteins collagen type II and aggrecan throughout culture incubation period. This further proved benign cartilage regeneration. The constant aggrecan release and diminished collagen type II release during the culture suggested that the locally synthesized cartilage-specific matrix proteins seemed to be successfully retained in the BNC implants. Therefore, the lack of in vivo biodegradability makes BNC a sustainable scaffold to support cell ingrowth and subsequent remodeling of the joint cartilage.

Wound Dressing

The absence of hemocompatibility rapidly unfolds into a severe immune response by the host. The ex vivo hemocompatibility and short- and long-term in vivo implantation response to (i) never-dried BNC, (ii) freeze-dried BNC, and (iii) dried BNC was investigated by determining hemolysis and clotting times (Osorio et al. 2019a). The interaction between the erythrocytes and never-dried BNC is reduced by the presence of liquid, reducing the hemolysis percentage to acceptable values. Whereas freeze-dried BNC leads to a quick adsorption of red blood cells, which induces friction, consequently weakening the cell membrane, leading to erythrocytes lysis. Dried BNC did not induce any hemolytic behavior due to its highly packed microstructure, which generates a smooth surface and reduces the friction between red

blood cells and the biomaterial. Thrombogenicity analysis showed complete clot formation in dried and freeze-dried BNC after 15 min. Never-dried BNC did not exhibit clot formation even after 45 min. The high concentration of water present within the never-dried BNC fibrils may reduce the deposition of plasma proteins. In vivo assessment of the immune response to never-dried and freeze-dried BNC demonstrated the absence of signs of discomfort, pain, or disease in the mice throughout the entire experiment. The wound healed after the first week, accompanied by new hair growth. Never-dried and freeze-dried BNC retained their shape, with no sign of dehydration nor purulent inflammation or adverse tissue reactions. Furthermore, all samples showed encapsulation by fibrovascular tissue. In conclusion and comparing dried BNC with never-dried and freeze-dried BNC-based materials, the latter exhibited lower immune response in the first week due to the presence of 3D micropores that allowed the free movement of immune cells and consequent homogeneous distribution. However, for never-dried and freeze-dried BNC the inflammation was resolved after 8 weeks, whereas for dried BNC this event only took 4 weeks. This may be the result of the higher surface area that keeps leukocytes active while they are infiltrating inside BNC. Fürsatz et al. crosslinked low-molecular-weight ϵ -poly-L-Lysine, an antimicrobial peptide with renowned antimicrobial activity, in pristine commercial BNC wound dressings and to carboxymethyl cellulose-functionalized BNC using carbodiimide chemistry. The functionalization had no significant effects on the BNC nanofibrous structure nor on the mechanical properties. ϵ -Poly-L-lysine-functionalized BNC exhibited efficient contact inhibition growth of *Staphylococcus epidermidis* and did not generate cytotoxicity. The primary human dermal fibroblasts cells cultured in contact with all samples, pristine BNC, functionalized BNC with ϵ -poly-L-lysine, and BNC functionalized with CMC and ϵ -poly-L-lysine showed a typical elongated morphology with alignment with the cells on their vicinity (Fürsatz et al. 2018). In another work, Khan et al. developed 3D microporous-regenerated BNC and gelatin scaffolds for the regeneration of skin tissues. Gelatin microspheres were used as porogens and to increase the biocompatibility by eliminating the cytotoxic effects of other porogens. In vitro cytotoxicity tests using human keratinocytes (HaCaT) cells showed good adhesion and proliferation in the matrix, penetrating up to 300 μ m in depth. Furthermore, in vivo tests in the dorsal flank skin of mice using the regenerated BNC and gelatin scaffolds showed complete skin regeneration with a wound closure efficacy of 93% after 2 weeks. In comparison, pristine BNC exhibited only 63% of wound closure efficacy with the same period (Khan et al. 2018). BNC was crosslinked with poly([2-(methacryloyloxy)ethyl] trimethylammonium chloride) (PMETAC) to achieve functional translucent material. This cationic BNC composite exhibited ultraviolet UV-A and UV-B blocking properties. Furthermore, its antifungal properties were evaluated and they exhibited a moderate disinfectant property against *Candida albicans*. The composite cytotoxicity, using human keratinocytes (HaCaT), proved to be dose dependent relatively to its PMETAC content. BNC containing 10 wt% and 40 wt% of crosslinked PMETAC reduced cell viability to $81.4 \pm 2.1\%$ and $72.4 \pm 3.1\%$, respectively. Nevertheless, the accepted threshold for cell viability in biomedical applications is 70%, thus the

BNC-PMETAC composites display a promising potential as a noncytotoxic, nearly transparent, UV-protective, and antifungal application (Vilela et al. 2019). This application is highly promising for see-through diabetic wound dressings.

Indwelling Devices

The potential of BNC conduits as blood vessels was studied by Bao et al. using different designs of bioreactors. As the first approach, the vessels were prepared by placing a single silicone tube inside a hollow glass tube. The cavity between the two was then filled with culture medium containing the bacteria. This method presented lower BNC content, which decreased the mechanical properties. A second strategy was using a similar design, with the sole substitution of the hollow glass tube by another made of silicon, which improved oxygen permeability. The third approach encompassed a glass rod placed inside the hollow silicon tube. These last two bioreactors produced thicker conduits with improved mechanical properties suitable for artificial blood vessel applications. However, still not comparable with expanded polytetrafluoroethylene (ePTFE). Nonetheless, the BNC conduits possessed adequate water permeability, percentage of platelet adhesion, plasma recalcification period, and pig iliac endothelial cells (PIEC) proliferation. Such results suggest better exchange of nutrients, hemocompatibility, and endothelialization after implantation (Bao et al. 2020). Weber et al. designed BNC-layered tubes with reduced wall thickness and smooth surface for small vascular grafts that were tested in vivo by replacing the right carotid artery in sheep. Results showed no delamination in the organism, even after months of implantation. Moreover, histological analysis showed no acute signs of foreign body reaction. However, the tubes were prone to thrombotic occlusion, requiring the administration of antiplatelet drug to lower the occlusion phenomena. Despite the drug therapy, the patency increased from 67% to 80% in a 9-month period (Weber et al. 2018). BNC conduits were biosynthesized in a bioreactor composed of a glass rod and an internal silicon tube. After being collected, purified, and mildly dehydrated using filter paper, chitosan was injected into its internal cavity. Chitosan nanoparticles were synthesized within the BNC fibrils via ionic gelation method. The mechanical properties and matrix structure of never-dried BNC were retained. Furthermore, composites depicted strong decontaminant antibacterial activity against *S. aureus* and *E. coli*. Furthermore, the composites were able to promote the adhesion and proliferation of Schwann cells and demonstrated good biocompatibility after subcutaneous implantation in rats. In fact, all tested samples exhibited absence of cytotoxicity and biocompatibility, including pristine BNC. Despite the occurrence of Schwann cell proliferation after 5-day incubation on all surfaces, the number of cells on the composite containing the highest concentration of chitosan nanoparticles was significantly less, which indicates that the material was not as conducive to cell proliferation in comparison to all the other tested samples. These results suggest that excessive chitosan nanoparticle concentrations have a cytolytic effect. Accordingly, the obtained results suggest that an adequate concentration of chitosan nanoparticles could prevent the potential

cytolytic and cell inhibitory effect due to excessive amounts of cationic chitosan nanoparticles, while maintaining the efficient antibacterial activities. Histological staining of pristine BNC and an intermediate concentration of chitosan nanoparticles (0.5%) confirmed the good biocompatibility of these materials. The staining demonstrated the absence of inflammatory response after implantation with fibroblasts attached to the surfaces of BNC and the composite. Masson staining showed a large number of collagen fibers formed around the material, demonstrating tissue integration (Wei et al. 2021). BNC's potential as an indwelling device, namely, as reinforcement meshes, was also analyzed. In soft-tissue repair materials, it is important to have implants with antiadhesive characteristics to minimize complications caused by intraperitoneal adhesions. Anton-Sales et al. developed an antiadherent reinforcement material to support hernia soft tissues by combining BNC with standard polypropylene (PP) meshes. First, the authors confirmed the suitability of double-layer BNC for abdominal wall reinforcement regarding mechanical properties (tear strength $>16 \text{ N cm}^{-1}$). Then, a hybrid material was developed by integrating PP meshes between the BNC layers and the antiadhesion properties of BNC with an in vivo rabbit model following the implantation process were evaluated. The results showed a general good integration to the abdominal wall. Histological analysis showed an inflammatory response in the peri-implanted area presenting fibroplasia and infiltration of diverse cell types, such as macrophages, lymphocytes, and heterophilic granulocytes, among others. Nevertheless, the antiadherent properties were clearly proved, underscoring its applicability in hernia repair solutions. The only identified issue was its suboptimal mechanical behavior, which may be surpassed by stacking dried BNC membranes or by the development of novel composites (Anton-Sales et al. 2021). A similar approach was performed by Ludwicka et al. The obtained PP mesh coated with never-dried BNC did not negatively influence the mechanical properties of the commercial PP mesh, and it envisioned less immunogenic reaction toward the composite by lowering mast cells adhesion and degranulation. PP mesh, pristine never-dried BNC, and the composite exhibited significantly less rat basophilic leukemia mast cells (RBL-2H3) cell adhesion in comparison to TCP (roughly threefold less). Regarding mastocyte degranulation level (percentage of N-acetyl- β -d-hexosaminidase (HEX)), it was reduced from approximately 32% in PP mesh to 19% in the PP coated with BNC composite. However, the degranulation in pristine BNC was slightly lower (Ludwicka et al. 2019). Therefore, the role of BNC in suppressing mast cell degranulation is clear. Mast cells are present in all smooth muscles; therefore, they will be in contact with all indwelling devices. Mast cells degranulate once they are activated, releasing a plethora of inflammatory mediators present in their up to 200 granules in each cell. These mediators are able to promptly unfold into a violent immunological response (Krystel-Whittemore et al. 2016). In the study carried out by Zharikov et al., never-dried BNC membranes were implanted in the abdominal wall of dogs to study its efficiency in hernia repair. The antiadhesive behavior of BNC was compared with a commercial PP mesh. After 14 days of implantation, a capsule of loose connective tissue around the BNC was observed, exhibiting good fixation to the anterior abdominal wall, and negligible adhesions between the BNC

membrane and the underlying tissues. Although some moderate inflammatory infiltration was occurring due to the accumulation of cell elements at the interface of BNC and the abdominal wall tissues. After 2 months, the host formed novel and stable connective tissue and angiogenesis were observed. Furthermore, negligible intraperitoneal adhesions between the intestinal loops and the BNC membrane were detected. Within this period, the commercial PP mesh-based grafts where coarser and scar structures were observed denoting the superior biocompatibility of BNC (Zharikov et al. 2018).

Conclusion

Nanocellulose clearly exhibits an enormous potential for the development of innovative and highly efficient biomedical applications. The fields covered by nanocellulose applications encompass scaffolds for tissue regeneration, enwalling devices, drug carriers, antimicrobial patches, among others. Interestingly, these properties are intertwined in a single device through modification and composite development. This is due to remarkable eclectic properties of nanocellulose, which virtually allow the stacking of functions and properties within a single use. CNC and CNF, the most emerging technologies, are focused on their use in producing ESNC, WSNC, and as printable applications. Printable applications allow the tailoring of macroscopic structures that possess the advantageous nanoproperties of CNC and CNF. BNCs' plethora of biomedical applications has highlighted that, despite all functionalizations and modifications, pristine BNC per se sometimes denotes an unmatched biocompatibility. In particular, never-dried BNC seems to have the most biocompatibility and hemocompatibility features in comparison to all nanocelluloses. Its use as a coating of materials, generated during bacteria culture, is a promising strategy for the development of superior biomedical applications.

Abstract

Cellulose in its nanostructuric form gained great attention among many researchers owing to the natural abundance, high aspect ratio, ease of surface functionalization, biocompatibility, and better mechanical and chemical properties. NC is recognized for its remarkable inherent properties like chemical inertness, amphilic nature, mechanical strength, high stiffness, and low density extends its application toward many electrochemical fields. Nanocellulose is used as a structural component in many electrochemical sensors due to the large number of hydroxyl groups on the surface, which can be structurally modify in order to tune the chemical and physical properties suitable for sensor applications. This chapter describes the features of nanocellulose, methods for structural modification, application as a structural component, etc., relevant to sensing applications. A detailed description on use of NC for application like electrochemical sensing including biosensors, molecular sensors, and gas sensors are included.

Keywords

Nanocellulose · Surface functionalization · Electrochemical sensing · Biosensing

Introduction

Nanocellulose (NC) is one of the most fascinating biomaterials present abundantly in nature. The main natural resources of NC are wood, blast fibers, marine animals, algae, bacteria, and invertebrates, extracted either by chemical, mechanical, or enzymatic methods. It is considered as a green sustainable substitute for the existing ever depleting petroleum-based material, currently prevailed in commercial and industrial applications due to its natural abundance and biodegradable nature. Other contributing factors of NC are the chemical inertness, excellent stiffness, low density, and plenty of surface functional groups present on the surface make NC a versatile material for many research applications. Consequently, NC is used in a variety of fields such as biomedical applications, energy sector, electrochemical sensors, and in reinforced plastics. Altogether NC is considered to be a futuristic material with lots of research potential and is in the pipeline in order to be implemented as a green sustainable material.

One of the interesting properties of NC is the presence of highly susceptible hydroxy groups present on the surface facilitating the tuning of physical and chemical properties. Also, the high aspect ratio (surface to volume ratio) of NC increases the scope of this material to be used as a substitute for many other synthetic nano-substrates. The process of surface functionalization is now turned out to be one of the best methods to tune the physical electronic and chemical properties to fit into desirable applications like sensors (Nguyen et al. 2019), biomedical applications (Jorfi and Foster 2015), drug delivery (Hasan et al. 2020),

etc. NC has hydroxyl groups enriched on its surface, making it a hydrophilic surface. Indeed this helps the researchers to tune the properties of NC through chemical (Habibi 2014), physical (Islam et al. 2013), and biological modifications (Heise et al. 2021) with suitable molecular receptors and catalysts. The role of selected functional moieties used to modify are transduction with specific analyte molecules. The surface modification can be done either by post functionalization or in situ functionalization. Also, the surface functionalization is a state-of-the-art technique to endow surface with appropriate charges like positive or negative charge so as to facilitate the physical absorption of foreign reactive molecules. Surface functionalization not only helps tuning of structural and chemical properties but also provides a uniform distribution of surface active agents, maximizing the analyte signal transduction property. Due to these properties, NC is considered to be the most suitable natural material for electrochemical sensors as it is biodegradable, renewable, and causes no incompatibility issues with biological systems.

Nanocellulose as a Structural Component in Electrochemical Sensors

In addition to plenty of hydroxyl groups on its surface, nanocellulose has high surface to volume ratio, which makes nanocellulose as a suitable material for electrochemical applications. In addition to this, the natural abundance and biodegradability increases the scope of this material to use in many electronic applications.

Surface functionalization is one of the key strategies to tune the electrochemical property of any desirable material for electrochemical applications. The surface hydroxyl groups present on NC is the best to subject to either post chemical functionalization, biological, or physical modifications using appropriate molecular receptors (Du et al. 2017). Many scientists have worked toward the development of NC as a base material for construction of electrochemical molecular and biosensors. The main component of an electrochemical sensor is a modified electrode as the working electrode, which interacts with the analyte, transducing the signal to a read out. The electrode architecture of a sensor consists of a series of layers called electrode base, active material, and receptors built using appropriate materials. A pictorial representation of the working electrode on the hierarchical pattern is represented in Fig. 1.

Fig. 1 Pictorial representation of electrode architecture of an electrochemical sensor

NC has been used as an active material for the preparation of electrode for electrochemical sensing. The primary reactive site is the hydroxyl group present on the surface and this will help to form a uniform distribution of the functional receptors. This is unlike the other nanostructures like carbon nanotubes or graphene used in many electrochemical sensors which possess the reactive functional groups on the periphery rather than in the middle. Another advantage of surface functionalization is the increase in the dispersion ability of the functionalized nanocellulose in hydrophobic media, enhancing the signal transduction property. Also, it reported to significantly improve the tensile and share properties of the composites (Lu et al. 2019). The surface of nanocellulose can be modified using many chemical receptors. These methods of modification involve sulfonation (Xu et al. 2020), covalent chemical modification, and polymer grafting ester modification, silylation, substitution with nucleophiles, carbamation, and oxidation (Horta-Velázquez and Morales-Narváez 2022). Another advantage of using nanocellulose is its ability to prevent aggregation or agglomeration as it is reported by Park et al (2013). Graphene is one of the widely used components in electrochemical sensors subjected to aggregation in hydrophobic media. Nanocellulose is used as a dispersion media to prevent agglomeration to stay graphene apart so as to enhance the transduction ability and signal strength. Nanocellulose can used to form a transducer surface in different forms, composites, membranes and films, form convinces the transduction ability (Edwards et al. 2016a; Ling et al. 2019). This will ensure a high catalyst loading, endow superior sensitivity, and selectivity. Also the formation of porous structures like hydrogel, aerogel, or sponge provides an additional improvement in surface area imparting excellent catalytic activity toward analytes (Bonné et al. 1985). Depending upon the source of the nanocellulose, the quality of the nanocellulose also varies. There are reports telling nanocellulose extracted from bacteria possess a 3D network structure with high degree of polymerization and crystallinity (Korhonen et al. 2011). This structure possesses a 3D network of cellulose fiber and imparts additional improvement in surface area in comparison to that of any other nanocellulose. This 3D structure caters as a structural material, as a carrier for a high amount of nanoparticles than any other nanocellulose synthesized from other conditions.

Methods of Surface Modification

The research of functional nanostructured materials has been a renowned subject of study because they have significantly improved features and qualities, allowing these high-value-added substrates to be used in materials science. The NC has a hydrophilic surface which prevents the usage of it in hydrophilic or polar media. The surface of NC which is hydrophilic in nature owing to the presence of hydroxyl (-OH) groups can be easily modified by physical, chemical, and biological processes. The surface modification of NC would increase all the properties such as tensile strength and tensile modulus which makes it a competent and innovative material for variety of applications.

Chemical Modification of NC

The surface modification can be achieved during preparation or post-preparation. There are many methods used for the functionalization of NC, Lin et al. (2012) stated surface modification of polysaccharide nanocrystals can result in polymeric matrices with improved thermal and mechanical capabilities. The cellulose nanofibers are highly reactive and can be readily functionalized using the hydroxyl groups present. Sulfonation, esterification, etherification, carbamination, polymer grafting, oxidation, nucleophilic substitution, TEMPO mediated oxidation, urethanization, amidation, silylation, and click chemistry are some of the chemical processes which can be employed to modify the surface of cellulose nanocrystals. A schematic representation of the chemical functionalization route with reaction conditions is represented (Fig. 2).

Pendant surface hydroxyl groups, typically the primary alcohol group (CH_2OH), are used to chemically modify the surface of cellulose nanoparticles. On nanocellulosic materials, various chemical modification strategies were used to (1) enhance the effectiveness of the separation process and (2) alter hydrophobicity of the surface, which enhances the dispersibility and compatibility of nanocelluloses in certain solvents. The partial functionalization of the surface of nanocellulose produced by sulfuric and phosphoric acid hydrolysis results in sulfate or phosphate esters. The charge which is required for aqueous dispersion and isolation operations are

Fig. 2 Showing the ways of chemical modification

introduced in this way. Phosphorylation, carboxymethylation, oxidation, and sulfonation processes have all been used to introduce ionic charge to the cellulose surface.

Lu et al. (2019) studied hydroxyapatite modified nanocellulose with polylactic acid (PLA) as in the matrix in order to overcome the inbuilt hydrophobicity of polylactic acid. According to the findings, the hydroxyapatite used modified nanocellulose which shows enhancement in the mechanical properties of poly lactic acid-based nanocomposite films by causing strong hydrogen bonding interactions at the surface, resulting in comparatively good dispersion in the polylactic acid composite. As a result of the surface modification, the tensile strength, Young's modulus, and thermal stability of the nanocomposite are increased which indicate that the hydroxyapatite-modified nanocellulose is a good PLA reinforcing material. Along with the chemical modifications there are certain physical methods to modify the surface of nanocellulose. Electric discharge or plasma treatment, ultrasonic treatment, irradiation (Pakharenko et al. 2016), and surface fibrillation (Wakabayashi et al. 2020) are some of the physical surface functionalization procedures employed by the researchers (Fig. 3).

For a variety of applications, click chemistry allows the synthesis of (bio)chemically active cellulose surfaces (Benkaddour et al. 2013). In addition, an interesting research shows how to make 2D crystalline cellulose oligomers containing surface-reactive azide groups utilizing click chemistry and an enzymatic reaction. The enzymatic method is helpful for the long-term production of cellulose oligomers in aqueous as well as in mild conditions, and is commonly accomplished by the process of glycosylation involving cellulose and cellodextrin phosphorylase. The merits of the reaction includes high yield and good functionalization.

Biochemical Modification of NC

Enzymes are also used for the surface modification of nanocellulose, and it is of two types: direct and indirect methods. Two of the most prominent types of enzymes are hydrolases and oxidoreductases. Examples for the hydrolase (Afrin and Karim 2017)

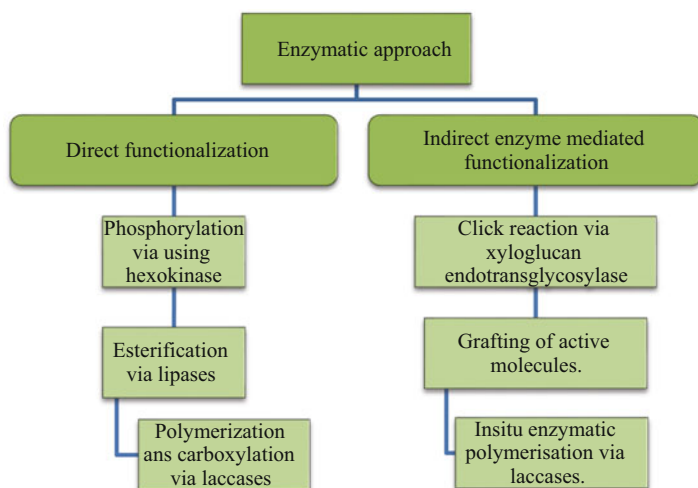

Fig. 3 Representative diagram showing the physical methods of modification of NC surface

enzymes includes glycosidases, lipases, and proteases that are commonly utilized, whereas oxidoreductases (Karim et al. 2017) include laccase, peroxidase, and tyrosinase that are commonly used. The enzymatically functionalized nanocellulosic materials have a considerable advantage over chemically functionalized materials since they prevent the toxicity of the transformed product so they can be used effectively in biomedical applications. Lipases, the most extensively employed class of enzymes for catalytic reactions, have been effectively exploited for stereoselective and regioselective acetylation (Mahapatro et al. 2006) of a variety of compounds, including cellulose. The high specificity of enzymes will soft the reaction conditions, and provide a non-destructive transformations of polymers. The enzyme modification of the polymer is safer and more advantageous than chemical techniques. Enzyme retting, for example, is able to solve the issues connected with dew and water retting since the fibers are treated in a carefully controlled environment and the fibers thus generated have the same quality as water-retted fibers and without large amounts of fermentation waste.

Some of the reports on enzymatic functionalization tells that nanocellulose was modified by oxidation with the help of the dehydrogenase enzyme (Lin and Dufresne 2014). Nanocomposites of nanocellulose/polypyrrole is used and due to the huge effective surface area of the composites generate large catalytic oxidation currents and enable charge storage. Again the enzyme galactose oxidase is used to perform direct oxidation of nanocellulose (Liu and Chen 2016) followed by selective carboxylation, yielding galacturonic acid derivatives with high conversion and yield.

Enzymatic polymerization of synthetic and natural materials onto substrate is environmentally acceptable as the synthetic process demonstrate the value of “green polymer chemistry.” It also benefits milder reaction conditions such as temperature, pressure, and pH without the usage of harmful chemicals. Enzymatic grafting onto NC is practiced to graft active compounds onto the surface of nanocelluloses. The process is divided into two categories: grafting onto it and grafting from. The

grafting-onto approach includes attaching synthesized chains to reactive cellulose hydroxyl end groups. For example, Akhlaghi and Najafpour-Darzi (2020), looked at the susceptibility of the corresponding bacterial nanocellulose fibers as a reinforcement agent in cement composites. It is observed that the resultant BNCs cement mortars have enhanced mechanical properties. Alternatively, the grafting techniques are used to boost the concentration of the active material on the surface and to ensure its stability for various applications. The interactions arise between nanocellulose and active molecule surface are physical, chemical or covalent interactions, are all necessary to immobilize active molecules onto the nano cellulose surface. The most serious issue with chemical grafting of active molecules particularly bioactive compounds is the uncontrolled linkage between nanocellulose and active molecules, which can result in protein attachment at a position that changes its structure, stability, or bioactivity. This will alter the course of the selectivity of the corresponding enzymes toward the substrate. Therefor an efficient and orthogonal strategy to overcome these limitations during transformation is to use enzyme-mediated grafting/immobilization. It also doesn't require any organic solvents and occurs under physiological settings. It could be used on a wide range of functional proteins because it is site-directed and regiospecific. Additionally, a chemo-enzymatic method for, for instance, grafting onto the surface of protein immobilization was created using the enzyme transpeptidase (Parikka et al. 2012), from Gram-positive bacteria, which is employed to covalently attach proteins to peptidoglycan layers. This enzyme requires two brief recognition sequences for ligation and creates a native amide bond. Enzymes are used in the production process to further functionalize nanocellulose, which makes it more environmentally friendly and widely accepted in both small-scale and industrial settings. They also appear to be less expensive than chemical processes due to their high enzymatic hydrolysis efficiency, which boosts manufacturing yield, low energy consumption, and relatively high power of penetration, which refers to their capacity to adsorb or cover the interior surface of biomass resources. As a result, using an enzymatic technique for the creation and modification of nanocellulose has numerous advantages over using a chemical approach.

Source of cellulose	Nano-cellulose type	Synthesis method of nano cellulose	Strategies for the surface modification	Properties enhanced	Application
Dry eucalyptus lap wood pulp	CNC	H ₂ SO ₄ hydrolysis	Using methylated canola oil fatty acids for transesterification ester	Improves higher thermal stability and hydrophobicity	Used to create hydrophobic coatings and nanocomposites with hydrophobic polymer as reinforcement (Wei et al. 2017)
From softwood pulp	CNF	Oxidation mediated by TEMPO method	Cetyltrimethylammonium grafting as a surfactant and bromide	The polymer has improved thermostability and hydrophobicity	It helps to improve the redispersibility of the TEMPO-oxidized nanocellulosic fibers in N, N-dimethylformamide (Qu et al. 2019)

(continued)

Source of cellulose	Nano-cellulose type	Synthesis method of nano cellulose	Strategies for the surface modification	Properties enhanced	Application
Sugarcane bagasse	CNC	H ₂ SO ₄ hydrolysis	The functionalization of CNC was done using adipic acid	Thermodynamic wetting and improved dispersion	Used as a reinforcement for the hydrophobic polymer matrices (Ferreira et al. 2018)
Softwood sulfite fibers	CNF	Grinding	Followed by sonication in the presence of lactic acid	Enhanced mechanical properties and the water draining	Applied as a performance-enhancement additive in traditional papermaking industry (Sethi et al. 2018)
Blue agave bagasse (A tequilana)	CNF	Homogenization is done at high pressure	Using 3-aminopropyl triethoxysilane to silane	Mechanical and hydrophobic properties were improved	Adding agent to PLA to create reinforced composites (Robles et al. 2015)
Blue agave bagasse (A tequilana)	CNC	H ₂ SO ₄ hydrolysis	Esterification with dodecanoyl chloride	The hydrophobicity and thermal stability enhances	Used as additives to strength various composites
Aspen Kraft pulp	CNC	H ₂ SO ₄ hydrolysis	Oxidizing CNC with sodium periodate and then immobilizing it covalently with black wattle tannin	Increased metal adsorption capability and improved regeneration and reusability	It can be used as novel nanocomposites to eliminate contaminants from industrial effluents (Xu et al. 2017)

Another aspect is NC can act as a template for the fabrication of sensing materials. The advantage of NC over any other conventional template molecule is its ability to cast its chiral nematic liquid crystal pattern to inorganic solids for a variety of photonic applications. In this method, NC is used as a template for inducing its structural features into matrix by post incineration.

Nanocellulose as a Structural Component in Sensors

NC is very unique toward construction of sensors owing to the superior mechanical, optical, thermal, and structural properties. The structural aspects like high surface area, high aspect ratio, and large specific properties are beneficial for construction of sensor devices. Also the functional groups on surface is succceptable for receptor functionalization improves the possibilities of using NC for variety of sensor application. Surface functionalization is a way to tune the physical and chemical properties in such a way that the analyte specifically interact with the NC substrate thereby improving the sensitivity. There are many kinds of electrochemical sensors, some of them are discussed with few examples.

Biosensor

A biosensor is an integrated system of transducer-receptor which has a physiochemical detector for sensing biological analytes. The immobilized matrix of biosensors has a substantial impact on sensing performance which helps in biorecognition units like enzymes, antibodies, cell receptors, or organelles. These sensors' tiny size, low cost, and ease of use make them perfect point-of-care diagnostic instruments. The transducer surface of the biosensor surface has a major impact on the sensing and detection limit of the biosensor. Based on the structural resilience, compatibility, and hydrophilicity of the nanocellulose, it is an ideal material to use as a structural component in biosensor.

Glucose Sensor

The need for glucose control in diabetic patients has been long recognized. This monitoring helps to reduce the risk of complications of acute diabetes, nephropathy, neuropathy, and microvascular complication of retinopathy. The 1-D nanocellulose-based sensor can be used to enhance glucose-sensing due to its active surface properties. Because of its high surface area, unique particle size, and pore shape, nanocellulose is an excellent organic support material for enzyme immobilization. The enzyme immobilization was done using glucose oxidase, peroxidase, and o-dianisidine (Cha et al. 2012) makes up the sensing system. The detection of glucose in serum and cell culture can be done by visual and nonenzymatic assay. Uddin et al. (2019) demonstrate the use of nanocellulose for enzyme immobilization in glucose detection in the disposable microfluidic sensor. In the microfluidic sensor, the nanocellulose create a storage for glucose oxidase and also act as microfluidic channel. The NC is also used as a support for non-enzymatic sensors. Liu et al. (2016) synthesized silver nanoparticles (AgNPs) with CNC as a substrate. The obtained AgNPs-CNCs are superior to the commercial ones, as they have lower minimal inhibitory concentration in the presence of CNC due to the dispersion of the nanoparticles. The following table describes the sensing techniques employed for sensing glucose along with its LOD, specificity, and the role of NC.

Nanocellulose category	Sensing technique	Role of nanocellulose	Detection limit	Reference
CNC	Colorimetric	Substrate/dispersant	0.116×10^{-6} M	Wang et al. (2016)
CNF	Colorimetric	Substrate	100×10^{-6} M	Liu et al. (2011)
CNC	Calorimetric	Substrate	1.5 mM	Neubauerova et al. (2020)

Cholesterol Sensor

Cholesterol is the most common sterol synthesized by most human cells; works as a precursor for the manufacture of steroid hormones, vitamin D, and bile acids; and is a vital component of cell membranes. High levels of cholesterol can lead to cardiovascular illnesses, heart attacks, strokes, peripheral arterial disease, and type 2 diabetes. The 1-D nanocellulose supported sensor is a self-powered novel cholesterol sensor. CNC is the perfect substance for enzyme loading of cholesterol oxidase (ChOx) and fabricating chloesterol sensor. Nanocellulose chemically modified with zinc oxide nanoparticles along with silylated graphene oxide and cholesterol (Anirudhan and Deepa 2018) shows good conducting characteristics. Limit of detection (LOD) values were 7.4 mol/L over a detection range of 5.18 mol/L to 25.9 mol/L. The ideal pH and response time were discovered to be 7.4 and 10 min, respectively. With a LOD value of 0.0986 mmol/L, DPV analysis showed strong linearity throughout the 0.6475–10.360 mmol/L range for cholesterol sensing. Again, it is reported that the in situ generated polyaniline (PANI) on CNC by the oxidative polymerization process is a suitable material for enzyme loading and improved conductivity. Abdi et al. (2019) also synthesized a cholesterol biosensor with polyaniline/CNC/ionic liquid to modify screen-printed electrodes. The cholesterol biosensor was fabricated by immobilizing cholesterol oxidase (ChOx) on the modified electrode. Some of the recent results are summarized in the following table.

Nanocellulose category	Sensing technique	Role of nanocellulose	Detection limit	Reference
CNC	Voltametric	Matrix/carrier	7.4×10^{-6} m	Anirudhan and Deepa (2018)
CNC	Voltametric	Matrix	0.48×10^{-6} m	Abdi et al. (2019)
CMNC	Voltametric	Matrix/carrier	7.43 μ mol/L	Anirudhan and Deepa (2018)

Human Neutrophil Elastase (HNE) Sensor

Studying the changes in the wound nature can enhance patient care pathways and clinical results considerably. The chronic wound biofluid contains proteolytic enzymes, chemokines, growth factors, electrolytes, and cytokines. Proteolytic enzymes, such as serine proteases (HNE), are suitable biomarkers because they reflect wound healing progress. The HNE sensor is a promising biomarker for inflammatory disorders. Nanocellulose of dimensions 1-D, 2-D, and aerogels performs as a substrate and matrix for the transducer in HNE sensor. The one-dimensional CNC is used to make a colorimetric sensor (Ligi et al. 2016) where the cotton-derived CNC is conjugated with tripeptide (Ligi et al. 2016). This glycine esterified CNC is covalently attached to HNE tripeptide *n*-succinyl-alanine–alanine-

valine-paranitroanilide (Suc-Ala-Ala-Val-pNA) shows higher HNE activity than CNC/peptide conjugate is supported on paper. Ling et al. (2019) produced 1D-nano-cellulose-based colorimetric biosensors, cotton derived nanocellulose to device peptide-cellulose conjugate HNE protease sensor. The higher degree of sensitivity and substitution of CNC compared to 2,2,6,6-tetramethylpiperidine-1-oxyl (TEMPO)-oxidized wood cellulose nanofibrils, which results in larger crystalline size and higher crystallinity gives an advantage of increased accessibility for peptide interaction and tetrapeptide immobilization on cellulose crystals.

Fontenot et al. (2017) developed a biosensor for the detection of HNE in chronic wound fluid using CNC and fluorescent elastase tripeptide or tetrapeptide. Due to the CNCs' great specific surface area, which enables for the loading of significant amounts of elastase peptide, their sensitivity can reach 0.5 U/mL. HNE et al. (Fontenot et al. 2017) developed a fluorescence sensor using peptide coupled cellulose and nanocellulose. Compared to matrices of cellulose, the nanocellulose has a higher sensitivity than their peers in detecting HNE, due to the increased specific surface area of CNC films and therefore CNC peptide products. The 3D nano cellulose structures are employed with an enhanced sensitivity. Edwards et al. reported the development of a protease detection sensor using aerogels made up of peptide and nano cellulosic. The C6 hydroxyl groups in the nano cellulosic aerogels were first esterified with a glycidyl-fluorenyl methyloxycarbonyl group, followed by the deprotection and coupling of tripeptides with immobilized glycine. The results are promising with a detection limit of 0.13 units per mL. Some of the similar examples are listed in the following table.

Nanocellulose category	Sensing technique	Role of nanocellulose	Detection limit U mL ⁻¹	Reference
1D-CNC	Colorimetry	Matrix	0.05	Edwards et al. (2013)
1DCNC	Colorimetry	Substrate	0.005	Ling et al. (2019)

2D-CNC	Fluorometry	Matrix	0.015	Fontenot et al. (2017)
Aerogels	Fluorometry	Matrix	0.13	Fontenot et al. (2016)

Human Serum Albumin (HAS) Sensor

Human serum albumin is one of the essential macromolecule in the plasma of human blood. Abnormal HSA levels have been linked to multiple myeloma, nephropathy, coronary heart disease, diabetics, nephropathy, liver cirrhosis, and other conditions. As a result, accurate and quantitative detection of HAS in biological science, molecular biology, clinical medicine, and other domains has enormous research and practical value. Naghdi et al. (2019) synthesized curcumin embedded bacterial cellulose nanopaper (CEBC) by simply soaking bacterial cellulose (BC) nanopaper in curcumin solution and drying it at 100 °C. The hydrophobic wall is created by printing a toner layer onto the dried film of CEBC which is used as nano paper-based

analytical device (NAD)-CEBC. The BC nano paper is a proper platform owing to its transparency, flexible, porous, biodegradable, and printable for the analytical device. The key strategy is, the various inhibitory effect of curcumin degradation by HAS in alkaline solution results in color change and this change in color can be monitored spectroscopically or visually. The results, which were compared to those from the industry-standard Bromocresol Green (BCG) Albumin Assay Kit, were consistent.

CNC	Colorimetric	Matrix	5×10^{-6} M	Edwards et al. (2016b)
CEBC	Voltametric	Matrix	200 mM	Naghdi et al. (2019)

Purines (Adenine and Guanine) Sensor

The essential components of both ribonucleic acid (RNA) and deoxyribonucleic acid are guanine and adenine (DNA). To understand the DNA sequence, protein metabolism in cells, oxidative damage, and hybridization sensitivity, and selective detection of adenine and guanine are required. These nitrogen bases hinder the direct electron transfer as well as induce irreversible adsorption on standard electrode surface tendering low repeatability and sensitivity, making it difficult to acquire enough sensing signals. In an effort to overcome these restrictions and provide things like a wide potential window, strong electrocatalytic activity, and antifouling property, many materials have been employed to improve electrodes. For fabricating a thin film for electrochemical activity, a new composite employing NC and SWCNH with the intention of creating a thin film for electrochemical uses. It is anticipated that this substance will have highly desirable antifouling and catalytic qualities for electroanalysis. Ortolani et al. (2019) proposed an electrochemical sensor for sensing guanine and adenine based on CNC and single-walled carbon nanotubes (SWCNH).

Bio-Thiol Sensor

Cysteamine, Cysteine, and glutathione are bio-thiols present in the biological system. For differentiating biothiols in human plasma, the sensor work by visual discrimination mechanism mainly by fluorometric technique. Abbasi-Moayed

et al. (2018) refined a ratio metric fluorescence (RF) sensor array for the selective visual sensing of the biothiol. This sensor was made with N-Acetyl L-Cysteine capped green CdTe quantum dots, Red CdTe QDs-CDs, and Rhodamine B (GQDs-RhB) (RQDs-CDs) on BC nanopaper as radiofrequency sensing elements. Thiol sensor as-prepared is capable of separate biothiols as well as their rapid/accurate identification plasma from humans.

BC	Fluorometric	Matrix	300 μ M	Abbasi-Moayed et al. (2018)

Bacteria Sensor

Bacteria Sensor gives a quick diagnosis of bacteria that can be used right at the point of care. The 3D porous structure of CNC facilitates dense and uniform adsorption of plasma nanostructures. Tian et al. (2016) used BC as a flexible SERS substrate. BC has a substantially reduced surface roughness than typical filter paper, ensuring high SERS activity uniformity throughout the entire substrate. This resulted in SERS signal enhancement than the plasmonic paper. So, the 3D BC-based SERSs can be used to recognize and detect bacteria such as *Escherichia coli* (*E. coli*).

Chemical Sensor

Ion-Selective Sensor

Ions are crucial because they can be used in a variety of disciplines, including clinical toxicology, the food industry, waste treatment, and environmental standards. Ion-selective sensors are often less expensive and easier to use than existing instrumental analyses like AAS, ICP, etc. Ion-selective sensors must be designed with adequate sensitivity, selectivity, stability, and adaptability with aquatic environments in mind. Nanocellulose-based films can improve sensor stability, reusability, and recyclability, as well as the morphology and optical

characteristics. Lee et al. (2007) during the study of fluorescence emission of pyrene observed that the fluorescence emission increased when modified with CNC, as a result of excimers formation. Based on this observation, he designed a sensor that shows high selectivity for Fe^{3+} with particular discrimination between Fe^{2+} and Fe^{3+} . In a novel fluorescence-based sensor, electrostatic adsorption and/or covalent bonding are effective ways to bind fluorescent compounds to nanocellulose. Rajawat et al. (2013) used anodic stripping voltammetry to construct a sensor for determination of cadmium and lead ion in water samples, for which a carbon paste electrode (CPE) was effectively constructed on the CNF. At an accumulated duration of 10 min, the detection limits for lead and cadmium are 33 and 88 g L^{-1} , respectively, which is attributable to CNF's good metal ion adsorption ability due to the presence of functional groups (carboxylate, hydroxyl, and aldehyde groups). Weishaupt et al. (2017) used cyanobacterial C-phycocyanin (CPC) as the sensing biomolecule inserted in TEMPO-oxidized CNF as the matrix to create a sensor to detect copper ions. Here, the amount is based on copper concentration on CPC fluorescence emission. Because of their consistent morphological and optical properties, the CNF-containing CySense films were made efficiently and may be examined using a variety of techniques, including fluorescence spectrometry. Pouzesh et al. (2019) constructed a plasmonic sensor for optical sensing of cyanide (CN) ion by embedding copper nanoparticles (Cu NPs) in nanocellulose films. The nanoparticle size is influenced by the concentration of precursor ($\text{Cu}(\text{NO}_3)_2 \cdot 3\text{H}_2\text{O}$), which in turn determines the maximum absorbance. Chauhan et al. employed pH-sensitive azo-dye-grafted CNC to create an optical pH sensor. The vinyl sulfone reactive moiety of the azo-dye-grafted CNC is employed to take advantage of the intrinsic reactivity of pure CNC and minimize the degradation of CNC morphology brought on by mechanical processes. The pH sensor, printable inks, and pH-sensitive inks are made using CNC-dye conjugate. A pH sensor composed of polyrhodamine-coated CNC that changes color reversibly in response to pH changes was also demonstrated by Tang et al. By employing distinct cross-reactive sensor elements, array-based sensing of target analyte in mammalian olfactory and gustatory systems is capable of producing unique fingerprint patterns for each analyte. As a result, it can recognize and distinguish a variety of target analytes as they produce unique fingerprint patterns. Abbasi-Moayed et al. reported a ratiometric fluorescent sensorarray (RFSA) with BC nano paper as a flexible and transparent substrate. The BC nanopaper was treated to produce hydrophobic walls with laser printing, due to the interaction between heavy metal ions and carbon-dots-rhodamine B(CDs-RhB)nanohybrids it produces color changes. The resulting sensor array can discriminate between metal ions such as Hg^{2+} , Pb^{2+} , Cd^{2+} , Fe^{3+} , and Cu^{2+} . When different heavy metal ions are added to the BC nanopaper-based RFSA, it displays various colors, which can be recognized using RGB analysis for their distinctive, fingerprint-like photoluminescent response patterns.

Metal nanoparticles are likely to discharge into the environment, which poses serious threats (Ruiz-Palomero et al. 2016) to biological species and human health. As a result, developing effective and efficient ways for determining their identification is critical. Ruiz-Palomero et al. (2016) used carboxylated nanocellulose and $\text{Ru}(\text{bpy})_2(\text{a-bpy})(\text{PF}_6)_2$ to create a highly luminous hydrogel-based sensor for AgNPs, with nanocellulose acting as a gelator. Wang et al. (2018) developed a carbon quantum dots (CQDs) functionalized CNF hydrogel for detecting AuNPs in aqueous solutions, with the hydrogel acting as a 3D framework and the CQDs as the fluorescent donor. The quenching of CQD fluorescence by AuNPs resulted in the sensing capabilities of CQD-functionalized CNF hydrogel toward AuNPs.

Organic Dye Sensor

The water bodies near textile industries are increasingly polluted due to the organic dyes. So, accurate determination of the organic dye is a need of time. Nanocellulose can also be employed as a reducing and stabilizing agent, providing significant stability and allowing plasmonic nanoparticles to monodisperse in solutions without aggregating. Since nanocellulose can be utilized as a framework for loading metal nanoparticles and as substrates for SERS because of its huge surface area and high aspect ratio. Ogundare and van Zyl (2019) developed a malachite green (MG) detecting sensor based on AgNPs/ SiO_2 /CNC nanocomposite, where CNC plays the role of both reducing and stabilizing agent in the synthesis of AgNPs.

The silica was made via a sol-gel technique, and the CNC kept the AgNPs from aggregating. The AgNPs/SiO₂/CNC nanocomposite is proven to be an excellent substrate for fungicide and insecticide SERS.

Gas Sensor

The primary sources of pollutants that regularly impair natural environmental conditions include growing population, industrial emissions, automobile exhaust, and open burning of rubbish debris. To avoid environmental degradation, ongoing monitoring of these contaminants is required. There is a variety of equipment available to monitor pollutants and dangerous gases, but they are time-consuming, costly, and rarely employed in real-time situations. For gas sensors, hierarchically porous aerogels are used for gas adsorption and storage which increase the possibility of improving the contact surfaces between analytes and sensing materials. The ability of 3D structures to improve gas sensing capability over their 2D counterparts has been widely shown, which may be ascribed to more reactive sites, the greater specific surface area, and bigger “space” for the storage or movement of electrons/holes and gases.

According to Wang et al. (2008) TiO₂ nanostructured sheets have O₂ sensing capability with sensitivity down to sub ppb levels. The film thickness and operation temperature have an impact on the gas detecting characteristics of the film. When the concentration is more than 1 ppm, the nitric acid becomes the cause of photochemical smog and acid rain which can be harmful for humans. Sadasivuni et al. (2016) used CNC sheets with iron oxide on the surface to create a flexible and reversible resistive NO₂ gas sensor. CNC provides good NO₂ molecule accessibility to the sensor surface, resulting in a highly sensitive sensor. CNC can also facilitate and stimulate the creation of an unbroken linked channel between iron oxide particles, hence increasing the electrical percolation sites and resulting in a stronger response than plain iron oxides and also sensor’s recoverability.

Koga et al. (2019) devised a paper-based molecular sensor based on paper, NO₂ sensor with graphite drawn from pencil as an electrode. Here, the device was constructed on a CNF paper substrate, the ZnO nanowire was tailored via the papermaking process to ensure the attachment of the nanowire to the substrate and accessibility of the analytes. Due to the cost-effectiveness and air stability, graphite is deposited by using a drawing process onto the ZnO nanowires/CNF nanopaper.

When exposed to NO_2 , the electrical resistance of the paper sensors increases, with good sensitivity.

Dai et al. (2017) have developed an ammonia gas sensor based on copper (II)-doped CNC cholesteric films. Due to the CNC's optical activity and nematic chiral signature, ammonia gas interacts with CNC and the chelated Cu^{2+} and the nematic layers of CNC and, a redshift in reflective wavelength and an effective colorimetric change occur. Narwade et al. (2019) investigated the efficacy of hydroxyapatite (HAp) nanoparticles blended CNF films with various topologies for NH_3 sensing. The films with 5% HAp have a detection limit of 5 ppm, a sensitivity of upto 57.5%, and a response/recovery time of 210/30 s, which is much superior to the HAp and CNF counterparts. The explanation for this is the increase in conductivity caused by the creation of H bonds between the OH groups of cellulose and the NH_3 molecules.

Zhang et al. (2017) worked on creating an I fuel-cell for alcohol sensing utilizing a CNF/graphene oxide (GO) membrane. The sensor reacts to ethanol vapor with a detection limit of 25 ppm at varying doses. In addition to being responsible for in-plane ion-transport channels of the CNF/GO membrane and through-plane and, the grafted sulfonic acid groups on the surface of GO and CNF nanosheets with 3-mercaptopropyl trimethoxysilane as a precursor are also in charge of proton conductivity. Because of their linear chain molecular structure with repeating glucose units and numerous exposed surface hydroxyl groups, CNF may be easily changed to transmit protons or hydroxide ions.

Wang et al. (2019) with PANI and carboxylated ginger-derived CNF fabricated a supramolecular aerogel (SA) with a porosity of 96.90% and conductivity of 0.372 mScm^{-1} . With carboxylated ginger-derived CNF and PANI. He created a conductive supramolecular aerogel (SA) with a porosity of 96.90% and a conductivity of 0.372 mScm^{-1} . Because its resistance changes with different gases and the response curves have distinct forms, the SA was also used as a gas sensor to detect ethanol, formaldehyde, chloroform, and toluene. The higher electrical resistance is produced by the conformation change and expansion of PANI chains which is caused by the assault of chloroform and ethanol molecules on the N-H sites. Toluene, on the other hand, produces electrons when it enters PANI, reducing the number of positive charge carriers and neutralizing positrons.

Toxic Compound Sensor

For detecting biological and chemical analytes, SERS has long been considered a label-free analytical tool. Nanocellulose-based planar materials (films, membranes, and sheets) make up 2D nano cellulosic materials. Microporous structure, flexibility, lightweight, thermal/mechanical robustness, chemical stability, and portability, are the characteristics of nano cellulosic material. They are also predicted to be utilized in the development of portable and disposable sensors. Since nanocellulose has a high aspect ratio and specific surface area it is a good substrate for SERS. (Chen et al. 2019) fabricated in situ non-invasive pesticide detectors in fruits and vegetables with the help of SERS. In this sensor, the jelly-like AgNPs were decorated on the nanocellulose surface, the SERS method shows a 0.1 ppm for thiram and 1 ppm for thiabendazole. A silver nanocellulose composite-based substrate for carbendazium detector was developed by Huang et al. (2019) A homogenous silver nanocellulose composite was developed by reducing silver and hydroxyl group on the surface of the nanocellulose (Morales-Narváez et al. 2015). Fontenot et al. (2017) proposed a colorimetric sensor for the detection of hazardous substances such as thiourea and cyanide by using gold nanoparticles (AuNPs) embedded in BC nanopaper (i.e., thiourea and cyanide). With the addition of thiourea, the AuNPs-BC changes from red to dark red due to the aggregation of AuNPs generated by thiourea. When cyanide is added the nanoparticle shrinks and the color changes from red to light pink.

Ruiz-Palomero et al. (2017) developed a fluorescence sensing hydrogel by embedding S, N-codoped graphene quantum dots (S, N-GQDs) on nanocellulose, in which the S, N-GQDs act as a luminophore and sensitizer, while the nanocellulose as the matrix for hydrogel. When GQDs are added to nanocellulose hydrogel as opposed to GQDs solutions, there is a considerable increase in fluorescence intensity because of stability of GQDs without aggregating in the hydrogel and the strong dispersity. The resulting GQDs/nanocellulose hydrogel was further explored for selectively sensing of 2,4,5-trichlorophenol due to a significant rise in photoluminescence intensity of GQDs while interacting with TCP (TCP). The photoluminescence intensity of GQDs is greatly increased as a result of these interactions. Furthermore, the hydrogel formation enhances the contacts between TCP and GQDs, resulting in high fluorescence emission. The photoluminescence intensity of GQDs is greatly increased as a result of these interactions. Furthermore, the hydrogel formation enhances the contacts between TCP and GQDs, resulting in high fluorescence emission.

Drug Sensor

For studying the pharmacokinetics of drugs and risks with the usage of drugs, drug detection, and monitoring are needed. The examination of human biological materials such as urine, blood, perspiration, saliva, and the exhaled breath is commonly used for drug detection and monitoring. Because of their great sensitivity, cheap cost, and quick analysis timeframes, electrochemical sensors are ideal for evaluating pharmaceuticals in pharmaceutical preparations and human bodily fluids. The flexible 3D-nano cellulosic includes hydrogels, aerogels, and sponges that are porous structures so they can combine with nanoparticles and nanostructures in sensing. The porous structure and various routes for analytes diffusion and sorbent capacity improve sensor performance. Hydrogels made from nanocellulose offer a range of chemical, mechanical, and biological properties as well as a high water retention capacity. For example, combining transparent nanocellulose hydrogel with the optical characteristics of a fluorophore might result in a high-sensitivity optical sensor. Lightweight biocompatible materials having structural features that are compatible with highly exudative wounds, such as nanocellulose-based aerogels/sponges, are appropriate for biosensor design. The structural stability of nanocellulose-based aerogels is often poor, resulting in the collapse or closure of interconnecting micropores. Furthermore, because of the poor connection between fluorescent and the aerogel skeleton molecules, fluorescent components aggregate and quench, resulting in lower fluorescence performance.

Morales-Narvaez et al. (2015) developed a coulometric sensor for the detection of methimazole by using the AgNPs-BC system. Due to the good optical transparency, high mechanical strength, flexibility, and high surface area of BC nano paper, it is used as an optical sensing platform. In the presence of methimazole, the color of the AgNPs changes from yellow to dark yellow because the thiol group in methimazole act as a linker promoting the aggregation of Ag NPs. For iron-chelating drug molecules, Faham et al. (2019) synthesized a calorimetric sensor based on a BC nananopaer. The curcumin-embedded BC nanopaper shows a complexation of Fe (III) and curcumin in the presence of Fe(III) which shows a decrease in the intensity of the color. With the addition of an iron-chelating drug, the intensity of the color can be recovered. Liu et al. (2019) used BC as a template to make p-type NiO nanoparticles for sensing volatile organic compounds such as benzene, toluene, and chlorobenzene. To produce NiO nanoparticles, BC and nickel acetate tetrahydrate

were mixed to form gels, which were then freeze-dried to produce nickel-adsorbed BC xerogels, which were then calcinated in air. Wu et al. (2019) created fluorescent aerogels containing CNF and CDs that can be employed for nitric oxide (NOx) detection since NOx may quickly quench the fluorescence. The cause of fluorescence quenching is the suppression of radiative recombination of electrons and interactions between NOx and CDs. The porous nature of aerogel aids in the adsorption and trapping of gas molecules.

The glassy carbon electrodes were modified using CNF-CNPs (carbon nanoparticles) nanocomposite films to create an electrochemical sensor (GCE). Electrodes were used to detect trace quantities of metoclopramide in clinical and pharmaceutical preparation. The modified electrodes work effectively for measuring minute amounts of metoclopramide (MCP) in therapeutic and pharmaceutical formulations. In comparison to bare GCE, these produced modified electrode that have a 49-fold better anodic response to MCP. A nanocellulose/functionalized-multi-walled carbon nanotube (f-MWCNTs) composite film based biosensor has been prepared for the sensing of nonsteroidal antiinflammatory medication, diclofenac sodium (Shalauddin et al. 2019). Nanocellulose has a lot of hydroxyl groups that can be used as binding sites for various analytes. Furthermore, the synergy of nanocellulose and f-MWCNTs increases the sensitivity and selectivity of electrochemical detection.

Physical Sensor

Proximity Sensor

A proximity sensor works without any physical contact with the analyte object. This can be integrated into any intelligent technology like guards, robots, wearable electronics, biomedicine or during tissue engineering. The sensor works on the principle of infrared emission, electromagnetic induction, and resistance measurement. Sadasivuni et al. (2015) presented a proximity sensor from ecofriendly and transparent CNC/rGO which can be used in both non-touch and touch screens which has the ability to detect finger approaches. Isophorone diisocyanate (IPDI), acts as a functional agent on GO and it also act as a coupling agent for CNC and GO. The CNC/GO composite was then reduced using anhydrous hydrazine. CNC influences

the semiconductor characteristics, which has an impact on sensing performance. As the finger approaches the sensor, a little electric charge transfer disturbs the fringe electric field, resulting in the detecting property. The sensor's quick reaction and great sensitivity may be ascribed to the CNC/GO composite's chemical modification and reduction, as well as its outstanding nanostructure. Remarkably, the sensors operate better under the combined influence of CNC and rGO than under the management of rGO alone.

Nanocellulose category	Sensing technique	Role of nanocellulose	Detection limit	Reference
CNC	Resistance	Substrate/spacer	6 mm	Morales-Narváez et al. (2015)

Temperature Sensor

Temperature mapping and monitoring are necessary for many heterogeneous environments such as medical fields. Flexible substrates such as nanocellulose can be used for the temperature sensor. Jung et al. (2017) created a thermoelectric sensor based on CNF, the thermocouple was made by inkjet printing thermoelectric materials (such as CNTs, AgNPs, and PEDOT-PSS) onto CNF films. The CNF substrate absorbs the conductive materials as a result it acts as a suitable substrate for inkjet printing. Vuorinen et al. created another temperature sensor by using an electrohydrodynamic inkjet (E-jet) printer and printing AgNPs on BC, which has a 10 times greater resolution than standard inkjet printers. This skin-conformable temperature sensor has a sensitivity of greater than 0.06% resistance change per degree Celsius.

Abstract

Ensuring the safe disposal of waste materials to prevent irreversible environmental damage is a major priority concern of the current century. The alarming rate of consumption of plastic-based packaging materials has steadily increased and plastic accumulation now seemingly contributes to the global carbon footprint substantially adding to greenhouse gas emissions. While it is difficult to reduce the global dependency on plastics as a cheap and easily polymerizable material source, nature provides a sustainable alternative to process waste into eco-friendly breakdown products that are recycled back as nutrients by microorganisms and are not harmful by-products. Packaging in the form of naturally occurring biodegradable matter is becoming an increasingly attractive alternative to replace common nonbiodegradable plastic. Biopolymers assembled in nature are by their intrinsic nature biodegradable but retain some ability to exhibit plastic-like properties. Hence in this review, the knowledge gap that currently

prevents the use of readily available natural biopolymers namely nanocellulose that have the potential to be engineered into biodegradable plasticized products is highlighted. This review aims to focus on discussion points that are underrepresented with regard to aspects on nanocellulose. Here, bond fragility of nanocellulose is one concern limiting its use as a viable biodegradable bioplastic. Material failure has its origins in chemical bond breakage and while much progress has been directed toward experimental investigations of nanocomposites formed from nanocellulose, the connection between an intrinsic understanding of chemical bonds with structural-functional nature of nanocellulose is lacking. Here, we explore these in more detail in our efforts to build a greater appreciation to broader areas covered elsewhere.

Introduction

Importance of Biodegradable Packaging

Cheap packaging has been synonymous with the birth of plastics since the turn of the twentieth century and has since symbolized the face of durability, strength, and tough polymer chemistry. The oversupply of the “make, consume, and dispose” business model is symbolic of a huge disposal waste problem for an industry worth \$450 billion dollars. Now decades into the new millennium, the future is firmly embedded by a plastic-dependent existence with overwhelming consequences to the environment and human and animal life by diminishing the eco-benefits of a plastic-free world. Plastic production and its disposal are major climate change issues and the world's dependence on plastics promises to be a significant growth driver by industries. While plastic has favored an economic advantage to the consumers and industries alike particularly in terms of packaging of products, recyclability has not featured heavily in the “plastic” business model largely due to the cost burden. Insight into the sense of scale of plastic consumption is appreciable from an expected drop of 100,000 tonnes if its utilization was met by a 50% reduction. In reality, less than 10% (Rahimi and Garcíá 2017) of plastics are recycled with little prospect of depolymerizing the most toxic plastics that contain liquids and food products. Figure 1 shows that the plastic industry is predominately driven by the packaging industry and this dominance is set to increase and plastic utilization (Fig. 1; green bubble) is not expected to slow down. The most popular plastics are related polyethylene low density (PE LD), polyethylene high density (PE HD), polypropylene (PP), polystyrene (PS), and polyethylene terephthalate (PET).

More than nine billion metric tons of plastic have been manufactured since the 1950s of which 40% represents single-use plastics. Such industry-led challenges

Fig. 1 The dominance of the packaging sector among other industries as a leading consumer of synthetic plastics. (Reproduced with permission from Lackner 2015)

pose a prime environmental concern of growing catastrophic proportions originating from technological gaps in the disposal of nondegradable plastic packaging. The accumulation of plastics in landfills impacts both land-based and marine animals as water-dissolved plastic waste is carried by rain water deeper into soils groundwater that connect streams, rivers, and oceans. This permits the systematic poisoning of all with types of ecosystems it encounters into a collective patch of plastic debris that accumulate into the Great Pacific Garbage Patch (GPGP), a vortex of marine debris which was surveyed to be the size equivalent to 1.6 million km² in 2018 (Lebreton et al. 2018). Plastics of varying size including millimeter-sized plastics find their way within marine animals and into the human food chain. Microplastics have been identified in table salt, tap water through water contamination, and synthetics like nylon and polyester can release thousands of microparticles into our laundry. It was also found that plastic feeding water bottles and injectors released as much as 393 particles/mL just from repeated opening and closing cycles (Song et al. 2021). Figure 1 shows that common cutting processes like scissoring, tearing, and cutting of packaging results in the release of microplastics demonstrated by the mass change (Sobhani et al. 2020). Further, microfragments originating from other everyday plastics like tearing of bag of chocolates, sealing tape, and bottle caps were visualized under SEM and the morphologies were correlated to FTIR and QCM analysis of freed microparticles by the tear (Fig. 2). More recently, examination of human feces for the existence of ingested microplastics in the guts of humans from a group of a small group of disease-free study subjects aged 33–65 years led to the identification of ten types of microplastics. Polypropylene and polyethylene terephthalate were

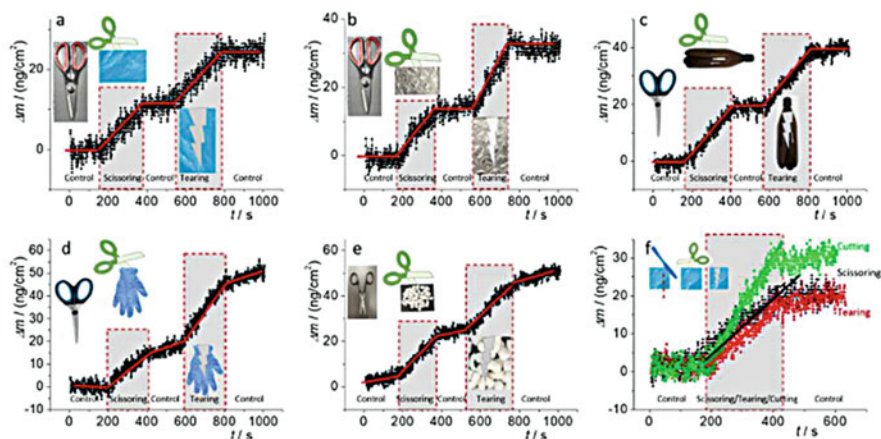

Fig. 2 Microplastics generated from scissoring, tearing, and cutting of plastic packaging. Increase in mass associated with microplastics was measured by quartz crystal microbalance. (Reproduced with permission from (Sobhani et al. 2020). This work is licensed under a Creative Commons Attribution 4.0 International (CC BY 4.0))

correlated to nine of the study subjects as the most commonly occurring type and eight samples revealed microplastics ranging from 50–500 μm in size (Schwabl et al. 2019). Microplastics have been shown to exert their effects which are cell dependent (Caldwell et al. 2021) and new methodologies have evolved to follow the biological effects of nanoplastics as small as 50 nm. Particle imaging by stimulated emission depletion (STED) (Fig. 3 RHS b, d, f and h) shows the shapes adopted by common in the form of nanoplastics which could not be resolved by confocal microscopy (Fig. 3 LHS a, c, e, and g) (Nguyen and Tufenkji 2021). With specifics to a model study using the commonly used packaging material polypropylene (PP), the biological fate of fluorescently tagged PP was followed in zebra fish embryos and was shown to be localized in the gut (Lee et al. 2022). This brings into awareness the existence of submicroscopic particles where the short-term and long biological effects on potential disease development and progression are completely unknown. The persistent nature of plastic packaging is a complex problem of global proportions. Implementing safeguarding strategies against accumulating plastics is energy demanding and current approaches may not be applicable in handling highly toxic plastics like polyvinylchloride (PVC).

The petroleum and fossil fuel origin of the most durable plastics and their future sustainability is a global concern. While plastics are indispensable for the important purpose they serve in packaging of a diverse range of products, the physical, chemical, and mechanical properties do not allow their recyclability at the end of their life cycle. The recyclability and renewability of synthetics are inefficiently low resulting only in partial degradation, the energy demands for breaking down the polymer structures is very high. For example, thermolytic processes that drive polymer breakdown require a high-energy input and control over product

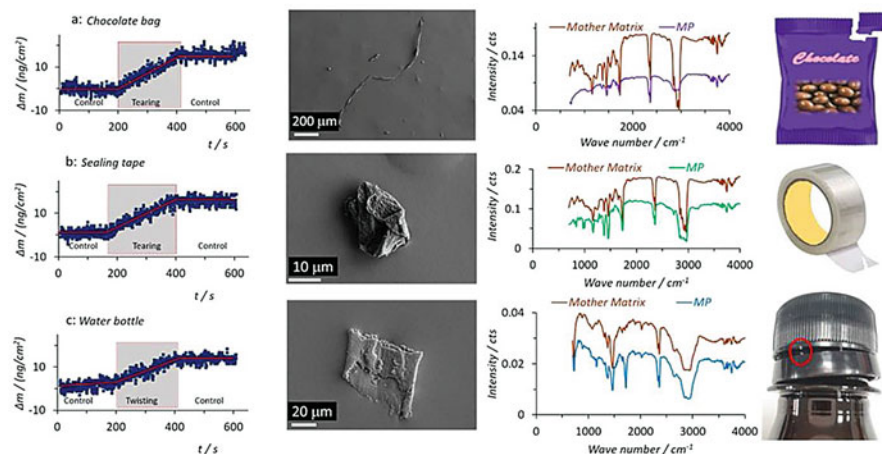

Fig. 3 Scanning electron microscopy (SEM) and Fourier transform infrared spectroscopy (FTIR) correlate to microfragments of plastics measured by quartz crystal microbalance (QCM) from tearing of plastic packaging of (a) chocolates, (b) tape, and (c) bottle cap. degradation is variable depending on the nature of the polymer due to strong bonding. However, thermoset polymers used in the rubber industry were recently engineered using polydicyclopentadiene as model for inserting cleavable cross-linked bonds to render the polymer degradable without affecting its mechanical properties (Shieh et al. 2020) which is a promising alternative to recycling of polymers (Hamad et al. 2013) which require areas of technological advancement to address the chemically diverse and different toxicities often associated with nonbiodegradable plastics and their degraded products. Work toward the design of building blocks that may function at the unit level of monomers and cross-linkers as reactive networks in polymers (Winne et al. 2019) could potentially in the future be used to take advantage of mechanical and physicochemical properties that facilitate depolymerization (Rahimi and García 2017). Currently synthetic polymers are not naturally cleavable in nature but instead were designed to durable and tough.

There is great demand for sustainable packaging which is both cost-effective and eco-friendly. At the leading edge of this endeavor is biodegradable packaging. For any plastic to be biodegradable, the material composition must be chemically and physically accessible to living entities such as microorganisms which can actively recognize chemical groups and release enzymes that specifically digest bonds into monomers and oligomers. The process is sustainable by virtue of the nature of the degradation products since they are a source of nutritional value and energy for the diverse ecosystem of living microspecies that inhabit our planet. Many of the synthetic plastics can potentially serve this purpose as a rich source of hydrocarbons as a feedstock for organisms that hugely outnumber the small number of core synthetic materials in circulation today. Such materials of high molecular weight

include polyethylene (PE), polypropylene (PP), polyvinyl chloride, (PVC), polystyrene (PS), polyethylene tetrathalate (PET), and polyurethane (PUR). While findings suggest that some bacteria and fungi can adapt their biological machineries to degrade synthetic polymers, biodegradation rates are poorly inefficient against the rising accumulation of plastics. However, factors such as structure, molecular weight, surface morphology, mechanical strength, and varying degrees of crystallinity/amorphicity effect degradation which reflect the overall bioavailability of the polymer. Natural or formulated semisynthetic biopolymers are currently of value. Biodegradable and semibiodegradable polymers are attractive targets for the replacement of plastics but lack durability and toughness of plastics. Examples include polycaprolactone (PCL), poly(lactic acid (PLA), polyethylene succinate (PES), polyhydroxyl butyrate (PHB), butylenes succinate (PBS), polyhydroxy alkanoate (PHA), and poly(butylenesuccinate-co-adipate) (PBSA), among others. Another distinguishing factor between synthetics and biodegradable materials is the occurrence of functional group sets that likely influence the broader reason for differences in their bioavailability.

With a greater focus on biodegradable materials, naturally produced environmentally compatible materials are in demand as packaging materials. Rising population and consumer demand is proposing a new technological vision for packaging being actively responsive to its environment particularly to microbes and such intelligent packaging may evolve into sophisticated sensing technologies equipped with indicators interacting with the surrounding atmosphere. Therefore, a strong mandate for “next-generation” materials are alternatives that are easily adaptable to different environments with the ability to be efficiently degraded or converted back into some form of usable packaging. Material availability, renewability, processability and ease of modification for improvement, disposability through efficient recycling, and eco-friendliness and biocompatibility are characteristics that are highly attributable to a class of biodegradable materials termed biopolymers found in nature. Their alignment with diverse microbial communities has evolved mechanisms to break down biodegradable polymers into digestible constituents and satisfy many of the abovementioned requirements.

“Sustainability” and “renewability” are umbrella terms synonymous with natural and biodegradable materials. While renewable materials impose a cost factor from natural sources such as sugar and ethanol, the abundance of natural biopolymers could potentially bring advantages to reduce cost barriers. However, the scale to which biopolymers will eventually need to be manufactured to meet the current and future consumer demands is challenging. The difference among biodegradable materials is the rate at which they degrade. The ideal targets are weak molecular structures that undergo disintegration. Nanocellulose is one such biopolymer. With consideration to renewability, nanocellulose as a bioplastic has numerous physical and chemical exploitative properties and can provide opportunities to introduce new and improved functionalities. However, much of the enthusiasm has been hindered by the cost of mass processing but expectations continue to be high (Lindström and Aulin 2014).

This chapter examines the broader potential of nanocelluloses as a feasible option for replacing petroleum-based plastic packaging and discusses these advancements in reaching the longer-term goals of bringing nanocellulosic materials closer to marketable quality. As plastic has been seen to revolutionize polymer chemistry, by the same token the future packaging materials will be looking to bring newer innovations and packaging will have a multifunctional purpose attached to it. To advance this, a thorough grounding of the fundamental properties of nanocellulose is essential to allow its modification to become a true innovative material for decades to come.

Nanocellulose

Potential Use of Nanocellulose in Packaging

Nanocellulose is probably one of the most interesting plant biodegradable biopolymers that exist. It is abundantly available from wood biomass, plants, and other inexpensive vegetation sources. The market value of nanocellulosic a raw material is expected to reach USD 963 million by 2026 (Markets and markets, 2022) and marks the increasing trajectory of global interest toward biobased renewables. An important requirement for material renewability is its degradable value for energy or food for organisms that rely on it. Because of the increasing demand for packaging as the global population expands, from the perspective of renewability it is also important to consider materials that can be degraded at rates higher than disposal rates to maintain a feasible cycle of replenished packaging material. This aspect directs to material performance and may well be an engineering challenge for biopolymer-synthetic material optimization. Material competency may have a direct or indirect relationship among parameters of surface modifiability, processability, and by-product degradation with overall efficiency and utility in packaging applications. For example, surface modification to provide rigidity to the nanocellulose framework for utility as a plastic may have implications at the biosynthetic interface in biosynthetic polymer blends. Structural and chemical synergy of nanocellulose as part of a blend can result in stiffness, strength, ductility, and toughness (Mautner et al. 2018) and depolymerization is a trade-off between mechanically strong plastics and biosynthetics resisting biodriven degradation. Figure 4 shows nanocellulose composed of unit size structural elements which form covalent bonds and extend into nanodimensional fibers. The large molecular weight can hinder the control of the biopolymer which is largely influenced by viscosity, hydrophobicity, and aggregation. The utility from a commercial point of view is very limited particularly if biopolymers suffer from fragility and brittleness and poor mechanical properties. Enhancement in the surface area facilitated by nanoscale dimensions provides heightened exposure and opens considerable opportunities for interaction with the surroundings. The intrinsic properties of the biopolymer strands can thereby be tailored to desired outcomes with a host of different materials and their blends.

A Brief Look at Degradation from a Biopolymer Bonding Perspective

Since nanocellulose is a biopolymer, its origins like all polymers such as polypeptides (proteins) and polynucleotides (RNA and DNA) are embedded in biological chemistry as it exists as a polysaccharide (chained sugars) linked by β -1,4-linked d-glucose units. This suggests that such polymers are intrinsically adapted to fold and minimise degradation unlike linear native conformations that more readily degrade in aqueous environments (Runnels et al. 2018). Interestingly Runners et al., describe the resistance to degradation of biopolymers as a possible mechanism operated through “kinetic trapping” of nonequilibrium states favored by folded assemblies. From the perspective of employing nanocellulose for biodegradable packaging, it would therefore be strategically essential to ensure folding states of biopolymers of this type are still accessible to degradation by microbial communities by preventing misfolding under aqueous conditions and that properly formed “transition states” are recognized by enzymes for degradation to occur through accelerated hydrolysis. It should therefore be a primary goal to develop new technologies that reduce the persistence of nondegradable states during processability of the bioplastic. Hence, the linkage stereochemistry and fiber elongation signified by the β - versus α -anomer states of biopolymerization is essential to its biocongruence bearing structural complementarity to enzyme active sites also engaged in reversing polymerization. Figure 5 describes the self-complimentary behavior that extends to all biopolymers (but illustrated by cellulose). Here, the network of hydrogen bond donors and acceptors ascribe to an important role that does not only result in precise alignment of the multilayer structures but also the chemical space generated within polysaccharides through linkage chemistry. Occupation of the chemical space by plasticizers and compatibilizers often have profound effects on both physical and chemical properties affecting the entire structure in the blend. Biopolymer properties

of cellulose at the submicroscale has been the focus of attention in numerous works and more relevance to the macroscale properties in correlation to chain dynamics of monomers has been lacking. Local flexibility, for example, is fundamental to identifying how unit scale behavior drives collective behavior at the macroscale where ultimately their utilization in applications will rely on a globalized structure. Structure-property relationships, however, are useful for predicting outcomes and can guide polymer engineers to more precisely tune materials in mapping three dimensions with biopolymer function. Scanning tunneling microscopy and electro-spray ion-beam deposition have been particularly useful in this regard in correlating levels of hierarchical structure in terms of sequence and chain confirmation of the biopolymer chain of cellulose with local flexibility. In a recent study using cellulose as a model (Anggara et al. 2021), changes to the primary structure through substitutions that affect intermolecular hydrogen bonding provided a series of archetypes to investigate chain flexibility, molecular conformation, and local secondary structure. The changes to the unmodified cellohexaose represented by [AAAAAA] as the native structure constituted substitutions defined by [ABAABA], [ACAACA], [ADAADA], and [AFAAFA] where A is Glc, B is Glc methylated at OH(3), C is Glc methylated at OH(3) and OH(6), D is Glc carboxymethylated at OH(3), and F is Glc deoxyfluorinated at C(3). Figure 6 demonstrates that the sugar chains for the

Fig. 6 A schematic illustrating the stability of cellulose by the hydrogen bond donor-acceptor network of complementary units which polymerize along the β (1–4) directional folding path. Fig. 7 Native and modified cellohexaose imaged by scanning tunneling microscopy (STM) showing the effect of substitutions on chain flexibility conforming to structures A, B, C, D, E, and F. Taken from (Anggara et al. 2021). This work is licensed under a Creative Commons Attribution 4.0 International License

native structure is linear and the modified chains are more flexible as they can adopt both straight and bent geometries. The conformation of the chain is defined by structural association between adjacent sugars with respect to their relative geometries. Figure 7 shows twisted and untwisted chains and its importance to the degree of chain flexibility. The corresponding angle measurements (Fig. 7, B, C and D) differentiate between H and V states of the Glc sugar separated by height of the ring either in a parallel or perpendicular orientation to the surface with respective H and V. The twisted linkages were determined to exhibit greater chain flexibility compared to untwisted chains. Twisting directly diminishes the interaction between adjacent Glc units and increases flexibility. The freedom to bend results from the exclusion of intermolecular hydrogen bonds and stresses the importance of extrinsic chemical factors that have the potential to alter the folding patterns of biopolymers affecting their ability to resist or enhance aggregation and interaction with key molecules like water. The study also revealed that mechanical parameters like stiffness is likely a consequence of modifications to intramolecular interactions and less influenced by surface-to-surface interactions.

Functional Group Similarity and Dissimilarity Between Synthetics and Biodegradable Polymers

The highly abundant hydroxyl moiety [OH-C] pronounced within the group chemistry of nanocelluloses positions this material as one of the most natural and easily biologically accessible functional group structures on the planet. It is not surprising that this single structural feature that is an integral part of the unique assembly of nanocelluloses appears to be commonly shared among natural product functional group repertoire displayed in Fig. 10. The overall polymer reactivity is connected to surface hydroxyl groups and their relative positions largely determine the biopolymer characteristics.

Since functional group in polymers renders them degradable or nondegradable and is the chemical epicenter of the polymer, it may be meaningful to correlate the occurrence of functional groups characteristic of its nature. It may be important to understand the chemical properties of semisynthetic polymer as a result of a blend with unknown behavioral properties. Dominant functional groups become important to the identity of a complex blend and so much can be inferred about the overall chemical nature of the material and behavior. Identifying patterns of behavior through molecular structure analysis using analytical approaches can also be supported by cheminformatics (Ertl 2017) and machine learning (Nalla et al. 2018) routes. Cheminformatics has been insightful in highlighting differences in the distribution function groups in natural systems in comparison to synthetic ones. In a recent computational study designed to identify differences in functional group occurrence, alcohol hydroxy group (61.1%), alkenes (39.9%), ethers (35.2%), esters (28.7%), and phenolic hydroxy group (28.4%) feature most commonly (given by the frequency percentage in the parenthesis) and the corresponding structures are shown in Fig. 8 (Ertl and Schuhmann 2019). It is not surprising that oxygen is the dominant atom that forms a part of the hydrocarbon structural backbone and is well aligned to

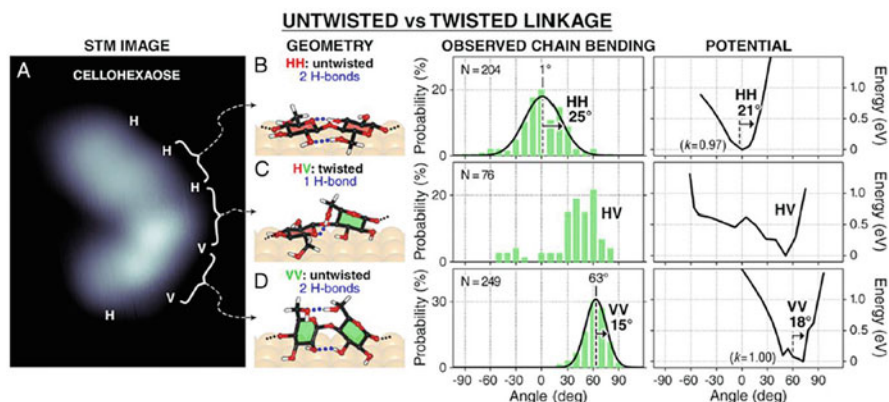

Fig. 8 (A) Cellohexaose showing two types of AA linkages, untwisted (HH and VV) and twisted (HV and VH). Corresponding bending angles and the computed potential curve are shown in B for HH, C for HV, and D for VV. Taken from (Anggara et al. 2021). enzyme active sites of biodegrading enzymes. This signifies that preoxidation of synthetic plastics is a necessary prerequisite to their biological degradation and the inclusion of oxygen likely reduces the energetic barrier relative to nitrogen bonds. Of greater relevance to assess the extent of the dissimilarity between natural and synthetic functional plastics is presented by Fig. 9 which highlights the distribution of the most frequently identified chemical functional groups. The plot reflects the diverse distribution of biodegradable functional materials that are of value in the microorganism food chain as natural substrate polymers while others are allied to the synthetic type. It can be reasoned that microbes show preference for biodegradable polymers which fall in the region of functional groups circled in Fig. 5. Polyethylene and polypropylene, for example, show a strong carbon-hydrogen backbone and are not readily degradable due to major differences in the functional groups that define characteristics and behavior. Polyethylene terephthalate, for example, also show different competency to biodegradability that reflects the variation in the functional groups and enzyme accessibility to the structure is made possible through exposure to UV light by photooxidation or hydrolysis. For synthetic polymers, functional group accessibility is followed by depolymerization. Table 1 summarizes the mode of trigger applied to different PEs and the functional groups isolated were identified. In the microbial environment, increased carbonyl index was observed during the biodegradation of LDPE over a

Table 1 Summary of functional group types after triggered degradation

Degradation trigger	Functional group	Category of polyethylene
UV	Aldehydes, Ester	HDPE, LDPE, and LLDPE
	Ketones	
Xenon	Carbonyl	LLDPE
	Acid	
Electron beam and gamma	Ester, ketone	HDPE
Photooxidation	Esters and lactones	PE with vinyl and t-vinylene groups
Thermo-oxidation	Ketones and acids	
Accelerated environmental conditions	Aldehydes, ketones	LDPE and LLDPE
Environment	Esters	Environmentally beached PE pellets
	Ketones	
Natural	Ketones and acids	HDPE

period of years with weight loss. Under accelerated growth, carbonyl products are also formed resulting from increased surface cracks and increased fragility during the timescale of the exposure period (Fotopoulou and Karapanagioti 2017) (Fig. 10).

Formulating Bioplastics: Considering Pre/Post-Extraction Phase of Nanocellulose

The purpose of bioplastics is one that drives an environmental goal but also attains to an economic one which while satisfying the greener concepts of sustainability, renewability, and biodegradability of eco-bioplastics can replace synthetic plastics without incurring a cost burden against the cheaper alternative to conventional plastics. International standards for biodegradation for environmentally degradable plastics and biobased products sets performance standards which must be met to categorize bioplastics as environmentally acceptable (ASTM D6954 2013). While CO₂ and evolution methane (CH₄) are the important measurement criteria from biodegradation, oxygen consumption has also been suggested to be important for aerobic biodegradation (De Wilde 2012). Currently, bioplastics are in the infancy of development despite the considerable research-based publications which point to considerable potential to formularize a truly biodegradable bioplastic of wide applicability. In this direction, nanocellulose is a popular target and example of the scope of blended products as semisynthetics. The prospects of using a naturally occurring biopolymer as a base material for sustainability while introducing strategically informed modifications to improve performance plastic replacements in an economic way are already underway. Currently, semisynthetics resembling bioplastics for packaging (Ibrahim et al. 2021) have their origins in biopolymers which are subjected to modification by chemical processes via abiotic routes (Ganie et al. 2021). Figure 11 emphasizes some of the performance outcomes the future envisages from technologically engineered bioplastics.

Nanoscale cellulose exists as cellulosic nanofibrils (CNFs) and cellulosic nanocrystals (CNCs) and these forms typify nanocellulose and are extractable by a combination of physical (e.g., mechanical homogenization) and chemical treatments (e.g., acid hydrolysis) (Phanthong et al. 2018). Acid hydrolysis can affect the hydrogen bond network and has been inferred to cleave on intramolecular hydrogen bonds at the macromolecular level on the O(3)H...O(5) bonds (Li et al. 2021). Morphological analysis also reveals bond breaking and bond reordering was

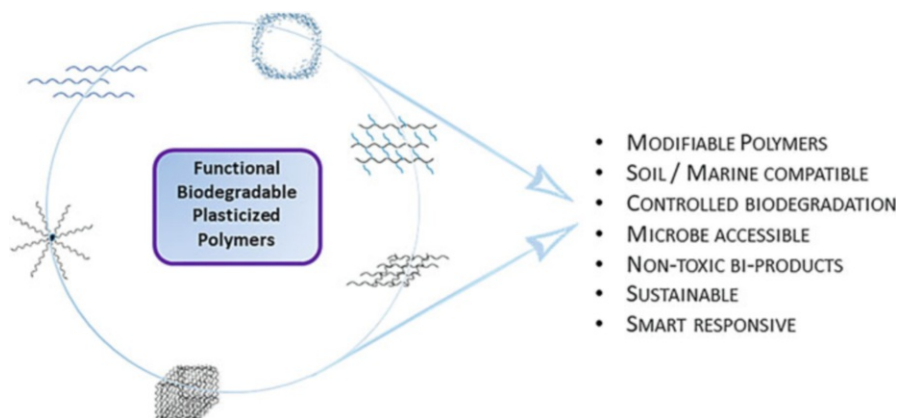

Fig. 11 A schematic summary relating different biodegradable polymers

Table 2 Relationship between nanocellulose type and dimensional size

Natural fibers/Plants	Type of nanocellulose	Dimensions of extracted nanocellulose	
		Length	Diameter
Eucalyptus pulp	CNC	150 nm	10–50
Pinecone	CNF	–	5–20
Soybean straw	CNF, CNC	>1 μ m	10
Hyacinth fiber (<i>Eichhornia crassipes</i>)	CNC	147.4 nm	15.6
Pineapple leaf fiber	NC	<(88–1100) nm	68
Rice hull	CNF	–	<100
Banana rachis, kapok, pineapple leaf, and coir	CNF	–	10–25
Oil palm trunk	CNF	170–800 nm	4–10
Bamboo	CNC	–	50–100
Waste paper	CNC	100–300 nm	3–10
Banana peels	CNF	455 nm	10.9
Palm residue	Coir NC	–	108
	Fronds NC	–	90
Coir fiber	CNF	–	37.8
Jute fiber	CNF	–	50
Beer industrial residues	NC	–	73–145
Coconut residues	CNF	–	70–120
Silkworm silk fiber	CNF	–	0.1–0.4
Flax	CNC	57 nm	6
Cotton	CNC	68 nm	8

accompanied by reduction in size. This change relates to the opening of the glycosidic bond which provides opportunities for reordering. Ultrastructural differences among nanocelluloses can indeed affect susceptibility by acids (Palme et al. 2016). A high variability in structural dimensions and shape and size can result from the source of the biopolymer and pretreatment methods used for extraction which affect yield, crystallinity, and can potentially tailor desired morphological, surface chemistry, and numerous physicochemical outcomes governed by methodology employed. Table 2 shows that the dimensional size of extracted nanocelluloses is largely source dependent (Khalid et al. 2021). Hence, chemical and mechanical processes can introduce profound changes to the structural properties of the biopolymer through pre- and posttreatment regimes which at the molecular level interfere with the inter- and intramolecular bonding (Fig. 12). It is necessary to understand the implications and consequences of these alterations before using nanocelluloses from different sources due to the broad variability in properties. For example, the crystal packing and the degree of crystallinity or amorphicity can comprise the integrity of the nanocellulose structure if penetrating water molecules can enter the chemical spacing between adjacent units and compete for bonds and thus reducing mechanical properties.

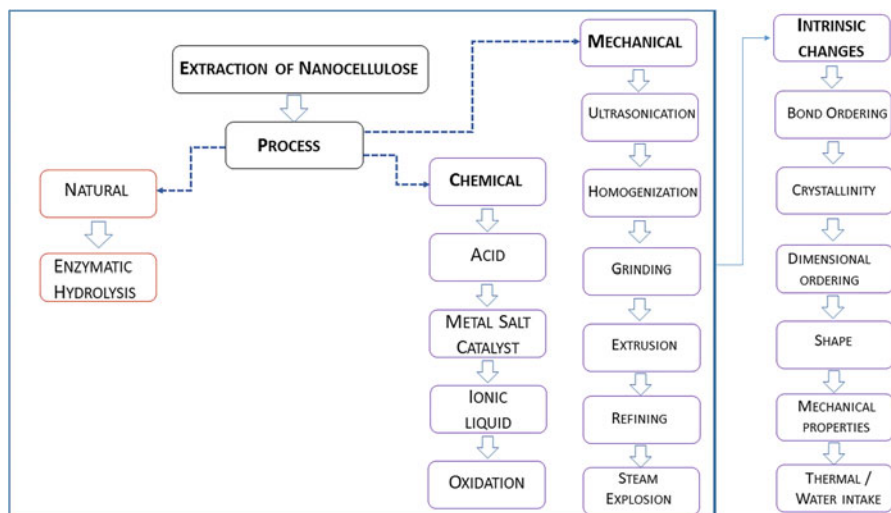

Fig. 12 Structural arrangement of intra- and intermolecular bonding in cellulose. Reproduced from the thesis entitled “Interfacial Forces in Nanocellulose-Based Composite Materials” (Olszewska 2013)

Scheme 1 Extraction processes for nanocellulose and the effect of intrinsic changes induced by external processes. (Adapted with permission from [Khalid et al. 2021]. This work is licensed under a Creative Commons Attribution 4.0 International [CC BY 4.0].)

However, in well-dispersed reinforced polymer nanocomposites, cohesive interaction between nanocellulose crystals offer less resistance to degradation by solvents and thus highlights the understanding of cohesive particle–particle interactions (Reid et al. 2016) and meets the design for bioplastic packaging. Blending with other materials may affect the nature and magnitude of forces such as van der Waals, hydrophobic, hydrodynamic, electrostatic (between layers), repulsive, and steric forces. The current challenge is to find a structural and functional balance of material combinations that are mutually synergistic with each other (Scheme 1).

Considerations of Nanocellulose from Nature's Perspective: Future Implications for the "Brittleness" Problem for Biodegradable Bioplastics

Much of the research for nanocellulosic materials has been devoted to engineering strategies for modification of the biopolymer surface with synthetic materials as blends. Such studies for packaging applications (Abdul Khalil et al. 2016) have centered on reinforcement for enhancing compatibility (Wang et al. 2021), dispersion (Chu et al. 2020), interfacial adhesion (Wolf et al. 2013), processability (Souza et al. 2020), stability (Santmartí and Lee 2018), moisture resistance (Cherpinski et al. 2018), and tensile strength to improve mechanical properties (Talebi et al. 2022). Some studies have escalated to provide active and intelligent functionality and smarter nanocellulose materials (Heise et al. 2021) including sensing (Fuertes et al. 2016) toward more innovative packaging. However, there has been little discussion focusing on using nanocellulose for biomimetic composites. Much of the emphasis has been to find reinforcements for nanocellulose as a biosynthetic composite to solve issues of fragility particularly in its interaction with water.

In nature, nanocellulose relies on its hierarchical existence to achieve many of the above properties that would readily endorse its use as a packaging material. This suggests that clues to mechanical optimization lie within the hierarchical makeup of the biopolymer. A very small body of knowledge has emerged that is pointing to improve our knowledge of structure and function which nature has inherently designed to be more adaptive than rigid. This could be taken to support the notion that natural materials may succumb to stress imposed upon them by the environment, but such stresses seldom destroy the material in its entirety or irreversibly. In contrast, mechanical and chemical processes can impose considerable stresses through deformation or fracture which primarily leads to bond loss.

Only under extreme deformation, irreversible disintegration can occur. Hierarchical cooperation from the nano- to macroscale exists and requires further appreciation. It is plausible to say that an understanding of material hierarchy is not understood such that the mechanical deformation at one scale due to hidden interconnections can affect the properties at other scales in the same material. Under bearable loads, biopolymers are capable of adjusting material responses that allow multimechanisms to operate which defines the robustness of a material. In this respect, studies that relate chemical bonding networks of natural structures and mechanical properties offer greater potential for new technological outcomes.

Bioinspired Biopolymer Synergy

Reduced toughness is a potential technological flaw in applying nanocelluloses for long-term applications in packaging for durability. This weakness is characteristically attributed to the lack of deformation – the mechanisms of which are still largely unaccounted for at the molecular level. Needless to say, attention has been given to improving the mechanics of the biopolymer in the form of composites with numerous synthetic molecules that bear many of the desirable mechanical properties biopolymer fall short on. The delicate balance between toughness and biodegradability is viewed as a critical setback of structure-function relationships. Lessons in sustainability of biopolymers rest in understanding how mechanisms unfold under normal

environmental conditions through the use of structure-sensitive tools which could better inform researchers of the behavioral aspects of nanocelluloses.

Surface cross-linking of nanocellulose takes advantage of the abundant hydroxyl group moieties inherent to its structure. The prevalence of hydroxyl groups in nature demonstrated by the functional propensity and frequency plot of Fig. 10 predicts that the probable deviation from its assigned role in nature might drastically reduce nature's ability to degrade the biosynthetic blend. This is particularly true if nitrogen-containing synthetics are blended within the nanocellulose structure as judged by the functional group content of plot 10. Consideration between physical- and chemical-based cross-linking of hydroxyl groups also give rise to concerns over “stronger” versus “weaker” arguments and implications of bond strength in resulting blends. In recent times, it has been rightly recognized that the surface interactions of nanocelluloses are far from trivial. This is certainly true of water vapor adsorption at the amorphous/crystalline interface that exists as a 1 nm layer (Niinivaara et al. 2015) and the availability of hydroxyl groups can affect its ability to swell to control permeability which may affect its use technologically (Capron et al. 2017).

Poor moisture resistance of nanocellulose is perceived to be major barrier to technologically advancing in the area of packaging and related areas (Cherpinski et al. 2018) and the sensitivity to humidity is professed to an unresolved issue. The persistence of humidity in the environment has a tendency to drive deformation and induce a loss of mechanical stability. Often, the material complexity of nanocellulose blended materials circumvent a better understanding of the accurate nature of the interaction of water vapor in the surroundings with the molecular intricacies residing in the biopolymer structure itself. In hindsight, the mediated effects of moisture are elusive in the midst of reported observations that support the role of water as a plasticizer (Mittal et al. 2018). The computational study revealed that while the presence of intercalated water molecules could be unfavorable universally for the global performance, a considerable change in shear modulus fits in with its bio-inherent ability of hierarchical fiber networks to respond to changes in the vapor content of the environment in the same way as a fabricated sensor might. In Fig. 13, simulation trajectories predict the molecular importance of water molecules (Chami Khazraji and Robert 2013) by forming associations termed “capillary bridges” at the nanocellulose interface and serve to increase the fracture energy by

Fig. 13 (a, b) Simulation of water molecules at the cellulose nanocrystal interface showing preferential contact between water molecules. (a, b) Taken from (Chami Khazraji and Robert 2013) (c) (Salmén and Bergström 2009).

acting to increase the interface prior to failure. Further, strain force has greater toleration under moist conditions compared to dry ones and a parallel-type arrangement of water molecules could be conducive to load-bearing operations (Salmén and Bergström 2009). This suggests water has a bigger role to play.

Greater relevance might come from deciphering the hydrogen bond network with interconnections to water molecules with the aim of predicting more precisely the role of water molecules under differing atomical arrangements. This scenario should reflect the competition for CNC binding sites that likely occur between CNC and water molecules. To this effect, with increased accessibility of water molecules, the study considers that under conditions of humidity, CNC–CNC bonds are intercepted by water molecules and rearrange to a water intercalated arrangement, CNC–water–CNC. A combination of multiscale simulations and experiments were applied to investigate differences between hydrogen (HBs), CNC–CNC (nanocellulose), and CNC–water–CNC bonding arrangements under variably defined conditions for humidity at the interfaces. The study is insightful in that it provides a relative percentage of humidity which is correlated to monitor changes in the mechanical properties mapped for all three bonding arrangements. The main findings of the study signify the formation of a denser hydrogen-bonded network for CNC–water–CNC and MD simulations and surprisingly strain-stress profiles comply with strain reinforcement applying to both tensile stress and the strain at break. Relative humidity (RH) falling in the range $30\% \leq \text{RH} \leq 50\%$ reveals the relative condition for the strain hardening phase which is lost to a weaker modulus and interfacial strength when $\text{RH} \geq 60\%$ resulting from a higher accumulation of water (Hou et al. 2021). Hence, depending on the conditions, the water-intercalated nanocellulose interface can switch between a mechanically strong and weak interface by adjusting to the environmental conditions in sensory fashion. Figure 14 shows the tensile stress curves and number of bonds as a function of water, and Fig. 15 shows tensile stress curves, tensile stress as a function of relative humidity profiles, and SEM images of fracture morphologies under variable conditions of humidity. Hence, self-modulation of mechanical properties in response to conditions of stress and strain hierarchy in nanocellulose has a multifunctional role that reaches far beyond the confines of structure.

Stress transfer between two different interacting components can serve a useful purpose for enhancing mechanical strength. Almost universally, strength increase is achieved at the cost of strain and toughness which is true for most nanocomposites. However, this mutually exclusive relationship is contradicted by increases in strength, elongation, and toughness. With brittleness as a primary problem of nanocelluloses, bioinspired strategies have proven to generate remarkable results for high-performance nanocellulose-based materials. In one study, a combination of two biopolymers comprising bacterial cellulose nanofibers (BC) and alginate were combined into a bioinspired hierarchical helical shape. The hydroxyl moieties of BC were readily accessible to the anionic polysaccharide carboxylate groups of alginates via a single capillary wet extrusion process in the presence of an aqueous CaCl_2 bath under a shear force and combined together under a wet twisted motion. The simultaneous accompaniment of all the three mechanical parameters of strength,

elongation, and toughness were also achieved with increase of 50 and 100% under variable conditions of relative humidity resulting from the twisted synergy of fibers. In contrast, untwisted nanocomposites in their dry states with considerable loss of water experienced inferior mechanical properties compared to the wet gel filaments (Gao et al. 2020). Figure 16 summarizes the fabrication of twisted morphologies of BC-Alg accompanied (a) by TEM and AFM images with height profiling (b–d) and the extrusion of hierarchical structures. Figure 17 summarizes the mechanical properties of BC-Alg morphologies in terms of their stress-strain, tensile strength, and toughness.

Concluding Comments

There is a slow but steady rise toward the development of biodegradable materials while researchers and technologists aim to re-formularize the way we create, utilize, and dispose of plastics. Hence, investment growth in new technologies and

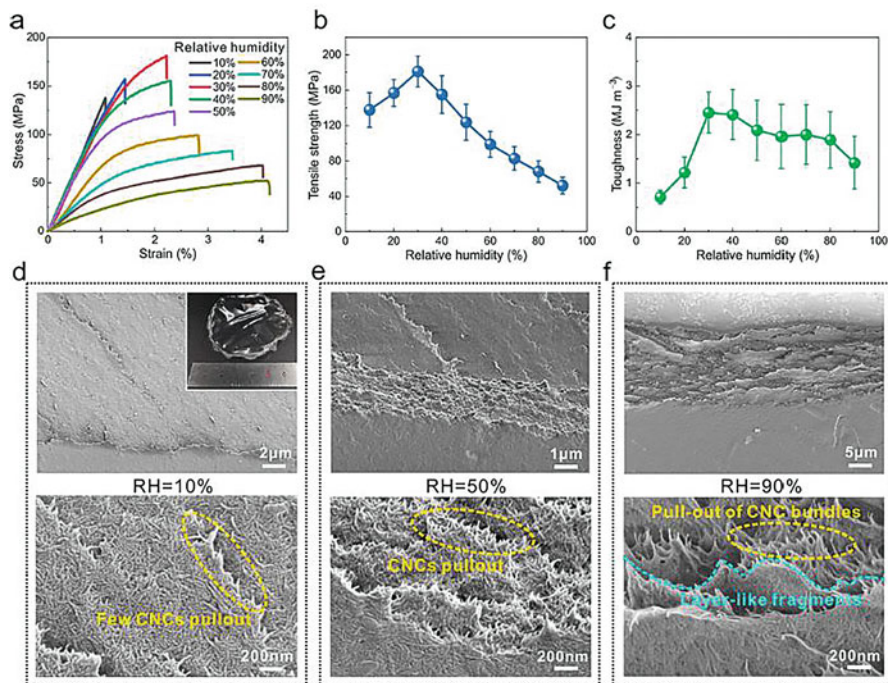

Fig. 15 (a) Tensile stress curve of CNC with 10–90% RH range, (b) Tensile strength measured as a function of RH, (c) toughness as a function of RH, and (d–f) SEM images showing morphology of fractures experimentally obtained under 10%, 59%, and 90% RH, and (d) prepared CNC film. innovative tools is elemental to material renewability and sustainability to visualize a new industry *in* bioplastics. However, till the present day, the situation still remains largely unchanged in implementing safeguarding strategies against accumulating plastics which are energy demanding and may not be applicable in handling highly toxic plastics like polyvinylchloride (PVC). Thus, rethinking the approach to plastic packaging has become a conceptual challenge from design to recyclability of by-products to reduce the carbon print. To strive for a carbon-free world as it relates to nondegradable packaging is unrealistic but the passage back to carbon neutrality necessarily means a bigger commitment to synchronize materials with nature. The conceptuality of this idea is being developed by adapting nonbiodegradable materials or their composites to resemble structurally and behaviorally natural polymers.

Nanocelluloses lie at intersection of bio- and synthetic polymer engineering. As the number of biosynthetic nanocellulose composites reportedly increase year by year, there is small yet concerted effort to better understand structure-function correlations that reside within nanocelluloses. A greater understanding of structure

in terms of bond connectivity across all hierarchical scales is key to elucidate performance-related mechanisms as a potential biodegradable material. An important area gaining attention relates to environmentally responsive structural changes that correlate to weak and strong mechanical performance. Switchable states that reflect mechanical performance of nanocelluloses is complex and requires an in-depth study to ascertain the intrinsic capabilities as a bioplastic. One emerging but insightful area has focused on the interfacial properties and behavior with water. A more extensive appreciation of the chemical and structural synergy with its environment and with other biopolymers could provide more effective solutions in challenging area of biodegradable plastics. To this end, the merger of natural resources and technology is imperative. Natural biodegradables offer considerable opportunity to leverage renewable technologies and related areas to improve plastic recyclability and cost reduction.

Abstract

Electronic devices frequently include flexible circuit boards, and soon the substrate of picture displays will be composed of flexible materials as well. Due to their innate flexibility and optical properties, plastics are potential choices; however, they also have significant thermal expansion. To prevent damage during the thermal cycles required in the production of the display, the substrate's expansion needs to be compatible with that of the active layers that have been placed on it. Reinforcing plastics with nanofibers is one method of lowering the thermal expansion of those materials without significantly reducing transparency. In nature, the primary source of cellulose is plants and animals which is the major source of nanofibers. Here are some of the researches to produce optically transparent composites based on natural nanofibers for use in flexible displays are presented and discussed.

Introduction

Cellulose is the abundant and most commonly used polymer on the earth synthesized by cell-free systems, microorganisms, and plants. It is chemically composed of repeating units of β -D-glucose monomers linked through β -(1,4)-glycoside linkage. A hemiacetal group found at the end of each cellulose chain enables the asymmetry in the cellulose chain's orientation. Nanocellulose can be synthesized in crystalline and amorphous form and can be methodized through a physical, chemical, and/or enzymatic reaction. Natural cellulose has a fibrous shape with occasional crystalline and amorphous portions. It is mostly extracted from cellulose-containing material, with wood being the most common source. Cellulose extracted from the wood source usually has a unique hierarchical and hollow structure. The production of these fibers and their use in composite materials have gained more attention in recent years due to the numerous advantages of nanocellulose, including their high melting temperature, 200 times the amount of surface area, high crystallinity, biodegradability, finer web-like network, and stiffness with low weight (Kim et al. 2015; Eichhorn et al. 2010).

Nanocellulose has gained a lot of attention in recent times due to its interesting properties and potential application in bio-generated and bio-renewable material (Klemm et al. 2011). The nanocellulose often called cellulose nanostructure is classified into three categories namely: (1) cellulose nanocrystals (CNC) also known as nanocrystalline cellulose, cellulose (nano)whiskers, or rod-like cellulose nanocrystals; (2) cellulose nanofibrils (CNF), which include nano fibrillated cellulose (NFC), micro fibrillated cellulose (MFC), or cellulose nanofibers; and (3) bacterial nanocellulose (BNC) also referred to as microbial cellulose.

Nanocellulose due to its distinctive property such as three-dimensional web-shaped reticulate fibrous structure, biocompatibility, good mechanical strength, high crystallinity, hydrophilicity, biodegradability, optical transparency, poly-functionality, high specific surface area, and the ability to be molded into three-dimensional structures. The three-dimensional hierarchical structures that makeup nanocellulose fibers at various scales, the combination of cellulose's physical and chemical properties like hydrophilicity and the ability to be functionalized and chemically modified by a wide range of reactions, as well as the key benefits of nanoparticles such as aspect ratio, high specific surface area, improved mechanical properties, optical transparency and low thermal expansion coefficient all contribute to the development of nanocellulose fibers (Yano et al. 2005; Nakagaito et al. 2010; Nogi and Yano 2008; Okahisa et al. 2011).

However, despite its many advantages, nanocellulose has drawbacks that limit its use, such as incompatibility with hydrophobic polymers, low-temperature stability,

and moisture absorption (Guimard et al. 2007). The current difficulty in using nanocellulose for high-value materials is to add functions through blending, covalent modification, cross-linking, polymerization, or a combination of these approaches. The presence of a significant number of hydroxyl groups inside the nanofiber's structure may act as a planned basis for surface alteration using various substituents, making it extremely hydrophilic and adaptable to a variety of chemical and physical modifications. Nanocellulose has thus been widely regarded as a suitable nanostructure for creating new high-value nanomaterials due to its great biocompatibility, mechanical strength, renewability, and low cost.

The use of nanocellulose in conjunction with carbon-based materials like graphene, carbon nanotubes, and carbon dots has been proposed as a viable strategy for the future of sustainable electronics (Lee n.d.). This new class of hybrid materials with a synergetic effect in a variety of applications, ranging from sensing to biosensing, catalysis, photonics, medical, wearer treatment, optics, and optic energy has also emerged. Some of the less popular nano-carbon materials used in CN-based hybrids are carbon black, activated carbon, carbon quantum dots, and carbon nanofibers (Oksman et al. 2006; Yoon et al. 2006).

A great candidate material to replace hard glass has been considered to be nanocellulose. Nanocelluloses can be used to perform a variety of optical tasks. The topic that has received the most attention is probably that of CNC's cholesteric liquid crystallinity, which produces tunable iridescence, including structural colors, and enables the transfer of such qualities into other materials via a template. Due to the chiral twisting of endogenous cellulose components, some berries can exhibit structural colors (<http://www.oled-display.net/oled-revenues-forecast>). In order to understand tactoid formation or in the case of microfluidic droplets, the formation of chiral nematic phases of CNC was also investigated in spherical confinement in emulsions. These investigations demonstrated the angle-independent photonic characteristics and radial symmetric orientation of the CNC layers. On the other hand, a significant area of nanocellulose-related research has been obtaining transparency in films (Forrest 2004).

A UV visible spectrometer can be used to evaluate the light transmittance in the wavelength range of 200–1000 nm in order to determine the optical characteristics of nanocellulose films. If the fibrils are small enough and packed closely enough, CNF films may be optically transparent. This will prevent light scattering by minimizing the interstices between the fibrils. Films with transmittance values above 80% are typically produced by TEMPO-oxidizing CNFs with widths of 3–4 nm. Due to the dense packing of the fibrils, slow filtering, drying, and compression films are often translucent rather than optically transparent and the electrostatic forces between negatively charged particles are characterized by an underlying cholesteric pitch. CNCs exhibit a lyotropic liquid crystalline behavior in water. A phase transition from an isotropic liquid phase to a chiral nematic phase is observed from a specific concentration threshold. If the pitch in the solid films is close to the wavelength of visible light, the CNC self-organization is maintained by straightforward water evaporation, resulting in Bragg's reflection of visible light. The pH of the CNC suspension can be changed by adding electrolytes, and the energy of the ultrasound/

sonication treatment used to disperse the particles in water can be changed to produce iridescent CNC films of various colors.

Nanocellulose has been regarded as the best option to replace hard glass. In order to create flat-panel displays (FPDs), functional materials like transparent conductive films, gas barrier films, and metal wiring are often deposited on huge glass substrates before being cut into commercial sizes. However, these methods are costly and cost-effective production using continuous roll-to-roll processing is anticipated to take its place. Many requirements, including those for optical characteristics, flexibility, and thermal expansion, are met by these materials that are used to replace the glass. As a result, it is envisaged that nanocellulose-reinforced nanocomposites will be a suitable replacement for glass. The optical and electrical qualities of the flat film are two of its most crucial characteristics for electronic displays.

The cellulose nanofiber is made up of semicrystalline cellulose molecule chains aligned parallel to their axes. The hydrogen connections that bind the cellulose chains to one another laterally inside the crystalline domains provide a highly organized crystalline structure. Since the benzene rings in aramid and the glucose rings in cellulose are both bonded together instead of folding, the density and modulus of the two materials are quite comparable (Whitton 1970). When the young modulus of the perfect cellulose crystal was measured, it was around 138 GPa (Dodds and Gudder 1992) and the tensile strength was beyond 2 GPa. Yano et al. (Hayakawa et al. 2012) were the first ones to report the synthesis of transparent nanocomposite made by adding bacterial cellulose nanofibers as the reinforcing phase. Because of the enormous hydrophilic surface area, BC is made up of a network of ribbon-shaped fibrils with a width of less than 100 nm that contains around 99 wt% water. The matrix before being treated with epoxy, phenol-formaldehyde, and acrylic resin, the surplus water was squeezed out and fully dried and then cured by UV light or hot pressing. The resultant matrix usually has a fiber content of 60–70 weight percent.

Despite having a high nanofiber content, the overall light transmittance in the visible range between 500 and 800 nm was more than 80%. Less than 10 percentage points were lost in light transmittance due to the reinforcing as compared to the plain matrix resin. Transparency is drastically reduced if there is even a tiny mismatch in the refractive indices of the fibers and the matrix, which is how light transmittance is predominantly controlled in typical micro composites.

The refractive index of cellulose is 1.618 along the fiber and 1.544 in the transverse direction at 23 °C, compared to 1.483 at 587.6 nm for impregnated phenol-formaldehyde, for example. The other types of resin used in the process exhibit comparable differences. The degree of transparency due to the reinforcing element reduced lateral surface area, because of the scattering of light due to the nanofibers.

Methods for Synthesizing Nanocellulose Materials

These nanofibers offer a fantastic platform for surface functionalization through diverse approaches due to their enormous specific surface area and abundance of

hydroxyl groups inside the nanocellulose structure (Habibi 2014). The characteristics of nanocellulose discussed above provide appealing methods for selective surface modification to include practically any desired surface functionality (Hofmann and Reid 1929). Utilizing esterification processes, the hydrophobization of cellulose surfaces was accomplished in the 1920s and early 1930s and employed for food packing. Acetylation and esterification of chitin (Nair et al. 2003), starch (Jeon et al. 1999), xylan (Peng et al. 2010), cellulose nanocrystals (Nakagaito et al. 2010), cellulose fibrils (Huang et al. 2012), and cellulose fibers (Vaca-Garcia et al. 1998) have been used in a number of methods during the past few decades to make materials hydrophobic. In order to reduce moisture absorption (Sethi et al. 2018), improve interfacial affinity between nanofibers and resins (Tan et al. 2015; Trinh and Mekonnen 2018), and increase thermal stability (Sharma and Deng 2016; Qu et al. 2018), a variety of long-chain aliphatic compounds have been grafted on CNFs and CNCs using various methods. More advanced cellulose derivative-based goods have started to be taken into account as cutting-edge technology throughout time. Innovative products based on nanocellulose, such as synthetic skin, biosensors, flexible electronics, and volumetric displays, have recently received a great deal of attention. It is important to change the structure of cellulose and give it new properties in order to accomplish this purpose.

Complex multi-stage procedures such as combinations of enzymatic, mechanical, or chemical treatments are used in the extraction of pure cellulose (Rajinipriya et al. 2018). Alkali treatment (using sodium hydroxide or potassium hydroxide), bleaching (delignification with sodium chlorite or hydrogen peroxide), and acid hydrolysis (using sulphuric acid, acetic acid, or oxalic acid) are the three main phases in nanocellulose extraction processes. While CNFs are produced via a number of mechanical processes, including grinding, cryocrusting, steam explosion, microfluidation, ultrasound, homogenization, etc., CNCs are recovered by direct acid hydrolysis of pure cellulose (Khalil et al. 2012).

The four primary categories of NC extraction therapies are mechanical, pressure-induced, enzyme-assisted, and green chemical extractions. CNFs are typically created using mechanical techniques such as ball milling, twin screw extrusion, cryo crushing, etc. Crystalline forms of nanocellulose can be created using pressure-induced techniques. On both a laboratory and an industrial scale, high-pressure homogenization (HPH) is one method that is particularly effective for creating CNCs (Deepa et al. 2015).

Algae, wood, wood products, and bacteria can all be used to extract cellulose. Wood is mostly composed of cellulose microfibrils, which have cross-sectional dimensions of 20–100 nm and fiber lengths of 100–200 nm. The amorphous and crystallized components of cellulose are known to be sequentially ordered along the direction of the fiber and to divide into nanofibrils in cross-section. It is nearly impossible to separate the cellulose crystal sections due to the strong hydrogen connections that exist between its hydroxyl groups. However, the amorphous parts of cellulose are very easily broken. Therefore, natural resources must first be handled and amorphous cellulose must be broken down in order to recover NC in CNC and

CNF forms. CNC and CNF are superior to other materials in terms of tensile strength.

However, it is challenging to extract CNF and CNC from natural resources due to the fact that there are numerous resources, each with a different composition and cellulose formation. In addition to wood, other sources of cellulose include bamboo, crop wastes, discarded fruit bunches from oil palm trees, sugar cane bagasse, tunicates, and bacterial cellulose.

A well-known method for chemically and mechanically rupturing wood fibers to produce wood microfibers is called pulping.

For CNF and CNC extraction, there are two distinct methods that use mechanical, chemical, and physical processes. However, a multi-stage technique involving powerful chemical and/or mechanical methods is required to eliminate CNF and CNC.

The three substances that makeup wood fibers are lignin, hemicellulose, and cellulose. Lignin stops the wood from separating into its individual fibers. Delignifying makes sense before starting the NC extraction process. The most widely used method of lignin removal is known as kraft pulping, which entails boiling a solution made of a digester that contains sodium hydroxide and sodium sulfide.

As an intermediate source for the CNF and CNC extraction, microcrystalline cellulose (MCC), from which the majority of the lignin and sizable amounts of hemicellulose have already been removed, can be used. Acid hydrolysis can successfully dissolve the amorphous cellulose, releasing CNC into the solution.

Similar to acid treatments, cellulose enzymes can target the amorphous regions of cellulose fibers, making it easier to extract micro fibrillated cellulose. By cellulose dissolution, microcrystalline cellulose can be expanded and made more likely to separate into nanofibers. There are many other kinds of cellulose solvents, but *N,N*-dimethylacetamide (DMAc) with lithium chloride is the one that is most frequently used to dissolve cellulose (LiCl). Cellulose may be dissolved using an ionic liquid, a solvent that is environmentally friendly and recyclable. An ionic liquid containing 1-butyl-3-methylimidazolium chloride was used to dissolve and regenerate cellulose, and subsequently, it was used to make electro-active paper.

TEMPO-mediated 2,2,6,6-tetramethylpiperidine-1-oxyl radical oxidation was used to extract cellulose nanofibrils that are 3–4 nm wide and a few microns long. Even when native cellulose is subjected to TEMPO-mediated oxidation of cellulose, a regioselective surface modification of crystalline cellulose microfibrils, the original fiber morphologies are not affected.

The cellulose microfibers' inter-fibrillar hydrogen bonding needs to disintegrate under intense mechanical pressure in order for CNF to be released. Depending on the degrees and types of mechanical forces, amorphous cellulose or hemicellulose domains, a type of inter-fibrillar hydrogen bonding, can be easily broken first and inter-molecular bonding by the Van der Waals force can be broken second. The intramolecular hydrogen bonds in cellulose are extremely strong and are seldom disrupted. Amorphous domains or interfibrillar hydrogen bonds can dissolve to

release CNF. High-pressure homogenizers and grinding procedures were employed to micro-fibrillate pulp fiber.

On the other hand, the treated pulp displayed a wider distribution in fiber width. The result of combining two strategies was uniform CNF. However, the hydrophilicity of this CNF increased water retention by 545%. Several methods, such as the bead mill, pearl mill, ball mill, dis mill, and twin-screw extruder, have been tried for the extraction of CNFs. Recently, a process for extracting CNF that is ecologically benign was created: aqueous counter-collision technology (ACC). This method uses just two water jets and no additional chemical changes to transform biobased materials into nano-objects.

The capacity of cellulose nanocrystals to create a liquid crystalline phase in water at a specific concentration is another intriguing characteristic of these materials. They have a high inclination to align along one vector direction as a result of their inflexible rod-like shape (Imai et al. 1998). The nanostructures of cellulose can form nematic ordered phase which is chiral with optical properties similar to a conventional cholesteric liquid crystal when the suspensions reach the critical concentration. After the water has evaporated, the chiral nematic ordering can still be present, leaving behind iridescent films of cellulosic crystal structure (Boisset et al. 2000).

Method for Preparing Nanocellulose Composites

In contrast to the dried BC sheets, which were translucent for surface light scattering, the nanofibers are able to reduce the light scattering if the nanofibers are closely produced and the pores between the fibers are small. The nanocellulose surface must be uniformly smooth in order to improve light surface scattering. There are various techniques for smoothing nanocellulose's surface. The first technique involves laminating optically transparent polymers onto sheets of nanocellulose. Impregnation in plastics has been the second technique that has been mostly used.

The difference between the refractive indices (RI) of nanocellulose and plastic is minimized to increase the light transmittance of the nanocomposite.

Since the RI of polymers varies, the RI of nanocellulose must also be controlled. Chemical processes are used to modify the RI of nanocellulose. As a result, it is important to correctly manage CTE and the substrate's optical transparency. Acetylation is the most used type of chemical treatment. Both BC/acrylic resin and pulp that have been ground, display optical transparency in their appearances. The sheet of pulp and acrylic resin that has been homogenized, on the other hand, seems translucent. In general, nanocomposites cannot be made more transparent after 30 refiner passes; however, extra processing, such as grinding, can make materials more transparent by making them more fibrillated.

The flexibility of the BC nanocomposites, which are made of epoxy-modified siloxane and nanoparticulate boehmite, varied depending on whether BC was never dried or cured. When never-dried BC was used, the nanocomposites were studied, and the results revealed that Young's modulus and tensile strength both increased

with a decrease in elongation at the break due to the effective relationship between the boehmite-GPTS sol and the BC microfibrils; water also acts as a plasticizer.

The properties of nanocomposite containing BC are also influenced by the method of plastic introduction. The first technique of introduction is the “in situ” method, which involves adding plastics directly into the developing BC media. The second method of introduction involves “impregnating” BC into a plastic solution. The ribbon-shaped structure of nanocellulose differs from other structures in nanocomposites, according to techniques of fabricating one another.

Nanocellulose requires a pre-treatment, oxidant, or dopant to enhance its characteristics and material compatibility in order to increase the electrical properties of nanocomposites working with bacterial cellulose.

Important Factor for Optically Transparent Application

Flexible circuits have a far longer history than most people realize. Electrical conductors coated on flat substrates were taken into consideration as early as the first decade of the twentieth century for usage in radios and telephony switching for exchanging lines. Circuit innovations were sought after by the developing electronics sector for mechanized mass production. These original stiff substrates gradually developed into flexible ones, and today flexible electronics can be used in almost every electrical or electronic product where there are requirements for electrical connection of moving elements or space, shape, or restrictions. As the field of flexible electronics develops, flexible substrates will soon be utilized in screens that can be rolled up for mobility or built into clothing, as well as solar panels that can be wrapped around the exteriors of buildings.

When viewing images through the substrates, bottom-emissive displays need to have a total light transmission of more than 85% over the visible light spectrum (400–800 nm) and less than 0.7% of haze. Applying a tough coating can produce barrier and solvent resistance, whilst a scratch-resistant covering can produce a smooth surface. The material's inherent features of thermal and dimensional stability necessitate the careful selection of the plastic in order to withstand thermal cycles and high temperatures experienced during the deposition of the coating and active layers during manufacturing.

In order to turn individual pixels on or off, displays need to use a thin-film transistor (TFT) circuit that produces a regulated current source. Displays need an inorganic TFT backplane placed on the substrate for that, which means they will experience thermal stress cycles throughout the production of the panel and will thus need a substrate material with an extraordinarily low coefficient of thermal expansion (CTE). Instead of the conventional rigid glass substrates, flexible plastic substrates offer the opportunity to create strong, thin, and lightweight displays that bend, flex, and conform to different shapes. Manufacturing can also use roll-to-roll processes that are affordable. Surface smoothness, High transparency, barrier capacity, thermal solvent resistance, dimensional stability, and decreased cost are still

requirements for plastic substrates. To avoid strain and damage during the thermal cycle, the coefficient of thermal expansion is expected to be below 2×10^{-5} K.

The use of nanocellulose in flexible displays has received a lot of attention. The flat-panel display (FPD) technology is transitioning from batch processing to less costly continuous roll-to-roll. OLED displays, which use organic light-emitting diodes, are among the flat-panel screens that are now gaining prominence. Because OLED is used in larger screens for desktop monitors, laptops, tablets, and mobile devices, the OLED industry is expected to rise. By 2015, the OLED market is expected to reach \$ 5.5 million.

The traditional method involves piling up on a big substrate, which is primarily made of glass. After that, depending on the equipment, cut the panel into different sizes (Forrest 2004). As a result, the most economical method of producing glass of different sizes was the traditional method. Due to their flexibility, plastics are employed as substrates in continuous roll-to-roll processes rather than glass. Plastic's elasticity allows for easy folding and rolling up for storage when a process is not in use. As a result, the roll-to-roll method has various benefits, including as low costs, ease of distributing functional material on the substrates, and product storage (Reuss et al. 2005). There are three prerequisites to meet in order to become a substrate in a roll-to-roll process. First, the high coefficient of thermal expansion (CTE) must be less than 3 ppm K^{-1} . However, the CTE of polymers is high (approximately 50 ppm K^{-1}). Additionally, foldable or flexible plastics (around 200 ppm K^{-1}) exhibit incredibly high CTEs (Yano et al. 2005).

According to an atomistic theory of materials, the profundity of the atomic bond energy function is connected with both thermal expansion and Young's modulus, however, the relationship between the two attributes is inversely proportionate. As a result, flexible polymers with low modulus have high CTEs by nature. One option is to reinforce plastics with fibers with low CTE in order to lower CTE while maintaining flexibility. However, the refractive indices of the fibers and plastic material are precisely matched, and the presence of elements, even at micrometer levels, lowers the transparency.

Functional materials can be destroyed and damaged during the assembly and mounting process due to the difference in CTE between functional materials and plastics. Second, flexibility not only enables the gadgets to be bent or flexed but also implies cost-effectiveness. However, the plastic is delicate to tiny cracks, making it susceptible to tearing during rolling. Thirdly, in order to use in a variety of applications, high optical transparency is required.

Instead of microfibers, tinier nanofibers with lateral dimensions far shorter than the wavelength of visible light are preferable. The size of this necessary dimension should be at least one order of magnitude less than the visible light wavelength, that is, between 40 and 80 nm. Such nanofibers are already present in nature as abundant renewable resources in the form of biopolymer cellulose. This chapter will provide a brief summary of the research on cellulose nanofiber-based transparent nanocomposites, focusing in particular on efforts to limit the thermal expansion of polymeric resins for use as substrates in flexible electronics.

Coefficients of Thermal Expansion (CTE)

CTE plays a crucial role in the roll-to-roll process. The functional materials that are attached to substrates would be harmed and destroyed by the mismatch between the CTE of materials if the substrate is unable to withstand the high temperature throughout the procedure. Glass used as substrates has a CTE that is sufficient to maintain the manufacturing process's temperature, but the glass is extremely fragile and cannot be folded.

Plastic reinforcements must be used in order to increase CTE. On adding reinforcement to plastics, it lowers the CTE of plastics without loss of optical transmission. The decreased CTE associated with nanocellulose balances out the high CTEs of polymers. On the other hand, the high Young's modulus of nanocellulose is complemented by the low Young's modulus associated with plastics. Nanocomposites have different CTEs depending on different types of reinforcements, polymers, and chemical treatments. By drying mats of fibrillated kraft pulp submerged in plain acrylic resin and cured with UV light, optically transparent composites made of these materials have been created. The composite thus formed has lower CTE (17 ppm K^{-1}) (than the CTE of the pure acrylic resin. This outcome shows that the pulp's fibrillation served as reinforcement in nanocomposites (Iwamoto et al. 2005).

Bamboo nanofibers that had undergone a leaching process to remove extractives had been added as reinforcement to acrylic resin. The dried nanofiber sheet was impregnated in acrylic resin to create the nanocomposites. Bamboo nanofibers and resin were combined to create nanocomposites, which demonstrated that their CTEs were lower than those of pure resin. One of the intriguing facts is that the CTE of mature bamboo is higher than another bamboo because mature bamboo has higher lignin content (58.1 ppm K^{-1}) (Hanic and Craigie 1969).

Yano et al. (2007) investigated the relationship between the degree of crystallinity, CTE, and modulus. When the degree of crystallinity is raised, the intermolecular hydrogen bonding between the cellulose molecular chains increases. Because thermal expansion is constrained by intermolecular hydrogen bonds, a high degree of crystallinity denotes a low CTE. Increased grinding causes the deterioration and disintegration of fibrillated fibers when more passes are made through the grinder. In conclusion, CTEs and material modulus are influenced by the degree of crystallinity. Furthermore, because cellulose contains nanofibers that are connected by hydrogen bonds between intermolecular, it is difficult to separate these nanofibers using mechanical processes (such as grinding, homogenizing, etc.).

Fukuzumi et al. (2009) transformed the majority of the hydroxyl groups of cellulose into negatively charged sodium carboxylate groups using 2,2,6,6-tetramethylpiperidine-1-oxyl radical (TEMPO) in order to split and divide into microfibril without destruction and damage. Then using a blender-style homogenizer, they produced TEMPO-oxidized cellulose nanofiber (TOCN). The CTE of TOCN (2.7 ppm K^{-1}) is lower than glass (about 9 ppm K^{-1}) compared with silicon (3 ppm K^{-1}).

Excessive acetylation causes negative effects on the CTE of nanocomposites including bacterial nanocellulose. The hydrogen bonding between the cellulose molecular chains is weakened by replacing the hydroxyl groups of BC with acetyl groups from acetylation. The nanocomposite of acetylated bacterial nanocellulose undergoes thermal expansion readily (Ifuku et al. 2007). If BC is used as a reinforcement, the coefficient of thermal expansion is affected by layer direction within BC. The rationale for the layers is that only bacteria near the surface of the culture medium can maintain their activity due to cell development. As a result of the strong hydrogen bonding between nanofibers made up of dense and finely branched fibers, it was discovered that the CTEs of plane direction for BC nanocomposites was 4 ppm K^{-1} . On the other hand, it was discovered that the CTEs of thickness direction for BC nanocomposites were 555 ppm K^{-1} (Nogi and Yano 2008).

When bacterial nanocellulose is added to the epoxy material, the CTE of the composite is reduced drastically from $6 \times 10^{-6} \text{ K}^{-1}$ to $120 \times 10^{-6} \text{ K}^{-1}$. The nanocomposite of BC/phenol-formaldehyde was smaller at $3 \times 10^{-6} \text{ K}^{-1}$. The modulus was around 20 and 21 GPa, while the tensile strength was 325 MPa for the nanocellulose composite. BC nanocomposites are flexible, light, and very transparent despite having a high modulus. Nogi et al. (Morand and Briand 1996) assessed how the refractive index of the matrix acrylic resin affected the transparency of nanocomposites of bacterial nanocellulose. The total and regular transmittances at a wavelength of 590 nm were greater than 85% and 75%, respectively, while the resin's refractive index ranged from 1.492 to 1.636. Similarly, when the temperature changed from room temperature to 80°C , the matrix refractive index changed by 0.014, while the regular transmittance of composites remained constant (Higgins et al. 2008).

The transmittance of resin reinforced by BC decreases linearly with fiber content; however at the fiber content of 66 wt%, the loss from neat resin to composite is only 13.7 percentage points. The CTE of acrylic resin is reduced from $86 \times 10^{-6} \text{ K}^{-1}$ for the neat acrylic resin to $15 \times 10^{-6} \text{ K}^{-1}$ and $10 \times 10^{-6} \text{ K}^{-1}$ with the addition of BC nanofiber at 30 wt% fiber content, and 50 wt% fiber content.

The high moisture content of nanocellulose, caused by the presence of hydroxyl groups in its molecular chains, makes cellulose-based products very hydrophilic. Nogi et al. and Ifuku et al. (Atalla and Vanderhart 1984) acetylated the BC nanofibers, substituting acetyl groups for the hydroxyl groups on the surface of the fibers, to decrease the sensitivity of moisture in BC nanocomposite. The water content of the untreated BC composite at 60 wt% fiber content was 3.12% when exposed to a relative humidity of 55% at ambient temperature, while the moisture content of the acetylated nanocomposite of BC was decreased to 1.33% at a fiber load of 66 wt%.

Young's modulus was decreased from 23.1 to 17.3 GPa, and the CTE of the BC sheet improved from $3 \times 10^{-6} \text{ K}^{-1}$ of the untreated to merely $0.8 \times 10^{-6} \text{ K}^{-1}$ of the acetylated sheet. The less hydrophilic acetylated BC's improved compatibility with the hydrophobic matrix may be the cause of the decreased CTE. The acetylated BC had transparency in the region of wavelength around 400 nm while maintaining visibility in the other portions of the spectrum, according to the regular transmittance in one of the BC/acrylic resin combinations.

The neat BC sheet is tightly packed, as seen in the SEM images, whereas the acetylated BC sheet is separated from one another. This suggests that the acetyl groups present on the surface of fibrils prevented their aggregation through hydrogen bonds, maintaining the uniformity of the individualized nanosized lateral dimensions of the nanofibers. The BC nanocomposite that is acetylated showed a lesser decline in transmittance than the untreated BC nanocomposite when both were exposed to a temperature of 200 °C for several hours, indicating that they resisted thermal degradation along with an increase in optical transparency.

BC was used with a translucent resin (VanderHart and Atalla 1984) which has a low Young's modulus to reduce the thermal expansion of composites, particularly at a fiber concentration as low as 5 wt%. Due to the resin's low modulus of only 25 MPa, the resultant composite has a modulus in the range of high-density polyethylene at 355 MPa. Due to its low modulus, the composite was incredibly flexible and even foldable without suffering any harm. The in-plane CTE was exceptionally low at just $4 \times 10^{-6} \text{ K}^{-1}$, despite the low modulus.

For materials with high Young moduli will have lower CTE which can be explained by the particular structure of BC pellicles, which consists of many layers of nanofiber networks that create strong in-plane networks which are poorly coupled along the thickness direction of the pellicles. The material expands its thickness, even at low concentrations, fibers are able to restrict the minor stresses produced by the expansion of the low modulus matrix in the in-plane direction. Although the in-plane CTE is extremely low due to its anisotropic behavior, the material has increased flexibility and can be folded more easily.

Optical Transparent

The nanofibers are dense and the pores in the fibers are small which suppress the light scattering property while the bacterial nanocellulose is translucent for surface light scattering. Nanocellulose is treated with emery paper to increase transparency. The nanocellulose surface must be uniformly smooth in order to improve light surface scattering. There are various techniques for smoothing nanocellulose's surface. The first technique involves laminating optically transparent polymers onto sheets of nanocellulose. Impregnation in plastics has been the second method that has been mostly used.

The optical transparency of nanocomposites made of nanocellulose and plastics is increased by the fact that the diameter of nanocellulose is smaller than the wavelength of visible light. The difference between the refractive indices (RI) of nanocellulose and plastic is minimized to increase the light transmittance of the nanocomposite. Chemical processing changes the RI of nanocellulose. As a result, it is important to carefully manage CTE and substrate optical transparency and acetylation is the most popular type of chemical treatment (Nogi et al. 2009).

Additionally, nanocomposites containing BC that had high DS displayed excellent transmittance because the RI of the BC dropped with increasing DS. Additionally, due to the improved bond that acetylation creates between

cellulose and polymers, BC that had been acetylated was successfully impregnated (Nakagaito et al. 2010). The insertion of bulky acetyl groups into nanocellulose led the thickness of the material to thicken, which allowed the thickened nanocellulose to interact with transmittance. Furthermore, excessively acetylated nanocellulose's RI would be lower than that of plastics.

In order to create opaque composites, bacterial cellulose (BC) seems to be a good source of nanofibers, however, the fermentation techniques used to make BC are incredibly sluggish. The more accessible wood or plant fibers might be used as a substitute, but first, the nanofibers must be removed. In a very intricate structure, cellulose nanofibers are discovered embedded in a matrix of hemicelluloses and lignin in the fiber cell wall of plants. In order to thoroughly reduce the size of the filament bundles and fibrillate the wood pulp fibers.

Iwamoto et al. (Horii et al. 1987) began with a cellulose shape known as micro fibrillated cellulose (MFC). He added an extra grinding process to the phases of refining and high-pressure homogenization. MFC produced by 14 homogenizer passes had a wide range of fibril widths, ranging from a few tens of nanometres to a few micrometers, which results in composites that are much less transparent than BC-based composites. The thicker fibril components impacts light scattering, which produces lower transparency. The 10 passes through the grinder added to the 14 passes through the MFC homogenizer to rise to fibril bunches that ranged in width from 50 to 100 nm. This MFC that had been ground into fibrillation was dissolved in water, and the suspension was vacuum filtered to create a thin sheet. Sheets were oven dried, coated with acrylic resin, and cured by UV radiation, and the light transmittance of grinder-fibrillated fiber/acrylic resin composite, pure acrylic resin, BC acrylic resin, and homogenizer-fibrillated fiber/acrylic resin was measured. The measured young modulus was lower than the modulus of BC composites, 7 GPa which means a more flexible substrate. The coefficient of thermal expansion for the matrix was 17×10^{-6} K from 86×10^{-6} K of neat resin.

Abe et al. (2007) created a new methodology that produced consistent nanofibers which has a diameter of 15 nm by only one run through the grinder to limit damage to the nanofibers in order to extract significantly greater nanofibers by grinding. Iwamoto et al. (2007) earlier investigated and analyzed the resulting nanocomposites' mechanical characteristics to determine how severe the mechanical shear that the grinder imparted to fibrillate was. Although composites were more transparent after five runs through the grinder and beyond, the morphology of the nanofibers had not changed, nor had their transparency. However, due to a decrease in the degree of polymerization and crystallization, its thermal expansion and tensile capabilities were severely diminished. It was also made clear how hemicelluloses affect nano fibrillation (Iwamoto et al. 2008). Hemicelluloses prevent the cellulose microfibrils from forming irreversible hydrogen bonds when pulp fibers are dried. Hemicelluloses are also plasticized by absorbing water when they are rewetted, which facilitates posterior nano-fibrillation. After chemically removing lignin and hemicelluloses, Abe decided to leave the fiber in a water-swollen state rather than dry it, which would have produced strong hydrogen bonds between the nanofibers. Later, Okahisa et al. (2009) created an organic light-emitting diode (OLED) layer on

top of a low Young's modulus resin-based optically transparent film, cellulose nanofiber was used as the reinforcing material which was produced from wood. Saito et al. (2006) discovered an even easier method of chemically extracting cellulose nanofibers. The C6 hydroxyl groups on the surface of the cellulose were changed into negatively charged sodium carboxylate groups by oxidizing the surface of the nanofibers using a 2,2,6,6-tetramethylpiperidine-1-oxyl (TEMPO) radical catalyzed method. The nanofibers' mutual adhesion was relaxed by electrostatic repulsion, and mechanical abrasion and agitation by a Waring blender were sufficient to separate the original fibers into nanofibers with diameters of 3–5 nm. The films produced by filtering of these nanofibers had transmittances exceeding 85% over the visible light spectrum and were optically clear (Saito et al. 2007). The films' tensile strength was comparable to that of Nogi et al. (2009) cellulose's nanofiber paper, but their coefficient of thermal expansion was considerably less, 2.7×10^{-6} K even though their Young's modulus was only about half that of Nogi's paper. Additionally, the films showed strong oxygen-barrier characteristics. Only three percentage points were lost in the light transmittance of the composite at 600 nm compared with 89% of neat resin when nanofibers were combined with polystyrene resin (Fujisawa et al. 2012) at a 10-weight percent fiber load. The coefficient of thermal expansion of neat fiber was 116.7×10^{-6} K to 63.7×10^{-6} K for the composite. The reduction of the coefficient of thermal expansion was similar to the values that were reported by Nogi et al. (2006), in his work on bacterial nanocellulose which was reinforced at a comparable fiber content by acrylic resin. These fibers that obtained the TEMPO oxidation method are finer and were produced by less energy-intensive extraction than mechanical methods and extracted more quickly.

Producing nanofibers using electrospinning is an alternate way to get around the pricey extraction process. In order to create continuous fibers with a nanometre diameter, Liu and Hsieh (2002) spun cellulose acetate using a solvent mixture of *N*, *N*-dimethylacetamide (DMAc), and acetone. To create cellulose nanofibers, these cellulose acetate nanofibers underwent further processing to hydrolyse the acetyl groups and restored the hydroxyl groups. Using polyvinyl alcohol (PVA) as the matrix resin, composites were created, and optically transparent films were produced (Tang and Liu 2008). PVA was fortified with cellulose acetate nanofibers, regenerated cellulose nanofibers with diameters between 250 and 940 nm, as well as nanofibers with a lower diameter and a narrower range between 160 and 290 nm, in order to examine the factors impacting transparency (Tang et al. 2011). The transmittance of the plain PVA was around 92% in the center of the visible spectrum. In the cellulose acetate nanofiber composite, the transmittance was about 80% at 20 weight percent and just 18% at 50 weight percent fiber load. The transmittance of the regenerated cellulose nanofibrous counterpart had the same diameter, which was over 85% at fiber quantities up to 30 weight percent and dropped to 38% at 50 weight percent. In contrast, the smaller regenerated cellulose nanofiber reinforced PVA films showed transmittance of 90% for fiber loads up to 30 wt%, remaining in the 85–88% range at 40 wt% fiber content, and reaching 55% with a 60% weight percentage of fiber. This research underlined the importance of fiber size while also highlighting their interfacial interaction with the matrix resin. Since cellulose acetates are less

compatible with hydrophilic PVA than reconstructed cellulose, they are more hydrophobic. Stronger fiber matrix adherence of cellulose-PVA interfaces results in progressive fluctuation in optical characteristic impedance, which improves transparency by reducing light reflections and refraction.

Later, a paper lacking matrix resins was produced that was optically transparent. It was given the name “cellulose nanofiber paper” by Nogi et al. (2009) and is constructed entirely of the same chemical components as regular paper, with the exception of a physical variation in the size of the fibers, which were produced using a process created by Abe et al. (2007). The morphology of cellulose is the only aspect of the paper that differs from standard paper. After filtering and drying, a nanofiber aqueous suspension was transformed into paper with a density of 1.53 g/cm^3 , which is quite similar to the 1.59 g/cm^3 of the cellulose crystallite (Sugiyama et al. 1991). Scanning electron microscopy measurements supported the virtually complete elimination of the tiny interfibrillar cavities. This paper was initially only translucent, but after meticulous polishing reduced the irregularity of its surfaces, the transparency increased to 71.6% at 600 nm wavelength. Along with having a tensile property of 13 GPa and a strength of 223 MPa, the thermal expansion coefficient of $8.5 \times 10^{-6} \text{ K}$ was comparable to that of glass. In order to smooth up the interfaces of the cellulose nanofiber sheet, the authors also coated it with clear polymers (Nogi and Yano 2009) and proposed that continuous roll-to-roll production techniques might be used.

Flexibility

Nanocellulose substrates' versatility has various benefits, including ease of processing and storage. Low modulus and high elongation at the break of nanocellulose are shown by the foldable and flexible substrates which demonstrate the flexibility of the nanocomposites that plastics provide. Pure acrylic resin has a very high elongation at break, yet the sheet tears when folded since the substance is sensitive to even the smallest fissures. Nanocellulose (BC) stops the spread of cracks in nanocomposites, allowing the materials to fold without cracking.

The flexibility and mechanical properties of nanocomposite depend on the dried and never dried BC. The flexibility of BC nanocomposite composed of nanoparticulate boehmite and epoxy-modified siloxane changes with the BC used never dried and dried state (Barud et al. 2012).

When utilized in dry BC (Barud et al. 2012), however, the elongation at break increases with a decrease in tensile strength and an increase in Young's modulus. The properties of nanocomposite containing BC are also influenced by the method of plastic introduction. The first technique of introduction is the “in situ” method, which involves adding plastics directly into the developing BC media. The second method of introduction involves “impregnating” BC into a plastic solution. The ribbon-shaped structure of nanocellulose varies depending on the process for creating nanocomposites.

Mechanical Strength

The hydrogen bonding between the nanofibers was broken off when PVA was coated on the surface of the BC, which increased the elongation at break when compared to pure BC. Young's modulus and yield strain in the case of MFC is influenced by the number of passes through the grinder. Young's modulus and yield strain decrease with more passes made. These findings suggested a connection between intermolecular hydrogen bonding and fibrillated fibers with pass number. The shape of the fiber was the source of the decrease in yield strain. First, additional grinder treatments led to the breakdown of the fibrillated fibers while also boosting hydrogen bonding. Second, the aspect ratio of the fiber fell as a result of the shear force that reduced the fiber's length.

Optical Application of Nanocellulose

For material-specific goals, photonic applications of nanocellulose are appealing. First, CNCs' liquid crystalline behavior produces opalescent films with specific optical properties; second, both CNFs and CNCs are capable of producing independent optically clear films.

The cellulose's structure and surface chemistry lend these materials their flexibility; with little effort, nanocellulose may be made compatible with both hydrophobic and hydrophilic substances, employed as a host for optically active nanoparticles, and modified to take covalently bound molecules. CNCs may easily create chiral films that are colored, nematic, and iridescent by evaporating aqueous solutions (Schlesinger et al. 2015).

The chiral nematic structure of CNCs is frequently left-handed because of the right-handed nanocellulose chirality, whereas liquid crystals formed from cellulose derivatives exhibit either right-handed or left-handed chirality. Therefore, when the helical pitching is in the order of the visible light wavelength, the chiral nematic CNC films selectively reflect left-handed light and appear colorful. Applications for such systems could be in chiral plasmonic, soft actuators, sensitive hydrogels, optical filters, anti-reflective coatings, and flexible electronics, and for chemical sensing CNC-templated composite which is mesoporous and has a fluorescent organosilica film.

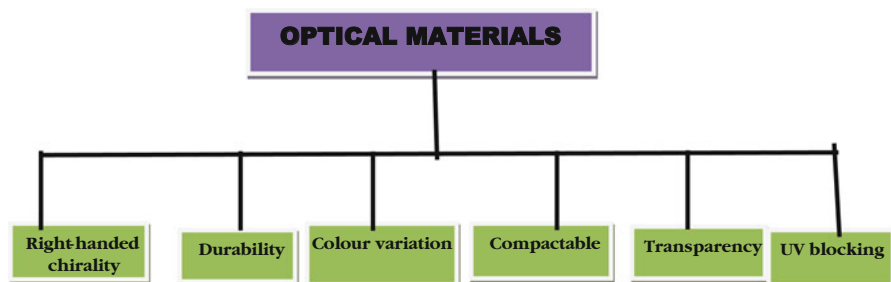

Furthermore, the modification of film color is rather simple because the helical pitch is sensitive to a range of factors. The spectacular photonic colors present in nature, such as those in butterfly wings and the seed hulls of the *Margaritaria nobilis* fruit, are comparable to the phenomenon of structure color. Over the past five years, a wide range of left-hand chiral materials, including cellulose, nanocrystalline, mesoporous silica, carbon, titanium, and organosilica as well as polymer/CNC nanocomposites, have been accessed via CNC templating. The overall strategy is to synthesize chiral nematic complexes from CNCs and materials of interest, often silica or polymers, and then either remove one element selectively or employ the component as part of nanocomposites.

Biomaterials are created by removing a portion of the basic nanocomposite to form a chiral highly porous substance that could contain components or serve as a

rigid template to create further chiral materials. Other CNC-based systems with varied optical characteristics, such as surface plasmons, UV blocking, fluorescence, and low refractive index, have been created in order to contribute to chiral nematic materials (Habibi et al. 2010). Greenhouse plastics, particle tracking, sensing, and anticounterfeiting technologies are some of the applications that have been suggested. ZnO absorbs UV light, therefore covering polyethylene with a combination of ZnO, SiO₂, and CNCs not only strengthened the plastic but also protected it against dangerous UV rays. Infrared blocking was also accomplished by the SiO₂ nanoparticles, which helped with energy conservation at night. CNF films are crucial as substrates for optoelectronic devices as well as in areas of packaging and coating due to their optical clarity and robust mechanical qualities (Haywood and Davis 2017).

CNF films employ additives like additional nanomaterials, polymers, or surface changes to add desirable qualities like hydrophobicity, similar to CNC-based systems. The drawback of CNFs and CNCs is their relatively high viscosity, even at trace levels preventing high-speed coating from using them. Given that the thickness of the NFC is less than the wavelength of visible light, it possesses good optical characteristics. Nanofibril-prepared paper is transparent as a result. This can be included in a number of applications, including those involving sensors, solar panels, and electronics. Jia Huang and colleagues documented the flexible field effect transistors that are imprinted on nano paper for use in green electronic transistor applications (Huang et al. 2013).

Numerous NC-based sensing devices demonstrated openness to various inputs. NC is frequently changed with different interfacial groups, other polymer chains, or even other nanoparticles to get a variety of properties and functionalities along its surface in order to create low-cost smart materials that are sensitive to biotechnology. The capacity to mix different functional nanomaterials with nano-scaled cellulose nanoparticles in various configurations opens up a wide range of possibilities for their future use in electrochemical, electrical, and optical devices. This recently developed nano cellulosic material proved a very adaptable choice for numerous sensing system application domains. According to Kan et al., a system based on the dispersion of pH-sensitive polyvinyl pyridine grafted CNC involving particle aggregation at basic pH was effective in biological applications for therapeutic release as well as industrial separation approaches. Additionally, NC has been employed as a support for conductive materials, fluorescent dots, or plasmonic, or catalysts. Here, new sensing platforms that induce sensing responses to chemical and physical inputs are identified (Soriano and Dueñas-Mas 2018).

Safety, coatings, and cosmetics labels can all use the eye-catching iridescent color of CNC self-assembly films. The visual quality of the films is immediately impacted by manipulating the direction of the cholesteric structure using external sources like magnetic fields, electric fields, or shear pressure. For instance, under various magnetic fields, the resulting CNC films exhibit a distinct color variation. The ability to use CNC self-assembly in film optics is made possible by the adjustable visual appearance. CNC films can be utilized as a color-controllable iridescent pigment. However, the sulfate ester groups on the surface of CNC limit the use of CNC films in pigments by making them prone to heat degradation and redispersion in water.

Thus, the pigment utilized in this CNC film can be applied to a variety of industries, including packaging for food, medicine, and cosmetics. Additionally, according to Zhang et al., CNC films can have some safety features by carefully regulating the use of the optical brightener (OBA) TINOPAL, which is used to modify the P and zeta potential. Public encrypting as an anti-counterfeiting strategy has become a feasible prospect. The safety elements include overt security (selected circular reflections and fluorescence) and covert security (iridescence).

A polysaccharide found in nature called cellulose has thousands of connected D-glucose monomer units. The primary structural element of the cell wall of plant cells is a natural polymeric type (pseudo-plastic) substance. In contrast, nanocellulose is a variety of forms of cellulose that has a nanostructure. Nanocellulose can be found in three different varieties. These are bacterial nanocellulose, micro/nano-fibrillated cellulose, and cellulose nanocrystals. The most often employed of these are cellulose nanocrystals and fibrillated nano cellulose structures, particularly in the creation of optical films.

Compared to bacterial nanocellulose, these two types offer a wide range of advantageous qualities, and they are much simpler to create in large quantities, thus they are employed more frequently. The characteristics of nanocellulose structures include high chemical stability, thixotropy, effective electronic and optical properties, high tensile strength (up to 500 MPa), high stiffness and strain, excellent barrier properties, no toxicity, and the capacity to self-assemble when deposited (i.e., through coating methods).

Optical Films

Nanocellulose-based films are well known for having optical transparency (i.e., low light scattering) as well as a variety of unusual optical characteristics, including iridescence, selective left circularly polarized (LCP) light reflection, and selective right circularly polarized (RCP) light transmission. They have been used in a variety of optical applications because of these characteristics, which are complemented by their high strength and wide surface area.

Additionally, nanocellulose is known (in certain conformations) to exhibit a birefringence through an optical anisotropy caused by the orientation of the nanocellulose structures during the self-assembly process when it forms multi-layer, multi-component films.

As optical filters, cellulose nanocrystals can self-assemble into three-layer sandwiched films with nanocellulose layers that are each in a separate liquid-crystal phase. These manufactured films are made of helicoidal cholesteric reflector materials sandwiched between a nematic-phase retardant layer.

The layered structure and various conformations of the nanocellulose replicate the polarization-insensitive reflectors discovered in the wings of *Plusiotis resplendent* beetles. These optical films are well recognized for having a high reflectivity that can be adjusted for both the visible and near-infrared spectrums. As a result, these optical filters may have a variety of uses, such as color filters, smart clothing, and solar gain regulation in building technologies.

Architectural windows, car windshields for navigating, and safety systems are just a few examples of vision-area applications where transparent nanocomposites used as OLED substrates can be used. Head-up display (HUD) navigation has recently begun to use this property in cars. Additionally, the adaptability of nanocomposites offers the possibility of using mobile phones, PDAs, tablet PCs, and sewing computer chips, cell phones, and GPS receivers into clothing. Additionally, transparent nanocomposites used as OLED substrates can be elastic and bendable, making it possible to develop flexible displays employing nanocomposites (Schultz et al. 1983). The current manufacturing process has to be enhanced for use as an industrial product. A fracture or other flaw might appear on a substrate's surface as a result of poor nanocomposite fabrication. Water and air contamination can also readily harm a display's surface (Dupeyre and Vignon 1998). Some of these issues are solvable. Fibrous cellulose can be manufactured by covering plastics with the substance. The manufacturing methods and their enhancements do not need additional funding because they can be produced using industry-standard technology. Depending on the conductance of the conductive polymer, electromagnetic shielding can be applied to optical equipment, display systems, sensing, batteries, etc., (Beg et al. 2000) easily by using transparent nanocomposites as packing material. Additionally, flexible, iridescently regulated, and multi-stimuli-sensitive optical films can be produced using cellulose nanocrystals. These nanocellulose films, which function as a composite material, have exceptional mechanical robustness, allowing them to be employed as free-standing iridescent photonic films with tuneable structural colors. They can be used to identify environmental changes like mechanical compression and humidity. They alter their color in response to outside stimulation to show that something has changed in the surrounding environment. They can be used repeatedly in various settings because the color change is reversible. These optical films may be used as decorative coatings, colorimetric sensors, and anti-counterfeiting technology.

The usage of ZnS-sodium carboxymethyl cellulose composite sheets as a sort of security paper for optical signatures is another potential use for cellulose. The quantity of ZnS-blende nanoparticles present in the composite affects its optical properties, particularly its optical transparency, which is highly tunable. Depending on how many nanoparticles are placed into the cellulose-based film, the optical transparency of such films can range from 50% to 90%. In contrast to many other optical applications, this one is less developed; therefore it might take some time before the potential benefits are realized.

For material-specific goals, photonic applications of nanocellulose are appealing. First, CNCs' liquid crystalline behavior produces opalescent films with specific optical properties; second, both CNFs and CNCs are capable of producing optically clear, independent films.

The cellulose's structure and surface chemistry lend these materials their flexibility; with little effort, nanocellulose may be made compatible with both hydrophobic and hydrophilic substances, employed as a host for optically active nanoparticles, and modified to take covalently bound molecules. Schlesinger et al. 2015 developed CNCs which may easily create chiral films that are colored, nematic, and iridescent by evaporating aqueous solutions (Schlesinger et al. 2015).

The chiral nematic structure of the CNCs is frequently left-handed due to the underlying right-hand nanocellulose chirality. Liquid crystals formed from cellulose derivatives exhibit either right-hand or left-hand chirality. Therefore, when the helical pitch is in the order of the visible light wavelength, the chiral nematic CNC films selectively reflect left-handed light and appear colorful.

Furthermore, the modulation of film color is rather simple because the helical pitch is sensitive to a range of factors. The spectacular photonic colors present in nature, such as those in butterfly wings and the seed hulls of the *Margaritaria nobilis* fruit, are comparable to the phenomenon of structure color. Over the past five years, a wide range of left-hand chiral materials, including cellulose, mesoporous silica, nanocrystalline titanium, carbon, and organosilica, as well as polymer/CNC nanocomposites, have been accessed via CNC-templating. The overall strategy is to synthesize chiral nematic compounds from CNCs and materials of interest, usually polymers or silica, and then either remove one element selectively or employ the component as part of nanocomposites.

A chiral mesoporous material that can host molecules or act as a hard template to create other chiral, mesoporous materials is produced by the selective removal of a section of the initial nanocomposite.

Potential uses for these systems include soft actuators, sensitive hydrogels, anti-reflective coatings, optical filters, flexible electronics, and chiral plasmonic. One example is a CNC-templated, mesoporous, fluorescent organosilica film for chemical sensing. Habibi et al. (2010) developed other CNC-based systems with other optical properties, such as UV blocking, fluorescence, surface plasmons, and low refractive index that have been created in order to contribute to chiral nematic materials (Habibi et al. 2010).

Greenhouse plastics, particle tracking, sensing, and anticounterfeiting technologies are some of the applications that have been suggested. ZnO absorbs UV light, therefore covering polyethylene with a combination of ZnO, SiO₂, and CNCs not only strengthened the plastic but also protected it against dangerous UV rays. Infrared blocking was also accomplished by the SiO₂ nanoparticles, which helped with energy conservation at night. Finally, CNF films are crucial as substrates for coatings and packaging as well as for applications like optoelectronics due to their superior mechanical qualities and optical clarity.

To learn more about the interconnected impacts of liquid crystalline phase behavior, flow alignment, and microstructural relaxation on cellulose nanocrystal

(CNC) films' alignment and optical properties, rheo-optics, micro spectrophotometry, and optical contrast studies were used. Cross-polarized microscopy pictures can be used to directly determine changes in anisotropy, and optical contrast measurements have been demonstrated to be a reliable and simple method for doing so. The anisotropy of dried CNC films as well as the microstructural relaxation following the cessation of shear were both constantly measured using this technique. Compared to isotropic or biphasic dispersions, aqueous liquid crystalline CNC dispersions show better alignment following shear. However, lower alignment was seen in CNC gels at equivalent shear (Haywood and Davis 2017).

CNF films integrate additives like additional nanomaterials, polymers, or surface changes to add desirable qualities like hydrophobicity, similar to CNC-based systems. The downside of CNFs and CNCs is their relatively high viscosity, even at low concentrations, which prevents them from being used for high-speed coating.

Due to its remarkable optical properties, nano-fibrillated cellulose has a thickness that is smaller than the wavelength of visible light. Nanofibril-prepared paper is transparent as a result. This can be included in a number of applications, including those involving sensors, solar panels, and electronics. Jia Huang et al. documented the flexible field effect transistors that are produced on nano paper for use in green electronic transistor applications.

The self-ordering nature of cellulose nanocrystals, like that of many polysaccharides, results in a variety of intriguing optical features. More than 20 years ago, it was discovered that films made of cellulose and cellulose derivatives kept ordered chiral nematic phases (Liao et al. 2006; Li et al. 2009). Gray and colleagues also discovered that when cellulose nanocrystal films were hardened by evaporation, they generated "helical structures mimicking those in many biological skeletal systems" (Liebert and Heinze 2008). Helicoidally arranged cellulose nanocrystal sheets that reflect polarized light are described by Revol et al. The visible, ir, and uv spectrums of the light reflected by these films were said to be controlled (Lisperguer et al. 2009; Lin et al. 2010). According to reports, the colors shift with viewing angles, making them appropriate for security papers and many applications.

Recently developed nano cellulosic material proved a very adaptable choice for numerous sensing system application domains. In a system based on dispersed pH-sensitive polyvinyl pyridine-grafted CNC involving flocculation at basic pH, Kan et al. stated that it has assured techniques of industrial and biomedical separation as well as in the biomedical application for therapeutic release. Additionally, NC has been employed as a support for conductive materials, plasmonic or fluorescent dots, or catalysts.

Ouyang et al. (2013) developed energy storage, triblock-copolymer ion gels, carbon nanotubes, and bacterial nanocellulose sheets have been proposed as supercapacitors.

Other than BNC, sources of nanocellulose have been obtained from plant materials such as kraft pulp, birch pulp, and sugarcane bagasse. Research on the development of CNC implementations in electro-active materials, such as electrically conductive materials, dielectric materials, microelectronic components, etc. is now underway and will likely include certain pertinent materials, such as proteins,

starches, and peptides. The significance of CNCs in electrical applications is primarily attributable to their adaptability, piezoelectric and dielectric capabilities, and durability characteristics that are comparable to those of other bio-derived materials.

CNC composite films are used for a variety of optical purposes. These composite materials, which also contain additional components, are frequently employed in security features, micro-optical devices, polarizers, and other things. The CNC/PEG thin film developed by Gu et al. (Demirci et al. 2014) was clearly iridescent, had good mechanical properties, and had great adhesion. Kumacheva and his co-workers (Schyrer et al. 2014) prepared a CNC composite by adding latex nanoparticle which has close-to-uniform fluorescence, circular dichroism, and birefringence. In order for the films to have the ability to prepare polarizers, the nanoparticles can alter the P of the liquid crystal and form CNC cholesteric structures on their own.

Khan et al. (Al-Homoud 2005) added phenol-formaldehyde resins to CNC self-assembly in order to create polymer composites that were guided by CNC self-assembly. Films that were porous were produced when the CNC was removed. Potential images may arise as the film swells by depositing acid or formaldehyde in various areas of the film. Text and images can be printed using inkjet technology as higher-resolution photonic patterns, making this material suitable for use as a security material.

Similar to this, Schlesinger et al. (Moon et al. 2011) generated CNC/SiO₂ composites using the EISA method by using a CNC/TMOS system, and then they removed the CNC and added gold NRs. A controllable cholesteric structure was produced as a result of the interplay between the surface plasmon resonance of CNC chiral nematic and gold NRs assembly. Security devices would be another area where this material has a lot of potential applications. Mark et al. (Eichhorn et al. 2001) used the reverse emulsion approach to grow CNC tactoid in water microdroplets to create the cholesteric structure of CNC in polymeric microspheres. They applied this technique to silica microspheres containing cholesteric structures, resulting in materials with a mesoporosity and large surface area which might be used to create micro-optical devices.

Conclusion

Many nanofibers are available in the nature, but cellulose is one of the remarkably useful nanocomposites which can be extracted from plant fiber in stems and leaves, the trunk of the tree, tunicates, bacterial cellulose, and so on. The cellulose is then used to make new composites with different properties with distinctive characteristics for uses not anticipated by their natural evolution. Cellulose has the chance to once again act as the reinforcing phase of transparent plastics for flexible electronic-based products, as it did with the common paper that once served our requirements. Electronic products frequently include flexible circuit boards, and soon the substrate of image displays will be made of flexible materials as well. The nanocellulose reinforcement significantly advances the development of film-display technology, as it has been emphasized throughout an entire chapter on the significance of

nanocellulose in optical applications, particularly electronic displays. This is due to the material's excellent optical and electrical conductivity properties. Additionally, there is a strong likelihood that the market will expand in the not-too-distant future, ensuring this material's bright future. It is to be assumed that the importance of nanocellulose composite has played a significant influence in the development of applications for electronic equipment. The fundamental research that has already been accomplished will serve as the foundation for more novel materials, whether or not this promise is realized commercially.

Abstract

Nowadays, there is an increased interest for developing of innovative edible food packaging, prepared as thin layer and then used as a wrapper on food materials, or edible food coatings adhering to the food surface. The essential benefits of edible food packaging systems, by comparison with petroleum-based food packaging materials, are the following: They represent an entire component of the food product, have a role in extending shelf-life, can be eaten without having to take out and discard the package, decay easily, and are environmentally friendly. The aim of this chapter is to investigate the advantages and limitation of the main biopolymers used for fabrication of edible and coating food packaging, their

Biopolymer · Edible film · Coating · Food application

Introduction

Global plastics production worldwide increased from 2015 to 2020 to 367 million metric tons, by roughly 3%. The aforementioned data shows the development of plastic manufacturing, with strong outcomes for the ecosystem and human health. Among this, food packaging is the most important sector, which creates packaging needed for our life, from bags to food containers. In 2015, the income generated by the food packaging domain was US\$ 839 billion, and up to 2020, the annual percentage growth rate was 3.5%. The main roles of food packaging are to keep food safe from chemical, physical, biological, and environmental contaminants (Theagarajan et al. 2019). Recently, the consumption of single-use plastics has gained an increase attention due to the generation of huge amount of waste. Plastics waste increased from 1% in 1960 to >10% by 2005. Data shows that every year, 5–13 million tons of plastics accounting 1.5–4% of global plastics production have ended up in the oceans [1]. It was estimated that from all plastic waste generated 11% are incinerated and only 19% are recycled (Buch et al. 2021). The initial strategy applied to plastic manufacturing was changed from “produce, use and throw away,” characteristic to linear economy toward the circular economy based on the closed-loop process through recycling, reduction, reuse, and recovery (Lombardi et al. 2021; Knappe and Schmidt 2021).

The most known materials used for food packaging materials are those obtained from petrochemical sources, such as poly(ethylene) (PE), poly(ethylene terephthalate) (PET), poly(propylene) (PP), and poly(styrene) (PS). These polymers represent optimal matrices for fabrication of food packaging in safe conditions and conform to the national and international regulations. Despite these advantages, conventional packaging materials raise a huge problem because of long persistence in the environment caused by the lack of biodegradability (Sid et al. 2021). In this context, the optimal conditions to minimize the impact of food packaging waste are to build biodegradable and edible food packaging, with low impact on environmental and human health. Thus, last time, scientists, scholars, customers, governments, and other interest groups were searching for sustainable and green materials to produce biodegradable packages to clarify the expanding issue of plastic waste disposal. In 2019, the global market value for biodegradable plastic packaging showed around \$ 4.7 billion. By 2025, it is predicted to increase approximately US\$ 12.1 billion (Mahmud et al. 2021). Biopolymers such as poly(lactic acid) (PLA), poly

(hydroxyalkanoates) (PHA), chitosan (CS), starch, and cellulose are used intensively in the food packaging field due to their environmental advantages regarding the global carbon footprint and waste decreasing. The biopolymers possess many advantages as compared with conventional polymers used for food packaging relating to their obtaining from natural resources and unique morphology, which allow to combine with other polymers, nanoparticles, and additive in order to gain adequate mechanical, thermal, optical, barrier, and antibacterial properties. Although biodegradable polymers and their associated mixtures and composites have been advanced in the world food packaging market in recent decades, the composting and recycling methods for waste management are not applied at industrial scale. For example, after composting, the PLA cannot be separated from the PET, and the PLA's microbial degradation is limited to some strains of microorganisms.

As a viable solution for biodegradable food packaging waste, the developing of innovative edible food packaging was proposed. Edible film and edible coating in food applications respond to the societal challenge concerning climate action, environment and diminishing resources, and raw materials, as well as the increasing of world's population and resources consumption. In accordance with the Food and Agriculture Organization of the United States, each year over 1.3 billion tones of food are wasted, from which horticultural crops (fruits and vegetables) waste represents 45–45% (Singh and Packirisamy 2022). Edible food packaging better solves the problems arising from the preserving of crop in a certain season, with annually balancing of demand and constant maintenance of market prices. Edible films are structures developed like thin layers and then used to coat the food products, as primary edible packaging with the purpose to protect the food, while edible coatings are referred to the dipping of food products into an aqueous solution of biopolymers. By comparison with conventional food packaging systems, edible food packaging systems have the following functions: (i) are an integral part of the food product; (ii) have the role to extend shelf-life; (iii) can be consumed together with packages; and (iv) are biodegradable and environmentally friendly. However, if the food packaging system is not eaten, its degradation occurs fast like the destruction of plastic material. The differences between edible films and edible coatings refer to the thickness and structure. The thickness is greater in the case of edible food films. A difference of about 300 μm in thickness, determined by the density, viscosity, coating time, and surface tension of the biopolymer solutions, was reported (Shahidi and Hossain 2022). The edible food films are self-fixed systems, while those edible food coatings attach to the food product surface (Galus et al. 2020).

The purpose of the present chapter is to investigate the advantages and limitations of the main biopolymers used for fabrication of edible and coating food packaging, their compositions with additives, plasticizers, and bioactive agents, as well as the performance required for use in food packaging applications.

Biopolymers Used for Edible and Food Packaging

Edible food packaging includes films and coatings based on natural and food-grade biopolymers that can be classified into three main groups: polysaccharides, proteins, and lipids (Dhumal and Sarkar 2018; Kumar et al. 2021; Iniguez-Moreno et al. 2021; Vukic et al. 2017) (Fig. 1).

Generally, edible films and coatings achieved by polycarbohydrates are distinguished by excellent gas barrier properties, while those obtained from proteins are considered to have great mechanical properties. However, both polysaccharide- and protein-based edible films display low water vapor barrier properties, which can be enhanced by the introduction of nanoparticles (NPs) such as zinc oxide (ZnO) (Anugrah et al. 2020), lipids, or adding one or more hydrocolloids (proteins and polysaccharides) (Fabra et al. 2014).

Polysaccharides

Among the most naturally occurring biopolymers, a special consideration has been given to polysaccharides, which are found in many components, are easily

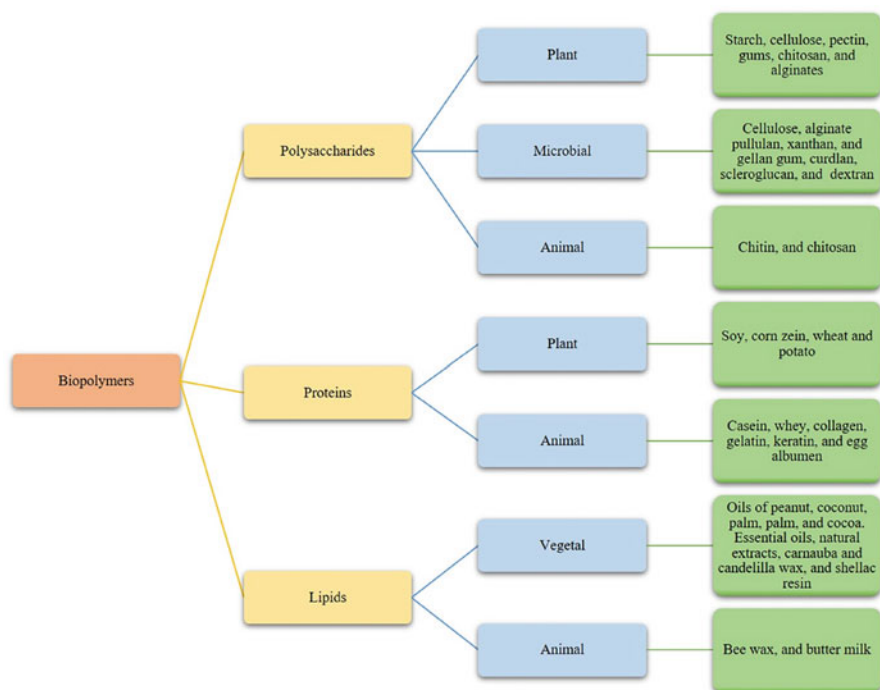

Fig. 1 Classification of biopolymers used for edible food packaging applications (Iniguez-Moreno et al. 2021)

accessible, and have a relatively cheap price. Different natural polysaccharides, for example, alginate, chitosan derivatives, pectin, cellulose, seaweed, and starch, are commonly accepted for fabrication of edible films and coating systems (Marangoni et al. 2021; Poverenov et al. 2014; Rapa and Vasile 2020; Senturk Parreidt et al. 2018; Soares et al. 2018; Kuprina et al. 2021). Polysaccharides, as the main component of biomass, accomplish the environmental considerations (being extracted from sustainable and biodegradable resources) and are potential to be used in edible food packaging, being metabolized by human body together with food. Scientists from the University of Nottingham have employed polycarbohydrates and proteins to design a fully environment-friendly and edible food packaging. Extracted from konjac flour, starch, proteins, or cellulose-sustainable biopolymers, edible food packaging with enhanced storage, safety, and food quality was reported (<https://www.packaging-gateway.com/news/university-nottingham-develop-edible-food-packaging/>).

Wheat bran is an outer skin of grain composed from pericarp, hyaline, aleurone layers, and remaining starchy endosperm cell layers. Commonly, wheat brain comprises almost 13–18% proteins, 12% water, 57% carbohydrates (hemicelluloses, starch, and cellulose), 4% fats, and 1% phenolic acids (Apprich et al. 2014; Luthria et al. 2015). Wheat cell walls contain a great amount of polysaccharide derivatives (for example, arabinoxylan fiber essential for healthy diet) and ferulic acid from phenolic acids acting as a cross-linker that binds to sugar debris. Ferrulic and vanillic acid compounds from wheat bran waste can be used for the production of sustainable bioplastics (Skendi et al. 2020). Agricultural residues are among the most promising next generation of raw materials for obtaining of biopolymers because they not only are naturally biodegradable and produced using renewable resources, but also can be edible, providing food for many people.

The cheapest edible films were prepared by Agceli (2022) from levan biopolymer synthesized by *Pseudomonas mandelii* and powdered ostrich eggshells, in the context of circular economy. The results indicated that the rising amount of ostrich eggshell in powder form led to a decrease in water absorption, water vapor barrier, and strain properties, although the strength and thermal stability of the material increased. Significant increase in the antioxidant activity proven by DPPH radical scavenging assay (83.03%) and antimicrobial effect against *Streptococcus pneumoniae* 6303 and *Pseudomonas aeruginosa* were noted in the case of using edible levan-based films.

Cellulose is a linear homopolysaccharide consisting of D-glucopyranosyl groups connected via β -(1 \rightarrow 4) glycosidic bond (Fig. 2). Nonetheless the use of cellulose to

Fig. 2 Chemical structure of cellulose (Nesic et al. 2020)

achieve food edible films is restricted as a result of its inability to form a solution in aqueous and chemical solvents (Iniguez-Moreno et al. 2021). This disadvantage could be reduced by chemical modification, which really corrects both water solubility and the thermoplastic nature of cellulose. Ethers (for example, carboxymethyl cellulose, methylcellulose, hydroxypropyl cellulose, and hydroxypropyl methyl cellulose) and esters (for example, cellulose acetate) are among the cellulose derivatives found in the manufacturing of edible food packaging.

Chitosan is a marine polysaccharide produced from the deacetylation of chitin. It contains >55% *N*-acetyl-D-glucosamine and D-glucosamine linked via β -(1 \rightarrow 4) glycosidic bonds. Chitosan is extensively employed as a film-forming ingredient for formulation of edible films or coatings with the purpose to protect fruits and vegetables, for example, carrots, pumpkins, avocados, fish, and cheese (El-Sayed et al. 2021; Le et al. 2021; Kang et al. 2022; Park et al. 2022; Poverenov et al. 2014; Soares et al. 2018; Song et al. 2017). A comparison between edible films by casting method based on chitosan and alginate, respectively, both containing *C. tomentosum* seaweed extract (SE) showed that the highest elongation at break was achieved in the case of chitosan formulation, when the SE acted as a plasticizer in film formulation facilitating the increase of polymer molecular mobility (Augusto et al. 2018). The thickness of the designed edible films ranges from 30 to 50 μm . The addition of *C. Tomentosum* to alginate led to the decrease of whiteness index values, a lower degree of film transparency, moisture of 24–28%, and decreased solubility and WVP. In the case of chitosan film, the transparency and solubility increased, moisture was in the range of 9–10%, and a greater flexibility and resistance to mechanical forces were achieved.

Alginate is another marine polysaccharide, which is extracted from many brown algae types (*Phaeophyceae* sp.) and few bacteria, being responsible for the cell walls elasticity and durability. The chemical structure of alginate is composed by guluronic and mannuronic acid units (Fig. 3). Food grade alginic acid sodium salt was

Fig. 3 Chemical structure of alginates (Nesic et al. 2020)

approved by the FDA in the Code of Federal Regulations (CFR) as a GRAS (generally considered safe) and registered as allowed thickener, emulsifier, and gelling and stabilizer food ingredients, being listed under E400–E404 numbers (Lisitsyn et al. 2021). Alginate compositions show acceptable hydrophilic properties and contribute to maintaining moisture, diminishing contraction, and enhancing the sensory attributes of packaged foods. Alginate-based edible layers may diminish the presence of microorganisms, and total losses occur during cooking, delaying the oxidative unpleasant aroma, as well as improving sensory acceptance (Theagarajan et al. 2019). Notwithstanding the capacity to make hard films, alginate films display insufficient ability toward water penetration because of their hydrophilic character. For reducing sensitivity to water vapor of alginate, Marangoni et al. (2021) proposed the combination with hydrolyzed collagen (HC) and nano-SiO₂.

Agar has a high molecular weight assigned to the agarobiose units, providing the support structure of some algal cell walls. Agarophytes are red macroalgae belonging to the Class Rhodophyceae. A composition of agar/alginate/glycerol in a 2/1/1 ratio was cast for obtaining an edible film with adequate physical, optical, and solubility properties for food and food supplement packaging (Puscaselu et al. 2021).

Carrageenans are marine biopolymers, derived from red algae types, which belong to sulfate galactans with linear backbones (Class Rhodophyta). After gelatin and starch, the carrageenans are tertiary very important hydrocolloids of the food industry. The usually commercial carrageenans found are *Eucheuma denticulatum* and *Kappaphycus alvarezii* (Mahmud et al. 2021). Edible coatings for fresh food preservation were obtained by Sousa et al. (2008) by extraction of carrageenan, alginate, and agar from a mixture of dead seaweeds named “Sargaco,” as a cheap alternative to commercial biopolymers. These edible coatings with possible application for fresh fruit preservation showed good water permeability.

Starch is a polymeric carbohydrate consisting of 1, 4-linked D-glucose units. Starch is constituted from two principal forms: amylose and amylopectin, both representing 98–99% from dry weight of starch (Fig. 4). Amylose (25–30%) is

Fig. 4 Chemical structure of starch (Nesic et al. 2020)

α -D glucose joined by α -(1 \rightarrow 4) linear glycosidic chains, which facilitates, in the main, the amorphous region of the starch granule. On the other hand, amylopectin is a branched architecture consisting of α -D-(1 \rightarrow 4) glycosidic bonds. Amylopectin chains subsequently form the peripheral crystalline structure of starch granules (Thakur et al. 2019).

Moisture absorption sensitivity and poor mechanical features are the main drawbacks of starch films for their use as food packaging material as compared with the petroleum polymers. Currently, the scientific studies advise that the introduction of plasticizing components or another active additive could significantly enhance the water vapor barrier properties of starch-based edible films or coatings. Plasticizers are essential ingredients necessary for the fabrication of edible films and coatings because they improve the elongation and strength of polymer matrices (Apprich et al. 2014). Polyols (e.g., glycerol and mannitol) have been documented as the most desirable plasticizer for starch. For making edible films, the starch gelatinization proceeds at a temperature of about 80 °C.

As reserve carbohydrates, galactomannans are encountered in widely albuminous or endospermic seeds. The physicochemical and conformational properties of the galactomannans are mainly described by the ratio between mannose (M) and galactose (G) and the spread of galactose residues in the principal backbone (Cerqueira et al. 2009). Lima et al. (2010) reported that the edible coatings of mangoes and apples performed with a composition of galactomannans, collagen, and glycerol resulted in reductions of 28% O₂ consumption, 11% CO₂ production, and 50%, respectively.

Beneficial properties obtained in the case of food processing by valorization of by-products, like biodegradability, low price, distinct durability, and lighter weight compared with glass have driven to a considerable evolution of edible films (Cuccolini et al. 2013). Thus, one of the most renewable natural resources of interest is pectin, which is the major constituent of plant biomass, ubiquitous in nature. Globally, the market need for pectin is increasing, showing an entire manufacturing capacity of around 45–50 Mton per year, while its demand was around 140–160 Mton per year in 2011. This demonstrates that the industry's interest in this carbohydrate is rising daily. Due to its versatility in nature, pectin and its derivatives are used in various biodegradable packaging materials having the roles in retaining moisture, oil, and aroma barrier, and to diminish the respiration rate and food oxidation (Hoorfar 2014). At acidic pH, low methoxyl (LM) pectin is cross-linked with the help of calcium cations in order to create strong gels. These gels show a greatly durable architecture and provide a barrier against water. LM pectin thin layers are mostly used as edible packaging materials because of their favorable characteristics (Zhang et al. 2014). Other raw materials for obtaining pectin with dry substance above 15% are various marc-based by-products from the agricultural and food industries, such as citrus fruits, apples, sugar beet pulp, and sunflower husks (Belkheiri et al. 2021). The apple mark (with a content of pectin ranging from 15% to 20%) and citrus fruit peel (where the pectin content varies from 30% to 35%), both extracted from the fruit juice industries, are the essential ingredients exploited for obtaining pectin on an industrial scale. Five extraction methods are the

most used in the case of pectin: heating-stirring extraction based on solvent, magnetic induction (EMI), microwave (MAE) and ultrasound assisted extraction (UAE), and enzyme-assisted extraction (Sen et al. 2021).

Proteins-Based Edible Films and Coatings

Developing protein-based functional materials derived from the food industry such as whey protein isolate nanofibers (WPNFs)/glycerol (Gly)/carvacrol (CA)/salted duck egg yolk edible coating (Wang et al. 2020), lysozyme and β -lactoglobulin isolated from eggs and milk (Shen et al. 2021), corn, soy, mung bean, pea, grass pea, whey, and surimi protein sources (Mihalca et al. 2021), which possess especially antioxidant activity, is beneficial for the reduction of environmental pollution and increasing economic value simultaneously. Common proteins used for producing edible food packaging are the following: casein, soy protein, zein, whey protein, collagen, gelatin, egg albumin, and milk protein (Daniloski et al. 2011; de Oliveira et al. 2021; Fu et al. 2021; Gialamas et al. 2010; Kuprina et al. 2021; Lima et al. 2010; Lin et al. 2011; Tao et al. 2018; Talens et al. 2012).

The commercial casein or caseinates adopted within the food sector ranged from 200,000 to about 2,500,000 t (Lisitsyn et al. 2021). Acidic casein is obtained by acidifying of precipitated casein from skimmed milk. Rennet casein is produced by treating of milk with rennet. Caseinates are compounds derived from water-soluble products of milk proteins created by neutralization reaction. Casein is a well-established dairy by-product exploited as an edible coating for numerous foodstuffs, including dairy farm products.

The disadvantage of edible films based on casein is being very sensitive to moisture and water absorption, which highly alters their mechanical and barrier properties. Moreover, casein edible films are often dissolved in water reducing their domain of utilization. However, the use of plasticizer does not improve the mechanical properties of casein-based edible films. One solution consists of crosslinking of polymer chains with glutaraldehyde, genipin, or transglutaminase agents. Sodium-caseinate plasticized with sorbitol with and without *Lactobacillus sakei* cells was cast for the development of a novel bioactive packaging for controlling *Listeria monocytogenes* in foods (Gialamas et al. 2010). The results showed that the incorporation of microorganisms into edible films made of sodium-caseinate did not affect their physicochemical characteristics. Supplementary, it significantly inhibited the *L. monocytogenes* growth in the case of fresh beef (food model system) as compared to the control samples.

Soy is another protein obtained from the solid waste produced by the food industry. Two soy protein types are commercially available: soy protein concentrate (SPC), which contains 65–72% protein, and soy protein isolate (SPI), which has more than 90% protein content (de Oliveira et al. 2021). Due to the amphiphilic character, by denaturation of soy protein, a stable network is formed. De Oliveira et al. (2021) reported that the soy protein can interact with carboxymethylcellulose (CMC) at pH below the isoelectric point (IP) of soy protein (4.5–5.0) to improve the

mechanical strength and oxygen permeability of edible films. The proteins isolated from plants such as corn, wheat, soybean, peanuts, cottonseed, and rice are still suitable and accepted by vegetarian people.

Zein is an amphiphilic protein rich in prolamins authorized by the FDA as a generally recognized safe (GRAS) additive for food applications. Zein is a biodegradable and biocompatible biopolymer, which corresponds to the strategy of agro-industrial by-products management, being deeply studied for the development of edible films (Salevic et al. 2022). Because the films fabricated from zein are brittle, the combination of zein with polysaccharides is preferred (Perez et al. 2021).

Studies performed by Taylor et al. (2005) showed that the kafirin, the prolamins protein extracted from sorghum, is more hydrophobic than zein. The kafirin edible film was obtained by casting method with glacial acetic acid as a solvent, at a temperature of 25 °C, and showed advantages compared to that obtained in the presence of aqueous ethanol, in terms of lower processing temperature and better tensile and water permeability.

Collagen is another extensive protein that is found in all connective tissues including bones, tendons, ligaments, skin, and cartilage, as well as fish waste (Bhuimbar et al. 2019; Mihalca et al. 2021). Collagen is composed of polypeptides and characterized by a triple helix structure, resulting from three cross-linked α amino acid chains consisting of two homologous $\alpha 1$ chains and one $\alpha 2$ chain. Marine sources, mainly fish by-products, such as sea urchin, starfish, and sea cucumbers, have been reported to be rich in collagen (Fu et al. 2021). Collagen films are characterized by an excellent barrier to oxygen, but poor water vapor permeability. Gelatin-plasticizer combinations were explored as potential durable edible films for food (Sancakli et al. 2021). A potential alternative to obtaining edible films with improved performance is to mix the collagen with other polysaccharides. Thus, blending of galactomannan of *A. pavonine*, collagen, and glycerol with the compositions of 0.5%, 1.5%, and 1.5%, respectively, led to obtaining edible films for decreasing the fruit gas transfer rates for mangoes and apples. Therefore, it will play an important role in prolonging the shelf life of postharvest fruits (Lima et al. 2010).

Lipids-Based Edible Films and Coatings

According to a review by Zubair et al. (2021), lipids are biorenewable feedstocks classified as vegetables, fatty acids, plant oils, or waxes, which possess interesting mechanical, barrier, antibacterial, antioxidant, and functional properties to target various applications in the food packaging sector. The use of lipids as matrix, plasticizer, or filler in the edible film or coating is recommended due to their hydrophobic properties and the capability to enhance the mechanical and antioxidant properties.

Lipids do not constitute cohesive films, unlike hydrocolloids. For this consideration, they are used specifically for food coatings or in mixtures with polysaccharides in order to achieve an advanced water barrier property. A new edible and active

film/coating material based on bioactive compounds extracted from *Aloe vera* leaves blended with proteins and polysaccharides was proposed by Maan et al. (2021). This combination of components could be an excellent edible film/coating for perishable food products.

Features of Edible and Coating Food Packaging

General Requirements for Edible Films and Coatings

Edible food packaging is a multifunctional one, characterized by good oxygen barriers, being capable of protecting the quality and expanding the validity of food products sensitive to spoilage. Edible films and coating may impede the oxidation of dried food products during dehydration and enhance the shelf life expansion disclosed by exposure to radiation and can also diminish the flavor, color, or vitamin content in foods that are liquid at room temperature at the time of fabrication and commercialization. They also can be an efficient transporter for antimicrobial and/or antioxidant agents and to manage the transfer of particles from the package toward the food product. In addition, edible food packaging has demonstrated favorable transmission properties, being investigated for food preservation. Edible food packaging may be beneficial for freeze-drying processes, since it can avoid the evaporation of volatile flavors.

Figure 5 illustrates the main steps and laboratory methods needed for fabrication and testing of edible films and edible coatings in food applications.

The first step to fabricate edible food films is concern casting of solution involving the preparing of the biopolymer solution with adequate additives followed by evaporation of the solvent. The prepared solution of biopolymer could be also used for the coating of food products. Natural biopolymers can be used as single, binary, or ternary combinations for creating edible films and coatings. The main functions of biopolymer compositions are the following: (i) to prolong the shelf life of stored food; (ii) to improve the physical characteristics of food products; (iii) to protect the stored food from oxidation, moisture absorption, and microbial growth; (iv) to preserve the high quality of the food product; and (v) to enhance food appearance. Generally, food protection, the physical properties or functionality of edible packaging, cannot be provided with a single biopolymer, and the introduction of plasticizers and other additives to the processing formula is required. Usually, the plasticizers include polyols such as propylene glycol, glycerol, mannitol, sucrose, honey, and fatty acid esters (Singh and Packirisamy 2022). For example, glycerol is a plasticizer used for film-forming solutions in concentrations ranging from 0.5% (w/w) to 2% (w/w) (Perez et al. 2021). The composition of the edible film should be accepted on the basis of the special uses of food, the type of food products, as well as the dominant quality depreciation technique (Talens et al. 2010). In addition, the biopolymers can be combined with other active compounds such as antioxidants, antimicrobial, nanoparticles, essential oils, vitamins, or foodborne pathogenic bacterium to add improved safety, nutritional and sensory features, to edible films

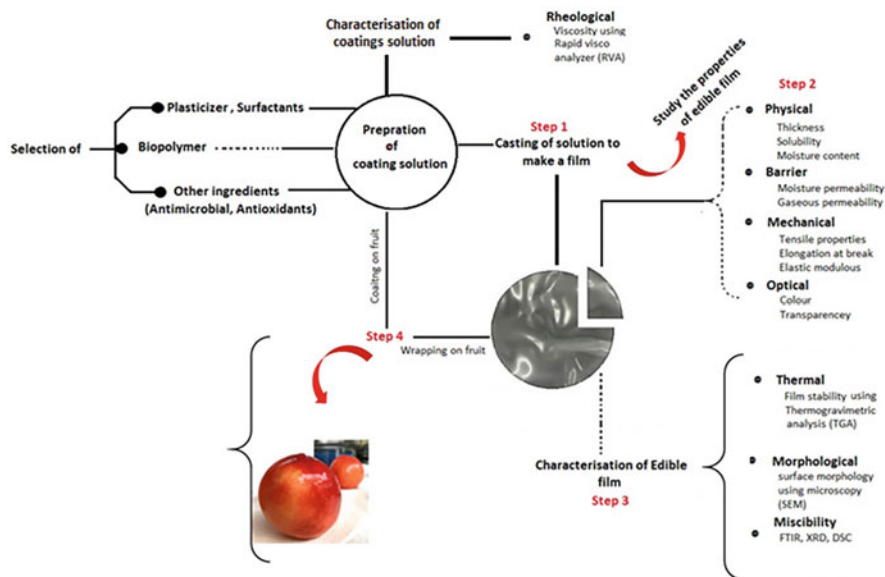

Fig. 5 General steps for the development of edible film and coating for food applications (Thakur et al. 2019). (With permission of Elsevier)

followed by casting of the film (Fabra et al. 2014; Gialamas et al. 2010). Bioactive compounds are added to edible film by the encapsulation process. Depending on its sized dimensions of particles, nanoencapsulation and microencapsulation of bioactive compounds resulted. Thus, the particles sized in the range of 10 to 1000 nm form mini-emulsions of bioactive compounds, while in the case of sized particles of 6 to 800 μm microemulsions result (Chaudhary et al. 2021).

Table 1 shows some bioformulations for edible food packaging prepared on a laboratory scale and tested for fruits and fish.

The following general requirements for ideal edible films or coatings are taken into account: They must not contain harmful, allergenic parts that are not broken down during digestion, and they must allow an acceptable adhesion on the food contact surface, to ensure architectural durability for avoiding mechanical deterioration at the transportation, manipulation, and exposure steps, to keep the migration of additives under regulations in force, to prevent the loss of ingredients that maintain aroma, flavor, and nutritional and organoleptic attributes required for consumer approval without adversely changing these characteristics, and to ensure a partial permeability to keep the internal balance involved in aerobic and anaerobic respiration. All these demands for edible packaging together with the easiness of manufacturing and economical feasibility will delay the senescence and provide the microbiological stability of the food items, maintaining and enhancing their sensory features (taste, appearance, etc.) (Fabra et al. 2014).

Table 1 Some biocompositions for edible food packaging

Composition	Edible food packaging/ technique	Target food	Ref.
Chitosan and chitosan/lauric acid	Coating/vacuum impregnation	Minimally processed pumpkins	Soares et al. (2018)
Caseinates or chitosan	Coating	Partially dehydrated pineapple-cereal system	Talens et al. (2012)
Chitosan-collagen composite	Coating	Fresh red porgy (<i>Pagrus major</i>) file	Liu et al. (2020)
Chitosan/nanosized titanium dioxide particles (CTS-TiO ₂)	Coating	Blueberries	Xing et al. (2021)
Sodium alginate solution	Dipping and vacuum impregnation coating	Fresh-cut cantaloupe melon	Senturk Parreidt et al. (2018)
Sodium alginate (SA)/hydrolyzed collagen (HC)/SiO ₂ nanoparticles	Film by casting		Marangoni et al. (2021)
Alginate/antimicrobial agent active edible coating	Coating/dipping	Fresh-cut Galia-type melons	Poverenov et al. (2014)
1% lactic acid solution (LA)/1% CH containing 64 µg/mL nisin/250 µg/mL ε-polylysine (ε-PL) (LA/CH/ Nisin/ε-PL)	Coating	Fresh-cut carrots	Song et al. (2017)
Soy protein isolate (SPI)/ Carboxymethylcellulose (CMC)/ glycerol	Film/casting		de Oliveira et al. (2021)
Gelatin/starch– butanetetracarboxylic acid dianhydride (BTCAD)– <i>N</i> -hydroxysuccinimide (NHS)	Film/casting	Apple	Tao et al. (2018)
Nanocomposite film based on gelatin prepared from waste fish scale, chitosan, and CaCO ₃ nanoparticles	Film/casting	Longan and banana	Fu et al. (2021)
Galactomannans isolated from <i>Adenanthera pavonina</i> and <i>Caesalpinia pulcherrima</i> seeds, glycerol, and collagen	Coating	Mangoes and apples	Lima et al. (2010)
Zein coatings incorporated with nisin (54.4 AU/cm ²) or nisin/ ethylenediaminetetraacetic acid (EDTA) 568 µg/cm ²	Coating	Fish balls	Lin et al. (2011)
Sodium alginate, chitosan, and protein hydrolysate	Coating	Semifinished fish product	Kuprina et al. (2021)

The specific edible food packaging should be tested from many points of view: mechanical properties, thermal resistance, morphology and other technical features, processability, and consumer acceptance as well as applicability and sustainability versus commercially available plastics used in the food packaging industry. The best mechanical and physicochemical properties of polysaccharides/proteins were investigated by response surface methodology (RSM). In a study conducted by Cortes-Rodriguez et al. (2020), 15 emulsions based on cassava starch (CS) (3.0–3.5%), beeswax (BW) (0–0.5%), and whey protein (WP) (0.5–1.5%) were prepared by casting method. The following properties of compositions were measured: moisture content, swelling capacity, thickness, water vapor barrier, and tensile properties, as well as the color parameters: yellowness index (Y_i), lightness (L^*), saturation (C_{ab}^*), tone (H_{ab}^*), chromaticity (a^*), and chromaticity (b^*). The study revealed that the optimal composition having a possible application in the preservation of fruits contains the following: 3.17% CS, 1.3%, WP (1.30%), and 0.50% BW.

The water solubility and swelling degree of edible food packaging materials influence the rate of the materials' breakdown during consumption and biodegradation (Salevic et al. 2022). Flexibility and mechanical strength are two essential material properties for food packaging associated with the capability of edible films to support the external force and keep completeness and barrier properties. The optical properties of edible films are essential for commercial appearance, leading to consumer acceptance. The color, firmness, reducing of sugar content, and weight loss of coated food are properties also evaluated during the storage period to predict prolonging shelf life of the tested food. The release of bioactive components from edible films involves the control of dissolution, swelling, and diffusion of bioactive agents. The wrapping/coating process used depends on the quality of food item's surface and the goal of coating layer. Coating development commences with the diffusion of the components on the food surface, being accompanied by the adherence of coating formulation with the food surface. The initial concentration of coating solution should be correlated with the coating film thickness as the firmness properties and appearance of the coated fruits should not be disturbed. It is accepted that the protective layer for the coating of food should be uniform and smooth.

Common techniques used to prepare edible films are the following: wet technique or solvent casting, dry techniques such as compression molding or extrusion as well as electrospinning. The wet process involves dispersion of biopolymers into solvents, and spreading of the obtained solution on the adequate substrate, then the evaporation of the solvent takes place. Encapsulation is a new technique for combining edible films with bioactive compounds, flavor compounds, and probiotics that provide controlled release and health benefits. Dry process, compression molding, or extrusion uses the high temperature above the glass transition temperatures of biopolymers, pressure, and adequate processing additives. Edible coating of food can be achieved by three methods: spraying, dipping vacuum impregnation, and soaking and electrospinning. Table 2 shows the main advantages and disadvantages of each edible food packaging method.

Chitosan-based edible coatings achieved on minimally processed pumpkins by soaking, and vacuum impregnation techniques reveal that the soaking is considered

Table 2 Advantages versus disadvantages of methods for preparing edible films and coatings for food applications

Technique	Advantage	Disadvantage	Reference
Edible films			
Solvent casting	Continuous and compact films were obtained A simple method, which does not require specific equipment	Compatibility of solvents with biopolymers Low availability at the industrial scale	Salevic et al. (2022); Singh and Packirisamy (2022); Taylor et al. (2005)
Electrospinning	The incorporation of bioactive compound in biopolymeric matrix extending the functionality of film	Low availability at the industrial level Compatibility of solvents with biopolymers	Salevic et al. (2022); Singh and Packirisamy (2022)
Compression molding and extrusion	Large-scale production	May affect the film properties (thermal degradation)	Chuaynukul et al. (2018)
Coating/antimicrobial coatings			
Dipping	Enhance the quality of fresh-cut fruits Increase the structural integrity of food Decrease of microbial spoilage Increase storage period of fruits Prevent the loss of volatile compounds Good esthetic appearance of fruits	Good adhesion is not achieved if food products' surface is hydrophilic Nonuniform thick coating Multilayer coatings	Poverenov et al. (2014)
Spraying	Small amount of coating solution is required due to the high pressure used Uniform thickness	The viscosity of coating solution should be controlled	Anugrah et al. (2020)
Electrospinning	Protect the bioactive compound by nanoencapsulation		
Vacuum impregnation	Thicker film	Greater component incorporation in the food product	Soares et al. (2018)
Soaking	Lower numbers of psychrotrophic microorganisms and coliforms Smaller change in the food product		

the best technique since it did not lead to changes in the properties of the food, as compared with vacuum impregnation, when higher modifications in pH, acidity, color, and firmness were produced (Soares et al. 2018). In a study performed by

Senturk Parreidt et al. (2018) about the comparison between dipping and vacuum impregnation techniques in the case of coating of melon pieces with sodium alginate solution, many coating parameters such as dipping time, draining time, time length of the vacuum period, vacuum pressure, and atmospheric restoration time were analyzed to obtain data about the percentage of weight gain, color, and texture of coated sample. It was found that although both methods improved the firmness of the tested food, the vacuum impregnation led to better mechanical and structural properties.

Singh and Packirisamy (2022) performed both dip-coating and electrospinning methods for coating of perishable banana and apples with a composition based on silk fibroin (SF)/poly(vinyl alcohol) (PVA) solution carrying nanocurcumin as bioactive agent and honey as natural moisturizer, as a cost-effective method. Dip-coating of the model foods was achieved by directly immersing them three times in the SF/PVA aqueous composite at 5-minute intervals for 30–40 s; next the coated food was kept for drying at room conditions, while in the case of the edible nanofiber coating, the optimized parameters were fixed at a volume of 0.5 mL which passes per hour, and the voltage of 20 kV. In both cases, the coated food models exhibited a prolonged shelf life as compared with uncoated foods.

Performance of Edible Food Packaging

The interest in active edible film/coating is increasing due to the extended shelf life of food by using natural antimicrobial components as substitutes for artificial supplements. Edible food packaging also has the role of carriers of bioactive substances and promotes the health of consumers. Some examples of bioactive molecules used for edible food packaging are the following: antimicrobial and antioxidant compounds (ϵ -polylysine (ϵ -PL), resveratrol), sage extract, clove bud oil, ZnO NPs, microcrystalline cellulose, honey, nanocurcumin, and pomegranate peel extract (PPE) (Bhuimbar et al. 2019; El-Sayed et al. 2021; Garcia et al. 2022; Kang et al. 2022; Le et al. 2021; Leena et al. 2020; Park et al. 2022; Salevic et al. 2022; Singh and Packirisamy 2022), probiotics (*Bifidobacterium lactis*, *Lactobacillus acidophilus*, and *Lactobacillus casei*) (El-Sayed et al. 2021; Pop et al. 2020), antienzymatic agents, polyunsaturated fatty acids, and different nutraceutical types.

Medicinal and aromatic plants achieved a huge concern in the food sector due to their active ingredients that are frequently discovered in the extracts/essential oil fractions. It is well proven that most of them show a large spectrum of activity for killing and inhibition of microorganisms leading to deterioration of food (Gavril et al. 2019; Gutierrez et al. 2008; Vasile et al. 2019).

Table 3 shows few examples of compositions of biopolymers together with bioactive components for obtaining of edible food packaging and the most significant properties reported for them.

Garcia et al. (2022) prepared four different biopolymer coating solutions referred as: zein solution (ZS), zein nanoparticle suspension (ZNP), and ϵ -polylysine solution (PL), and zein- ϵ -polylysine nanoparticle suspension (ZPL), together with a test

Table 3 Active edible food packaging compositions and related properties

Composition	Food packaging and method	Properties	References
25% w/v of zein in 80% aqueous ethanol/ glycerol, 2.5% w/v/ of resveratrol (containing 0, 2, 5, and 10% w/w of polymer)	Electrospinning at following optimized conditions: 8 cm distance from the spinneret tip, voltage of 14 kV, and a constant flow rate of 0.5 mL/h	DPPH scavenging abilities of resveratrol-loaded zein nanofibers differed from about 66.2 to 81.1% keeping the antioxidant capacity of resveratrol The fastest release of resveratrol up to 39% was registered at 2 h immersion in PBS Nanocoating of apple thin slices revealed an acceptable controlled moisture loss and maintained their color during the 6-h examination period	Leena et al. (2020)
Zein and ϵ -PL nanoparticles (ZPL), zein nanoparticles (ZNP), ϵ -PL solution (PL), and zein solution (ZS) coating films together with control (C)	Dip-coating	Up to 36 days of study, the ZPL coating showed the inhibition of fungal ZPL and ZNP coatings exhibited good physical appearance and texture of avocados as compared with control	Garcia et al. (2022)
Zein (25% w/w in aqueous ethanol solution (80% v/v))/ sage extract (SG) (10, 20, and 30% w/w)	Solvent casting mono-axial electrospinning	The solubility and swelling degree in water increased with the content of sage extract Similar DPPH• and ABTS•+ radical scavenging abilities for film and mats Inhibition the growth of <i>S. aureus</i> and <i>S. enterica</i> serovar Typhimurium bacteria	Salevic et al. (2022)
Edible films containing red cabbage (RC) and clove bud oil (CBO) filled with chitosan or carrageenan capsules	Encapsulation using the ionic gelation method	High potential for use in fresh fish preservation	Park et al. (2022)
Solutions of 1% chitosan and 0.03 g ZnO nanoparticle, respectively, were prepared into 1% acetic acid solution	Coating	Extend the shelf life of wild-simulated Korean ginseng root The growth of <i>B. cereus</i> and <i>E. coli</i> was inhibited	Kang et al. (2022)

(2013)

witness (C) in order to evaluate their influence concerning the extent of shelf life for 220 Hass avocados. All fruits were coated in one of the five coating solutions. The coated fruits were rapidly removed from the coating solutions followed by drying in the air 1 h. The data showed that the coated avocados with ZPL and ZNP compositions led to less weight loss, less breathing, more firmness, and less color change. Up to 36 day of study, at room temperature, the ZPL and ZNP coatings led to no changes in the initial physical appearance and texture of avocados as compared with control. The antimicrobial ϵ -PL solution added to zein (ZPL coating) favored the inhibition of fungal incidence.

A different preservation approach for cut carrots to keep them fresh was developed by Song et al. (2017), who investigated the association of nisin/ ϵ -polylysine (ϵ -PL)/chitosan (CH) as coating solution. After the storing of coated cut carrots at 4 °C for 9-day storage, the modifications in sensory qualities, physicochemical indicators, respiratory rate, microbiological growth, and white blushing were recorded. The authors demonstrated that the lactic acid (LA)/CH/Nisin/ ϵ -PL coating solution significantly ($p < 0.05$) obstructed the respiration rate, decreased the ascorbic acid and expansion of microorganism (*S. aureus* and *Pseudomonas spp.*, mold and yeast, total coliforms count, and total viable count), and raised total phenol content and phenylalanine ammoniolyse (PAL) properties related to the control. The acceptance of consumers carried out by a sensorial panel was enhanced, proved by the strong inhibition of the white blush of fresh-cut carrots. Also, the LA/CH/Nisin/ ϵ -PL coating solution significantly ($p < 0.05$) decreased the lignin formation in fresh-cut carrots, as well as Dc4CL and DcC4H gene expression. Thus, it is supposed that the synergetic effect produced by small intercellular peptides (nisin and ϵ -PL) should have an essential role in plant growth and development.

Leena et al. (2020) developed bioactive edible films based on zein 10% glycerol and resveratrol. The plasticizing effect of glycerin was evidenced by reducing the electrical conductivity and apparent viscosity and increasing the surface tension of the zein solution, which resulted in increased fiber diameter. The high efficiency of $97 \pm 2\%$ nanoencapsulation was permitted by incorporation of only 2% resveratrol into zein composition, while the high content of antioxidant agent could not be totally encapsulated in the zein matrix wall.

Four edible coatings based on caseinates or chitosan were performed for investigation of the effectiveness of coating of partially dehydrated pineapple-cereal system (Talens et al. 2012). After 6 months of analysis of coated systems at 20 °C, the study evidenced that caseinate-based coating by vacuum impregnation technique prolonged the shelf life of the food product with respect to coating made with chitosan. Covering the fruit with films based on caseinate applying by vacuum impregnation technique and followed by the drying of the product highly extends the service life of the pineapple-cereal combination in respect to other coating methods. For the 6-month storage period, the coatings based on chitosan were not capable to prevent the cereals from gaining the demanding moisture content.

The study performed by Tao et al. (2018) showed that the gelatin film was cross-linked with starch/butanetetracarboxylic acid (BTCAD)/dianhydride-*N*-hydroxysuccinimide (NHS) (SBN), a novel macromolecular cross-linker, with different ratios of SBN to gelatin (0%, 5%, 10%, 15%, 20%, 25%, and 30%) to form an innovative edible film by casting for coating of peeled apples. It was shown that the weight loss of the coated peeled apples during 25 days was about 17% ($p < 0.05$) compared with that of native film, which recorded a weight loss of 73%.

Poverenov et al. (2014) coated the freshly cut melons with various solutions of alginate in concentration of 0.5%–6% (w/v), 2% chitosan, 1.5% alginate-2% chitosan matrix, and 1.5% alginate-0.5% citral. The authors established that the combination between alginate and chitosan favored a good adhesion of coating and evident antimicrobial protection for fresh cut melon. The coating time of fresh cut melon was 2 min into alginate solution/alginate/antimicrobial solution and,

additionally, 2 min in an aqueous solution 5% of CaCl_2 , necessary for cross-linking of alginate COOH groups.

A compatibility between sage extract and zein matrix was reported by Salevic et al. (2022), who prepared edible films by casting and electrospinning methods. The antioxidant activity of both zein/sage extract casting films and electrospun mats determined by 2,2-diphenyl-1-picrylhydrazyl (DPPH•) radical and 2,20-azino-bis (3-ethylbenzothiazoline-6-sulfonic acid) ($\text{ABTS}^{+\bullet}$) radical cation scavenging capacity assessments as well as antimicrobial activity against *S. aureus* and *Salmonella enterica* subsp. serovar Typhimurium are illustrated in Fig. 6a–d.

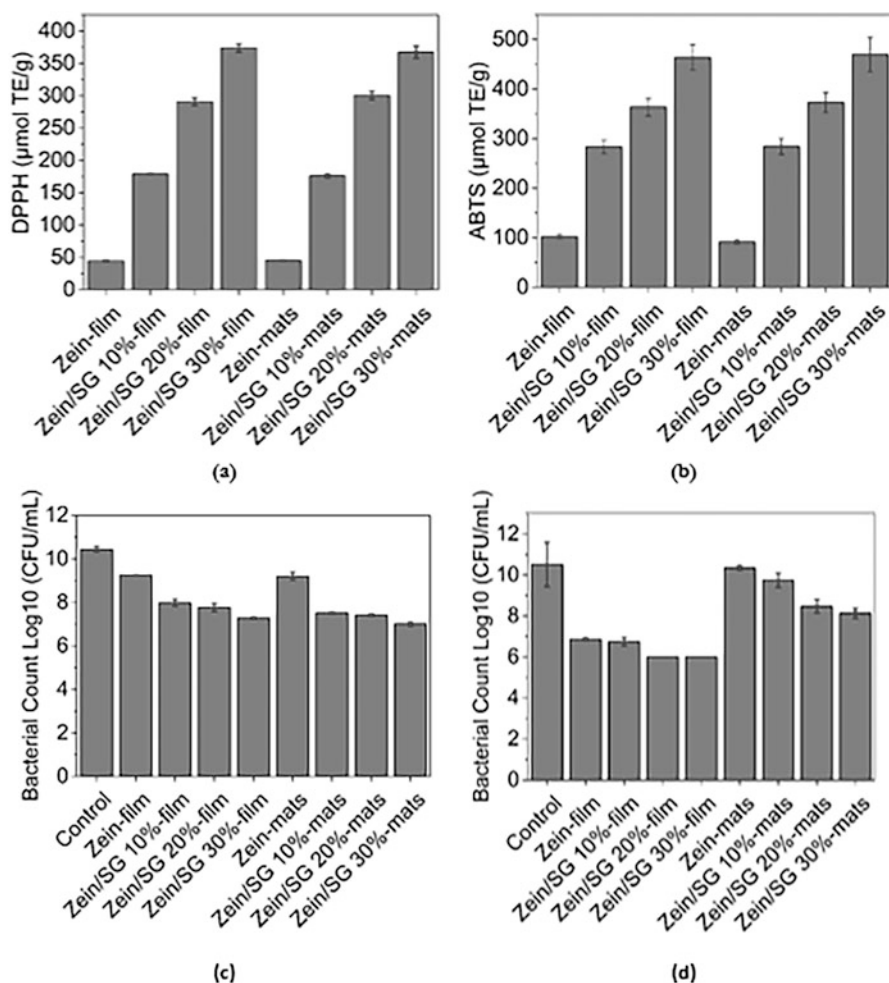

Fig. 6 Bioactive properties of the zein/sage extract obtained by solvent casting versus electrospinning method: (a) DPPH• scavenging ability; (b) $\text{ABTS}^{+\bullet}$ radical cation; (c) *S. aureus*; and (d) *Salmonella enterica* subsp. serovar Typhimurium. (Adapted from Salevic et al. 2022)

In Fig. 6a, b, we see an enhancement in the capacity to scavenge both radicals by the sage extract incorporation, due to the phenolic compounds from its composition. No difference is observed in the antioxidant activity of edible films prepared by those two methods. Initial antioxidant activity is due to the amino acid's residues and short peptides, and xanthophyll pigments from the chemical structure of zein protein, acting as free radical scavengers. The growth of tested foodborne pathogens is reduced due to the inherent antimicrobial activity of sage extract. Another observation from the antimicrobial test refers to the materials with the same compositions, prepared by different methods and their influence on the foodborne pathogens. Thus, the inhibition on growth of *S. aureus* was more evident in the case of electrospun mats than in the case of casting films (Fig. 6c, d). The films prepared by solvent-casting method highly inhibited the growth of *Salmonella enterica* subsp. serovar Typhimurium compared with the behavior of electrospun mats. These results can be explained by the difference in surface antibacterial efficiencies (Salevic et al. 2022).

Clove bud oil (CBO, *Syzygium aromaticum* L.) was used as a natural antimicrobial material for preparing edible chitosan-based films containing red cabbage (RC) as spoilage indicator and antimicrobial agents for fish preservation (Park et al. 2022).

The improvement of edible films was proposed by El-Sayed et al. (2021), who incorporated *Bifidobacterium lactis*, *Lactobacillus acidophilus*, and *Lactobacillus casei* probiotic strains into different polysaccharides and antimicrobial microcrystalline cellulose (AMCC) for coating of UF soft cheese surfaces. The coating of cheese cubes was performed by suspending of cheese cubes into control (containing probiotic strains), and different solutions of biopolymers containing 1% ACMC and 3% probiotic strains for 2 h at ambient temperature.

Natamycin and nisin are antimicrobials approved as food additives for edible food packaging. A composition based on zein, tapioca starch, glycerol, natamycin, and nisin edible film was tested by casting method for producing edible films with a thickness of 0.162 ± 0.002 mm and improved mechanical properties in terms of the decreased elongation at break, barrier property, and film dissolving in water without reducing the antimicrobial activity of film (Perez et al. 2021).

Lin et al. (2011) demonstrated the best antimicrobial activity of EDTA ($568 \mu\text{g}/\text{cm}^2$ of zein film) incorporated into nisin/zein coating against the growth of *E. coli*, *E. aerogenes*, and *C. freundii* for coated fish balls as a commercial product. In 15 days of experiment under cold storage of 4°C , the microbial count decreased from 3.19 ± 0.03 log CFU/g for uncoated fish ball to less than 1 log unit for coated food products, while the control recorded a microbial count of 6.08 ± 0.23 log CFU/g.

Extending the shelf life of avocado was achieved by means of an edible coating based on chitosan, gum Arabic, and ZnO NPs (Le et al. 2021). It was shown that the increasing of ZnO content to 0.5% led to the coated avocado with rough surfaces, due to the agglomeration of ZnO NPs. The preservation effect of the coating layer on the avocado's surface was evaluated by the luminosity parameter on the pericarp of the avocados and by the internal appearance of the avocados cut in half (Fig. 7). After 7 days of coating with edible formulation, it is observed that the avocado had

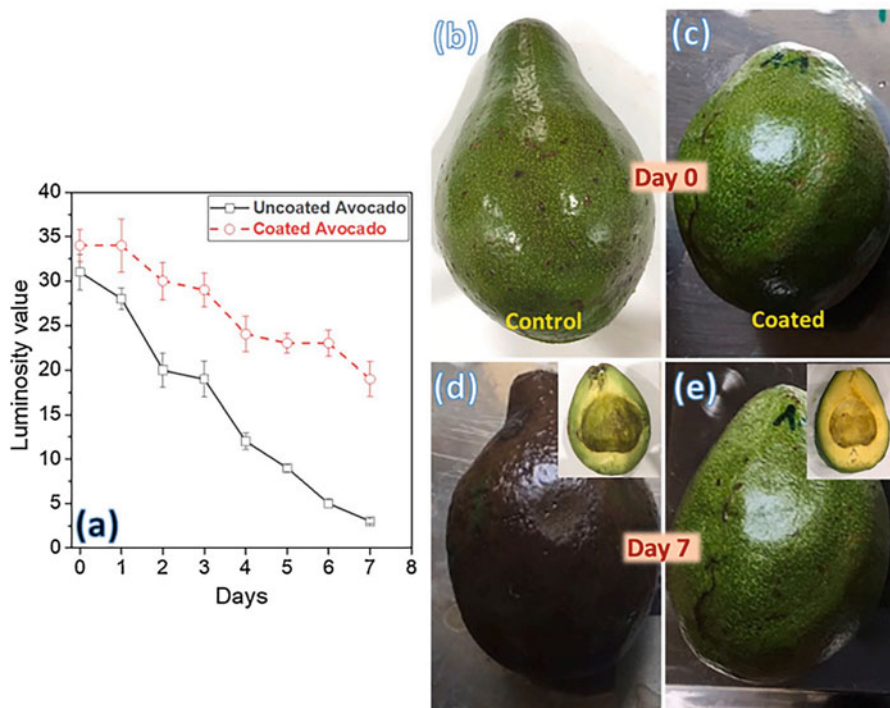

Fig. 7 (a) Luminosity parameter of the avocados treated with chitosan/gum Arabic/ZnO NPs edible coating during the 7 days of storage, appearances of uncoated (b, d) and coated (c, e) avocados. (Permission from Elsevier) (Le et al. 2021)

an improved surface (Fig. 7e) as compared with control (Fig. 7(d)), due to the glossy texture of the edible coating. Also, the pericarp of coated avocados remained unchanged in contrast to that of the uncoated avocado, for which the color was gray. Another advantage of coating is that during the ripening process, the mass loss of avocados is not significant. These are attributed to the antimicrobial activity of ZnO NPs.

Another antimicrobial coating was prepared from chitosan and nano-TiO₂ by Xing et al. (2021) to preserve the quality of coated blueberries at 0 °C. The authors reported that after 32 days of storage at 0 °C, the treated blueberry showed a high firmness, a rapid increase of sugar, acids, and vitamins, from day 4 to day 16 of storage, indicating the postharvest quality and maturity of the fruit, an increase in the ascorbic acid amount in the case of control (11.9 mg/100 g), chitosan (14.57 mg/100 g), and CTS-TiO₂ (13.45 mg/100 g) composite coating, respectively. Further, the enhancing of the anthocyanin, total polyphenol, flavonoid content, and the antioxidant ability of the edible CTS-TiO₂ composite for coated blueberry fruits have improved.

Fig. 8 Edible nanofibers coating of banana (coded C) with SF/PVA composite solution (an electrospinning time of 150 min was necessary to change the position of the banana to favor the adequate coating of all parts) and uncoated banana (coded NC) and their appearance up to 10 days (a); and Banana without peel, on the 6th day (b). (Permission from Elsevier) (Singh and Packirisamy 2022)

An edible coating composition approved by the Food and Drug Administration (FDA), based on silk fibroin, PVA, honey, and curcumin, was processed by electrospinning and dip-coating methods for protection of perishable bananas (Singh and Packirisamy 2022). It was found that the banana coated (C) with edible SF/PVA solution loaded with active and antimicrobial agents enhanced its texture and quality for 8–9 days as compared with uncoated banana (NC) when the good conditions were maintained for only 3–4 days (Fig. 8). In addition, nano-coatings provided extra nutrition to coated food products.

Hydrophilic protein-polysaccharide-based nanocomposite edible film was prepared by Fu et al. (2021) by valorization of fish gelatin and proved to have multifunctional characteristics, such as UV absorption, antimicrobial, oxygen screening, and mechanical and nontoxic properties. In addition, the shelf life of longan and banana was prolonged by 3 days and 5 days, respectively, when compared with the control groups.

Bhumbar et al. (2019) found that the adding of 1% pomegranate peel extract (PPE) to collagen extracted from fish waste/chitosan film did not modify its solubility, while the increased amount of PPE to 5% has the reduced solubility effect declining solubility immensely (36.3% and 18.1%, respectively). Furthermore, the structural integrity of all films was maintained after 24 h and the antimicrobial activity of films increased with the content of PPE.

New edible food-packaging materials were created by Susmitha et al. (2021) with the purpose to valorize the mango and pineapple by-products. Thus, film-forming solutions set up on corn starch/gelatin (CSG) with various concentrations of mango puree with peel (MPP), mango puree (MP), and pineapple pomace (PP), employing glycerol and sorbitol as plasticizers, were mixed and cast for obtaining the edible

films with thickness ranging from 0.22 to 0.30 mm and thermal stability up to 200 °C. The tests showed that the moisture content of edible films increased, tensile strength and elongation at break decreased, maybe due to the presence of free sugars such as glucose, fructose, and sucrose from mangoes, which acted as plasticizers. Adding of puree and peel of mango and pineapple pomace to polysaccharide matrices decreased the water solubility and extended the shelf life of food due to the natural antioxidants from MP, MPP, and PP components.

Recently, an antimicrobial edible food film was produced by Zhang et al. (2022) by casting from edible insects such as grasshopper protein, 30% soy protein isolate (SPI), and cinnamaldehyde (CIN) as an antimicrobial agent. In the presence of 10% xylose as a crosslinking agent, the tensile strength reached 3.4 MPa, elongation at break was of 38%, and antimicrobial activity toward *E. coli* and *S. aureus* increased with the decrease in the water vapor permeability.

Regulatory and Risk Concerns for Edible Films and Coatings

The regulations for edible films and coatings stipulate that all packaging components should be generally recognized as safe (GRAS) in order to keep the product safe and eating quality. In the case when the producer should prove the safety of edible packaging, even the biopolymer-based materials are not GRAS, a GRAS Affirmation Petition to the FDA should be filed or to market without FDA concurrence (self-determination) (Galus et al. 2020).

Edible food packaging must fulfill the Regulation (EC) No 1935/2004, which stipulates the general requirements for all food in contact with packaging, as well as the Regulation (EC) No 2023/2006 which lays down the rules on good manufacturing practices for materials and articles intended to come into contact with food.

In addition, each antioxidant, antimicrobial, food additive, and nanoparticle incorporated into biopolymer formulations with the purpose of improving the performance of edible films or coatings should be identified on food packaging conforming to the European Union regulations, including their substance name or E-number.

Usually, the use of whey, casein, soybeans, fish, peanuts, nuts, and gluten for food coating generates allergens. The manufacturers are obliged to state on the label, the quantity of allergens with the appropriate warning about the allergenic ingredient (Jan and Naig 2021).

Essential oils used as antioxidant and antimicrobial agents for ready-to-eat fruits are analyzed and recorded by the European Commission as well as by the United States as GRAS; however, they may induce allergic reactions. The low concentration of essential oil does not have the expected effect, while the high content leads to undesired organoleptic impacts inducing oral toxicity.

Conclusion and Future Trends

Innovations in the food packaging sector have triggered development of edible films and coating to improve the quality of food, in a sustainable way, and with purpose to reduce environmental impacts.

Biopolymers based on polysaccharides, proteins, and lipids are promising materials used to expand the future of edible food packaging. To obtain optimal properties related to moisture, mechanical strength, and enhancing the shelf life of packaged food, special bioactive compounds are added to biopolymeric matrices, which increases the cost of final products. The composition of edible food packaging must comply with the food regulation regulations of each country (Iniguez-Moreno et al. 2021). However, special attention should be drawn to the solubility of these additives in biopolymers in order to not exceed the specific limits imposed by Regulation 1935/2004/EC (Mahmud et al. 2021).

It is still necessary to expand the fabrication of edible films from laboratory scale when the compositions are poured into Petry plates to scale up and to test the innovative formulations in contact with different foods (fruit, vegetable, fish, or meat).

The trends in edible film and coating are to find new and potential resources of raw materials for biomaterials, like eggshells, as well as to develop edible probiotic coating and nanocoatings. Edible insects are a novel source for edible food packaging with many health benefits (Jeong and Shin 2020).

Nonetheless, to check out if the final quality and real effectiveness of the edible films or coatings are able to safeguard packaged food, a sensory evaluation should be carried out. The aim is to demonstrate that the edible food packaging has not changed the taste and flavor of the final food product.

Abstract

The emergence of peptide- and polypeptide-based materials in the field of biomedicine and biotechnology is gaining importance due to its unique physical, chemical, and biological properties like biocompatibility, tunability, ease of synthesis and removal from body, and lack of toxicity. These biocompatible materials are the most suitable for biomedical applications in vivo. The clear

understanding of the protein-structure function and their self-assembling mechanism can pave way to obtaining molecular models suitable for different biomedical applications. This chapter aims to focus on the basic properties, synthesis techniques, design principles, and biomedical applications of peptide-based biopolymers.

Keywords

Peptides · Biopolymers · Peptide-based polymers · Biomedicine

Introduction

Polymers represent a long chain entity of different repeating monomers. They can be classified into synthetic polymers and biopolymers. Biopolymers are obtained from natural resources or living organisms like animals, plants, bacteria, and algae. These can be further divided into polypeptides, polysaccharides, and polynucleotides. One of the major areas of biopolymers includes peptide-based polymers which are derived from basic building blocks, amino acids. Polypeptides represent a general class of polymers comprised of repeating chain of different amino acids. However, there are two types of polypeptides, synthetic and natural occurring. Peptides are small molecules rather smaller than proteins consisting of about 2–50 amino acids. The short chains of amino acids are linked together by a chemical bond called peptide bonds. The chains which consist of less than 20 amino acids are called oligopeptides which can include dipeptide, tripeptide, tetrapeptide, etc. These are essential for several vital functions in the body. There are different peptides that are of medical use since they possess antioxidant, antimicrobial, and antithrombotic properties. There are more than 60 peptide-based drugs that are approved and available in market in the USA (Lau and Dunn 2018).

Synthetic peptide-based polymers include engineered peptide-based polymers with advanced properties that can be utilized for different applications. There have been interesting reports on the use of these engineered synthetic biomaterials in the field of biomedicine and biotechnology. Bioinspired materials are more capable for obtaining biomaterials that are capable of obtaining and fulfilling the various needs of the human body. Several novel functional materials comprising of polypeptides with polymers have been reported to have applications in biomedicine and biotechnology especially for the fabrication of scaffolds, drug delivery carriers, biosensing, etc. A clear understanding of the protein–structure function is crucial for developing new repetitive polypeptide-based materials. In contrast to natural biopolymers, engineered polypeptides can be controlled with respect to chain length, mono-dispersity, and stereochemistry (Varma and Gopi 2021).

This chapter provides an insight into the design and principles of peptide-based biopolymers, their properties and characteristics, and their applications in the field of biomedicine and biotechnology.

Peptide-Based Biopolymers

Structure: Almost all the physical, chemical, and biological properties of peptide-based biopolymers depend on structure functionalities be it the primary amino acid sequence, the secondary and 3D tertiary structure. The various interactions between different chain moieties of the sequence result in different characteristic properties of the peptide and polymers.

Properties: Peptide-based biomaterials are mostly soft and wet enabling them to be used in aqueous environment. Thus, they are a blessing for applications where an aqueous environment is required since they can come in contact with water surfaces. In this aspect, they are completely different from traditional materials like metals and ceramics use in bioscience which are hard and not suitable for use in aqueous environment.

The properties of peptides mainly depend on their basic building block, amino acids. However, the number of naturally occurring amino acids is less which is an advantage compared to synthetic polymers. These biocompatible peptide-based materials possess the most important advantage, which is they degrade easily and harmlessly within the body through the usual metabolic process, and they can be widely employed for drug delivery vehicles and tissue-engineering applications. All the physical, structural, and rheological properties need to be carefully studied to evaluate the functionality of these biomaterials. Biophysical properties like molecular weight can be determined by MS or MALDI-MS, and protein concentration can be noted spectrophotometrically or using colorimetry. The clear idea of hydrodynamic radius and protein folding are crucial for applications in protein purification, and drug delivery.

Self-assembly and other ways of directed assembly of various peptides are methods to obtain different functional biomaterials for therapeutic use. Ranging from very small peptides, these can self-assemble to different nano-morphologies like vesicles, micelles, and nanotubes that enhances their stability and makes them suitable for encapsulation of other moieties. Also in terms of biocompatibility, immunogenicity, and biodegradability, the self-assembling peptides typically exhibit favorable features that can result in nontoxic waste products (Ghosh and Chmielewski 2004).

Different Types of Polypeptide Proteins

Compared to synthetic polymers, biomaterials derived from recombinant proteins like silk-like polypeptides (SLPs), elastin-like polypeptides (ELPs), collagen-like polymers, extended recombinant polypeptide (XTEN) polymers (Saxena et al. 2005), and archetypal peptides including leucine zippers are suitable alternatives for use in biomedical applications. These are the protein polymers, comprised of natural or de novo engineered repeated amino acid sequences obtained by the recombinant biosynthesis or via genetic engineering. The main advantage is the tunability of the molecular weight, sequence, length, and monodispersity of the

resultant material. Also the most striking feature is the biodegradability and biocompatibility of these protein polymers owing to the natural polypeptide chains present. Hence the metabolic products comprise of only small peptides and amino acids (Er et al. 2000).

Silk-like polypeptides: Spiders of the order Arachnida, which are arthropods, create silk, a natural protein, and it is also reported that silkworm caterpillars of the order Lepidoptera have exceptional material properties. For instance, spider silk is found to be a light-weight, elastic material with good impact resistance. They are water insoluble and a fibrous protein which consists of sericin and silk fibroin (SF) which are two main proteins. Sericin is a hydrophilic and amorphous protein which is composed of 18 amino acids in a nonrepetitive arrangement. However, sericin may cause immunogenic reactions hence they are separated from SF prior to use in biomedical applications. SF is a high molecular weight, amphiphilic block copolymer protein complex held together by a single di-sulfide bond. The hydrophilic portion of SF is made up of nonrepeated sequences, whereas the hydrophobic portion is made up of a highly repetitive dipeptide motif of Gly-X, where X can be any of the amino acids alanine, serine, tyrosine, or valine (Varanko et al. 2020). Due to their high order structure, silk fibers show ductility, high toughness, and also they are biocompatible and biodegradable. The combination of all these properties makes them ideal candidates for use as high-performance structural components used for biomedical applications. There are also regenerated silk materials that are chemically reconstituted from natural silkworm cocoons to eliminate the binding proteins, sericin, and dissolve silk fibroin solutions to obtain hydrogels and resins (Nagarajan et al. 2019). β -sheet is the main structural component of silk fibroins. Native silk proteins have crystalline domains that are highly repetitive and are separated by crystalline or amorphous areas. The crystalline portion of *B. mori* fibroin has a repetition of 59 amino acids [GAGAGSGAAG[SGAGAG]8Y], with a 3:2:1 ratio of glycine, alanine, and serine (Tsuda and Suzuki 1981). Using the repeating motif [GAGAS], Capello and coworkers found that silk-like proteins (SLPs) developed crystalline structures that resembled the β -sheet structures of native silk proteins. Additionally, they discovered that blocks of amino acids like GAAGY can be used to adjust the degree of crystallinity. In their study, it was mentioned that the incorporation of SLPs with elastin-like blocks affects the crystallinity and also SELPs are more water soluble since the ELP blocks can influence the protein's molecular chain properties (Cappello et al. 1990). The thermal stability and adaptable mechanical properties of SLPs make them utilized for the formation of hydrogels and scaffolds. Recombinant silk-like peptides have also been used for biomedical applications.

One limitation is the level of expression when producing silk in large quantities. The most extensively used expression host, *E. coli*, cannot efficiently translate the highly repetitive gene sequence of silk protein. High levels of expression (2% of all soluble protein) were shown by transgenic species like potato and tobacco (Hood and Jilka 1999).

Elastin-like polypeptides: This class of polypeptides comprises of a genetically engineered kind of tropoelastin-derived protein polymers. They are genetically

encodable biopolymers, in the class of elastomeric proteins present in living organisms. Elastin is among the profuse extracellular matrix protein, in addition with collagen and glycosaminoglycans (GAGs). Environmental factors like temperature, pH, or ionic strength can cause them to go through a reversible phase shift. ELPs are soluble at temperatures below the inverse phase transition temperature and insoluble at temperatures beyond this threshold. The ability of ELP-based biomaterials to generate coacervates in response to temperature variations is one of their most important properties.

They are responsible for giving elasticity to tissues. Elastin-like polypeptides (ELPs) consist of hydrophilic and hydrophobic cross-linking domains. ELPs mostly consist of repeat units, Val-Pro-Gly-X-Gly, where X may refer to be any amino acid. At the fourth residue, amino acid proline is mostly avoided because it may interfere with coacervation (Wise et al. 2014). Different biofunctional groups can be incorporated into ELPs without affecting their thermal behavior. Recombinantly synthesized ELPs are genetically encoded, and they produce a monodisperse solution which is suitable for biomedical applications in contrast to synthetic polymers (Chilkoti et al. 2006). ELPs are very useful for biomedical applications since the phase transition temperature can be specifically programmed. Phase transition temperature is the maximum value at which ELP aggregation occurs (Fig. 1). Second, their molecular mass can be tuned when employed as drug carriers since molecular mass influences the half-life of the drug in the body, third, their expression level is high (typically expressed in *Escherichia coli*) compared to synthetic polymers, and also they can be purified by reverse phase transition without employing chromatographic methods (Kowalczyk et al. 2014). A very fine control over the sequence and length of ELPs can be beneficial for the biomedical application since depending on the above two, the chemical reactivity, biological activity, and physical properties of ELPs can be manipulated. Due to their broad range of applications, they have widespread use in drug delivery and tissue engineering.

A good understanding of the requirements and conditions of the amino acid sequence is necessary to design ELPs at the genetic level. Urry and coworkers studied by estimating the free energy change involved in the transition of ELPs containing a single guest residue, the effect of amino acid guest residues on the

Fig. 1 The ELP aggregation mechanism. (The image is reproduced with permission from Kowalczyk et al. (2014) Copyright © 2014)

transition temperature, and the impact of hydrophobicity on the transition temperature of ELP (Urry 1997).

Synthesis

Polypeptides represent a large class of macromolecules comprised of amino acid sequences. Generally, their synthesis and design can be divided into main classes: the synthetic approach methods and the recombinant DNA techniques. In the synthetic techniques mainly include solid phase polypeptide synthesis (SPPS), ring-opening polymerization of α -amino-N-carboxyanhydrides (NCAs), and native chemical ligation (NCL). These techniques are based on the use of peptide monomers and nonpeptide monomers for the design of hybrid structures. A limitation to this method is the lack of control over polymer chain length and stereochemistry. Whereas recombinant DNA techniques are genetically encoded approaches toward the synthesis of polypeptides, through this method we can obtain highly specific sequence and stereochemistry in the synthesized polypeptide. The main drawback is that some of them cannot be adequately expressed into a heterologous host, and nonpeptide moieties can only be added after postexpression modification procedures (Duro-Castano et al. 2014).

Synthetic Techniques

To obtain polypeptides with comparable control of size and uniformity as those of genetically encoded approaches, there has been tremendous work taking place. Through this method, there is the possibility of incorporation of artificial amino acids, β -amino acids, and stereochemically unique amino acids all of which can prevent protease degradation. The main advantages of this technique include the following:

- (a) A vast number of unnatural amino acids can be employed for the synthesis to obtain different polypeptides with varying structure-function relationship and properties.
- (b) Large-scale synthesis is possible.
- (c) Easier and faster methodology compared to genetically encoded techniques.
- (d) Moreover, it enables the blending of polypeptides along with other synthetic polymers (Duro-Castano et al. 2014).

Solid Phase Peptide Synthesis (SPPS) as a procedure for preparation of polypeptides was first introduced by Merrifield in 1963 (Merrifield 1963, 1969). It consists of multiple coupling-wash-deprotection-wash cycles. In his work, Merrifield attached the first N-protected amino acid group to a partially chlorinated polystyrene resin through an ester bond. The protecting group was further removed to yield a free amino group that can react with next N-protected amino acid. The peptide is immobilized onto the solid phase and filtered. The resin is finally removed leaving behind the synthesized peptide. This method is highly advantageous since it

allows the synthesis of natural peptides, and certain control over peptide composition is achieved (Duro-Castano et al. 2014).

Native Chemical Ligation involves the chemoselective reaction of two unprotected peptide moieties diminishing the possibility of other side reactions and undesirable by-products. They form a nonamide bond at the ligation site.

Ring-opening polymerization technique is commonly used to produce peptides and polypeptide block copolymers. Due to the multiple functionality, structural homogeneity can favor self-assembly to define nanostructures that can find applications in biomedicine and biotechnology (Duro-Castano et al. 2014).

Genetically Encoded Polymers

The procedure basically consists of three steps:

- (a) A recombinant gene segment that codes for the desired protein is created. More specifically, a protein target is found, and its genetic code is translated.
- (b) Inserting this segment onto a plasmid from bacterium that is a DNA vector to create a recombinant DNA molecule.
- (c) The recombinant DNA molecule is transformed into a host cell.

The recombinant DNA molecule is subsequently used to successfully alter cells, which are then cultivated in culture. The accomplishment of recombinant genes is the rate-limiting step when the synthesized polypeptide chain has a large number of repeats.

On an automated solid phase synthesizer, DNA sequences up to 100 nucleotides can be chemically directly synthesized. The assembly of the gene into the desired vector is the rate-limiting step in genetically encoded synthesis (Fig. 2).

Characterization Techniques

The biophysical, structural, and rheological characteristics of peptide-based materials can be ascertained using a variety of methods that were initially created to evaluate the solution properties of peptides and proteins and the mechanical properties of hydrogels.

Biophysical Properties

Numerous characterization methods that were first created for the characterization of proteins can also be used to characterize repeated peptides. It is possible to quickly assess the protein concentrations of peptide-based biomaterials using spectrophotometry, colorimetry, a Coomassie brilliant blue assay, or bicinchonic acid assay. These materials' molecular weights can be determined using analytical ultracentrifugation based on sediment coefficients, electrophoresis-based techniques like SDS-PAGE, mass spectrometry (MS) techniques like matrix-assisted laser desorption ionization (MALDI-MS) and electrospray MS, or electrophoresis-based techniques like SDS-PAGE. The lower critical solution temperature (LCST) or transition temperature (T_t), which is frequently calculated by the turbidity (optical density at 350 nm as a function of temperature), is typically used to indicate the inverse temperature transition behavior for ELPs.

The binding behavior of peptide-based biomaterials can be quickly and conveniently ascertained using surface plasmon resonance spectroscopy (SPR). Using a simple conjugation chemistry, such as 11-mercaptohexadecanoic acid, peptides can be easily immobilized on a gold-coated glass chip (MHA). It is possible to examine the binding thermodynamics of peptides with their binding partner using isothermal titration calorimetry (ITC). Calorimetric data can be used to calculate thermodynamic parameters such as binding enthalpy, entropy, free energy, and binding constant.

Structural Properties

Protein purification, tissue engineering, and drug delivery applications all depend on structural characteristics like hydrodynamic radius and appropriate folding. The best techniques for discovering detailed structural information about proteins are nuclear magnetic resonance (NMR) and X-ray crystallography. Circular dichroism (CD) spectrometry, which recognizes the unfolding and folding transitions of peptides, can also be used to study protein folding.

To specifically assess the proportion of alpha helices and beta sheets in a polypeptide, CD examines the absorption of left- and right-handed circularly polarized light. The functionality of peptide-based biomaterials, particularly those having enzymatic and biological capabilities, is significantly influenced by protein folding. Understanding the folding and refolding characteristics of peptides during chilling

and heating is possible with the help of differential scanning microcalorimetry (DSC).

The state of protein folding can be ascertained by measuring the amount of heat needed to raise the temperature of the peptide during a physical transformation, such as a phase transition, using DSC. The hydrodynamic radius (R_h) of polypeptides in aqueous solution can be calculated via dynamic light scattering (DLS), sometimes referred to as photon correlation spectroscopy. In DLS, an optical beam is sent through an aqueous sample, and the scattered light from the particles travels in all directions.

The measured scattered intensity changes over time due to constructive and destructive interference of the light scattered by nearby particles, which occurs because the particles are small enough to undergo random thermal (Brownian) motion. The diffusion coefficient of the particles can be determined by analyzing the intensity time correlation curve. DLS is particularly helpful for investigating how self-assembled polypeptide micelles are formed.

Rheological Properties

Since peptide-based biomaterials' main function is as a structural element to support cell growth, their rheological qualities are particularly crucial in tissue engineering scaffolds. By performing oscillatory rheological characterization in a solution state, it is possible to assess the load-supporting capacity of cross-linked or self-assembled polypeptides.

Another significant rheological metric for elastin-like polypeptides is gel swelling, which may be quantitatively characterized by the swelling ratio. When the swelling ratio is larger than one, the gel is said to be expanding, and when it is less than one, it is contracting. The swelling ratio can be quickly determined by weighing the peptide-based gels before and after incubation with buffer and then normalizing the measured weight to the initial weight.

Applications

Biopolymers have always been categorized as an efficient material for biomedical applications due to their properties like biocompatibility, biodegradability, low toxicity, and also the presence of biomimetic chemical entities, and they release no toxic elements upon degradation which is an important factor during human body metabolism. Hence they are widely used in the formulation of drug delivery vehicles, tissue-engineering scaffolds (Nagarajan et al. 2019). Peptide-based biopolymers are also utilized for biomedical applications in the field of therapeutic molecule delivery, tissue engineering, and food-packaging applications. Peptides or protein-based materials possess advantages like low cytotoxicity, abundant drug binding sites, and significant uptake to the targeted cells. Also owing to the different multiple functional groups in the amino acid sequence of polypeptides, they can be tuned to

create different interactions with the therapeutics forming a 3D network (Elzoghby et al. 2012).

Drug Delivery

Therapeutic drug delivery vehicles require a porous morphology to allow fast diffusion across the body to the target site. Peptide-based biomaterials have improved properties in terms of in vivo drug delivery and efficacy. There are several advantages of polypeptide over synthetic polymers since they are made up of amino acids which are biocompatible, and their metabolic products can be eliminated through natural metabolic process. Also most of the genetically encoded polypeptides have uniformity in sequence and molecular weight which can contribute to a great extent in properties like transport, biodistribution, and degradation (Das et al. 2019). Similar to synthetic polymers, amphiphilic polypeptide can encapsulate drugs into structures like vesicles and micelles. They also have the added advantage of reducing systemic toxicity, increasing plasma half-life, and increasing the solubility of poorly soluble drugs. The wide variety of functional groups, within the primary sequence of polypeptides, can be tuned for different interactions with the drug entity, also capable of forming a 3D network that can provide protection, targeted delivery and a reversible binding (Hoare and Kohane 2008).

Peptides have been reported to show great results in targeted drug delivery using peptide-modified polymer systems. The efficacy of the drug can be increased by delivering them directly to the target cell. It can also reduce adverse reactions and dosage. There are many reports in which these biomolecules are used to develop hosts of drug delivery platforms as such in drug depots for delivery of therapeutic drugs, injectable particles, small molecule drugs, and nucleic acids. Controlled drug delivery was first envisioned by a Nobel laureate, Paul Ehrlich, in the twentieth century who thought of a magic bullet therapy that could deliver drugs to a the desired target while also avoiding off-target toxicity. Collagen was among the first protein-based material used as a drug release system to treat Glaucoma (Varanko et al. 2020). Furthermore there have been many developments in the field of drug delivery using peptide-based biomaterials that can even help in cure of different types of cancers (Bertsch et al. 2019).

A quorum-sensing peptide from *Clostridium acetobutylicum* that had been previously discovered to pass the blood brain barrier was used by Ran and colleagues in their system (BBB). In order to deliver the chemotherapy drug paclitaxel to glioma cells, their technique utilized mPEG-PLA copolymer micelles modified with the D-retroenantiomer of this peptide produced from bacteria. Since the D-retroenantiomer has improved stability and glioma-targeting capabilities, the retro-inverso isomerization approach was applied to create their peptide. The usage of their mice model successfully targeted brain cancers (Tibbitt et al. 2016). The chemotherapy drug docetaxel was successfully loaded into a biodegradable system by Logie et al. to target breast cancer cells. They made use of micelles of poly (D,L-lactide-co-2-methyl-2-carboxytrimethylenecarbonate)-graft-polyethylene glycol (P(LA-co-TMCC)-g-PEG)

that had been altered with a brand-new taxane-binding peptide and linked to the antibody 73JFab. It was found that their peptide increased the drug loading about twofold, which indicated that this novel peptide can greatly enhance the capacity and, therefore, the efficacy of the delivery system (Logie et al. 2017). In a work carried out by a group of people, they developed O-carboxymethyl chitosan nanoparticles (O-CMC NP) and reformed them with a peptide that targets CXCR4 receptors that are able to deliver docetaxel to lung cancer cells. The reports showed that their targeted system performed significantly better than a nontargeted control at inducing apoptosis and causing cancer cell death (Wang et al. 2015).

Peptide-based nanoparticle devices are explored as potential drug and gene delivery vehicles for controlled release and delivery to the target site. A controlled release pattern is required for treatment of various diseases like malaria. Bhadra and coworkers created nanocarriers using poly-L-lysine-based dendrimers that were coated with chondroitin sulfate A (CSA) and PEGylated in order to deliver an antimalarial medicine called chloroquine phosphate in a regulated and sustained manner (CQ). The drug's cytotoxicity and hemolytic activity were significantly reduced after being entrapped in this peptidic carrier. Additionally, compared to the free drug, a significant decrease in the levels of the ring and trophozoite stages of *Plasmodium falciparum* was seen after treatment with drug-loaded CSA coated dendrimers (Bhadra et al. 2006).

Tissue-Engineering Applications

Peptide-based biomaterials are extensively used in regenerative medicine since they controlled degradation rate in vivo, are chemically biocompatible in vivo and in aqueous solutions, minimal cytotoxicity, the by-products are amino acids that can be easily eliminated from the body since they have controlled. Also, they can be functionalized to have better interactions with cells, thus providing an optimal platform for tissue functions and cellular activities. There have been several reports regarding the use of peptides and polymers for tissue-engineering applications mainly as implant scaffolds and for promoting tissue growth. For use in this field, the peptides need not be specific for a certain cell type (Okamoto and John 2013). The peptides will interact with components found in all cell types to increase or enhance interaction with cells; this property makes it ideal for design of scaffolds used in vivo and in vitro. The liquid-like precursors are handled and injected directly into the locations of the tissue defects before use. The polymers quickly come together after injection to produce a hydrogel that can act as a 3D artificial extracellular matrix. There are essentially three ways for polypeptides to gel: (1) by self-assembling in response to environmental stimuli, (2) by crosslinking, and (3) via physical cross-linking procedures (Chow et al. 2008; Hosoyama et al. 2019).

Garty and coworkers synthesized a polyethylene-oxide and polypropylene-oxide block copolymer thermoresponsive gel modified with Arginine-Glycine-Aspartate (RGD) peptides. It was reported that the gel exhibited low viscosity properties at ambient conditions that is suitable for direct injection at the targeted site. On

increasing the temperature, polymerization occurs which enables the formation of a rigid, supportive matrix that can restore function to damaged tissues and organs through previously embedded engineered stem cells (Ward and Georgiou 2011). Tissue-engineering scaffolds restore the function of diseased, injured, or aged cells, tissues, and organs. Self-assembling peptide and polypeptides can form hydrogels with well-defined nanostructure, 3–10 nm diameter fibrils. Zhang and coworkers have synthesized short oligopeptides comprising 12–16 amino acids that can form stable β -sheet structures which have been used to form self-assembled hydrogels that can support cell attachment to a variety of mammalian cells. These ionic oligopeptides have amphiphilic character with the charged residues, on the one hand, and nonpolar residues, on the other. The structures are very stable since they are formed by strong intermolecular interactions, ionic interactions, and Van der Waals interactions (Zhang 2003). Kisiday et al. formed hydrogel from oligopeptides containing leucine, lysine, and aspartic acid that supported the growth of chondrocytes. These hydrogels have also been utilized for cartilage tissue repair (Zhao et al. 2010) (Fig. 3).

Tissue Growth: ELP based polypeptide substrates have focused on cartilage repair as Betre et al., reported that above transition temperature, a gel-like material formed by aggregated ELPs can encapsulate chondrocytes which can maintain their distinctive morphology and phenotype in vitro for about 15 days which concludes that ELP aggregates supported the growth of chondrocytes. The cells could accumulate the characteristic proteins of cartilage, sulphated glycoaminoglycan (GAG) and collagen type II (Betre et al. 2002).

Biosensing

It is equally important to view the biomolecules clearly for the diagnosis, prevention, and treatment of diseases. Clear observation and results are required for identification of the problem. Peptides are regarded as recognition elements in the field of

Fig. 3 Molecular model of a single β -sheet forming ionic oligopeptide positively charged Lysine (K), negatively charged aspartic acid (D) are on lower side of the sheet and hydrophobic Leucine (L) are on upper side facilitating self-assembly through intermolecular interactions (Zhao et al. 2010)

biosensing due to advantages like stability against denaturation, easy modification, chemical versatility, and cost effectiveness. Various peptide-based biosensors have been developed by conjugating a peptide with signal markers. They have been used for the detection of various analytes like cell proteins, nucleic acids, antibodies, and metal ions. They have also been used as probes in biosensors due to their property of forming several tertiary structures. There have been several reports on the use of peptide-based electrochemical biosensors for analytical approaches (Karimzadeh et al. 2018). Polypeptides have been utilized for the application of biosensors such as elastin-like polypeptides with a fusion protein A, G, or L that can bind to an antibody where it can act as a concentration mechanism to enhance signals (Gao et al. 2006). Also the biomolecules on the surface can be identified individually by immobilizing the biomolecules in a spatial controlled manner using local environment changes (Frey et al. 2003b). The reversible phase transition behavior of elastin-like polypeptides to regenerate the biosensing surfaces to create an actively controlled surface in which the surface properties such as hydrophobicity and functionality can be rapidly modulated through a simple temperature switch were reported (Frey et al. 2003a). Peptides being used as recognition nanoprobe were introduced by Kou and coworkers which utilized a peptide and DNA S_1 -modified platinum nanoparticles (P_1 -PtNPs- S_1) immobilized on electrode surface. They proposed this label-free electrochemical biosensor for sensitive detection of metalloprotease -7 (MMP-7). The peptide with the amino acid sequence (NH₂-KKKRPLALWRSCC-SH) provided a MMP-7 cleavage place (Kou et al. 2016). Proteases are enzymes that are involved in tumor growth and progression at primary and metastatic sites. One of the members of the serine protease family, trypsin, has been considered as a specific cancer biomarker. A work was reported on a low-cost, accurate biosensing method based on peptide-microbeads for the determination of trypsin. Here they have immobilized a short synthetic peptide sequence that is dually labeled with fluorescein isothiocyanate (FITC) and biotin onto neutavidin-modified magnetic microbeads. This biotin-modified peptide probe on the surface of magnetic microbeads further cleaves the target enzyme and enzymatic labeling. The biosensor showed good specificity against other proteins and proteases found in samples (Cristina et al. 2020).

Protein Purification

Recombinant proteins must be readily available for their numerous biological uses as medicines and diagnostics, as well as in regenerative medicine and biosensing. Proteins are essential tools for high-throughput screening, lead identification, and drug discovery. Even though recombinant expression allows for the mass production of numerous proteins, the cost of the finished product, which is primarily (70%) attributed to purification, might occasionally be too high for routine use. Additionally, it is still challenging to produce many additional proteins in sufficient quantities for biopharmaceutical applications, mostly because of issues with protein expression and purification.

These restrictions largely also apply to peptide-based polymers. Numerous methods have been created to enhance protein expression, and they have all been covered in-depth in other reviews. It is usual to use a variety of expression hosts, including bacteria, mammalian cells, and insect cells. The choice of these hosts is mostly determined by the characteristics of the proteins that will be produced. The requirement for appropriate folding and posttranslational modifications, which control the bioactivity of the purified protein, also influences the decision. Once the expression host has been chosen, the expression parameters, such as medium composition, feeding schedule, and metabolic waste disposal, must be optimized in order to maximize the protein production.

Controlled Drug Delivery to Tumors

Numerous investigational medicines have demonstrated effectiveness *in vitro* but have insignificant *in vivo* efficacy. Transport issues are typically to blame for this performance disparity; many medicines have poor pharmacokinetics or systemic toxicity, which limits their efficacy. Therefore, improvements in drug delivery are required to enhance the pharmacokinetics of possible treatments for numerous diseases, and peptide-based biomaterials hold considerable promise for *in vivo* drug administration. The strategies for delivering cancer therapies to solid tumors are the main topic of this section. Paul Ehrlich effectively invented the field of targeted medication delivery when he suggested the use of a carrier capable of delivering “therapeutically active groups to the organ in question” in 1906. In this method, drug carriers are created to increase the medication’s accessibility at a particular site while reducing systemic exposure to the drug. By directing the drug to a particular place, this approach provides an enhancement over the delivery of free medication. The drug’s effectiveness is raised, and the buildup at off-target locations is reduced, which reduces the compound’s toxicity.

However, targeted medicine delivery must get past the intricate transport obstacles in the body. Three transport phases can be identified in the process of delivering substances throughout the body: from injection to tissue location; from vasculature to interstitium; and from interstitium to molecular site of action. Additionally, depending on the site of action, medicines that have subcellular targets (such as the nucleus or lysosome) will need a fourth transport step. When a medication is taken systemically, the substance will build up at the site of action, but it will also build up in healthy tissue and may also be removed by the reticuloendothelial system at the same time (RES). Studies showing homogeneous distribution throughout the body imply that low MW medicines will quickly diffuse from the bloodstream into healthy tissues. The majority of the adverse side effects related to systemic therapy are brought on by the homogenous localization of the drug, which results in low drug concentrations at the tumor site. Small compounds are also quickly excreted from the bloodstream, necessitating repeated injections to exert therapeutic effects. The physiology of tumor vasculature differs from normal vasculature, which is one characteristic of tumors that can be used in medication administration. Normal

blood arteries have modest permeability, whereas tumor vasculature is asymmetrical and has leaky areas, which raises the overall permeability. The interstitium of the tumor also lacks functioning lymphatics. The enhanced permeability and retention (EPR) effect, which is a result of these two characteristics of tumors, increases the uptake of blood-borne chemicals into the tumor.

Gene Delivery into Mammalian Cells

Poly(amino acid)s, which include polypeptides and peptides, can be used as a functional material to create a variety of value-added materials, such as stimuli-responsive, self-assembling, nanoscale, and self-healing materials. Target-specific transport of bioactive chemicals into plant/animal cells and organelles is another illustration of how peptides are advantageous. Such delivery systems would be even more useful if they were biodegradable, biocompatible, and mechanically resilient. They would also be more advantageous if they could be made and processed in ambient water conditions without losing the bioactivity of the molecules that need to be delivered.

Because the resilience and stability of poly (amino acid)s may be altered by changing their amino acid sequences and secondary structures, such as β -sheet and α -helix structures, they have the potential to satisfy these requirements. Currently, this kind of material does not lend itself to chemo-enzymatic peptide synthesis. Due to its self-assembly, mechanical toughness, processing flexibility, biodegradability, and biocompatibility, silk, a structural protein, can assist in meeting these criteria and offers significant value for a variety of human therapeutic interventions.

Block copolymers made of spider dragline silk have been created and genetically engineered for application in tissue engineering and the delivery of genes. Due to their ability to destabilize membranes, condense DNA, and buffer pH, cationic components can be added to silk-based copolymers to deliver genes effectively. Cell-penetrating peptides (CPPs), for example, are 10–50 amino acid sequences that differ greatly in their sequence, electrical charge, hydrophobicity, polarity, and ability to translocate through membranes. Molecules and chemicals can be delivered to particular targets using signal peptides and antibody fragment sequences.

Gene Delivery to Specific Organelles

At different stages of life, organelles play crucial roles in cellular metabolic pathways. To build artificial metabolic pathways, it is essential to comprehend the core mechanism of cellular activity known as trafficking of biological molecules between organelles. However, the limitations of current organelle transfection techniques preclude both the use of organelles as a reaction site for the production of value-added biomolecules and the knowledge of the function and role of organelle genes. The double membrane, small size, and remarkable mobility of mitochondria, in

addition to their huge population size in cells, present significant obstacles to mitochondrial transfection. It has not yet been possible to successfully introduce foreign genes into the mitochondria of whole, vascular plants.

Conclusion

Peptide-based biomaterials have been reported to have immense number of applications in the biomedical field due to their unique properties and biocompatibility. Special emphasis has to be made on the detailed study of the design principles and structure-property relationship of the peptides and sequence of amino acids. The self-assembling of peptides to α -helix or β -sheet structures enable them to form unique nanostructures. Although most of the peptide-based materials enhance growth of specific cell types, more works can be done to make it more suitable for in vivo tissue-engineering applications. More techniques are required for identification and peptide modification and attachment to polymers. There are some limitations that are still causing problems like the thermal stability of peptides that can arise from aggregation, charge distribution, or ambient conditions. A clear picture of the design and properties of different peptides can make these biobased peptides a promising material for applications in the biomedical sector.

Abstract

Biopolymers are preferred materials for medical applications on account of the great biocompatibility they exhibit. Their natural origin makes them highly bioactive and eco-friendly. But poor technological properties and quick deterioration rate pose enormous challenges on their performance and utility in proposed applications. The issues associated with lack of desired mechanical properties and aqueous stability of biopolymers can be managed to a great extent through cross-linking. Cross-linked biopolymers are found to behold great potential for biomedical applications like tissue engineering, drug delivery, and wound healing. Although, cross linking enables the biopolymers to meet the prerequisite of mechanical strength for various applications, it negatively interferes with other natural properties that made these biopolymers highly beneficial for biomedical applications. The reduction in degradability associated with cross-linking will have a negative impact while fabricating biomaterials for implants and drug

delivery systems in general. On the other hand, this negative side effect is extremely necessary and beneficial when longevity of implants or prolonged duration delivery of the pharmaceutical agent has to be ensured. Thus the equilibrium between mechanical strength and degradability must be decided during cross-linking biopolymers for their efficient functioning. Among the various options for biopolymer cross linking, the highly favored chemical cross-linking comes along with the grave disadvantage of cytotoxicity. In this regard, finding sustainable methods of cross-linking and newer cross-linkers are thrust areas of concern in order to ensure desired properties to biopolymers for medical applications. This chapter discusses about the main biopolymers, their cross-linking strategies, and the biomedical applications of cross-linked biopolymers.

Biopolymers · Cross-links · Biomedical · Applications · Tissue engineering · Scaffolds · Drug delivery

Introduction

Mankind have been using polymers since long time by virtue of their natural characteristics and properties to meet the primitive requisites of ancient times like employing natural plant gum as adhesive or natural rubber latex for water proofing. The ancients neither modified these biopolymers nor synthesized newer ones to improve their qualities to meet growing demands. Although natural rubber has been known for a long time, the mighty status it enjoys today in mobilizing the modern world is attributed to a patented modification process viz. vulcanization discovered by Charles Goodyear in 1844 which uplifted its status from a waterproofing material to a technological marvel that caters to infinite number of applications in diverse fields. The biodegradable biopolymers may be varying in their source of origin such as from plants, from microorganisms, or from animals as represented in Table 1.

The Major Biopolymers

Starch and cellulose (polysaccharides) (Fig. 1) are the most important biopolymers in the large carbohydrate family. Starch can be produced from corn, wheat, sorghum, potato, etc. through a variety of environment-friendly green processes. Linear amylose and branched amylopectin serve as the components of starch. The amylopectin may be of varying structures defining the different physical properties of starch. The properties of starch can be improved and modified through cross-linking whether it is self-cross-linking or using multifunctional reagents. Both chemical modification and cross linking play decisive roles in the characteristics of the final modified starch and hence the quality of product. Starches find immense role in food, paper, and other nonfood industries. Ethanol production from starch is yet another promising application of starch (Sun 2013).

Table 1 Classification of biopolymers based on source of origin

Source of origin	Biopolymers
Microorganisms	Polyhydroxyalkanoates (PHA) Bacterial cellulose Hyaluronan Xanthan, curdlan
Plants	Cellulose and derivatives Lignin Starch and derivatives Alginate Lipids Gums Poly lactic acid
Animals	Chitin Chitosan Hyaluronan (polysaccharides) Casein Whey Collagen Albumin Keratin Leather (proteins)

Fig. 1 Structure of starch and cellulose

Cellulose is a major constituent of natural fibers and is made up of linear polymer chains composed of anhydroglucose units. Cellulose chains form three dimensional network structures via hydrogen bonding between the chains which contributes

toward mechanical and chemical characteristics. Cellulose derivatives like cellulose acetate, cellulose acetate propionate, and cellulose butyrate find applications in the field of thermoplastics. Cellulose is used in biomedical applications like structuring controlled drug delivery devices, scaffolds for various regenerative applications, wound dressings, etc. (Yadav et al. 2015). Methylation of cellulose yields methyl cellulose, the most important and simplest cellulose derivative. Methyl cellulose finds immense applications such as tissue engineering, wound healing, and pharmaceutical formulations (Salihu et al. 2021). Carboxymethylcellulose (CMC) is another biodegradable and ordinary derivative of cellulose having hydrophilic carboxylate groups in its polymeric backbone. Its hydrophilicity and associated swellability make it an ideal candidate for preparing hydrogels (Mali et al. 2018). CMC has high tendency to form intramolecular cross-linking thereby lowering the mechanical strength of the fabricated products which is usually addressed combining with another cellulose derivative like hydroxyethylcellulose (HEC) to improve the intermolecular cross-linking. Esterification of hydroxyl groups of cellulose generates yet another class of commercially important thermoplastic cellulose derivatives called cellulose esters (Salihu et al. 2021).

Lignin is a biopolymer obtained from lignocellulosic biomass. Chemically, lignin is a randomly branched amorphous phenolic polymer cross-linked with cellulose and hemicellulose units. Lignin is obtained from common biomass through various processes and further extracted to obtain what is called technical lignin which is the usable form of lignin. As it is generally obtained as an unwanted by-product of agricultural, paper and pulp industries' lignin qualifies the economic and availability requirements for any reliable raw material for several applications. Besides, lignin possesses a high carbon content, considerable stability at processing temperatures, coupled with biodegradability and biocompatibility ensuring it to serve as a promising material for several applications. The industrial applications of lignin are guided by another driving force that it reduces the carbon footprint of a manufactured product. Lignin has been successfully employed in applications like asphalt and concrete preparation, antioxidant for polymer and cosmetic products, raw material for synthesis of carbon fiber, adhesive, foams, packaging paper industry, preparing different phenolic chemicals, dispersing agent, etc. The antioxidant, antitumor, antimicrobial, antidiabetic, and antiviral effects of lignin have been exploited by pharmaceutical industry (Spiridon 2018). Advanced scientific research has contributed greatly toward the vast and popular use of lignin composites for a handful of prominent biomedical applications such as in fabrication of scaffolds, dressing materials, delivery carriers, etc. (Terzioğlu et al. 2020; Yu and Kim 2020).

Alginate is calcium, magnesium, and sodium salt of alginic acid, and it is a biopolymer extracted from brown seaweed (Fig. 2). Alginate is a copolymer of guluronic acid and mannuronic acid in which both the monomers contribute greatly toward the toughness and elasticity of the polymer. Alginate possesses a wonderful combination of tackiness, gelling properties, and firmness all supplementing its industrial applications. Pharmaceutical industry favors it on grounds of its lower noxious potential, commendable biofriendliness, and possibility of easy gelation by divalent cations and low cost. The use of alginate hydrogels for tissue drug delivery

Fig. 2 Structure of alginic acid

Fig. 3 Schematic representation of formation of poly lactic acid

is being widely used nowadays. Alginate simulates the structure and makeup of extracellular matrices of living tissues, making it the right choice for a wide array of biomedical applications like delivering bioactive agents, fabricating scaffolds for wound healing and cell transplantation.

Poly lactic acid (PLA) is a natural, eco-friendly, and compostable biopolymer obtained from sustainable sources like cornstarch or sugarcane. Bacterial fermentation of the plant raw materials yields lactic acid, which on dehydration gets converted to the lactide dimer which can be polymerized to high molecular weight polymer without further dehydration as represented in Fig. 3 (McKeen 2012). PLA, being a polymer, owes its technical properties to its molecular weight, crystallinity, and stereochemistry of PLA backbone (DeStefano et al. 2020). PLA is a thermoplastic of high strength and high modulus that can be used to fabricate products for industrial packaging or the biocompatible/bioabsorbable biomedical applications. PLA has been regarded as a promising biopolymer that caters to a handful of biomedical applications in various fields of healthcare such as tissue engineering, ortho and dental prosthetics, and medical tools/equipment/accessories owing to its excellent biodegradability into nontoxic products (DeStefano et al. 2020). Photocross-linked lactide copolymers in which PLA undergoes copolymerization of another monomer unit such as polyethylene glycol, tetramethylene oxide, caprolactone, polyglycolide, poly (trimethylene carbonate), etc. contribute to a

Fig. 4 The structure of chitin and chitosan

special group catering to the calls of biomedical industry as scaffolds for tissue engineering or drug carriers (Bednarek et al. 2020).

Chemical structure of chitosan can be described as a straight-chain copolymer of D-glucosamine and N-acetyl-D-glucosamine obtained through deacetylation of chitin. Chitin is the second most abundant natural polysaccharide and is commonly found in the exoskeletons of crustacean arthropods. The structures of chitin and chitosan are illustrated in Fig. 4. Since chitin is a waste from food industry, chitosan production is cost-effective and eco-friendly. Chitosan resembles cellulose in structure. The extent of deacetylation of chitin plays a decisive role in determining characteristics like solubility, biodegradability, reactivity, and adsorption capacity of a particular chitosan sample (de Alvarenga 2011). Generally, extent of deacetylation falls in the range 60–100% in commercial chitosans as determined by NMR spectroscopy. High antimicrobial activity provides a promising future for chitosan in food industry as preservative and packaging material while its biodegradable, biocompatible, antimicrobial, nontoxic, and antitumor attributes favor biomedical and pharmaceutical applications. Although chitosan is widely used for drug delivery and tissue engineering, its molecular weight has to be decided according to specific applications. High molecular weight chitosan is obtained through grafting it with synthetic monomers to produce cross-linked modified chitosan copolymers having improved physicochemical properties. Since the amino groups are responsible for the distinct characteristics, the characterization of the polymer in either chitin or chitosan (degree of deacetylation) is extremely important while deciding a possible industrial application. Chitosan finds immense

Fig. 5 Structure of the repeating disaccharide units of hyaluronic acid

Repeating disaccharide units of Hyaluronic Acid

applications in fields like photography, biotechnology, cosmetics, food processing, biomedical products pharmaceuticals, waste water treatment via adsorption techniques, etc. (de Alvarenga 2011).

Hyaluronic acid (hyaluronan, HA) is a linear polysaccharide biopolymer of N-acetyl-D-glucosamine and glucuronic acid (Fig. 5). The molecular weight is generally about millions of Daltons. HA is a component of almost all body fluids and tissues enabling its widespread applicability as an indicator for several diseases. It is also administered as intra-articular injections to augment defected synovial fluid in arthritic patients. Another thrust application area is in the fabrication of biomedical scaffolds. HA is greatly recognized for its wound-healing attributes. High molecular weight HA is naturally delivered to injured skin, where it initially helps to form clots by binding with fibrinogen and forms a gel medium for immune cells. Later, HA breaks down to molecular weights around 120 kDa, which promote inflammation – useful at that stage of healing – and blood vessel rebuilding. During final stages of healing, HA further breaks down to oligomers, which suppress inflammation and help proliferation of new skin cells and collagen.

Collagen, the prime structural matter of vertebrates and the most abundant protein in mammals is synthesized by fibroblasts and accounts for about 20–30% of total body proteins. Collagen molecule have a triple helical structure extended to rod-shaped structure with an average length of about 3000 Å and a width of about 15 Å to attain a molecular weight of 300 kDa approximately (Yadav et al. 2015). In addition to its nontoxic, biocompatible biodegradable nature, it possesses high tensile strength and water affinity, and its weak antigenicity ensures easy absorption. Collagen is considered as a highly useful biopolymer due to its low immunogenicity and high biocompatibility. On the other hand, due to the destruction of assembly structure and natural cross-linking during extraction mechanical strength, thermal stability, and enzyme resistance, becomes inferior hampering the biomedical potential of natural collagen, which can be circumvented through modifications like chemical, physical, or biological cross-links to minimize degradation thereby enhancing mechanical stability. Introduction of additional cross-links restricts collagen molecules from sliding past each other under stress thereby increasing its mechanical strength, improving stiffness and tensile strength, and reducing extensibility. Potential applications of cross-linked collagen in tissue repair and biopharmaceutics include wound dressing, tendon and joint repair, treatment of corneal and cardio-vascular diseases, tissue engineering, bone-tissue engineering,

neural regeneration, prosthetic heart valves and vascular prosthesis, drug/gene/cell delivery agents, scaffolds, etc. (Gu et al. 2018).

Gelatin is a water-soluble material derived via partial hydrolysis of collagen to disrupt the tertiary, secondary, and to some extent the primary structures. Gelatin is a protein (polymer) formed from a remarkable array of amino acids comprising of all the vital amino acids except tryptophan (Yadav et al. 2015). Gelatin has excellent biocompatibility, plasticity, and adhesiveness contributing to its ability to form foam and emulsions and moisturizing effects. Its inherent hydrogel nature of gelatin simulates extracellular matrix (ECM) extending its suitability for in vitro cell culture. Cross-linked gelatin matrices have been fabricated for different biomedical applications for tissue engineering and drug delivery (Xiang and Cu 2021).

Keratin is the cysteine-rich fibrous protein that assists in the formation of structures such as hair, horns, feathers, wool, and nails. The wide range of properties and structures accomplished by keratin can be related to the sulfur content in them. Hard keratins with a higher amount of sulfur cross-links form hard skin structures. Soft keratins with lower sulfur content are comprised of slack bundles of cytoplasmic filaments and serve to offer pliability to epidermis. Keratins are classified into alpha-keratins and beta-keratins based on their structure. Alpha-keratin consists of polypeptide chains arranged as alpha-helices while beta-keratin is formed by pleated beta-sheet arrangement of polypeptide chains. Keratin is extracted from keratin-rich materials through a wide variety of techniques like chemical (reduction, oxidation, alkali extraction, and ionic liquids), enzymatic, physical (steam explosion), or radiation exposure (microwave irradiation) methods (Feroz et al. 2020; Rouse and Van Dyke 2010).

Applications of Biopolymers

Biopolymers find immense applications in construction materials, automobile parts, furniture, packaging, utensils, printing, coatings, and related industries as products like adhesives, resins, plastics, binders, fibers, paints, inks, additives, solvents, etc. Plant polysaccharides find extensive applications in food industry as source of carbohydrates, monomer sugars, sweet syrups, sweeteners and dietary fibers, jelling agents, immune boosters, additives, thickeners, emulsifiers, gelling and texturizing agents, fat and/or sugar replacers, etc. Polysaccharide biopolymers, especially starch, are found to be well-suited raw material for biodegradable plastic production and nano-material science due to their self-assembly capabilities and stimuli responsiveness. Cellulose from wood pulp finds applications in the production of paper and cardboard, coatings, building materials, pharmaceuticals, foodstuffs, and cosmetics. The nano-materials derived from these biopolymers find immense uses as reinforcing elements in composite materials, biosensors, environmentally sensitive membranes, artificial muscles, solar materials, etc. The growing demand for sustainable biofuels depends mostly on polysaccharide biopolymers (like corn starch for biodiesel production) as the raw material (Poli et al. 2011).

Natural polymers are increasingly used for bone replacement and hard tissue augmentation. Natural polymers like collagen (proteins), chitosan, alginate, starch, cellulose (polysaccharides), etc. are widely employed for different pharmaceutical and biomedical uses owing to their nontoxic, biocompatible, biodegradable, and water-soluble nature. Biopolymers are mostly employed as delivery vehicles for drugs or bioactive agents, fillers in pharmaceuticals, dressing products, scaffold and implant components in tissue engineering, etc. Different biopolymer classes were found to be associated with various health benefits such as lowering blood cholesterol (pectins), lowering intestinal transit time, increasing stools bulk (dietary fibers), and anticancer, antioxidant, antibacterial, antiviral, and chemopreventive effects (several plant polysaccharides) (Poli et al. 2011). Such biopolymers were exploited for such beneficial roles in medical service to a greater extent.

Cross-Linking Biopolymers

The process of cross-linking has been a promising research realm as far as processing and applications of biopolymers are concerned. The very success of biomedical applications of these biomaterials is determined by the effectiveness and efficacy of cross-linking. The poor mechanical properties exhibited by biopolymers are mostly compensated through cross-linking them to form a firm network. A cross-link is a physical (interactions such as ionic bonding, hydrogen bonding, etc.) or chemical bond (covalent bonding) that connects the functional groups of different polymer chains creating a three-dimensional network with improved qualities. The agents (physical/chemical/radiation) used for cross-linking are termed as cross-linkers or cross-linking agents, and chemical cross-linkers that can form covalent bonds between different functional groups of the polymer chain are the most favored ones. Cross-linking affects polymer properties like tensile strength, rigidity, cell-matrix interactions, thermal stability, solubility, degradation resistance, shape memory retention, etc. (Balakrishnan and Jayakrishnan 2005). Tailored cross-linking enables modulating controlled release of encapsulated materials which is now a highly active research area in theranostics (Thakur et al. 2018). Multiple options are available for cross-linking biopolymers so as to fabricate them as scaffolds or delivery vehicles. The type and chemical nature of the biopolymer plays a decisive role in this respect.

Physical Cross-Linking

Physical cross-linking involves electrostatic interactions between polymer chains through ionic bonds forming a stable three dimensional network structures (Fig. 6). Such ionic bonds are formed in sodium alginate gels when exposed to calcium ions which involve bridge formation between alginate chains. When borax is added to polyvinyl alcohol, hydrogen bonds (weak interaction forces) are formed between boric acid and the alcohol groups of the polymer. Biomaterials like gelatin, collagen, agarose, agar-agar, etc. can undergo physical cross-linking. Generally, physical cross

Fig. 6 Schematic representation of physical cross-linking

links are less stable both mechanically and thermally in comparison with covalent cross-links.

Cross-Linking via Irradiation

Exposure to ultraviolet, visible, or gamma radiations are the common irradiation methods of cross-linking. The major setback of such cross-linking is the absolute lack of control over the cross-link density attained by the polymer matrixes which in turn hamper with the release properties. Cross-linking biopolymers via irradiation-based techniques either make use of high-energy-ionizing radiation or photo-initiator molecules or are widely used for collagen scaffolds (Fang et al. 2020). Irradiating biopolymers with high-energy radiations trigger two competitive and mutually opposing processes, namely degradation via fragmentation of polymer chain and cross-linking (Fig. 7). Preserving the balance between the two processes is a critical factor that eventually influences the mechanical degradation behavior of cross-linked products. Photo cross-linking can also be carried out with visible light making use of photo initiators. Using trisbipyridyl ruthenium as a photo initiator to cross-link a chitosan hydrogel for bone regeneration suggests the feasibility of such an approach (Lin et al. 2018). Reports point to cross-linking collagen and silk fibroin-based biomaterials specifically for ophthalmic uses through ultraviolet radiation (Bhattacharjee and Ahearne 2021).

Dehydrothermal Cross-Linking (DHT)

Dehydrothermal cross-linking involves thermally induced dehydration leading to condensation reactions between monomers to generate polymeric networks (Fig. 8). In DHT, the reaction is driven forward by removing the by-product of cross-linking (water) applying heat and vacuum according to Le Chatelier's principle. Although this method is commonly used for synthesis of synthetic polymers like polyesters, polyethers, polyamines, polyamides, etc. via bonding two complementary functional groups by removal of water molecules through thermal stimulation, recent reports

Fig. 7 Schematic representation of cross-linking via irradiation

Fig. 8 Schematic representation of dehydrothermal cross-linking

suggest repetitive use of this method for cross-linking of the polymeric scaffolds (Nair et al. 2020).

Chemical Cross-Linking

Chemical cross-linking leads to covalent bonds between functional groups of biomaterials through common chemical reactions like acylation, carboxylation, esterification, alkylation, etherification, halogenation, and Schiff alkalization reactions (Wang et al. 2020). Chemical cross-linkers are either nonzero-length cross-linkers or zero-length cross-linkers. Nonzero-length cross-linkers are bifunctional or multifunctional molecules linking different polymer chains through different functional moieties. These cross-linkers bridge the functional groups such as free carboxylic acid groups, amino groups, and hydroxyl groups that present on the polymer chains so as to form cross-links between biopolymer chains. Glutaraldehyde, polyepoxides, and isocyanates are examples of nonzero-length cross-linkers. The zero length cross-linkers like acyl azides, transglutaminase, and water-soluble carbodiimides create covalent bonds by inducing chemical reaction between the reactive functional groups on the polymer chains itself. A schematic representation of chemical cross-linking is given in Fig. 9.

Fig. 9 Schematic representation of chemical cross-linking

Fig. 10 Schematic representation of cross-linking gelatin chains using glutaraldehyde

The mostly employed chemical cross-linkers for biopolymers are briefly discussed below.

Glutaraldehyde (GA) has been a widely used chemical cross-linker for various biopolymers as it can appreciably advance the technical capabilities and service-life of biomaterials. GA acts on the amine or hydroxyl functional groups through a Schiff-base reaction to join the individual biopolymer chains through intra- or intermolecular interactions resulting in a cross-linked network (Fig. 10). Irrespective

of the fact that this method has been the gold-standard cross-linking method for many years, the cytotoxicity and biohazard problems induced by aldehyde functional groups of GA may give rise to rigorous inflammatory responses. These serious negative impacts led to a handful of detoxifying counter measures to ensure safety and reliability of GA-cross-linked biomedical products (Oryan et al. 2017).

1-Ethyl-3-(3-dimethyl aminopropyl)-carbodiimide (EDC) is the most commonly used carbodiimide for cross-linking biomolecules by virtue of its water-soluble nature and reactivity with carboxyl, hydroxyl, and sulfhydryl functional groups. EDC offers a noncytotoxic, zero-length, cross-linking alternative to GTA as the access is limited to “neighbouring” free amines alone (Nair et al. 2020). EDC serves as a suitable cross-linker for collagen scaffolds for numerous tissue-engineering applications. N-hydroxy-succinimide (NHS) is also used in such cross-linking reactions to activate carboxylic acid groups (Fig. 11) (Yang 2012). Although it possesses lower cytotoxicity than GA, it shows poor biomechanical properties and more rapid biodegradation profiles, in comparison with GA-cross-linking in most cases (Oryan et al. 2017).

Genipin is a natural, colorless, water-soluble cross-linking agent extracted from gardenia fruit (*Gardenia jasminoides* ELLIS). Geniposide is the parent compound from which genipin is obtained via enzymatic hydrolysis with β -glucosidase. Genipin is widely used in customary Chinese remedies owing to its antiphlogistic, anti-inflammatory, diuretic, choleric, and hemostatic properties (Butler et al. 2003; Oryan et al. 2017). Several studies point to its lower cytotoxic potential in

Fig. 11 Schematic representation of cross-linking collagen chains using EDC

comparison with glutaraldehyde. Hence, Genipin finds wide employability as the cross-linker while fabricating most of the biopolymers for various biomedical applications (Oryan et al. 2017). Genipin forms blue-colored hydrogels on cross-link formation with the amine groups of biopolymers like chitosan and gelatin. The most important applications of genipin include the fabrication of hydrogels as cartilage substitutes, carriers for controlled release of drugs and bioactive molecules, scaffolds for medication of wounds, etc. (Muzzarelli 2009). The cross-linking reaction pathway associated with genipin cross-linking has been investigated in detail, and two possibilities have been put forth. The possibility of an S_N2 nucleophilic attack by a primary amine group on the biopolymers that replaces the ester group on the genipin molecule by a secondary amide linkage to form a compound of genipin linked to the amine residue of the biopolymer is an option. Another possibility is an initial nucleophilic attack on the genipin C3 carbon atom by a primary amine group of biopolymer to form an intermediate aldehyde along with the opening of the six membered dihydropyran ring giving rise to a secondary amine. The amine thus formed will now attack on the aldehyde group to form heterocyclic compound of genipin linked to the amine residue of the biopolymer. The bifunctionality of genipin can ensure cross-linking between biomolecules via both these proposed mechanisms (Butler et al. 2003). Schematic representation of cross-link formation using genipin is given in Fig. 12 taking chitosan as a representative biopolymer.

Citric acid (CA) is yet another natural cross-linker for biopolymers found in citrus fruits. Its ability to react with both amine and hydroxyl groups qualifies citric acid as a promising cross-linking agent for polysaccharides and proteins biopolymers (Fig. 13) (Uliniuc et al. 2013). Besides, the residual pendent groups remaining

Fig. 12 Scheme for cross-linking chitosan with genipin

Fig. 13 Schematic representation of cross-linking starch using citric acid

after CA cross-linking of biomaterials can form ester bonds, which contributes positively toward hemo-compatibility, maintenance of hydrophilicity of the polymer network, and augmenting sites for bioconjugation (Mali et al. 2018).

Enzymatic Cross-Linking

Another well-sought approach toward modification and cross-linking of polymers makes use of enzymes to achieve cross-linking of biopolymer chains (Fig. 14) (Broguiere et al. 2018). Transglutaminase (TGase) is a common enzyme for most living organisms and is found to be associated with many biological activities like epidermal keratinization, blood clotting, and regulation of erythrocyte membranes and many human diseases (Parkinson's, celiac disease, and cancers). Enzymatic

Fig. 14 Schematic representation of enzymatic cross-linking

cross-linking employing transglutaminases was used for diverse tissue-engineering applications with respect to increased cross-linking efficiency, feasible conditions, and commendable cyto-compatibility. Some of the transglutaminases are commercially available and FDA-approved cross-linkers on grounds of their nontoxic and nonimmunogenic nature. Enzymatic cross-linking using Tgase has also been explored for controlled drug release. The “substrate specificity” eliminates issues of side reactions in the case of enzyme cross-linking. Irrespective of all these advantages, the poignant influence of reaction conditions on the catalytic activity of enzymes shadows the widespread possibilities of enzymatic cross-linking for biomedical applications (Song et al. 2021).

Cross-Linking Biopolymers for Biomedical Applications

The greatest advantage of employing biopolymers for biomedical applications is their great biocompatibility. Their natural origin enables them to be highly bioactive and support normal body functions they are destined to perform. Eco-friendly nature of biopolymers is an added advantage in many of their biomedical applications. On the other hand, disadvantages like poor technological properties and rapid deterioration rate though hamper their performance, and application options might be overcome through proper chemical modification and cross-linking (Litowczenko et al. 2021). Tissue engineering is a potential research field that caters to replacement and repair of injured or unwell tissues and body parts with simulated substitutes fabricated from natural or synthetic materials. Prostheses, parts that assist tissue regeneration, delivery vehicles for drugs, cells or biomolecules, coating of non-biological devices with biocompatible materials, etc. (Vukajlovic et al. 2019) will all fall under the vast heading of tissue engineering. Need for improving the mechanical strength of biopolymers is a prerequisite for fabricating them for various applications. From biomedical point of view, however, it must be considered that cross-linking not only enhances mechanical properties but also interferes with other natural properties like degradability, solubility, gas permeability, etc. The reduction in degradability is a basic effect associated with cross-linking, and this might have negative impact while fabricating biomaterials for biomedical applications like implants and drug delivery systems. On the other hand, cross-linking is extremely necessary and beneficial when longevity of implants or delivery of the pharmaceutical agent has to be ensured for prolonged duration (Bednarek et al. 2020). Thus the equilibrium between mechanical strength and degradability must be decided during

cross-linking biopolymers so as to enable them to fulfill the requirements of the target application.

Biomedical Applications of Cross-Linked Biopolymers

The biopolymers are biocompatible and biodegradable which make them useful in applications, like drug transport materials, medical implants, wound healing, tissue scaffolds, and dressing materials in pharmaceutical industries. When the incompetency associated with mechanical properties is circumvented through cross-linking, these biopolymers provide ample raw materials for fabricating biomaterials according to various creative scientific and technological approaches. Cross-linked biopolymers are promising candidates for drug delivery, scaffolds for hard and soft tissue regeneration, wound dressing, grafts and implants for tissue replacement, cancer treatment, etc. The important ones are discussed in detail.

Scaffolds

Scaffolds are porous and degradable structures that are used to offer mechanical support to bone defects, and simultaneously permit unhindered proliferation and differentiation of surrounding cells (Vukajlovic et al. 2019). Bioscaffolds mean scaffolds made by using natural polymers or with the addition of active bioagents. Biocompatible and biodegradable polymer scaffolds are indispensable for tissue engineering and drug delivery (Balakrishnan and Jayakrishnan 2005). Scaffolds are expected to meet certain basic requirements: (a) Scaffold surface should permit cell adhesion and proliferation; (b) scaffold should not induce inflammation or an immune response (biocompatible); (c) degradation products of scaffolds cannot be cyto-toxic; (d) scaffold should closely simulate the native tissue it is trying to mimic with respect to structural and mechanical properties; and (e) scaffold should be porous enough to allow unhindered cell growth and nutrient diffusion (Dovedytis et al. 2020; Litowczenko et al. 2021). The most popular polymers for scaffolds fabrication are chitosan, cellulose, alginate, hyaluronic acid collagen, gelatin, fibrin, etc. which find potential applications in tissue engineering of skin, nerves, bone, cartilage, heart, liver, muscle, retina, vascular system, etc. (Kramschuster and Turng 2013).

Bone Tissue Regeneration

Among prostheses, orthopedic implants are in particular demand and bone transplantation is the second most common tissue transplantation all over the world. Tissue engineering has developed several synthetic bone graft substitutes especially hybrids. A hybrid is a composite of an inorganic and an organic material, whose properties are improved over the individual properties of the two materials through mutual interactions between them. Based on these interactions, hybrid materials are classified as Class I hybrids (weak bonds like electrostatic, van der Waals, and hydrogen bonds), Class II hybrids (covalent bonds). An initial attempt in this direction is collagen and calcium phosphate composites which are suited for dental

applications and repairing joints and broken bones. These composites share a similar composition as that of natural bone and tissue (inorganic phase and an organic phase) and can probably achieve better mechanical properties complimented by the strength of ceramics and flexibility of polymers.

Nerve Regeneration

Peripheral nerve regeneration is an intricate and a very old remedial dispute that requires proper leads for reconnecting neural damages and reinstating the proper state of nervous system. Researchers have exploited the possibilities of several polymers, both natural and synthetic to find the best candidate for constructing nerve conduits that can achieve desired nerve-regenerative functions. Natural polymers like chitosan, collagen, gelatin, hyaluronic acid, and silk fibroin are used to fabricate nerve conduits by virtue of their biocompatibility, absence of serious immune response, regenerative signaling without growth factors, and degradation by natural enzymes. However, quality-wise inconsistency demanding elaborate refinement and characterization requisites, low technological properties, and high degradation rates associated with biopolymers demands chemical modification, cross-linking, and blending with other structural components (Wang and Cai 2010) so as to fit them in for most of the applications.

Drug Delivery Systems (DDS)

The physiological responses of the body following its administration primarily decide the efficacy of a drug. Once administered, the drug must triumph over metabolic and immune processes of the body so that it will remain active for a sufficient time to yield a desired effect without getting degraded and/eliminated. These challenges have motivated and guided the researchers to fabricate new drug carrier/delivery systems to ship and deliver pharmaceuticals in sustained and continuous fashion ensuring the right amount of medicinal agents reaching its desired target imparting desired effects. Generally, drug delivery systems are fabricated biopolymers into which therapeutic agents are loaded (DeStefano et al. 2020).

Transfer of drugs from DDSs to the desired target is controlled by a mechanism which is dictated by the response of the carrier to environmental stimuli such as light, temperature, pH, chemical actions, electric and magnetic fields, etc. (Seddiqi et al. 2021). Biodegradability and possibilities for its manipulation are one or the primary attribute that makes a biopolymer suitable for designing effective DDSs. Degradation kinetics could be prolonged to facilitate and sustain incessant release of medicinal agents enabling the drug to induce its effects. For example, low molecular weight drugs which are highly likely to be immediately filtered and eliminated from the bloodstream through the hepatic and renal systems can be embedded in specific carrier vessels that specifically target specific sites in the body (DeStefano et al. 2020) ensuring optimum therapeutic results.

Wound Healing

Skin, the largest organ in our body, envelops us as a whole and sets up the first line of defense against both physical and chemical threats as a shielding coating. Skin is

often vulnerable to injuries caused by exposure to conditions such as high or temperature, mechanical trauma, microbial attack, contamination, cuts, and so on. Such injuries may cause wounds which might further lead to soreness or such clinical issues ultimately leading to severe secondary injuries if not properly treated in time. Hence skin injuries should be treated quickly and effectively so as to ensure prompt wound healing. A handy and effective way to treat skin injuries is to apply dressing over the wound to facilitate damaged skin repair process. An efficient wound dressing should support the growth and differentiation of injured cells besides setting up material barriers. In general, wound dressing materials should not induce toxic biological responses leading to secondary damages to the affected region. They should also possess adequate gas permeability, capability to absorb the fluids oozing out of the wounds, and should facilitate easy removal. Antimicrobial and anti-inflammatory nature of the raw materials used for preparing such dressings is added advantages. In short, dressing materials should assist the course of curing such as reinstating the defense barrier, averting dehydration, and eliminating the chance for microbial contamination. Further, serious injuries like burn wounds demand skin grafting treatments which necessitate the fabrication of newer bandage materials. In this line, biopolymers have proved their efficacy in wound-dressing applications (Seddiqi et al. 2021).

Key Biomedical Applications of Individual Biopolymers

Cellulose and Starch

In order to use cellulose for tissue engineering applications like primary or scaffold material, it should possess matching mechanical properties to that of real tissues providing porous structures or anchoring sites, for osteoblasts and fibroblasts. The alkyl and ester derivatives of cellulose are mostly used for tissue engineering. Cellulose-based polymers were recognized with high potential for wound-dressing applications (Salihi et al. 2021; Seddiqi et al. 2021).

Hydrogels based on chemically modified and citric acid cross-linked starch are associated with variable hydrophilicity and corresponding variations in swelling characteristics in aqueous environments. These hydrogels can be regarded as environmental friendly and fully biodegradable smart polymeric materials to facilitate controlled release of hydrophilic drugs. The controlled release of levofloxacin a hydrophilic antibiotic drug from modified starch-based hydrogels cross-linked with citric acid could successfully encapsulate and release drugs at physiological pH and temperature (Uliniuc et al. 2013). Similarly, citric acid cross-linked hydrogel films of carboxymethyl cellulose-tamarind gum (CMC-TG) have been found effective for topical drug delivery. Citric acid cross-linked CMC-TG hydrogel films in the form of implants or wound-healing films were investigated for their potential in topical delivery of Moxifloxacin hydrochloride (MH), an extensively employed drug for treating skin sepsis (Mali et al. 2018).

In an attempt to counteract the inherent characteristics like hydrophilicity and poor water resistance which limits the application of starch nanofibers, periodate

oxidation together with adipic acid dihydrazide cross-linking strategy was adopted. The modified cross-linked starch nanofiber showed excellent mechanical strength, superior water resistance, and excellent cyto-compatibility suited for a wide range of biomedical applications (Lv et al. 2020). Physically cross-linked (via freeze–thawing) biodegradable hydrogel membranes made of hydroxyethyl starch, poly vinyl alcohol, and ampicillin were prepared with inherent potential for wound-dressing applications (Kenawy et al. 2014). Bacterial cellulose was improvised using citric acid through thermal cross-linking process preserving its cytocompatibility for wound dressing and scaffolding applications (Salihu et al. 2021).

Targeted drug release system delivers pharmaceuticals at predestined body parts through effective manipulation of their reaction to optical, thermal, chemical, electrical, or magnetic stimuli. The inclusion of cellulose and its derivatives in hydrogels changes its structural and morphological properties like enhancement of pore sizes leading to large swelling ratio which in turn promotes stimulus–response rate. Thus, hydrogels for drug delivery can be enhanced in terms of target specificity and biocompatibility through cellulose incorporation (Kabir et al. 2018).

Cellulose nanofibrils have been widely used to prepare hydrogels used to fabricate scaffolds for biomedical applications. But, poor mechanical properties restrict their applications as ink for three-dimensional bioprinting to fabricate scaffolds for tissue engineering. The former issue has been successfully overcome through a dual cross-linking approach in which a hybrid hydro gel ink was produced via Ca^{2+} -mediated cross-linking of poly(ethylene glycol) star polymer and 2,2,6,6-tetramethyl-1-piperidinyloxy (TEMPO)-oxidized nano-cellulose fibers. The physical cross-links facilitated through interactions between cellulose nano-fibers and calcium ions were reinforced via photo-cross-linking PEG under visible light. This enabled developing a versatile hydro gel ink suitable for 3D printing of bioscaffolds for regenerative medicine applications (Monfared et al. 2021). The major biomedical applications of cellulose are summarized in Fig. 15.

Lignin

Lignin, mostly in a modified form in combination with other materials, has been employed successfully for the production of hydro gels owing to its high mechanical

Fig. 15 Major biomedical applications of cellulose

strength, and inherent antioxidant and antibacterial properties. Lignin hydro gels are highly recommended raw material for scaffolds as they could effectively shield the injured part from secondary further damages or infections. Lignin amine synthesized from sodium lignosulfonate was cross-linked with poly (vinyl alcohol) (PVA) and treated with silver nitrate and was used to fabricate hydrogel scaffolds with enhanced antimicrobial and elastic properties. Another example is the use of lignin obtained from sulfite pulping and chitosan dissolved in PVA to form lignin–chitosan–PVA composite hydrogel. This hydrogel was characterized by a high mechanical strength and high antioxidant activity due to the ionic cross-links between sulfonate groups in the lignin and amino groups in the chitosan. Major physical properties like swelling, hydrophilicity, adsorption, tensile strength, and elongation of the hydrogel were found to increase with lignin concentration. Lignin was found to be a useful candidate for three-dimensional-printed wound dressings. A composite of PLA pellets coated with castor oil, lignin, and tetracycline was used for 3D printing wound dressings with antioxidant and antimicrobial properties. This 3D printing strategy comes along with the underlying potential to realize the concept of customization in the field of wound dressings. Lignin, its derivatives, and composites have also been used for drug delivery applications as they are cheap and cytocompatible. Lignins extracted from sugarcane were successfully fabricated as a methotrexate transporter to treat rheumatoid arthritis (Yu and Kim 2020). The Fe_3O_4 -encapsulated lignin nanoparticle showed super paramagnetic behavior, which makes it promising for targeted drug delivery using magnetic targeting (Spiridon 2018).

Implantation of artificial nerve grafts creates oxidative stresses, resulting in the generation of reactive oxygen species in nerve cells leading to necrosis and DNA damage which can be counteracted by the antioxidant properties of the lignin (Kumar et al. 2021). Hence, the inherent antioxidant property of lignin was employed while fabricating an antioxidative scaffold for nerve regeneration by enhancing polycaprolactone (PCL) nano fibers through preparing PCL/lignin -PCL copolymer composite fibers. Lignin–PCL was found to impart benefits like enhanced technological properties coupled with excellent antioxidant activity and biocompatibility to the fibrous scaffold. Alginate–lignin hybrid aerogels show improved texture, morphology, flexibility, biocompatibility, etc. and showcase wide range of fabrication options in tissue engineering and regenerative medicine (Terzioğlu et al. 2020). The major biomedical applications of lignin are summarized in Fig. 16.

Alginate

The best candidates for injectable scaffolds are hydrogels made from natural proteins and polysaccharides owing to their biocompatible and biodegradable nature and close resemblance with extracellular matrix (ECM). These hydrogels can influence cell resettlement, proliferation, and organization during tissue regeneration to simulate natural wound healing because of their resemblance to ECM. By cross-linking (enzymatic or chemical) or photo-polymerizing their custom-made monomers, in situ gelling biopolymers are created. Alginates possess gelation property in presence of divalent cations owing to the G-moities which are being exploited while using

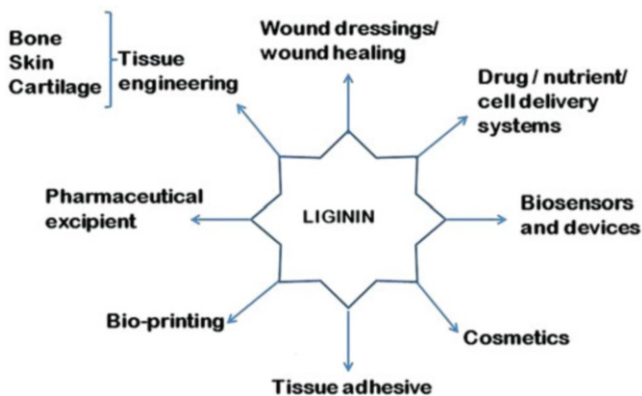

Fig. 16 Major biomedical applications of lignin

them as cell transplantation vehicles and as wound dressings. However, the uncontrollable degradation kinetics and dissolution rates have led to attempts for covalent cross-linking which in turn suffers from the toxicity of chemicals employed. According to reports, oxidized alginate and gelatin can self-cross-link with tiny concentrations of borax to create an injectable, in situ-forming, nontoxic, biodegradable polymer scaffold for use in tissue engineering and medication delivery (Balakrishnan and Jayakrishnan 2005). This is accomplished by placing the cell/drug entity in one syringe, which is in a gelatin solution, and the oxidized alginate in the other, which is in a solution containing borax. The two polymer solutions integrate within the hypodermic needle forming cell/drug entity encapsulated in an insoluble hydrogel matrix through gelation and cross-linking. The primary mechanism for the cross-linking is Schiff's base formation between the alginatedialdehyde and the lysine or hydroxylysine side groups of gelatin. Hydrogels of alginate were fabricated through covalent cross-linking by attaching tetrazine and norbornene groups to it. These hydrogels could efficiently encapsulate and deliver bioactive species in various applications of tissue engineering. Tissue-adhesive hydrogels can assist hemostasis, as sealants, and dressing. An enhanced tissue-adhesive hydrogel has been prepared from gelatin through dual-enzymatic (horseradish peroxidase (HRP) and mushroom tyrosinase) cross-linking system. Through di-phenol interaction between the tyrosine groups on the tissue surface and the phenol groups of gelatin, HRP induced hydrogel-tissue adhesion. Besides, tyrosinase converts phenol moieties into highly activated quinones that can react with various nucleophiles to form a covalent bond which supplements the HRP-induced bonds (Song et al. 2021).

Easy gellation/cross-linking with divalent cations under mild conditions, feasibility of modifying controlled-release performance, and drug loading coupled with provisions for surface modifications/functionalization for targeted delivery makes alginate an ideal candidate for drug delivery applications. Targeted DDSs for cancer therapy envisages enhanced therapeutic efficacy with minimized side effects through their ability to accumulate specifically/preferentially at the tumor site. Several

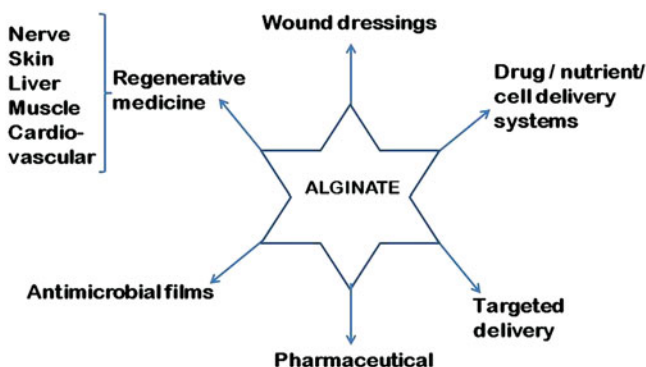

Fig. 17 Major biomedical applications of alginate

nanosized alginate platforms, like nanoparticles, micelles, nano gels, nano droplets, and nano complexes, have been established for targeted DDSs for cancer therapy. Strategies like passive targeting (enhanced cellular uptake, EPR effect) and receptor-based targeting (folic acid receptor-based endocytosis, epidermal growth factor receptor-mediated endocytosis, stimuli-responsive targeting, (pH, ionic strength, temperature, and sensitivity magneto/ultrasound-responsive nature), etc. were extensively used for targeted DDSs for cancer therapy using alginate-based systems (He et al. 2020). The major biomedical applications of alginate are summarized in Fig. 17.

Poly Lactic Acid

A two-phase cell delivery system was created using a mechanically robust elastomeric scaffold and a hydrophilic cell-encapsulating hydrogel for the replacement and/or repair of load-bearing soft tissues via UV cross-linking a lactide-acrylate copolymer and hydrogel of modified chitosan. The scaffolds after UV cross-linking of the elastomers morphology had mechanical properties resembling soft tissues ensuring viable chondrocytes that can effectively proliferate. It was being claimed that such scaffolds are promising alternatives for an injectable and in situ cross-linkable cell delivery system for tissue repair/regeneration (Bednarek et al. 2020). Structural adaptability and biocompatibility make PLA an attractive biomaterial for dental-related uses. Effective osseointegration of dental implants with oral hard tissue is aided by poly lactic acid. A PLA implants have been fabricated to composite materials to hold drugs and assist bone regeneration. PLA is also employed for designing dental resins (with improved mechanical properties) using PLA composite scaffolds which are essential for several restoration procedures. PLA/ Al_2O_3 nano-scaffolds (composite) with increased flexural strength, modulus, and compressive strength compared to traditional resins were synthesized via cross-linking the PLA with Al_2O_3 nano particles (DeStefano et al. 2020).

Biodegradable orthopedic devices are another thrust area for PLA application like resorbable fracture fixation plates. PLA and its copolymers offer increased material

Fig. 18 Major biomedical applications of polylactic acid

strength, prolonged degradation time, robust sterility, etc. enabling effective use in internal bone fixation. Another interesting development is osteogenic or anabolic bioactive infused orthopedic implantables composed of PLA to encourage cell proliferation. Such precisely tailored 3D-printed PLA-based scaffolds with optimized porosity sizes/depth, and connectivity comes along with superior osteo-inductive capabilities. PLA biodegrades to nontoxic products, and it eliminates the need for further surgeries for implant removal. Due to its slow rate of deterioration and ability to withstand dissolving for a long time, PLA has been lauded as a superior drug delivery medium. This characteristic of PLA has been established with cancer drug delivery, wherein compounds like tamoxifen encapsulated in poly (lactic-coglycolic acid) nano particles were found to show enhanced bioavailability in comparison with nonloaded control samples. Additionally, PLA is used in numerous implant techniques to deliver antibiotic agents to sites of implantation which in turn lowers the risks of postoperation infections and probability of implant failure (DeStefano et al. 2020). The major biomedical applications of PLA are summarized in Fig. 18.

Chitin and Chitosan

Chitosan hydro gels are 3D polymer networks. Water infiltration in aqueous environment causes the gel to swell up due to the presence of hydrophilic groups. Cross-linking the gel network through electrostatic or covalent bonds can prevent gel dissolution, thereby increasing the lifetime of the gel and safeguarding its performance. Most of the cross-linkers used for chitosan hydrogel preparation induce an increase in gel toxicity thereby setting a limit on their viability. Natural substance genipin, obtained from *Gardenia jasminoides* fruits, is found to strengthen chitosan hydro gels to improve their mechanical properties through cross-links with remarkably low toxicity. In an environment with a higher pH, genipin can self-polymerize limiting cross-linking efficiency but offers a chance to prepare genipin cross-linked

chitosan with varying properties by varying the reaction conditions to manipulate the extent of cross-linking.

In the recent past, chitosan has been considered as a potential component for Class II hybrid scaffolds with bioglasses. Chitosan is found to be a promising choice for wide range of tissue engineering owing to its peculiar combination of characteristics such as nontoxicity, biocompatibility and biodegradability, and antibacterial properties. Sol-gel synthesis ensured functionalization and covalent cross-linking of chitosan and bioglass with glycidoxypolytrimethoxysilane (GPTMS). Such chitosan-bioglass hybrids are advocated as smart options for regenerative medicine applications with respect to mechanical properties, composition, and structure comparable to human cartilages and bones. Self-cross-linked oxidized alginate/gelatin hydrogels have been developed for cartilage regeneration (Wang et al. 2020).

Due to their biocompatibility and predictable biodegradability, chitosan materials are frequently employed to create guided bone regeneration (GBR) barrier membranes, which limit soft tissue penetration into the graft region during treatments in dentistry that use bone grafts. On the other hand, degradation rates of such membranes may at times be too high for clinical applications. Advances in research have now come up with solutions like cross-linking of chitosan so as to optimize the clinical time frame target of 4–6 months of such membranes. In such an attempt, chitosan mats for guided bone regeneration membranes have been fabricated using genipin to lengthen the degeneration period (Norowski et al. 2012).

Sustained drug delivery is a common application of cross-linked chitosan. A biocompatible hydrogel system for buccal drug delivery was designed such that a catechol functional group was attached to the chitosan backbone followed by genipin cross-linking. A pH-controlled swelling-shrinking nanogel with cross-linked N-lysinal-N'-succinyl chitosan and poly (N-isopropylacrylamide) core enclosed inside a cross-linked bovine serum albumin shell was developed as a potential effective chemotherapeutic drugs carrier. Pharmaceutical and biological applications such as transdermal, parenteral, ophthalmic, and nasal drug administration use chitosan-based nanoparticles, microspheres, hydrogels, films, and fibers. By using the water-in-oil emulsion solvent diffusion technique with ethyl acetate as the oil phase, chitosan microspheres may be created as drug delivery vehicles. AgSD (a combination of silver and sulfadiazine) is a highly recommended drug for topical wound treatment, as it promotes wound convergence and possesses biocidal activities toward a wide spectrum of microorganisms. When the poor water solubility of AgSD was addressed through nanocrystal technology, increased surface area and physical stability after nanosization aggravated the cytotoxicity risks leading to retarded wound healing. Genipin cross-linked chitosan hydrogels were found to be a potential carrier dressing for AgSD nanocrystals promising sustained drug release and reduction of cytotoxicity (de Alvarenga 2011; Gao et al. 2016).

A comparative study of uncross-linked chitosan, chitosan membrane cross-linked with genipin, and chitosan membrane cross-linked with glutaraldehyde was carried out to evaluate the characteristics used as an implantable drug-delivery system. The genipin-cross-linked chitosan membrane was preferred above the other two based on the study's findings for creating an implanted drug delivery system (Mi et al. 2001).

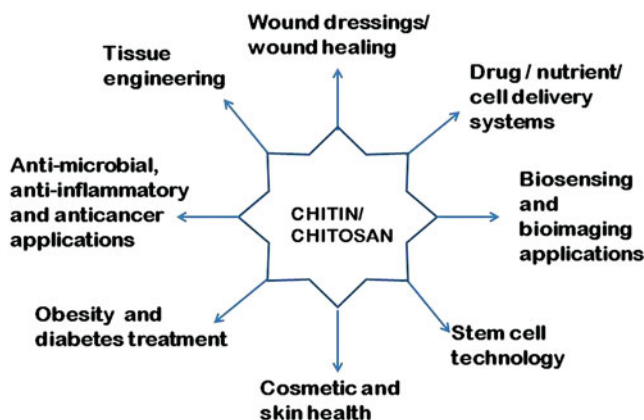

Fig. 19 Major biomedical applications of chitin and chitosan

Though excellent biocompatibility and antibacterial activity favor chitosan to fabricate nerve tubes and scaffolds, pure chitosan cannot be processed due to its high glass transition temperature (T_g of $203\text{ }^{\circ}\text{C}$) and very low thermal stability. One such attempt to employ modified Chitosan was by dissolving it in acetic acid followed by cross-linking with formaldehyde to form porous viscous gel (Mi et al. 2001). This gel was lyophilized and filled with longitudinally aligned poly (glycolic acid) (PGA) fibers and casted into nerve conduits. Physical cross-linking can be achieved by mixing alginate and chitosan/acetic acid solutions owing to their opposite charges which in turn can be used to prepare hydrogel nerve tubes.

The major biomedical applications of chitosan and chitin are summarized in Fig. 19.

Hyaluronan

Hyaluronan (HA or hyaluronate) is a high molecular weight glycosaminoglycan (GAG) found in extracellular matrix of humans. HA possesses a special set of properties like nonimmunogenic, nonadhesive, and bioactive (associated with many cellular processes and axonal in growth) enabling wide prospects for biomedical uses (Angra et al. 2021). HA-based hydrogels, films, scaffolds, foams, topical formulations, and nano formulations are used for wound dressings (Vasconcelos and Cavaco-Paulo 2013). To provide stability and enhance the functionality of gels, HA must first be cross-linked. Chemical cross-linking gives the chance to impart tailored mechanical properties and degradation rates to HA-based hydrogels through side group modification and cross-linking without interfering with its capabilities to perform biological functions. For the transport of molecules and cells, cartilage tissue engineering, and the creation of microdevice systems, cross-linked HA hydrogels are extensively used (Vasconcelos and Cavaco-Paulo 2013; Dovedytis et al. 2020). HA can be cross-linked chemically or physically to form three-dimensional (3D) structures with ample mechanical strength for fabricating nerve conduits. The handling characteristics of cross-linked HA is so weak

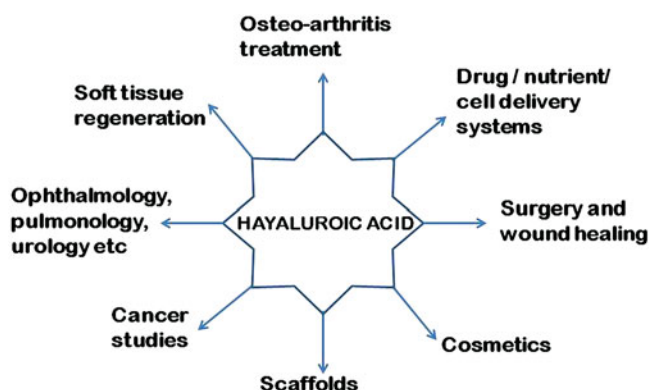

Fig. 20 Major biomedical applications of hyaluronan

that it has to be supplemented by an outer layer prepared from another biodegradable material to ensure its proper functioning during nerve regeneration period (Angra et al. 2021). Because these scaffolds enable greater cell migration and proliferation in wounds, HA nanofibers are thought to be more effective at healing wounds than solid HA. Since HA nanofibers guarantee the quick release of medications when in contact with wet environments, they are also suitable for drug administration. However, due to their fast disintegration and release, they are unsuitable for long-term drug release implants (Vasconcelos and Cavaco-Paulo 2013).

HA scaffolds find role in therapeutic purposes like bone, nerve, and brain tissue repair and muscle regeneration due to their excellent biocompatibility. Large skin defects can also be temporarily covered with HA-based dressings until autologous skin transplants can be employed. Several HA-based products for wound healing are commercially available such as Hyalofill-f, Hyalofill-R, Connettivina, Connettivina Plus, Jaloskin, Hyalomatrix, and Hyalosafe (Vasconcelos and Cavaco-Paulo 2013).

The major biomedical applications of hyaluronan are summarized in Fig. 20.

Collagen and Gelatin

Collagen hydrogels cross-linked with 1,4-butanediol diglycidyl ether (BDDGE) have been found useful for manufacturing temporary dermal scaffolding for explicit skin lesions as they promote tissue regeneration, reduce wound contraction, and reduce immunogenicity. Another example is quercetin-cross-linked collagen a popular temporary scaffold for nonhealing skin ulcers. The initial cytotoxicity invoked by implanted materials leads to chronic inflammation and delayed healing induced by retention of inflammatory cells at the material interface. This often leads to failure and chronic inflammation associated with tissue grafts for complex surgical cases. In this context, cross-linked collagen is found effective in masking immunogenic epitopes, thereby minimizing the chances for host immune responses to trigger off. Researchers have proved that genipin cross-linked collagen scaffolds inhibit proliferation of precise lymphocyte populations and decrease the cytokine release of

helper T cells, all of which contributed toward minimal inflammatory responses (Gu et al. 2018).

A biodegradable cationized gelatin hydrogel has been fabricated to an ophthalmic drug delivery system by air-drying and dehydrothermal cross-linking to deliver an epidermal growth factor. The results of this study suggested that these hydrogels effectively accomplished a controlled release of epidermal growth factor that led to accelerated wound healing (Bhattacharjee and Ahearne 2021).

Enzymatic cross-linking has been employed to fabricate an anti-inflammatory hydrogel for osteoarthritic cartilage repair by Jin et al. in which hyaluronate-tyramine conjugates and gelatin were cross-linked using tyrosinase. In another attempt, collagen-fibril hydrogel was cross-linked by transglutaminase for skin regeneration (Song et al. 2021).

JellaGel is a fibrillar collagen, extracted from jellyfish *Rhizostoma pulmo* formulated to form three-dimensional gels, and is suitable for tissue-engineering applications especially for cartilage restoration with good biocompatibility and little immunogenic. 3D cross-linked JellaGel™ hydrogels fabricated through genipin cross-linking were found to support and facilitate embodiment of human chondrocytes (Riacci et al. 2021).

Gelatin hydrogels modified with methacrylamide (MA) form GelMA, which on exposure to ultraviolet radiation undergoes addition-type polymerization of methacrylamide and methacrylate side groups on the GelMA chains to form a 3D network structure assisted by the presence of a photo-initiator. GelMA hydrogel has been discovered as a promising biomaterial for uses in tissue engineering, including the repair and regeneration of bone, heart, cornea, epidermal tissue, cartilage, vascular, neuron, skeletal muscle, etc. Provisions to manipulate the mechanical properties and the minimum inflammatory response ensured by good biocompatibility make GelMA a reliable candidate for repairing skeletal tissues. GelMA/PEGDA, GelMA/MBG, and GelMA/liposome scaffolds have been developed for bone defect regeneration. Three-dimensional printing technology has been applied to develop multilayered GelMA/HA scaffold for bone defect repair which can repair the damaged bone surface through tissue regeneration and can simultaneously deposit extracellular matrix and type II collagen (Xiang and Cu 2021).

Nerve repair materials fabricated from GelMA hydrogels were further optimized via 3D printing technology and electrospinning technology to ensure better performance. Three-dimensional printing technology has been exploited to improve the efficiency of GelMA/MPEG-PCL [(Methoxy poly (ethylene glycol)-poly (ϵ -caprolactone))] conduits for repairing peripheral nerves. GelMA hydrogel fibers fabricated through electrospinning technology could mimic the components and microstructures of spinal cord in a better way with regard to their good swelling rate and lower Young's modulus and hence effective in spinal cord regeneration.

Unique three dimensional structure and electrostatic interactions facilitate the wide applications of GelMA and its combination with other materials like materials, such as nanomaterials, liposomes, etc. in the drug delivery and controlled drug release field. GelMA for sustained release of abaloparatide for up to 10 days, GelMA-liposome scaffold for controlled release of drugs in stages,

nanocage-laden GelMA hydrogels facilitating pH-assisted controlled drug release, GelMA/chitosan nanoparticles composite hydrogel for promoting cell proliferation and sustained release, and core-shell microparticles fabricated using GelMA for cancer treatment drug delivery are a few instances (Xiang and Cu 2021).

Collagen is a highly favored biopolymer to prepare structures (outer tubular and central lumen) for nerve regeneration. Once, the issues associated with its low mechanical properties are overcome through cross-linking, stable nerve conduits can be fabricated. The three most often used cross-linking reagents are glutaraldehyde, formaldehyde, and the 1-ethyl-3-(3-dimethylaminopropyl)-1carbodiimide (EDC)/N-hydroxysuccinimide (NHS) combination. There is also a cross-linked bovine collagen (type I) nerve conduit tube called NeuraGen (Integra) that has received FDA approval. The potential toxicity of cross-linking agents has led to strategies like microwave cross-linking of collagen with comparable results.

The inconveniences associated with the water solubility of gelatin when circumvented by cross-linking render a suitable biopolymer favoring suitable processing characteristics, mechanical properties, and handling characteristics to fabricate tubular structures for nerve regeneration. Injection-molded or dip-coated gelatin tubes are immersed (the mold or mandrel) into cross-linking agent solutions. Genipin, proanthocyanidin, and EDC/NHS are commonly employed to cross-link gelatin via amino groups on the chain backbone. The free residual amino groups serve as an indicator for determining the cross-link density. A significant factor in determining how quickly a structure deteriorates is the extent of cross-linking, which can also have an impact on how quickly nerves regenerate.

The major biomedical applications of collagen are summarized in Fig. 21.

Keratin

Keratins are naturally derived proteins and are widely used to fabricate structures of several morphologies such as films, sponges, and hydrogels to meet various biomedical requirements in tissue engineering and controlled released applications. The wide range utility of keratin biomaterials is propelled by their inherent advantages such as amino acid sequences that simulate those present in extracellular matrix

Fig. 21 Major biomedical applications of collagen

(ECM), biocompatibility, and biodegradability. Similarity to ECM facilitates keratins' ability to support cellular attachment, proliferation, and migration (Feroz et al. 2020; Vasconcelos and Cavaco-Paulo 2013).

Keratin biomaterials were successfully employed for controlled drug delivery and bioactive materials delivery. In one such case, diclofenac drug was loaded on keratin films cross-linked with transglutaminase (TGase). It was discovered that the solubility of keratin films was determined by TGase cross-linking which in turn delayed the drug release owing to the enhancement of the mechanical characteristics of the films (Vasconcelos and Cavaco-Paulo 2013). Immobilization of bioactive agents like lysozyme within keratin sponges is facilitated through the presence of free cysteine residues which allows immobilization via disulfide and thioether bonds. The duration period of lysozyme release varied according to the type of cross-linking which has led to the conclusion that judicious selection of the cross-linker, in accordance with the requirements, can guarantee adjustments and regulations over the release characteristics of keratin sponges (Vasconcelos and Cavaco-Paulo 2013). Three-dimensional, biocompatible, biodegradable scaffolds have been fabricated from wool-derived keratin for bone regeneration in which the issues associated with their fragile nature were circumvented through cross-linking keratin fibers. An example for such an approach is the development of a hydroxypropyl methylcellulose (HPMC) cross-linked keratin scaffold for alveolar bone regeneration. This novel scaffold contains hydroxyapatite as a major inorganic component. The major highlight of this attempt is that HPMC is a hydrophilic, biodegradable United States Food and Drug Administration (FDA)-approved polymer which rules out the toxicity issues associated with common chemical cross-linkers. Besides, HPMC offers additional sites for interaction between keratin and hydroxyapatite particles contributing toward highly porous anisotropic structure of the scaffold (Feroz and Dias 2021).

A chitosan-keratin composite possessing enhanced technological properties, degradability, cyto-compatibility, cell adhesion, and growth properties that can cater toward wound-dressing applications was reported to be prepared through UV cross-linking. The fabrication claimed to be more ideal, ensured by the absence of residual toxic effects of chemical cross-linking agents (Lin et al. 2018).

A tenacious and flexible film was prepared from reduced keratin via chemical cross-linking with ethylene glycol diglycidyl ether (EGDE) and glycerol diglycidyl ether (GDE). These chemically cross-linked keratin films were found to be more stretchable and water resistant than keratin–chitosan composite film. Additionally, they kept their mechanical qualities after redrying at par with the original. Though the initial cell attachment on chemically cross-linked keratin was a bit slower, once attached, the cells proliferated well indicating their biocompatibility (Tanabe et al. 2004).

The major biomedical applications of collagen are summarized in Fig. 22.

Albumin

Biomaterials made from albumin rouse increasing interest in the creation of scaffolds for tissue engineering and biomaterials for the controlled delivery of therapeutics

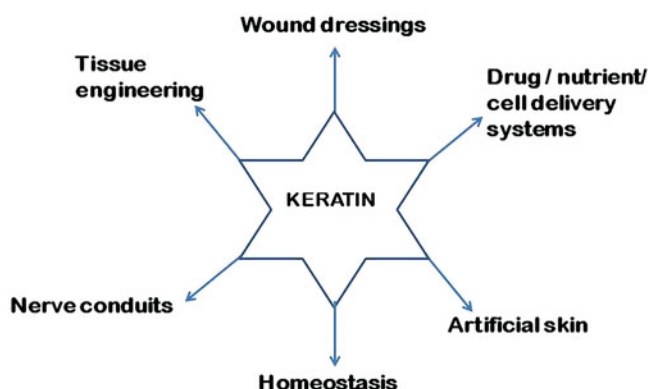

Fig. 22 Major biomedical applications of keratin

such as medicines. Albumin hydrogels inherit nontoxic and nonimmunogenic properties that make them desirable for several biomedical fabrications. Ultraviolet (UV) light-induced cross-linking was used to fabricate bovine serum albumin (BSA) hydrogels with tunable tensile strength and pore size regulated by extends of cross-linking. The 3D scaffolds prepared using these hydrogels were found effective in cell encapsulation and in vivo implantation thereby indicating possible applications in in vitro cancer research, wound-healing techniques, and regenerative medicine (Lantigua et al. 2020). In another approach, poly (ethylene glycol) was used to cross link bovine serum albumin (BSA) through the formation of urethane link between PEG and aminogroups of the protein to form hydrogels that can be used for controlled drug delivery applications and enzyme immobilization (Fortier et al. 1997). A low-cost BSA-based hydrogel was designed through dynamic double cross-linking technique which is expected to realize wide biomedical applications owing to its flexibility, mechanical properties, antibacterial nature, minimal cytotoxic effects, and self-healing capabilities. Glutathione, which joins with BSA to form a disulfide bridge network, and tetrakis (hydroxymethyl) phosphonium sulfate (THPS), which grafts the amino groups of BSA by a Mannich-type reaction, work together to enable the dynamic double cross-linking (Xia et al. 2021).

The effectiveness of small interfering RNA (siRNA) in cancer therapeutics is dictated by its safe and systemic delivery for which several carriers have been widely employed. Human serum albumin (HSA) has been developed as a tumor-targeted siRNA transporter. To increase their binding affinity to one another, thiols were added to both the siRNA and HSA molecules and subjected to chemical cross-linking and self-cross-linking to form stable nano-sized complexes (psi-tHSAs). According to studies, psi-tHSAs aggregated preferentially in tumor locations, where they effectively and sequentially silenced tumor genes exhibiting their possibilities in systemic siRNA therapy of various human cancers (Son et al. 2013).

To create high-performance BSA hydrogels, a hybrid cross-linking technique combining physical and chemical cross-linkings was adopted. Covalently joined BSA molecules via dityrosine bonds were thermally denatured to generate physical

Fig. 23 Major biomedical applications of albumin

cross-links between BSA molecules thereby generating high-strength hybrid dual-cross-links (Lu et al. 2020).

Due to their potential use as tracers and sensors (for molecules, enzymes, temperature, etc.), fluorescent hydrogels are attracting a lot of scientific attention. A biocompatible and biodegradable protein hydrogel with green and red auto-fluorescence was fabricated from glutaraldehyde cross-linked BSA (or HSA) and is likely to elaborate the reach of protein hydrogels in biomedical applications significantly as claimed by the authors (Ma et al. 2016).

The major biomedical applications of albumin are summarized in Fig. 23.

Biomedical Applications of Natural Rubber Latex (NRL)

Natural rubber latex is chemically polyisoprene chains and is comprised of cis 1,4 isoprene units. In natural rubber latex, rubber particles serve as the core of the colloidal system, which is supported by an anionic coating of phospholipids and proteins. Natural rubber latex (NRL) obtained from *Hevea brasiliensis* has been the first and last raw material choice for industrial production of gloves, condoms, balloons, and parts of quite a lot of medical and dental equipments. The protein content present in NRL is believed to be the reason behind latex allergy experienced by some people while using latex products. NRL can be deproteinized through centrifuging and/or with the action of suitable enzymes to obtain deproteinized natural rubber (DPNR) which lowers the risk of latex allergies. Vulcanization is the key process that converts natural rubber from a plastic material to a technologically demanding strong elastic material by a cross-linking reaction. Sulfur vulcanization, radiation vulcanization, and peroxide vulcanization are the three main options for vulcanization of NRL. Sulfur vulcanization creates monosulfide, disulfide, or polysulfide cross-links by the combined action of vulcanization agent (sulfur), accelerator, and activator (zinc oxide and stearic acid) by the application of heat. Both peroxide vulcanization and radiation vulcanization of natural rubber

yields a cross-linked elastomer with simple C–C cross-link structures. The technological properties of sulfur-vulcanized NR are superior to other two methods of cross-linking (Courtney and Gilchrist 1980). The biomedical applications of rubbers can be internal (in vivo) or external (in vitro). Internal uses include both short-term applications such as catheters and long-term implants. External applications include skin contact applications like drug infusion patches and much larger number of medical related applications such as disposable gowns, gloves, sheets, etc. (Mcmillin 2006).

Though NRL has been widely employed for manufacturing medical gloves and catheters, the excellent biocompatibility and ability to stimulate cellular adhesion and extracellular matrix formation promote tissue replacement, and regeneration of NRL has suggested several new biomedical applications such as delivering proteins, drugs, and nanoparticles, enhancing soft tissue curing, and stimulating hard tissue development in guided bone regeneration (GBR) method (Borges et al. 2015). Substitute for arteries, esophagus, pericardium, and abdominal wall have been made using NRL biomembranes. All the experimental results pointed that NRL biomembrane promoted rapid tissue repair through responses resembling normal healing process (Kerche-Silva et al. 2017).

Guided bone regeneration (GBR) technique enhances bone repair especially for large fractures with significant reconstructive problems that demand unusual measures for regeneration. In GBR technique, an occlusive membrane ensures optimum conditions needed for osteogenic cells to perform bone remodeling. NRL membranes when used as occlusive barrier in GBR enhanced bone regeneration process indicated by statistically higher volume of mature bone. The NRL membranes served as a passive protective sheath to stop the migration of connective and epithelial tissue. This made it easier for regenerating bone cells to grow and move into the wound without inducing any foreign body inflammatory reactions (Ereno et al. 2010).

Calcium phosphates (Ca/P) have shown promising applications in the field of orthopedic and dental implants, owing to their inherent structural properties and biocompatibility due to similarity with hydroxyapatite $[\text{Ca}_{10}(\text{PO}_4)_6(\text{OH})_2]$ a component of bones and teeth. Though Ca/P can promote osteointegration, the brittleness, low mechanical strength, and low biodegradation exhibited by ceramics have to be manipulated for efficient applications. The physiological, chemical, and technical characteristics of NRL plated with calcium phosphate resembled those of the mineral components of bone. Further, hemolytic test results assure that this NRL did not affect the blood cells (Borges et al. 2015).

A dissimilar purpose of NRL in biomedical sense is in the area of magnetic resonance imaging (MRI) which was also investigated. NRL was applied to iron oxide (Fe_3O_4) magnetic nano particles (MNPs) for use as MRI contrast agents. It has been reported that NRL-coated Fe_3O_4 MNPs exhibit improved physical properties proving their effectiveness as a contrast agent in diagnostic techniques. NRL is found to be an angiogenesis-inducing biomaterial and has proved its worth in treatment of diabetic wounds through a number of clinical trials. The wound-healing action of NRL membranes has been found to follow a process in which a Vascular

Endothelial Growth Factor (VEGF)-like material is released from NRL membranes which assist rebuilding veins and arteries and carrying nutrients aiding healing. Hence, NRL has been evaluated as a successful candidate for replacement/regeneration of tissues through several animal trials (Guerra et al. 2021).

Broken bones are treated using complicated and invasive surgery like autografts, allografts, xenografts, the use of synthetic biomaterials, or guided bone regeneration (GBR) techniques. NRL membranes are among the most sensible options for the GBR method since they do not require surgical intervention after healing. By eliminating bone grafts and transplants, NRL membrane offers significant health advantages. Little cost, ease of material availability, and low danger of disease transmission are further benefits. NRL's primary benefits for use as an occlusive membrane include biocompatibility, cell occlusion, osteoconductive, osteoinductive, and osteointegrable nature; vascularization and tissue restoration attributes; constitution and support of the curing area; flexibility, elasticity, and structural strength; and surface porosity and permeability (Guerra et al. 2021).

The drug release kinetics of NRL matrices can be modified by modifying the surface morphology and porous density of the matrix and can be easily tuned for various controlled drug release applications. Moxifloxacin, a broad-spectrum antibiotic, ketoprofen, an anti-inflammatory, ciprofloxacin, a synthetic broad spectrum antibiotic, etc. were successfully subjected to controlled releases upon integration with the NRL. It has been found that 60% of the drug release took place in a controlled manner presenting no cell-damaging effects, with negligible hemolysis level suggesting that the controlled delivery ideally minimizes the adverse side effects associated with systemic drug administration. NRL was suggested as a delivery route for numerous peptides and proteins as well as phyto-constituents with therapeutic qualities because of its benefits for clinical use and cyto-compatibility (Guerra et al. 2021).

Conclusion

Utilizing biopolymers in the biomedical field is an interesting aspect for research as well as the demand of time. Hence, more and more studies are undertaken to optimize and elaborate the use of biopolymers for fabricating biomaterials. In order to suit themselves for biomedical applications, these biopolymers should essentially possess characteristics like low toxicity, biodegradability, biocompatibility, and the potential for further chemical modifications. And most of the biopolymers have these characters embedded in them inherently by nature which act as both a strong pillar of support and a driving force for advanced research while employing them for newer biomedical applications and improving existing applications. Starch, cellulose, lignin, alginate, collagen, gelatin, PLA, HA, chitosan, keratin, albumin, etc. have proved themselves as promising candidates for biomedical applications, either independently, after modification, or in combination with other materials. Research works so far have highlighted the potential of these biopolymers for biomedical application like fabrication of scaffolds, drug delivery systems, tissue-

bone-, and nerve-regenerative medicine, wound healing, etc. However, comprehensive knowledge and advanced understanding of the biological, chemical, and physical properties of these materials is still essential to widen the horizon of their applicability and to fine-tune the existing roles played by them in the biomedical field as most of the researches are in the initial stage presenting in vitro results. Hence it is essential that these promising results are to be extended properly to in vivo studies and to adapt the results with respect to the challenges encountered with different demands in vivo. Emerging research will certainly improve the performance of these materials to assist therapeutic recoveries in order to bring better results to make our lives happier in a healthier fashion.

Overcoming the Limitations of Natural Fiber as a Biopolymer Reinforcing Material 1189

Conclusion 1191

References 1192

Abstract

Building and construction industries are clawing into non-renewable natural resources for scaling up their demands globally. Massive energy expended on the manufacture of raw materials, and giant carbon footprints of construction and demolition have raised environmental concerns. Scientists worldwide are reviving the use of traditional building materials and are striving to develop sustainable eco-friendly raw materials that can be customized to meet demands of building and construction domain. This chapter leads us through one such breakthrough which is biocomposites made of biopolymers incorporated with natural fibers which are durable, strong, sustainable, and eco-friendly. Here we gain an insight into the types of natural fibers used, and how it enhances the properties of biopolymers when developed as biocomposites. Further, it highlights the advantages of biocomposites and several applications. The chapter concludes by addressing the challenges faced in use of natural fiber as reinforcement material and remedies for overcoming these limitations.

Keywords

Biopolymer · Natural fiber · Bio-composite · Construction materials

Introduction

Building material promotion council has estimated that India generates a stark 150 million tons of construction and demolition waste per year. The fact that only 1% of it is recycled and reused is of grave environmental concern. Thus, demanding the development of biodegradable, eco-friendly, and sustainable construction materials. These can be used to replace conventional building materials in constructing transient civil structures like make-shift stadiums, military shelters, shopping malls, and architecture vulnerable to dynamic natural forces, etc. Engineers and scientists take inspiration from age-old traditional construction raw materials and have been developing eco-friendly alternatives. Natural fiber-reinforced biopolymers composites are one of the most promising innovations (Yan et al. 2016). This chapter begins by addressing the need for biodegradable construction materials and emphasizes biopolymers. Further along, it enumerates all the animal and plant fibers currently used as reinforcement material. Finally unfolding the challenges faced in the process, highlighting the outstanding advantages of biopolymer reinforcement with natural fiber, and its innovative and promising applications.

Demand for Biodegradable Construction Material

Environmental issues tagged to the construction industry include massive land space depletion due to landfills, unchecked natural resource consumption, and extreme pollution. The collapse and demolition of abandoned stadiums, tunnels, bridges, and unauthorized buildings, leave behind massive debris which can emit toxic greenhouse gases. Natural disasters across the globe also add millions of tons of debris and have severe socio-economic and environmental impacts. Such crises force us to steer the wheel towards reuse, recycling, and the use of eco-friendly biodegradable construction raw materials.

A biodegradable composite construction raw material should not be mistaken as a vulnerable readily disintegrating material. When compared to nonbiodegradable synthetic construction materials a biodegradable composite with creditable strength and mechanical properties will eventually disintegrate due to microbial action at the site of demolition or collapse but without releasing toxins.

Globally there is an emerging concept of including biodegradable materials in mainstream construction as part of sustainable construction (Sassi 2006). Natural fiber-reinforced biopolymer composites are making a smooth slide into the construction industry owing to their creditable strength, and durability. Fiber composites play a crucial role in rehabilitating bridges and apartments which are exposed to marine salt-corrosive environments. They also find use in the constructions of roofs, girder, floating river walkway pedestrian bridge, water tanks, structural portal frames, and truss systems for deployable shelter (Ticoalu et al. 2010). Use of jute-based composites for key structural applications like interior fundamentals of building, and provisional outdoor purposes like affordable construction for defense, and rehabilitation are increasing. The use of jute as construction materials for developing ceiling panels due to their insulating characteristics is being explored (Sanjay et al. 2016). Straw and coconut leaf sheaths are used for the development of composite building materials (Bharath et al. 2022; Mansour et al. 2007). Load bearing property of bamboo has been an efficient replacement for reinforcing steel in concrete (Sutharsan et al. 2020). However, these are just a few of the many utilities of such materials. There is vast potential for the use of biodegradable materials at a large scale remaining to be uncovered.

Biopolymers in Construction

- (a) Polymers that are extracted from sources of biological origin are commonly referred to as biopolymers. Like all polymers, biopolymers constitute several blocks repeating to form chain-like molecules and can extend to great lengths. Biopolymers are an efficient means for storage and preservation of energy, transmission of genetic information, and cellular construction. They have been regarded as sustainable and eco-friendly as they are biodegradable, thus minimizing carbon footprint. They are obtained either from living organisms or from biological materials which are abundant, renewable, and biodegradable (Shadhin

and Shuvo 2019). Starch-based biopolymers have the potential to replace polyolefins. PLA can substitute Polymethyl methacrylate (PMMA). It is interesting to note that cashew nut shell liquid resin (CNSL) is an emerging biopolymer resin (Lalit et al. 2018).

Some common biopolymers are as follows:

- Polysaccharides such as cellulose, hemicellulose, chitin, chitosan, glucans, and starch
- Proteins such as gelatin, zein, fibroin, and casein
- Derived polypeptides such as gelatin, and collagen peptides
- Polyphenols or modified polyphenols such as tannins, crosslinked tannins, and lignin
- PLA (Polylactide), polyglycolic acid (PGA), poly-b hydroxy alkanates (PHA), polycaprolactone (PCL), and polycaprolactone (PCL)

Applications of biopolymers in the construction industry are listed as follows:

- Use of biogenic polymers as additives or supplements has been reported in construction engineering. One such study shows that treatment of natural soil with beta-glucan enhanced the strength of soil by 300–400% with low CO₂ emission. These qualities displayed by the biopolymer make these ideal choices over. It is also noteworthy that a little amount of biopolymer (about 0.5% of total content) compared to a large amount of cement (10% of total content) can increase the unconfined compression strength of soil (Chang et al. 2015).
- Biopolymers can be used as wood protection agents in construction due to their biocidal action. It reduces the dependence on chemical agents to prevent the destruction of wooden structures (Patachia and Croitoru 2016).
- In the construction and operation of dams, biopolymer slurry is used for drain/reactive barrier trench excavation. It reduces installation costs and time and is much safer. It allows for reduced dewatering so the damage on surround structures is less (Aminpour and O’Kelly 2015).

Natural Fibers: Eco-Friendly Companions of Biopolymer

For a long time, fibers have been used by the construction industry for various purposes. Fiber is the reinforcement used to bear the load transferred through the matrix. They provide strength and stiffness to the polymer (Lalit et al. 2018). Fibers are broadly categorized into two kinds: natural and synthetic (Table 1). Natural fibers are obtained from environmental sources and synthetic fibers are chemically synthesized. Natural fibers are gaining importance because they are greener and more sustainable materials (Mohajerani et al. 2019). Over two decades, the use of fibers as reinforcement materials for polymers has shown positive benefits which include increased strength, lightweight, corrosion resistance, and reduction in the total cost

Table 1 Comparison between synthetic and natural fibers properties (Sanjay et al. 2016)

Aspects	Property	Natural fiber	Synthetic fiber
Technical	Mechanical	Moderate	High
	Moisture sensitivity	High	Low
	Thermal sensitivity	High	Low
Environmental	Production	Low	High
	Resource	Infinite	Limited
	Recyclability	Good	Moderate

of construction. Added advantages are that it takes less labor, less maintenance, and saves time. Unlike traditional reinforcement materials, fibers are required in lesser quantities.

The fiber composites utilize the principle of fibers as reinforcement in the resin matrix. Fiber provides strength and resin provides a binding platform as well as protection for fibers. However, fiber alone cannot sustain actual loads. The type of resin, type of fiber, fiber to resin ratio, industrial procedure, and properties of fiber composites can be selected and combined to develop the desired end product (Ticoalu et al. 2010).

The potential of flax, hemp, and kenaf as composite reinforcement has been studied. These studies have shown that they exhibit properties like specific modulus and strength which resemble the values exhibited by glass fibres (Bari et al. 2021).

Natural fibers are considered to be the new generation of reinforcement materials for polymers and recently, they are seriously being explored owing to their renew-ability, energy conservation applications as well as properties which help them to be nominated as efficient materials in place of synthetic materials (Sanjay et al. 2016).

Natural fibers are easily available and can be obtained from waste materials. The energy required for production is low and also causes less damage to the environ-ment (Mohajerani et al. 2019). Bio-composites are manufactured by using biopoly-mer as a binder and natural fiber as the reinforcement material. For enhancing the strength of bio-composites, reinforcements of natural fibers such as bamboo fiber, ramie, flax, kenaf, jute, etc., are used (Gupta et al. 2019).

Straw-reinforced clay for bricks was the earliest known example of utilization of natural fiber composites (Ticoalu et al. 2010). The use of natural fibers is increasing for constructing low-cost buildings. Structural beams and panels are designed, manufactured, and tested for bio-based composite materials, particularly on plant oil-based resins and natural fibers (Sanjay et al. 2016).

Retting is the process of unraveling and mining the fibers from non-fibrous tissues of plants by detaching, disintegrating, and deteriorating the pectin, gums, and other adhesive substances. Retting can be of varying types based on the method used. This includes biological, mechanical, physical, chemical, or enzymatic retting (Aaliya et al. 2021).

Reinforcing natural fibers to biopolymer matrix requires a fabrication process to prepare preforms and then reinforce the preforms to the matrix. There are several techniques used for fabrication based on the type of natural fiber, biopolymer used,

and conditions for reinforcement. The two main types are open and closed molding techniques. Open molding techniques allow exposure of resin to the atmosphere during curing and include simple unsophisticated techniques which contribute to low processing costs. Some of the open molding techniques are hand lay-up, spray-up, filament winding, etc. Closed molding techniques do not allow exposure of resin to the atmosphere during curing and are opted for constructing three-dimensional composite parts which have better quality, reduced material waste, and aesthetic finished parts. They include techniques like compression molding, injection molding, resin film infusion, etc. (Faruk et al. 2012).

Types of Natural Fibers That Can Be Used with Biopolymers

Natural fibers are broadly classified into two types: animal fibers and plant fibers.

Animal Fibers

Animal fibers are obtained from animal hair, feathers, silk, or any other animal part. Animal fibers exhibit extraordinary chemical, physical, and mechanical properties which make them ideal reinforcement materials. Silk obtained from butterfly larvae is the most potential animal fiber. It shows excellent chemical resistance and mechanical strength owing to the presence of fibroin protein. The tensile strength of silk is approximately 600 MPa. Feather fiber shows good specific strength and is recyclable, making them suitable for reinforcement for developing biocomposites. It was revealed in a study that when a chicken feather along with coir was used as a hybrid, the feather increased the flexural strength whereas coir increased the tensile and impact strength (Prakash et al. 2022). The use of animal fibers in the construction industry is being looked upon and is being explored further. It should also be kept in mind that this also paves way for animal abuse if not regulated strictly.

Plant Fibers

Natural fibers obtained from plants are known as plant fibers and have been used as reinforcement materials for composite development. The chemical composition of plant fibers varies depending upon the plant source. However, they mainly consist of cellulose, hemicellulose, lignin, waxes, etc. Table 2 gives the chemical composition of some plant fibers.

There are four major types of natural plant fibers (Mohajerani et al. 2019) (Table 3)

- (i) **Bast Fibers** – These fibers extracted from exterior parts of plants show high tensile strength. They also showcase good thermal insulation. Examples of bast fibers are flax, hemp, jute, kenaf, etc.
- (ii) **Palm Fibers** – These are the fibers obtained from palm trees. Their mechanical characteristics include low tensile strength, high water absorption, resistance against deterioration, and low modulus of elasticity. Some examples are coir, date palm fibers, oil palm fibers, etc.

Table 2 Chemical composition of some natural fibers (Bari et al. 2021) <http://creativecommons.org/licenses/by/4.0/>

Type of fiber	Cellulose	Lignin	Pentosan	Ash	Silica
Flax	44–57	21–23	24–26	5	–
Jute	57–77	21.26	18.21	0.5–2	–
Kenaf	45–63	15–19	22–23	2–5	–
Sisal	–	7–9	21–24	0.6–1	–
Cotton	–	0.7–1.6	1–3	0.8–2	–
Hemp	87–91	9–13	14–17	0.8	–
Ramie	–	–	5–8	–	–
Bagasse	26–43	19–24	27–32	1.5–5	0.7–3.5

Table 3 Tensile strength and Young's modulus of some natural fibers (Bari et al. 2021)

Type of fibers	Tensile strength (MPa)	Young's modulus (GPa)
Hemp	550–900	70
Jute	400–800	10–30
Flax	88–1500	60–80
Sisal	600–700	38
Coir	220	6
Ramie	500	44
Cotton	400	12
Kenaf	295	–
Banana	355	33.8
Pineapple	170–1672	82

- (iii) **Cereal Straw** – Straw obtained from cereals plants are good natural fibers. They were used throughout history as reinforcement materials. They are good at reducing shrinkage, improving ductility, and enhancing tensile and compressive strength. They also exhibit high water absorption. Some examples are wheat straw, barley straw, etc.
- (iv) **Leaf Fibers** – Leaves of plants contain fibers, fibers which are obtained from leaves and are known as leaf fibers. Some examples are sisal fibers, banana fibers, pineapple fibers, etc. (Figs. 1 and 2).

Plants as a source of natural fibers are elaborated below:

(a) **Jute**

Jute, also known as “Golden fiber,” is a lignocellulosic bast fiber; the scientific name is *Corchorus capsularis* belonging to the Tiliaceae family (Sanjay et al. 2016). They are commonly found in India, China, and Bangladesh as it requires a wet monsoon climate. Jute plants are cut and soaked in water for retting. Jute fiber exhibits reduced thermal conduction, moderate water holding capacity, and good mechanical

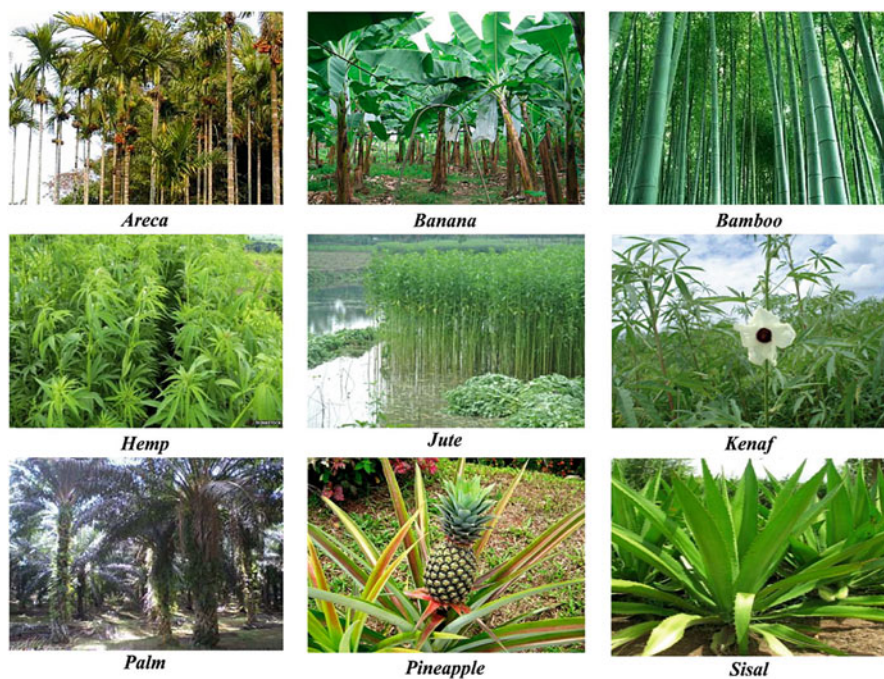

Fig. 1 Plants as a source of natural fiber (Sanjay et al. 2016)

Fig. 2 Examples of biodegradable commercial composites for buildings (Bari et al. 2021)

properties (Aaliya et al. 2021). Jute is the most studied vegetable fiber. They are extracted from the exterior (bark) of jute plants as the fibers are contained in the bark.

They mainly form porous material which helps in filtration, drainage, and soil stabilization and are used in pavement engineering (Mohajerani et al. 2019).

PLA (Polylactide), in combination with jute fabric, increased tensile strength, tensile modulus, flexural strength, impact strength, and water absorption capacity. The bonding between PLA and jute was good and no air voids were present. However flexural modulus was reduced which needed to be investigated further. Jute can be applied in architectural interiors in building construction sector (Gupta et al. 2019).

Another study based on soy protein-jute fiber composite showed that using water as the plasticizer instead of chemicals makes the bio-composite biodegradable and at

the same time useful for various applications because of increased flexural strength, tensile strength, and acoustic properties (Reddy and Yang 2011).

A study by Mohanty et al. showed that surface modification of jute/biopolymer increased tensile strength by 50%, flexural strength by 30%, and impact strength by 90% in composites compared to normal biopolymer (Faruk et al. 2012).

(b) **Flax**

Linum usitatissimum L. is mostly known as flax and is mainly grown for the oil industry but it is interesting to know that it can be used both as reinforcements and as a polymer matrix in bio-composites. The application of flax as reinforcement material is increasing because of its properties which can replace the use of synthetic fibers. The strength and modulus of flax-reinforced composites depend largely on the volume of fiber present. Techniques are being explored for increasing efficient mechanical characteristics of flax fiber (bast fiber) to increase the durability of the flax biocomposites (Shadhin and Shuvo 2019).

(c) **Kenaf**

Kenaf (*Hibiscus cannabinus*, L.) is an herbaceous annual plant. Kenaf and hemp fiber bundles as well as their mixtures significantly increase tensile strength and Young's modulus of composites. They remarkably lower the impact strength of pure Poly lactic acid (Sanjay et al. 2016). Kenaf bast fiber has superior flexural strength with excellent tensile strength which makes it the material of choice for a wide range of extruded, molded, and non-woven products (Babatunde et al. 2015).

(d) **Hemp**

Hemp is an annual plant belonging to the *Cannabis* family. The fiber obtained from hemp is classified as a bast fiber. Hemp fiber reinforced wheat gluten matrix composites were studied by Kunanopparat et al., regarding their thermal treatment and plasticization effect on mechanical properties (Kunanopparat et al. 2008).

Hemp fiber-reinforced Polylactic acid (PLA) fabricated by hot press method was studied for a variation in mechanical properties after alkali treatment on fiber. The results showed that a 40% volume fraction of alkali-treated fiber exhibit the best properties – 54.6 MPa (tensile strength), 8.5 (elastic modulus), and 112.7 MPa (flexural strength) which are much higher compared to PLA alone (Hu and Lim 2007).

(e) **Coir**

Coconut fiber or coir is a lignocellulosic fiber which is present amid the external shell and the husk of coconut (*Cocos nucifera*), a tropical palm belonging to Arecaceae family. Coir shows striking durability and hard-wearing quality (Aaliya et al. 2021).

Coir mainly contains cellulose, hemicellulose, and lignin. The high lignin content makes it more durable compared to other natural fibers. They are used in the

production of building boards, roofing sheets, insulation boards, and building panels, as a lightweight aggregate (Verma et al. 2013).

(f) Sugarcane Straw (SCS)

Sugarcane straw is primarily the waste generated by sugar industry. It is composed of glucans (37%), hemicellulose (28%), lignin (24%), and ash (5%). SCS was studied for its properties to be used as a reinforcement/filler with the biopolymers matrices thermoplastic starch (TPS), Polylactic acid (PLA), and green polyethylene (GreenPE) that are synthesized from renewable sources, and polyhydroxy butyrate (PHB) and polyhydroxy butyrate-co-hydroxy valerate (PHBV) that are synthesized intracellularly from microbial fermentation. The biocomposites were formed by a simple dry blending technique followed by compression molding. The study showed that there was an increase in tensile and flexural modulus. But the water susceptibility was high so these materials are not ideal for humid conditions (Robledo-Ortiz et al. 2021).

(g) Cotton

A study conducted using multi-layer bio-composites consisting of poly(lactic acid) or poly(3-hydroxybutyrate-co-3-hydroxyhexanoate) matrices film stacked with cotton twill fabric showed that among the combinations, cotton- PLA showed better flexural properties. When load-bearing ability, according to standards, was analyzed the results showed good results. This study is promising for the future of bio-composite in construction (Battagazzore et al. 2019). Cotton fibers cause high impact strength but also show lower tensile strength and stiffness (Sanjay et al. 2016).

(h) Sisal

Sisal fiber is a strong, coarse, and hard fiber extracted from the leaves of the sisal plant (*Agave sisalana*) which belongs to the Asparagaceae family (Sanjay et al. 2016). The plant is native to Mexico. It is commercially produced in India, Indonesia, Brazil, Haiti, and East Africa. These fibers show specific strength and modulus comparable to glass fibers and high resistance to insects and pests (Aaliya et al. 2021). Sisal finds application in civil construction, fiber core of steel wire cables of elevators, assortments of building materials, etc. (Bari et al. 2021).

It is seen that when sisal fiber and coir are added in combination to soil blocks, observable cracks are removed, ductility increases and compressive strength also increases (Mohajerani et al. 2019). Sisal- CNSL composites are used for roofing applications (Lalit et al. 2018). According to Zhang et al., sisal/plasticized wood flour composites are fully biodegradable (Faruk et al. 2012; Zhang et al. 2005).

(i) Banana Fiber

Banana fiber is extracted from the stem of the banana plant (*Musa acuminata*) which is a plant native to Southeast Asia. Banana fibers are also obtained from *Musa textilis*

of the family Musaceae. The banana fiber is also known as abaca fiber. Banana fibers display high variability along length and across fibers, a characteristic feature which makes it suitable for applications in natural fiber-reinforced composites. The balance of structure and property shown by banana fiber reinforced composites is the reason which they can be manufactured at a cheaper price (Gupta et al. 2020). Banana fiber is also resistant to seawater.

(j) **Pineapple Leaves**

Pineapple leaf fiber (PALF) is obtained from the leaves of the plant, *Anannus comosus*, belonging to the Bromeliaceae family. The PALF fibers are strong, white, fine, and silky (Sanjay et al. 2016).

Pineapple leaf fiber (PALF) is an excellent candidate for being used as reinforcing filler in green composites due to their superior mechanical properties which are in turn dependent on their high cellulose content. PALF exhibits a rough surface, hence increasing its capacity to be used as an excellent choice for reinforcement with PLA matrix which in turn results in better bonding between PALF and PLA matrix, due to mechanical interlocking. By increasing PALF loading content PALF/PLA composites showed remarkably enhanced tensile properties (Kaewpirom and Worrarat 2014).

Pineapple leaf fiber reinforced polycarbonate composites involve treating the fiber with silane. This results in fibers with the highest tensile and impact strength but thermal stability decreases with increasing fiber content compared to neat polycarbonate. Enhancement of pineapple leaf fiber is carried out by surface modifications like dewaxing, alkali treatment, cyanoethylation, and grafting acrylonitrile onto dewaxed fiber (Faruk et al. 2012).

(k) **Bamboo**

Bamboo (*Bambusa* spp.) is a perennial plant. The fibers are extracted by steam explosion technique. Bamboo fibers show specific strength comparable to glass fibers. Bamboo fiber also shows good absorption of ultraviolet radiation (Faruk et al. 2012).

Mechanical Properties of Natural Fiber Reinforced Biopolymer Composites

The hallmark of using natural fiber-reinforced biopolymer composites for construction purposes is their creditable mechanical properties. These properties are mainly affected by the chemical composition and physical properties of natural fiber and biopolymer, surface modification of the fiber, composite processing techniques (temperature and force applied), processing environment, fiber loading concentration, and the orientation of fiber in the matrix, copolymerization, and plasticization. Waxy substances present in fiber also affect the adhesion and wettability of composites.

The important mechanical properties of biopolymer composites are mentioned below.

Tensile Properties

Tensile strength defines the amount of deformation a material can resist/withstand under the action of external load. Young's modulus (a measure of stiffness) is the ratio between stress and strain of material at the elastic stage. Young's modulus and tensile strength, both depend on the type of fiber and the biopolymer in the biocomposites (Table 4).

Strength and stiffness are more for fiber compared to biopolymers reinforcing fibers to biopolymer matrix enhance the tensile properties of the biocomposites. Tensile properties also depend greatly on the concentration of reinforced fiber.

Flexural Properties

Flexural properties indicate the ability of materials to resist bending deflection when a load is applied to the structure. It is also known as bending strength. Flexural stiffness is one factor which determines deformability. Flexural property is dependent on two factors of material, Young's modulus, and moment of inertia. Hemp, ramie, sisal, and curious fiber-reinforced biocomposites show better flexural modulus of rupture. In some cases, increasing fiber content results in decreased flexural strength due to kinking (which means weak spots in fibers), which causes an increase in the stress concentration in the matrix (Aaliya et al. 2021).

Impact Properties

Impact strength is the ability of a material to resist fracture under stress applied at high speed (Faruk et al. 2012). Generally, natural fibers have low impact strength. The impact strength depends on parameters such as the type of fiber and type of biopolymer of the composite, particle size, interfacial adhesion, etc. The impact strength can be increased by various techniques like treating fibers with silane, etc. (Aaliya et al. 2021).

Table 4 Details about tensile properties of a few natural fibers/biocomposites (Aaliya et al. 2021)

Fibers	Tensile properties
Bast fibers	Highest tensile strength and Young's modulus
Flax	High tensile strength and Young's modulus due to low microfibrillar angle and high cellulose content
Ramie and curaua	Excellent rupture modulus
Hemp	Stiffness greater than E-glass fibers
Ramie fiber (unidirectionally oriented)-reinforced soy protein concentrate	Tensile properties are comparable to steel
Coir	Low tensile strength due to high microfibrillar angle and low cellulose content

Dynamic Mechanical Thermal Properties

DMTA (Dynamic Mechanical Thermal Analysis) is used to determine the Heat Deflection Temperature (HDT) of biopolymer composite. The elastic response (storage modulus), viscous response (loss modulus), and damping ($\tan \delta$) are values of material given as functions of temperature at 3 °C/min. A strong modulus for a natural fiber-reinforced biopolymer is good. A study by Oksman et al. demonstrated that flax reinforced PLA composite shows increased strong modulus (Oksman 2001; Aaliya et al. 2021).

Toughness and Hardness Properties

The strength and ductility of a biopolymer composite determine its toughness and hardness. Toughness is defined as the ability to absorb energy and plastically deform without fracturing is regarded as the toughness of a material. Hardness is the ability to resist permanent plastic deformation when a compression force is applied (Aaliya et al. 2021).

Creep and Fatigue Properties

Creep in a biopolymer composite is the tendency to deform slowly but permanently due to mechanical stress. Fatigue is the structural damage due to cyclic loading and unloading of material. It depends on the shape and structure of the biopolymer composite (Table 5).

Brittleness and Ductility Properties

If a biopolymer composite under stress, breaks with or without noticeable deformation then the material could be considered brittle or ductile. Natural fibers deform before fracture compared to glass fibers. Various studies show that natural fiber reinforced biopolymers have enhanced ductility due to small-sized fiber particles, surface area, and elevated aspect ratio of the fiber. Homogeneous distribution of fiber in the matrix and strong interaction between fiber and matrix also contribute significantly (Aaliya et al. 2021).

Tribological Properties

Tribology is the study of friction and wear of two mating surfaces. Research reveals reinforcing natural fibers on biopolymer matrix, friction, and wears performance can be improved (Aaliya et al. 2021).

Table 5 Mechanical properties of various natural fiber reinforced composites (NFRCs) (Syduzzaman et al. 2020)

Reinforcement fiber	Matrix	Treatment (fiber/matrix modification)	Fabrication technique	Properties		
				Tensile strength (MPa) and modulus (GPa)	Flexural strength (MPa) and modulus (GPa)	Impact strength (KJ/m ²)
Hemp	Polylactic acid	Alkali treatment (4 wt.% NaOH)	Compression molding	6%↑-strength 17%↑-modulus	8%↑-strength 14%↑-modulus	17.5%↑
Sisal (20 wt.%)	Glycerol/thermoplastic starch	Compared to neat thermoplastic starch	Roll mill mixing and hot-press molding method	115%↑-Strength 1410%↑-modulus	–	–
Jute fiber	Polylactic acid	Compared to jute/polypropylene	Hot-press technique	52.6%↑-strength 119%↑-modulus	130.8%↑-modulus	–

Advantages of Natural Fibers as Reinforcement Materials of Biopolymer

Biopolymers and natural fiber composites help in reducing overreliance on non-renewable energy/material resources. They decrease greenhouse gas emissions and pollutant release, improve energy recovery, and increase biodegradability. These sustainable materials lower the structural cost and weight. It increases structural performance (Battegazzore et al. 2019; Yan et al. 2016).

Natural fibers (jute, sisal, pineapple, banana, flax, and hemp) because of their exceptional properties such as reduced density, biodegradable nature, non-corrosive nature, vast accessibility, non-toxic nature, and low carbon release can be suitable candidates for replacing the synthetic fibers. The alluring highlights of the natural fibers are their ease of procurement, high specific modulus and light weightiness (Prakash et al. 2022).

The use of natural fibers as reinforcement of polymer and cement matrices improves the mechanical properties of the matrices such as tensile, flexural, and impact properties, etc. (Yan et al. 2016). The reinforcing property of the natural fibers is due to their lignin content and their crystallinity (Gupta et al. 2020).

Thermal applications find the use of natural materials beneficial since they show significant thermal insulation properties and can regulate temperature and humidity with more ease. (Mohajerani et al. 2019). Fiber composites also have properties like high strength, lightweight, water resistance, chemical resistance, fire resistance, and resistance to corrosion. The properties can be engineered according to needs and have proven to be cost-effective (Ticoalu et al. 2010). Laminations and panels made from a combination of polyester, phenolic, or polyurethane resins with sisal, jute, and coir fibers show unique properties similar to their synthetic alternatives (Bari et al. 2021).

Challenges of Using Natural Fiber Reinforced Biopolymer Composites

Albeit biopolymers are abundant and eco-friendly, there are certain challenges which have to be addressed before large-scale application. Biopolymers do not possess all the desired properties which are characteristic of synthetic polymers. They have limited mechanical properties. Hence, manufacturing biopolymers of desired shapes and sizes can be difficult at times. Biopolymers also degrade much faster; so, the development of the same should have predictable degradation pathways. Sometimes the current pieces of equipment cannot be used to process the biopolymers properly and therefore overcoming these limitations include the use of natural fibers to reinforce the biopolymer matrices. This improves the properties whilst maintaining biodegradability (Bari et al. 2021).

Factors such as the hydrophilic nature of plant-based natural fibers and hydrophobicity of the polymer in biocomposites may result in poor interfacial bonding between matrix and reinforcing material. Other factors which are a hindrance in the development of natural fiber reinforced biopolymer are mainly low thermal stability,

high moisture absorbency, and low wettability of cellulose content. Moreover, the properties of natural fibers vary depending on changes in weather, season, cultivation conditions, and processing techniques (Syduzzaman et al. 2020).

Another challenge of using natural reinforced materials is difficulty in gauging durability (Aaliya et al. 2021). Biocomposites have negative impacts on them due to weathering factors such as humidity, temperature, rain, and UV radiation.

Factors which govern the durability of biocomposites are:

Moisture Absorption

Both natural fibers, as well as biopolymers, are plasticized by water. Hence it reduces the stiffness of composite resulting in higher moisture absorption which indicates loss of tensile and flexural properties and isn't considered an ideal indicator. The fact that natural fibers have high moisture absorption capacity is another challenge.

Thermal Stability

Another concern amongst biopolymers is low thermal stability. However, reinforcing with natural fiber enhances the thermal stability of biopolymers but care must be taken for getting the desired properties of composites by the adequate and appropriate blending of the fiber and matrix which have different thermal properties.

Fire/Flame Retardancy

When natural fiber-reinforced biopolymers are used for building materials, flammability and flame retardancy property are of prime concern as natural materials are easily flammable. Biopolymer composites show varied flammability depending upon the parameters which control them which include; the type of natural fiber and biopolymer, type of reinforcement, adhesion between reinforcement and matrix, and the structure of the composite. Various additives are mixed with biopolymer composites to improve their flame resistance without affecting their mechanical properties. An example is kenaf/E-PHBV composites which when incorporated with metal oxide (Sb_2O_3) and a phosphate-based additive, act as a flame retardant. But there are major limitations to adding certain flame retardants like halloysite nanotube as it weakens the mechanical properties. Therefore, more research has to be carried out to determine new fire retardants which do not lessen the mechanical properties.

Ultraviolet Resistance

Lignin which is present in natural fibers is susceptible to photodegradation which imparts a yellow discoloration to the composites. UV radiation reduces covalent

bonds in biopolymer resulting in surface roughening, degradation of mechanical properties, and embrittlement that are harmful to the composite. An experiment done by Campos et al. showed that UV exposure on thermoplastic like sisal/starch composite reduced their mechanical properties and produced holes in the surface, causing embrittlement and discoloration. The addition of chemicals to strengthen the cell wall polymers has shown reduced lignin degradation and also has been key in keeping degraded fibers structures together on UV exposure. Yet, the use and availability of such chemicals without compromising on the mechanical properties and sustainability are still in the pipeline.

Biodegradability

Biodegradation is the ability of the material to serve as a platform for microbial growth. Natural fiber-reinforced biopolymer composites derived from PHB, PBS, and PLA, are biodegraded by anaerobic digestion and/or enzymatic degradation. A study by Barkoula et al. showed that flax fiber-reinforced PHB matrix composite had reduced tensile strength in the primary stage of biodegradation studies. Although the presence of lignin reduces the microbial attack, all-natural fibers are not lignified. Biodegradability can be reduced by making natural fibers less hygroscopic as well as less susceptible to enzyme degradation. But if chemical agents are to be added then the whole purpose of the eco-friendly approach will need to be considered from square one. Therefore, the field faces major challenges like these which need more exploratory research that focuses on finding ways to make durable bio composites without compromising on mechanical properties and sustainability principles.

Overcoming the Limitations of Natural Fiber as a Biopolymer Reinforcing Material

One of the major disadvantages of natural fibers is high moisture sensitivity (Sanjay et al. 2016).

They have the drawback of poor durability due to their natural origin so degrade with time and plant fibers are hydrophilic which are being studied to enhance the overall efficiency of natural fibers (Mohajerani et al. 2019).

When a mechanical property is considered on a whole it is found somewhat inferior to synthetic fibers but works are in progress to improve these problems of mechanical properties. The compatibility of biopolymer and its corresponding natural fiber can suffer greatly due to the hydrophilic nature of the natural fiber. Certain chemical and physical methods are under experiment to overcome the barrier (Lalit et al. 2018).

Before processing reinforcement fibers, they must be modified to improve the interfacial bonding usually by improving the wettability of fibers and moisture absorption of fibers/matrix. Interfacial bonding between the reinforcement fibers

and the polymer matrix is improved by implying fiber modification techniques which can be chemical or physical methods (Syduzzaman et al. 2020).

When chemical treatment is done for surface modification of fibers it reduces the hydrophilic nature and increases the fiber-matrix interaction thereby improving the tensile properties of biocomposite (Aaliya et al. 2021).

Physical modifications of natural fibers include methods like stretching, calendaring, thermo treatment, and the production of hybrid yarns. These modifications help change structural and surface properties for improving mechanical bonding while keeping chemical composition intact. The interface is enhanced by an increase in mechanical bonding only (Faruk et al. 2012) (Table 6).

Chemical modifications of natural fibers are mainly done using chemicals like alkali, silane, acetyl, etc. In a chemical modification, the chemical used causes changes in the hydrophilicity of natural fibers by altering the hydrogen bonding, etc., and thereby increasing interfacial adhesion and other mechanical properties (Table 7).

Some of the future trends that should be focused to enhance natural fiber reinforced biopolymer development and their importance in the market are (Aaliya et al. 2021):

Standardized protocol development for composite preparation which will help in proper time management, energy and raw material optimization.

Developing optimized natural fibers by modification techniques for ensuring quality.

Novel investigational systems have to be designed to monitor and control factors like durability and biodegradability of natural fiber reinforced biopolymer composites.

Table 6 Physical modifications on some fiber and their improved property (Faruk et al. 2012)

Fiber	Physical modification method	Property improved
Hemp, flax	Corona treatment	Increased tensile strength and modulus
Flax	Plasma treatment	Increased stiffness
Jute	Plasma treatment	Increased interfacial adhesion

Table 7 Chemical modifications on some fiber and their improved property (Faruk et al. 2012)

Fiber	Chemical treatment	Property improved
Kenaf	Silane treatment	Increased strong modulus, reduced $\tan \delta$
Coir	Silane treatment	Increased tensile strength, modulus, hardness, etc.
Sisal	Alkali treatment	Improved compressive strength and water resistance and interfacial adhesion
Pineapple leaf	Alkali treatment	Improved mechanical properties
Ramie	Alkali treatment	Improved tensile strength
Jute	Alkali treatment	Improved flexural strength
Flax	Acetylation	Reduced moisture absorption
Abaca	Acetylation	Improved tensile strength, modulus, and impact strength

Structural applications for the construction industry need the development of load-bearing, long-term natural fiber reinforced biopolymer composite with remarkable strength and properties.

The reusability of composites is to be explored further as they can be used once again after proper processing.

The development of nanofibers from natural fibers for biocomposites should be explored for constructions as nanotechnology-based coatings help to increase water uptake, reduce biodegradation and volatile organic compounds and even flame resistance. They can improve performance, durability, value, service life, and utility while at the same time ensuring the quality of the material.

Conclusion

Millions of tons of waste generated by the construction sector is one of the prime reasons for environmental degradation. Land space is being consumed and landfills are getting depleted, water and air are being contaminated, and natural resources are overexploited. Globally there is an escalating demand for modern infrastructure and architecture that keeps this sector sourcing humungous quantities of construction raw materials.

Taking responsibility for their negative role in ecological disruption, engineers have resorted to recycling, or direct reuse of materials through integration into construction or as fill dirt.

The problem still is prominent and has to be dealt with at a different level which is biodegradable alternative construction material.

Natural fiber-reinforced biopolymer composite combines the advantages of both the materials and gives rise to a stronger alternative for construction. The biopolymer serves as the matrix for the reinforcement of natural fibers. The mainly used biopolymers for the purpose are PLA, Thermoplastic starch, CNSL, etc. Natural fiber may be of animal or plant origin, majority of research is done on plant fibers as they are available abundantly, and have less production cost, with comparable properties to the synthetic ones. Animal fiber is new to the list and has excellent properties needed for construction. Bird feathers, silk, etc., are commonly used. Silk shows excellent properties like tensile modulus as that steel. Hence, more research is to be done on animal fibers. Some of the products developed using these bio composites are roofing materials (e.g., Sisal-CNSL composites), building boards (coir composites), panels, doors, etc.

The topic is of great importance for the biopolymer sector, as the construction industry will meet its needs using biopolymer reinforced with natural fiber as they offer ease of availability, biodegradability, and strength comparable to synthetic counterparts and due to ever-increasing reliance of the construction industry on raw materials.

Natural fiber reinforced biopolymer possesses some limitations like durability, require treatment for increasing interfacial adhesion between natural fiber

(hydrophilic) and biopolymers (hydrophobic), photosensitivity against ultraviolet radiations and less flame resistance.

Future research is focused on developing techniques which can overcome the limitation and challenges impeding the advancement at present in the field. Developing natural fiber hybrids which can be reinforced with biopolymers for fabricating composites with supreme characteristics. Nanofibers from natural fibers have to be explored since they have comparable strength as that to steel and aluminum. So reinforcing nanofibers along with biopolymer will be more effective and feasible in future.

The future of the construction industry is going to be sustainable with the development of such alternative building materials.

Abstract

Polylactic acid (PLA) is an excellent biopolymer that can be synthesized from renewable resources. It is a thermoplastic polyester generated from starch, rice, and corn. The features of PLA such as renewable origin, easiness in composite formation, simplicity in processing, and recyclability make it an exceptional polymer in many commercial applications. Its biodegradability, biocompatibility, and bioabsorbability extend its interest in biomedicine. These properties also make PLA stand out as a good choice when environmental pollution is

concerned. These features assist the material in substituting conventional polymers in many fields of applications. The mechanical, thermal, and rheological properties of PLA create contributions to medical, food packaging, textile, and many other industries. Blending PLA with other biopolymers results in value-added composites that have features better than neat PLA. The chapter focuses on various properties of PLA and the latest developments in its applications in different fields.

Introduction

Traditional fossil-based plastics like polyvinyl chloride, polyethylene terephthalate, and polyethylene which have become an ubiquitous part of our daily lives are nonbiodegradable and persist in the environment for a long period of time, adding to the exponentially increasing carbon footprint (Agrawal 2010; Malinconico et al. 2018; Zheng and Suh 2019). The increasing demand for energy and decline of petroleum-based resources has forced researchers to look for bio-based, greener, sustainable, and more economic alternatives. Bio-based polymers are the front-runners in replacing petroleum-based ones which are marred by their severe economic, health, and environmental impacts (Chen and Yan 2020; Pellis et al. 2021; Sousa and Silvestre 2022).

Biopolymers are derived from natural resources. They are either biosynthesized entirely by living organisms or chemically synthesized from biological materials. A majority of the biopolymers can be degraded into nontoxic small molecules like water and carbon dioxide with the aid of microorganisms, making them an environment-friendly material (Aaliya et al. 2021; Baranwal et al. 2022; MacGregor 2003). Currently, bioplastics represent only a small-scale market compared with conventional plastics. However, the global market for bio-based polymers is expected to undergo significant growth in the coming years as a result of the increasing demand for greener materials and stringent regulatory policies on the use of nondegradable synthetic polymers (Masutani and Kimura 2017; Rodríguez et al. 2020; Song et al. 2018).

Among the biopolymers, PLA is touted to be the most promising and economically viable polymer and has received extensive attention from researchers in the past few decades. Attractive properties including biodegradability, biocompatibility, nontoxicity, thermoplasticity, high strength, high modulus, and good processability has made this polymer an ideal candidate in many areas of applications like biomedical devices, food packaging, disposable household items, and agricultural films (Ahmed and Varshney 2011; Lasprilla et al. 2012; Jandas et al. 2013a; Calcagnile et al. 2019; Liu et al. 2020a; Knoch et al. 2020; Boey et al. 2021). Innovations and developments in processing techniques of high molecular weight

polymers have led to the large-scale industrial production of PLA, which has brought down its cost to a great extent (Kühnert et al. 2018). An abundance of literature is available on the synthesis, properties, and applications of PLA. This chapter aims to present these results in a concise manner, with main focus on the applications of PLA in diverse fields.

Synthesis of Polylactic Acid

Poly(lactic acid) or polylactide (PLA) is a linear aliphatic thermoplastic polyester of lactic acid, which can be easily obtained by fermentation of renewable carbohydrate resources. Glucose, sucrose, lactose, maltose, and starch are the commonly utilized carbohydrates in lactic acid fermentation and are produced from feedstocks such as beet sugar, molasses, whey, and barley malt. Microbial fermentation is a frequently employed approach for the preparation of lactic acid. Fermentation temperatures vary, depending on the microorganisms utilized, but are normally between 30 and 60 °C with a pH of 5.0–6.5 (Masutani and Kimura 2018; Montané et al. 2020; Pretula et al. 2016).

The monomer, lactic acid, exists in two optically active configurations, D-lactic acid and L-lactic acid. Hence, PLA has several configurational isomers in which the D- and L-lactic acid units are present in different ratios and different sequences. Poly(L-lactic acid) (PLLA) and poly(D-lactic acid) (PDLA) are enantiomeric polymers that solely include L- and D-units, respectively, whereas poly(DL-lactic acid) (PDLLA) is a racemic polymer that contains a random sequence of both enantiomeric units (Fig. 1). Different grades of PLA with a wide range of properties can be prepared by varying the ratio of the D- and L-isomers (Averous 2008; Chan et al. 2018; Dorgan et al. 2000; Gupta et al. 2007; Rivero et al. 2017).

PLA was first synthesized by Theophile-Jules Pelouze in 1845 by condensation of lactic acid (Blukis 1992). Later, Wallace Hume Carothers et al. devised a technique for polymerizing lactide to generate PLA in 1932, which DuPont patented in 1954 (Carothers et al. 1932; Lunt 1998). PLA is currently approved for use in food and medical applications by the US Food and Drug Administration (FDA) and European regulatory authorities (Li et al. 2020; Singhvi et al. 2019).

PLAs can be synthesized by three different routes, viz., direct condensation polymerization, azeotropic dehydration condensation, and ring-opening polymerization (ROP) of lactide, as shown in Fig. 2 (Li et al. 2020; Masutani and Kimura 2018; Rivero et al. 2017).

Direct polycondensation of lactic acid is a two-step process in which first lactic acid undergoes self-esterification through a reversible step-growth mechanism to form low molecular weight oligomers (or prepolymers), which in a second step will form higher molecular weight polymers with the aid of chain-coupling agents (Balla et al. 2021; Masutani and Kimura 2014). Both these steps are reversible and require the removal of water, which is formed as a side-product, to shift the chemical equilibrium in the forward direction. The water removal which is a crucial step in this reaction becomes difficult with increase in the molecular weight and hence viscosity of the polymer. Hence, this method is more suitable for the preparation of low molecular weight PLA (Montané et al. 2020; Ren 2011; Södergård and Stolt 2010).

Azeotropic dehydration condensation is a modification of the direct polycondensation method wherein an azeotropic solution is used to increase the efficiency of water removal. This method was patented by Mitsui Toatsu Chemicals in 1994. In this method an organic solvent with a high boiling point is used as the azeotropic solvent which forces the removal of water and shifts the equilibrium in the direction of esterification. This is a single step process in which the equilibrium between the

Fig. 2 Synthesis of poly(lactic acid). (Reproduced from Rivero et al. 2017. Copyright © 2017 with permission from Elsevier)

monomer and polymer can be tuned by choosing appropriate organic solvent. PLA with comparatively high molecular weight can be synthesized by this method. The solvent selected in this method plays a key role in the polymerization conditions and properties of the final PLA product (Montané et al. 2020; Sabu et al. 2014; Södergård and Stolt 2010).

Ring-opening polymerization of cyclic lactide diesters is the most popular method used for the preparation of high molecular weight PLA on an industrial scale. As mentioned before this method was first reported in 1932 by W. H. Carothers. In this technique lactic acid is converted into low molecular weight prepolymer by condensation reaction, which in turn is converted into its cyclic dimer or lactide by controlled de-polymerization. The lactide after purification is allowed to undergo ring-opening polymerization to yield PLA with controlled molecular weight (Carothers et al. 1932; Montané et al. 2020; Södergård and Stolt 2010; Thongchul 2013). Different catalysts based on Al, Zn, Sn, Mg, Ca, Fe, Ti, Sm, Y, Lu, and Zr have been used for ring-opening polymerization, of which stannous octoate is the most extensively studied one because of its high catalytic efficiency (Ghalia and Dahman 2017; Jiménez et al. 2014; Stefaniak and Masek 2021; Toshikj et al. 2020). Ring-opening polymerization of the lactide can take place through three different mechanisms: cationic, anionic, and coordination insertion mechanism. The type of mechanism followed depends on the catalyst used (Masutani and Kimura 2014; Mehta et al. 2005; Stefaniak and Masek 2021). Complete discussion on the different ring-opening polymerization mechanisms is beyond the scope of this chapter and can be found in various reviews and books dedicated to synthesis of PLA (Masutani and Kimura 2018; Mehta et al. 2005; Södergård and Stolt 2010; Yao and Yang 2009).

Properties of Polylactic Acids

Thermal Properties

The degree of crystallinity determines many of the properties of PLA (Gawel and Kuciel 2020; Jiménez et al. 2014). PLA is a semicrystalline polymer with a glass transition temperature (T_g) of around 50 °C–80 °C and a melting temperature (T_m) of about 130 °C–180 °C (Ren 2011; Vouyiouka and Papaspyrides 2012). Different structural characteristics, such as molecular weights and composition (percentage of stereoisomers), could influence PLA's thermal performance (J Ahmed et al. 2009; Hamad et al. 2015). The impact of molecular weights and composition (L/D ratio) on the thermal characteristics of PLA polymers was studied by Dorgan et al. (Dorgan et al. 2000). They showed that the T_g value of PLAs varied with the number average molecular weight according to the Flory-Fox equation:

$$T_g = T^\infty - \frac{K}{M} \quad (1)$$

Fig. 3 Glass transition temperature of PLAs with different L/D ratios as a function of number-average molecular weights (M_n). (Reproduced from Dorgan et al. 1999. Copyright © 2005 with permission from AIP Publishing)

where T^∞ is the glass transition temperature at infinite molecular weight, M is the molecular weight, and K is a constant and is related to the free volume of the end groups for the polymer chains. Figure 3 shows the variation of glass transition temperature with change in composition and number-average molecular weight of PLA.

Several studies have shown that the crystallinity of PLA is determined by its optical purity. Differential scanning calorimetry is the most common method used for determining the crystallinity of PLA. The equation used for calculating the crystallinity $C[\%]$ of the polymer is given below:

$$C[\%] = \frac{\Delta H_m}{\Delta H_m^0} \quad (2)$$

where ΔH_m is the enthalpy of fusion of the studied sample and ΔH_m^0 is the enthalpy for 100% crystalline PLA samples, assuming that no cold crystallization takes place during the heating run. Otherwise, the cold-crystallization enthalpy should be subtracted from the melting enthalpy (Müller et al. 2015). Depending on the molecular weight and amount of L-, D-, or meso-lactide in the main chain, the polylactides can be either amorphous or semicrystalline at room temperature. PLA resins with a higher concentration of D-lactic acid show a lower tendency to crystallize (Hamad et al. 2015). Figure 4 DSC curves PLA films with different D-lactide contents. PLA film with 1.4% D-lactic acid exhibited the lowest cold crystallization temperature at 104.1 °C with a sharp and narrow exothermic peak. The films showed a lower tendency to crystallize on increasing the D-lactic acid

Fig. 4 DSC curves of the PLA films with different D-lactic acid contents. (Reproduced from Pölöskei et al. 2020)

content to 4.3% which is represented by a wide cold crystallization exothermic peak at 117.3 °C. PLA films with the highest D-lactic acid content (12%) did not show any tendency to crystallize (Pölöskei et al. 2020).

High molecular weight, on the other hand, can reduce the crystallization rate and thus the degree of crystallinity (Casalini et al. 2019; Jiménez et al. 2014; Müller et al. 2015). A decrease in percentage of L-lactic acid and increase in percentage of the D-isomer are observed to decrease the crystallinity of the polymer. The relationship between the T^∞ and the concentration of D-lactide (X_D) can be given by the following equation (Saeidlou et al. 2012):

$$T^\infty = \frac{13.36 + 1371.68 X_D}{0.22 + 24.3X_D + 0.42X_D^2} \quad (3)$$

Rheological Properties

The rheological properties of PLA and its blends and composites have been investigated extensively by different characterization techniques (Fang and Hanna 1999; Hamad et al. 2010, 2011, 2012; Huneault and Li 2007). Dorgan and co-workers investigated Schulz-Blaschke and Mark-Houwink constants for dilute PLA with 0–20% D-lactic acid and different chain lengths in solvents like chloroform,

tetrahydrofuran, and a mixture of acetonitrile and dichloromethane. Their findings showed that the relative percentage of the optical co-monomers in the PLA chain did not impact the fundamental rheological parameters. The viscosity of branched PLA was higher than that of linear PLA in the Newtonian range, which implies that PLA behaves as a linear polymer with random coil conformation in the tested solvents (Dorgan et al. 2000). Chile et al. studied PLA with controlled stereochemical configuration and concluded that only the isotactic chain of PLA developed higher viscosity than the other types of configurations (Chile et al. 2016). Kim et al. revealed that branched and starlike structures decreased the intrinsic viscosity of PLA compared with the linear polymer chain of equivalent molecular weight (Kim et al. 2004). The dependence of hydrodynamic radius on molecular weights in solvents like tetrahydrofuran has been investigated extensively by various authors. The values obtained were characteristic for random coil polymers in good solvent (Othman et al. 2011, 2012).

To understand the processability and flow during melt processes, study of the viscoelastic behavior as a function of temperature is useful. Due to the low thermal stability of PLA during rheological measurements, PLA often fails to comply with the time-temperature superposition principle. Palade et al. developed a method, now often employed, using tris(nonyl phenyl)phosphite (TNPP) as a stabilizer to suppress thermal hydrolysis of PLA. PLA exhibited Newtonian behavior at the low shear rates ($<10 \text{ s}^{-1}$), whereas it exhibited shear thinning at the high shear rates ($>10 \text{ s}^{-1}$) (Palade et al. 2001). Numerous studies have described the rheological behavior of PLA and indicated that PLA obeyed the power law over a certain range of shear rates and temperatures in the same way as other polymers. The tacticity of the macromolecules had some impact on the melt rheology, where isotactic PLA had a higher zero-shear viscosity and syndiotactic PLA had a lower zero shear viscosity than heterotactic PLA (Hamad et al. 2014; Saeidlou et al. 2012; Shin et al. 2010; Wang et al. 2011). The increase in melt viscosity can be achieved by stereocomplex technology. The connection between stereocomplexed domains could be varied from chain entanglement to direct molecular bridging by changing the content of stereocomplex (from 10 to 23%) (Ma et al. 2015).

Mechanical Properties

PLA has better mechanical properties, especially tensile elastic modulus and tensile and flexural strength, in comparison with conventional polymers like polystyrene or polyethylene. However, they have a low elongation at break and impact strength which limits their applications in areas requiring deformation at a higher stress (Farah et al. 2016; Hamad et al. 2015; Sanivada et al. 2020).

Mechanical properties of PLAs can be improved by plasticization, copolymerization, or blending with other biodegradable polymers (Cheng et al. 2009; Liu and Zhang 2011; Zou et al. 2021). It has been observed that the mechanical properties of PLA are to a great extent dependent on their molecular weight, stereochemistry, and crystallinity. Semicrystalline PLAs are shown to exhibit better mechanical properties

in comparison with their amorphous counterparts. Semicrystalline PLA has a tensile strength of ~50–70 MPa, a tensile modulus of 3–4 GPa, a 2–10% elongation at break, a flexural strength of 90–100 MPa, and a flexural modulus of 4–5 GPa (Farah et al. 2016; Ilyas et al. 2022; Perego and Cella 2010). Many researchers have looked into the relationship between PLA mechanical characteristics and its molecular weight. A 20% increase in tensile strength was observed by Engelberg and Kohn on increasing the Mw of the polymer from 107 to 550 Kg/mol (Engelberg and Kohn 1991). The variation in mechanical properties relative to molecular weight becomes less pronounced at higher molecular weight. PDLA and amorphous PLLA exhibited different tensile and flexural properties in a selected range of molecular weights, which can be attributed to the stereochemical makeup of the polymer backbone. Hence, by manipulating the molecular weight, stereochemistry, and crystallinity of PLA, one can tune the mechanical properties of PLAs from soft elastic materials to stiff, high-strength materials (Farah et al. 2016; Hamad et al. 2015; Perego and Cella 2010).

Biodegradation

Degradation of polymers generally occurs by scission of their main or side chains. This can be induced by hydrolysis, enzyme action, photolysis, oxidation, or thermal activation (Madhavan Nampoothiri et al. 2010; Zaaba and Jaafar 2020). Polymers containing hydrolytically unstable linkages like esters, anhydrides, or amides will undergo biodegradation (Saad and Suter 2001). PLAs contain ester linkages in their backbone and can undergo biodegradation. PLA biodegradation occurs in two stages: first hydrolysis of the ester bonds and then enzymatic breakdown of lower molecular weight fragments (lactic acid or water and carbon dioxide). The rate of hydrolytic breakdown is mostly determined by temperature, pH, and humidity (Rudnik 2013; Siakeng et al. 2019; da Silva et al. 2018; Tokiwa and Calabia 2006). Degradation of PLAs under natural conditions has not been successful. Soil burial tests of PLLA showed that they were not degraded even after three years (Calabia et al. 2010). A study by Tsuji and co-workers showed that blended films of PLLA and poly(ϵ -caprolactone) had better biodegradability than the neat polymer itself (Tsuji et al. 1998). Several investigations have shown that biodegradability of PLAs can be improved by mixing them with natural materials like cellulose and starch (Cheung et al. 2010; Kalita et al. 2021; Wan Ishak et al. 2020; Yu et al. 2020). Brdlik et al. demonstrated the improvement in biodegradability of PLA on incorporating natural-based plasticizers like acetyl tributyl citrate (ATBC), CaCO_3 , and lignin-coated cellulose nanocrystals (L-CNC) into the polymer. Figure 5 shows SEM images of the surfaces of neat PLA film and PLA films with different additives after processing and after three months of biodegradation (Brdlik et al. 2021). The surface of the neat PLA films was relatively smooth, with a small number of cavities. PLA films with plasticizer, on the other hand, had a rough surface with many eroded pinholes which is an indication of higher biodegradation rates of these films compared to a pure PLA film.

The slow degradation rate of PLA under natural conditions is due to the low population of microorganisms capable of degrading PLA in the environment

Fig. 5 SEM images of (a) neat PLA film after processing, (b) neat PLA film after biodegradation, (c) PLA/ATBC film after processing, (d) PLA/ATBC film after biodegradation, (e) PLA/ATBC/L-CNC film after processing, (f) PLA/ATBC/L-CNC film after biodegradation, (g) PLA/ATBC/CaCO₃ film after processing, and (h) PLA/ATBC/CaCO₃ film after biodegradation. (Reproduced from Brdlik et al. 2021)

(Tokiwa and Calabia 2006). Nevertheless, degradation of PLAs can be achieved by different microorganisms under controlled conditions. PLAs degrade within a period of a few weeks to months in a compost, where the temperature and humidity are high (Calabia et al. 2010; Ho et al. 1999; Satti et al. 2018). *Amycolatopsis*, *Lentzea*, *Kibdelosporangium*, and *Saccharothrix* are some of the microorganisms which are capable of degrading PLAs (Jarerat et al. 2002; Sukkhum 2011). Several enzymes, including pronase, esterases, and bromelain, have been used to study their effect on PLLA degradation rate. Among these, proteinase K which is isolated from *T. album* Limber has been shown to significantly accelerate the degradation rate of PLLA (Lee et al. 2014; Sukkhum 2011; Tokiwa et al. 2009; Williams 1981). Degradation studies of PLA are of particular interest due to their applicability in the medical field to make drug delivery vehicles, implants, or surgical sutures (Baranwal et al. 2022; Calabia et al. 2010; Saad and Suter 2001).

Applications of PLA

PLA is called the “polymer of the twenty-first century” owing to its multifunctional properties. As discussed in the previous sections of this chapter, PLA is a bio-based polymer derived from renewable resources like corn, sugar cane, rice, wheat, and other starch-rich products. The FDA has approved PLA for direct contact with biological fluids. PLA on degradation gives lactic acid which is naturally present in our body and hence is compatible. Biocompatibility and bioresorbability are two qualities of PLAs which have made them popular in the healthcare sector to make active packaging materials, tissue engineering scaffolds, drug delivery vehicles, medical implants, and medical instruments. PLA is also in demand in other industrial sectors like automotive, textile, and agriculture due to its relatively low production cost and commercial availability compared to other biopolymers. PLAs can be used to prepare breathable, lightweight, recyclable fabrics. Moreover, PLA fibers have good UV resistance, inherent biological resistance, and good anti-flame property. It is the only bio-based biodegradable polymer which can be melt-spun into strong textile fibers on a large scale (Yang et al. 2020). They also have gained interest in the packaging industry to make compostable eco-friendly packaging materials. PLA exists in a glassy state at room temperature which prevents the movement of large molecules through the polymer matrix. Hence, PLA materials are excellent barriers to aroma, flavor, or other large molecules. Thus, PLA packaging can protect the product inside from extrinsic elements like moisture, unwanted odors, and other contaminants. It also prevents the odor or flavor molecules of the product to escape the package, thereby keeping the product fresh (Whiteman et al. 2001). PLA-based products have several advantages such as good thermomechanical properties, durability, corrosion resistance, lightweight, ease of processability using existing techniques (injection molding, extrusion), and relatively low cost. As a result, PLA plastics are becoming more appealing for long-lasting applications such as electrical, electronic, and automotive products, as well as mechanical components that require high-performance materials with low environmental impact.

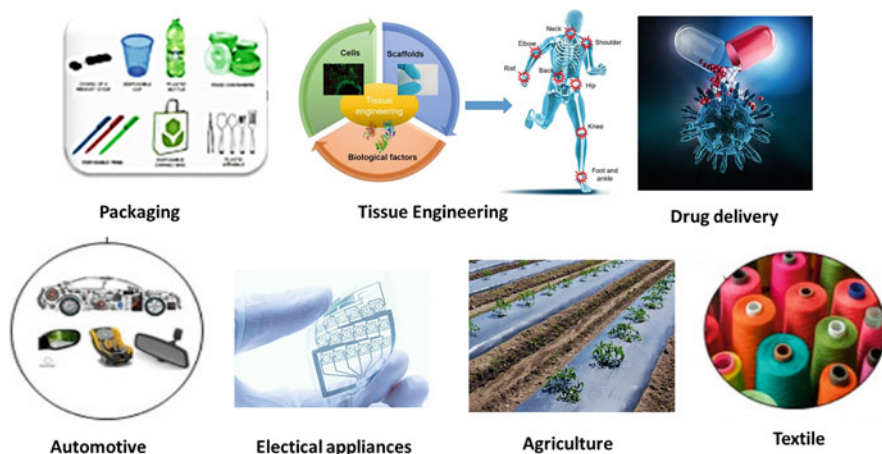

Fig. 6 Various applications of PLA

In many research works, PLA is blended with other biopolymers or composites to attain the desired features. It can be formulated to be both rigid and flexible to suit different applications. Both physical and chemical features of PLAs may be further enhanced by surface modification. The following sections cover the applications in tissue engineering, drug delivery, and so on. Figure 6 gives the various applications of PLA.

Biomedical Industry

Biomedical industry demands biocompatible materials for numerous applications. Nowadays, traditional biocompatible materials are substituted by biopolymers in many fields. In addition to biocompatibility, biodegradability of these biopolymers is also a significant feature that attracts researchers to use them in biomedical devices. PLA is an important polymer possessing these properties. Degradation of these biopolymers results in nontoxic products that can be easily eliminated from the body by means of usual cellular functions (Uzun et al. 2015). Bioabsorbability of PLA is also highly advantageous when used in fixation devices as dissolvable suture meshes. It can overcome many of the limitations of metallic implants. During bone implants and scaffoldings, a second surgery can be avoided by the usage of bioabsorbable polymer such as PLA as the implant material. A gradual recovery by the regeneration of the tissues is possible along with the degradation of the device.

Tissue Engineering

Tissue engineering is an interdisciplinary field that finds a solution to organ failure and tissue loss. It aims at restoring injured tissues, thereby improving their functions. Earlier, metals have been used as implants and in regenerative medicine. But the usage

of metals is limited due to their lack of biodegradability. These metals are nowadays replaced with biopolymers, which offer better biodegradability and biocompatibility.

Cell proliferation and growth demand temporary support known as a scaffold or template. When cell growth and regeneration happen, the scaffold slowly degrades along with the development of the new tissue. Current research suggests that biomaterials are an important choice to act as scaffolds. Easy processing, cell adhesion, porosity, biocompatibility, and biodegradability are the major characteristics for a biomaterial to act as an excellent scaffold. Such scaffolds should never induce any inflammatory or cytotoxic responses in the body (Monnier et al. 2018). Also, degradation products should be easily metabolized and removed from the body. The mechanical properties of the scaffold should be similar to those of the restored tissue. Biomimetic structures can be successfully fabricated by 3D printing. It is a promising technology through which bone regeneration can be achieved. Synthetic polymers have been widely chosen for 3D printing owing to their excellent mechanical properties and easiness in fabrication. In the case of the synthetic polymer PLA, ductility and toughness may be enhanced by copolymerization and the formation of nanocomposites. Many research works have been proposed to generate scaffolds for bone tissue engineering by the copolymerization of PLA with hydroxy apatite, polyethylene glycol, and so on. Such copolymerization enhances the mechanical properties, which is highly beneficial in the case of tissue regeneration. Along with good mechanical properties, bioactivity is also essential in generating new tissues. It can be achieved by surface modification of the polymer by proteins or peptides, DNA molecules, and so on. As a result, cell adhesion and proliferation can also be enhanced. In a recent work, bone-regenerating 3D scaffolds were prepared from PLA and gelatin with mucic acid. It was found that the physicochemical properties were improved compared to the neat synthetic polymer. The viability of mouse mesenchymal stem cells remained unaffected when seeded onto this PLA/gelatin/mucic acid scaffold. This proved that the 3D printed PLA scaffolds coated with gelatin and mucic acid have potential applications in bone tissue engineering (Velioglu et al. 2019).

3D printing is a brilliant methodology to fabricate macro- and microporous structures from polymers, metals, and ceramics. Among 3D printing techniques, fused deposition modeling is a prominent one for fabricating scaffolds. Bone tissue engineering is a complicated process since many factors such as pore size, shape, mechanical properties, biocompatibility, and biodegradability are taken into consideration during regeneration. Fused deposition modeling is utilized to develop PLA scaffolds containing polydopamine and collagen I. In the synthetic method, PLA scaffolds are dipped in dopamine solution followed by the conjugation of polydopamine. When polydopamine is coated, it assisted in the coupling of collagen onto the PLA scaffolds. High cell density on the scaffold controlled the level of F-actin cytoskeleton and vinculin adhesive plaques (Teixeira et al. 2019). A similar work was done by Ritz et al. by developing PLA scaffolds loaded with collagen I and stromal-derived factor-1 by means of fused deposition modeling. It produced both disc-like and cage-like scaffolds, and they could promote endothelial cell growth. The results prove that these scaffolds have potential applications in bone tissue

engineering (Ritz et al. 2017). The same synthetic method was used by Oladapo et al. to prepare the PLA/hydroxyapatite composite. These scaffolds possess a cylindrical shape that mimics the architecture and structure of the bone. Also, the ability of bone regeneration and bioactivity can be enhanced by the incorporation of hydroxyapatite in PLA (Oladapo et al. 2019). In another work, phenylenediamine functionalized carbon dots were composited with silk fibroin and PLA to obtain bioactive scaffolds. A uniform distribution of carbon dots was obtained, which improved mechanical, physical, and chemical properties. These nanofibrous porous scaffolds displayed an improvement in young modulus and good efficiency in implantation. These prepared scaffolds were implanted into rat cardiomyocytes, and the cell viability was significantly improved when made into a composite with carbon dots. This proves its potential to act as well organized scaffolds for cardiac tissue engineering (Yan et al. 2020).

Scaffolds prepared from nanofibers of PLA have been widely used in regenerative medicine. The high surface area, ability to mimic living cell architecture, and tunable mechanical properties of these scaffolds offer a design apt for tissue regeneration in the body. PLA is often opted for tissue regeneration since it has good thermal processability (Farah et al. 2016). But the brittleness of PLA is an important drawback to be considered. Modification of PLA may be performed to improve chemical inertness, hydrophilicity, degradation rate, and toughness. PLA nanofibers act as potential scaffolds for nervous, cutaneous, cardiovascular, and musculoskeletal tissue engineering. The most significant factor in the construction of scaffolds is cell adhesion. To improve mechanical properties and cell adhesion, scaffolds have been fabricated by different methods such as melt mixing, leaching, electrospinning, and so on. Blending with different polymers and composite formation also modify the properties. For bone tissue engineering, 3D printing is considered as a recent procedure to develop a porous scaffold (Roseti et al. 2017). Such scaffolds could provide strong osteoinduction activity and fast vascularization. In bone tissue engineering, it is very essential that the engineered bone must integrate completely with the native bone and surrounding environment. The lack of such integration may lead to many complications in physiological functioning. Implantation of such a biomaterial may not be able to achieve the expected result of tissue regeneration and immune response. An excellent result was observed when PLA was blended with hydroxyapatite. In this case, each component in the blend affects the features of the other components (Bae et al. 2011).

Mechanical properties, porosity, biodegradability, and bioactivity influence the quality of a scaffold. PLA/calcium phosphate composites have been prepared to integrate into host tissues, and it was seen that these porous scaffolds can be successfully utilized for the proliferation of osteoblasts. This modified scaffold could bring about a better cell adhesion as the pure PLA offers a poor adhesion to the cells. In addition, porosity also improved to 97% from 93%. These composites established superior mechanical properties when compared with the pure PLA scaffold. Hassanajili et al. proposed an indirect 3D printing to fabricate bone scaffolds using PLA/PCL/HA composite. The porosity of the scaffold was found to be 77%, and the mechanical properties were comparable with the normal tissue. The

in vitro studies on the osteoblast cells found that the excellent cell adhesion, as well as cell proliferation of the scaffold, makes it a potential candidate for bone tissue engineering (Hassanajili et al. 2019). Figure 7 shows the demonstration of PLA/PCL/HA scaffold for osteoblast cells.

In a recent work, the electrospinning technique was used to prepare zeolite-hydroxyapatite blended PLA/PCL nanofibers for dental tissue engineering. Ring-opening method was used for PLA/PCL polymerization, and zeolite and hydroxyapatite were prepared via hydrothermal synthesis. Cell viability was tested by the MTT assay, and it was seen that blended nanofibers act as potential scaffolds for dental tissue regeneration (Mohandesnezhad et al. 2020). Figure 8 demonstrates the electrospinning method for the preparation of nanofibers from zeolite-nHA blended PCL/PLA for dental tissue engineering.

Table 1 shows various PLA scaffolds for tissue engineering. The aim of tissue engineering is to develop scaffolds for the regeneration of damaged tissues. Recent studies prove that nanofibers are well suited to form porous structures that can provide mechanical support as well as mimic the normal tissue. PLA is a synthetic polyester, and its degradation rate can be altered by changing the structure, porosity, molecular weight, viscosity, and crystallinity. PLA and its blends and composites have been widely studied for various types of tissue engineering.

Drug Delivery

The efficiency of a drug is mainly assessed by the responses given by the body after its administration. Bioactive carriers are usually chosen as drug delivery system, and PLA is a good choice owing to its features. Degradation rate is also a determining factor in the case of drug delivery systems. The desired effect can be obtained by altering the degradation rate. For a constant, timely, and continuous release of the drug, the rate of breakdown of the drug carrier plays a prominent role. In some cases, this drug release should be prolonged for a sustainable drug release. Such a drug release assists in providing sufficient time so that the expected result may be obtained. Also, in some cases, targeted drug delivery at some specific sites is essential for the better action.

Polymeric nanofibers are widely used for many biomedical purposes among which the encapsulation of antitumor drugs for drug delivery applications covers a major area. Polymers possessing stimuli-responsive abilities and biocompatibility are well suited for this purpose. PLA is an excellent material because of its good biodegradability and dissolution in the extracellular environment. The FDA (US Food and Drug Administration) has approved the usage of PLA as a biomaterial (Liu et al. 2020b). PLA scaffolds possess nanofibers of variable pore diameter, which permits the delivery of different types of drugs. A controlled drug release is also possible by this characteristic nature (Martin et al. 2019).

Electrospinning is a widely accepted technique to obtain nanofibers from polymeric materials. Electrospinning always produces fine fibers with a large surface area, which assists in improving the properties. It can be used to produce nanofibers with a high surface-area-to-volume ratio which supports efficient drug delivery. Before loading the drug into the polymeric material, dissolution should be tested. Drug can be dissolved directly, if both the polymer and drug are soluble in the same solvent. Otherwise, another solvent is used for solubilizing the drug. Drug-releasing mechanism proceeds via desorption of drug from the surface of nanofiber. Nanofiber diameter, morphology, and porosity are the different parameters regulating the drug-release kinetics (Fig. 9).

The design of nanofiber-assisted drug release systems depends on both the nature of the drug and the purpose of drug delivery. Such a delivery mechanism can be either by immobilization on the nanofiber surface or through encapsulation. Figure 10 depicts these two mechanisms of drug delivery. The quantity of drug release depends on various factors such as the interaction between the drug and the carrier, nanofiber diameter, and the drug content (Cheng et al. 2018). In a recent study, polylactic acid-hydroxyapatite-doxycycline nanofibers obtained via electrospinning have been used as the drug carrier. Drug-releasing abilities were tested in phosphate buffer solution and simulated body fluid. In vitro drug release analysis and its kinetics confirmed that 3 and 7% of the drug-loaded samples obtained via physical adsorption are acceptable systems for prolonged release of drugs (Farkas et al. 2022).

It is significant to note the physicochemical processes that affect the drug release rate and steps in the release mechanism before developing a drug carrier. The various ways of drug release may happen while passage through the polymer, water-filled pores, or by dissolving in the encapsulated polymer. In the case of PLA, water-filled pores are the most convenient way. Various mechanisms

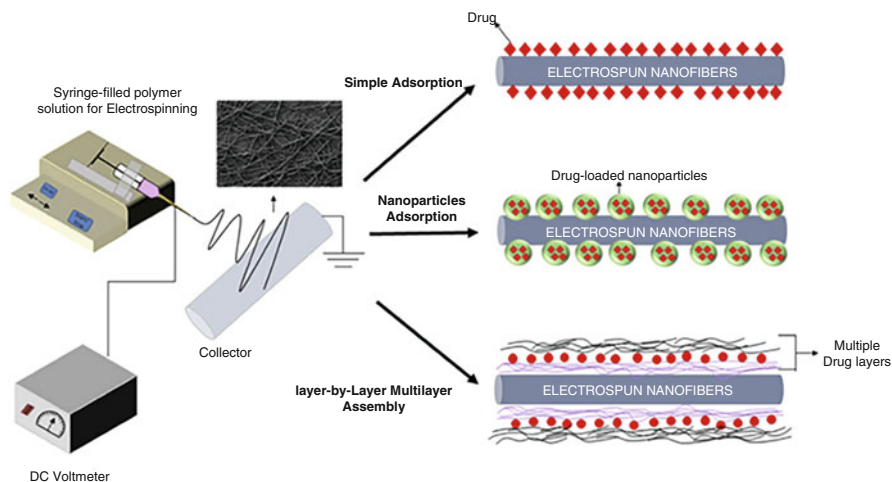

Fig. 9 Electrospun nanofibers for drug delivery. (Reprinted with permission from Stack et al. 2018)

Fig. 10 Two different routes of drug loading. (Reprinted with permission from Farkas et al. 2022)

involved are diffusion from the surface and diffusion of particles at the time of degradation of the polymer, through swelling of matrix. These mechanisms are depicted in Fig. 11.

Packaging

Plastics have been considered as the chief source of packaging material for decades, and synthetic plastics are heavily consumed by the packaging industry. But these packaging materials leave a bulk amount of waste which pollutes the environment,

Fig. 11 Mechanisms of drug release. (Reprinted with permission from Vlachopoulos et al. 2022)

and now it's a real threat to the existence of life. So, it is a necessity to replace conventional plastics with biodegradable materials that can function as packing materials. Biopolymers are a good choice of green materials which can serve the purpose. Among these biopolymers, PLA is a well attracted one, but some disadvantages limit its performance. Fast hydrolytic degradation is one such drawbacks which limits its application as a food packaging material. It is important to improve the barrier properties against moisture while acting as a packing material. To enhance the barrier properties, several methods may be adopted. Coating of biopolymer with materials which improve hydrophobicity is a method to overcome the issue. But these drawbacks can be successfully nullified by blending PLA with natural fillers making composites. PLA-polyethylene glycol and PLA-polycaprolactone blends are some examples.

While used as food packaging materials, in addition to biodegradability, both flexibility and hardness are significant parameters for excellent handling. In the form of film or food tray, the packaging material should ensure sealability. PLA and its blends are well known to be used as food tray and packaging films as they possess the abovementioned features. Technological parameters should be optimized to regulate the processing features and are varied according to their applicability. Figure 12 shows the various steps for obtaining food packaging system from biopolymers.

Automotive Applications of PLA

Plastic materials cover a major portion of automotive applications, and currently, composites of synthetic polymers are in high demand in this sector on account of the reduction of vehicle weight upon their usage. Composites containing organic fillers are found to be easy to recycle. Hence, environmental concerns also favor the utilization of such bioplastics and their composites. Recently, natural fibers are composited with polymers like PLA to attain a biodegradable matrix for use as automobile parts. In such cases, measures have to be taken to enhance the interfacial adhesion between fiber and polymer matrix to achieve the best results. Ductility and

Fig. 12 Steps for obtaining food packaging system from biopolymers and blends (Darie-Niță et al. 2021)

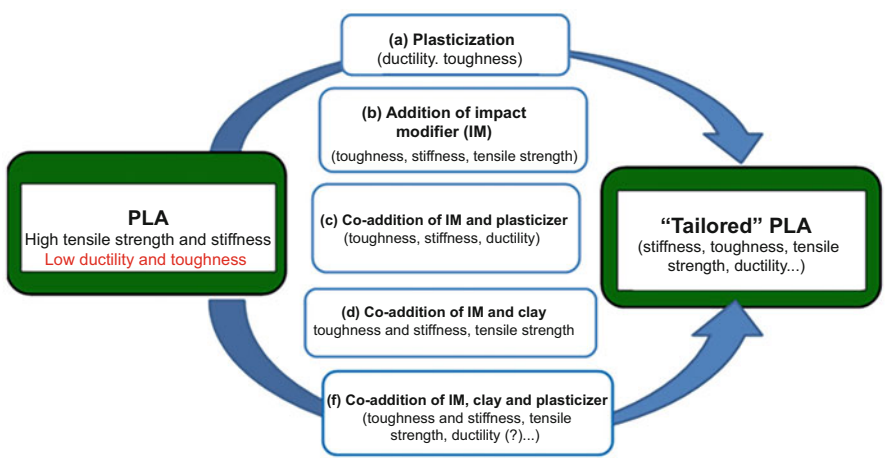

Fig. 13 Tuning PLA features for automotive applications

toughness also need to be improved, which is generally attained by plasticization (Balieu et al. 2013). Among the various plasticizers, those with good mobility and high molecular weight are usually preferred. As seen in Fig. 13, different methods may be adopted to enrich the properties of neat PLA.

Textile

PLA being biodegradable, it finds many applications in textile industry. The degradation process is also comparatively easy as it needs only cleavage of ester linkage.

Even though it is biodegradable, mechanical properties are comparable to plastics. It can be molded into decided shapes with a variety of features, as in the case of other plastics. Other parameters such as renewable origin, recycling possibilities, and ease of melting also make PLA an acceptable material in the textile industry. Thermal stability and resistance to shrinkage during ironing were also found to be highly advantageous while PLA stereocomplexes were formed. Another property is its comfort, as in the case of other natural fibers like silk, cotton, and so on. These properties make PLA fibers excel in various textile applications.

Spinning can be done to process PLA into fibers. Organic compounds can be absorbed easily, and this property can be utilized in fiber applications. It also has the ability to absorb moisture due to its polar nature, which makes it a good candidate for wiping applications. Potential wicking features of PLA can be used to generate disposable products. These properties of PLA increase its use in the textile industry, and nowadays it replaces many of the synthetic polymers such as polyethylene terephthalate and nylon. The use of PLA-cotton blends is wide in garment industries, and it is found that its buffering ability to sweat and thermal insulating properties enhance its usage in sports. Good resiliency of PLA is utilized in the manufacture of jackets also. Good crimp and retention features of PLA make it suitable for embroidered fabrics. PLA also finds applications in homeware products such as pillowcases and curtains. These significant features of PLA prove its potential in textile and fiber applications. Dyeing processes are done by varying different parameters such as pH, temperature, and time. It is a challenge to attain the suitable temperature in finishing as PLA is easily susceptible to degradation. Another limitation of PLA textiles is that their ironing temperature is comparatively lower than conventional textiles like cotton.

Some PLA composites were fabricated to enhance productivity and reduce waste to obtain some tailored products in textile industry. For instance, carbon black and carbon nanotube are composited with PLA to improve the adhesion properties for fabricating functional fabrics. In many works, 3D printing is done to develop such products. In such synthetic procedures, the various parameters of 3D printing, such as printing speed and temperature, influence the adhesion strength. Comfort and durability of a textile manufactured from polymeric composite materials are the major challenges during 3D printing. In a work, 3D printing was adopted to obtain PLA-carbon deposited into polyethylene terephthalate. The results show that tensile properties were affected during composite formation due to diffusion of the polymer, and that in turn led to a weak adhesion.

Agriculture

The use of flexible plastic films in the agriculture sector has increased immensely in the past few decades. Plastics like polypropylene and ethylene-vinyl acetate copolymer have been widely employed as greenhouse films, mulch films, silage films, stretch films, etc. This has helped the farmers in improving their crop quality, obtaining higher yields, minimizing water consumption, and reducing their ecological footprint (Rocha et al. 2018). According to a report by Sintim and Flury, plastic

mulch films accounted for approximately 40% of the total plastic films used in agriculture (Sintim and Flury 2017). Plastic mulch helps to conserve soil moisture, reduces the loss of minerals, improves fertility of the soil, minimizes weed growth, protects the plants from insect attack, and keeps the fruits and vegetables clean. However, the incorrect post-use disposal of these nonbiodegradable plastic films poses a serious threat to the environment. Biodegradable mulch films are a superior alternative to plastic mulch films and can be discarded into the soil to be degraded by the action of microorganisms. This eliminates the cost and labor associated with the removal and disposal of plastic mulch and is safer for the environment. PLA, which can be composted without leaving any harmful residues in the soil, is a good option to prepare mulch films. PLA is blended with other polymers or fillers to improve their flexibility, and these blends are more suited for agricultural applications than virgin PLA. PLA-based plastic films can also be used to manufacture biodegradable sandbags, weed prevention nets, vegetation nets and pots, etc. (Malinconico et al. 2018; Rocha et al. 2018).

Jandas et al. reported the preparation of completely biodegradable agricultural mulch film made from PLA/poly(hydroxybutyrate) blend with maleic anhydride as the reactive compatibilizer. Flexibility and impact modification were considerably enhanced by the addition of poly(hydroxybutyrate) and maleic anhydride. The films were reinforced with nano-clays to improve their tensile strength and tensile modulus without affecting their ductility. These films also showed an increased rate of biodegradation compared to virgin PLA. Environmental sustainability studies as well as mechanical testing showed that these films could be used for short-term crops that can be completed within around 100–150 days (Jandas et al. 2013b).

Calcagnile and co-workers developed a completely biodegradable composite material from PLA and cellulose-based super-absorbing hydrogel. This material is capable of acting as a source of water and fertilizers and can release them into the soil in a controlled manner. This allows for more efficient management of water and fertilizer and causes less chemical damage to the plants (Calcagnile et al. 2019). Durpekova et al. also reported a similar super-absorbing hydrogel prepared by blending low molecular weight PLA, acid whey, and cellulose derivatives, which could be employed as a reservoir of water and nutritive whey agents for crops and also for measured release of fertilizers (Durpekova et al. 2022).

Paschoalin et al. developed a wearable electrochemical sensor based on PLA for the detection of bipyridinium and carbamate pesticides on the surface of food and agricultural samples. This economic device consists of a three-electrode system which is deposited on solution-blow spinning mats of PLA by screen-printing technology. The flexibility of these sensors allows them to be on flat, curved, and irregular surfaces of leaves, fruits, and vegetables. The researchers could attain a detection limit of 57 nM and 43 nM for diquat and carbendazim, respectively, using this device. This sensor could also differentiate and measure the amount of carbendazim and diquat on cabbage and apple skins without any interference from other pesticides (Paschoalin et al. 2022).

Crop mulching promotes root development by promoting soil warming. This process reduces the usage of herbicides and improves production quality. In

traditional agricultural methodologies, low-density polyethylene is used as mulching materials. The good mechanical and optical properties of these conventional materials enhance the growth of agricultural crops. But, when environmental sustainability is concerned, the exceptional mechanical properties and long life of these mulching materials pose a threat. Various climate agents spread these materials to different locations, and these residues may in turn cause contamination of the soil. Poor agricultural methods and repeated use of these mulching agents cause adverse effect on the environment. Hence, it was a necessity to replace these conventional mulching agents with some biodegradable materials in a reliable method. Degradation of a mulching agent which should be done in a fast time is the solution to the problem. In such a case, it is possible to rely on biodegradable PLA and its derivatives to avoid such issues. Complete degradation of PLA films is possible by the activity of soil bacteria if there is moisture content in the soil.

Electronic Appliances

The upgradation of electronic devices at a very fast pace is resulting in a huge accumulation of electronic waste. The use of plastic materials for preparing lightweight flexible electronics is adding up to this crisis. Developing greener electronic devices using degradable polymers is a solution to this problem. Among bio-based polymers, PLAs are potential candidates for the manufacture of electronic appliances (Shi et al. 2017). However, reports on the use of PLA for making electronic devices are limited in the literature. This may be due to their low glass transition temperature, brittleness, low impact strength, low heat resistance, and unsatisfactory dielectric properties. Properties of PLA can be altered through orientation and annealing. This increases the crystallinity, mechanical performance (increased strength, stiffness, and ductility under tension), and thermal stability of PLA films. Addition of nucleating agents such as microcellulose, talc, and nanocomposites can also enhance the mechanical strength and crystallinity of PLA (Luoma et al. 2021). The heat resistance of PLA can be increased by blending with resins having a higher thermal resistance like acrylonitrile butadiene styrene (ABS) and polycarbonate (PC). Integration of glass fiber, plant fiber, and inorganic filler particles into the PLA matrix or the use of stereocomplex of PDLA and PLLA can also improve the thermal resistance of PLA. The effects of metal hydroxides and phosphorus reagents on the flame-retardant property of PLA have also been investigated (Obuchi and Ogawa 2010).

Some major companies have adopted PLA as parts of their electronic gadgets. For example, Sony used the injection-molding technique to make the casing of its Walkman in 2001. Sanyo Marwick Media manufactured CD/DVD discs and cases made of PLA. Toshiba and Samsung used PLA for their remote control and phone chassis. Fuji Xerox successfully used PLA-based interior drum cover for several copying machines in 2007. PLA was used by Fujitsu and PEGA for the hard shell case of their notebooks (Obuchi and Ogawa 2010).

Recently, Luoma et al. studied the performance of the different grades of PLA films in printed electronics processing. They observed that orientation and annealing

increased the crystallinity of the PLA films and enhanced their mechanical and thermal properties. These PLA films were used as eco-sustainable substrates for functional light-emitting diode foils with screen-printed silver conductors and die-bonded LED chips (Luoma et al. 2021).

Utilizing the flexibility, biocompatibility, and biodegradability of their own PLA, Prontera et al. showed that it is possible to produce optoelectronic devices on PLA layers. The PLA substrates prepared by melt extrusion showed ~90% optical transmittance in the visible region and 12 nm surface roughness, which are suitable parameters for OLED applications. Using hybrid technology, various structures were created on top of the PLA substrates using solution-based and thermal evaporation deposition techniques. Biocompatibility assays of the devices prepared showed that PLA is a strong contender for making bioelectronic devices (Prontera et al. 2022).

Carbon nanotube-loaded poly(lactic acid)/ethylene-vinyl acetate copolymer blends were used to make broadband microwave absorbing materials by Soares and co-workers. These composites showed excellent microwave absorption properties and a wide absorption bandwidth at low concentrations of carbon nanotubes and can be considered as potential candidates for flexible materials suitable for shielding electronic devices in wide frequency ranges (Lopes Pereira et al. 2022).

Sensing

Piezoelectric materials can generate electric charges on the surface when subjected to pressure or strain, converting mechanical energy into electrical energy making them attractive for sensing applications. Polymers with piezoelectric properties have the advantage of being lightweight, transparent, and flexible and can be used for the preparation of thin films. Semicrystalline PLLA and PDLA exhibit piezoelectricity when the polymer chains are highly oriented by the drawing process. Among these, PLLA is the more popularly researched stereoisomer. Racemic PDLA, which is amorphous, does not show piezoelectric effect. PLA has an inherent chiral molecular conformation which has different optical properties for each substituent group. The coordinated motion of the permanent dipoles present on the helical chain molecules of PLLA is the source and main reason for its piezoelectricity. When a shear stress is applied to the chain molecules in PLLA with a 10/3 helical structure through its methyl groups, it causes the displacement of all the atoms present in the chain. In particular, C=O bonds with large dipole moment will rotate, which changes the polarization of the entire long-chain molecule, generating the shear piezoelectricity of PLLA. PLLA and PDLA have helical structures due to the presence of chiral carbon. PLLA has left-handed helical structure, and PDLA has right-handed helical structure. As the helical structures of PDLA and PLLA have oppositely oriented clockwise and counterclockwise spirals, respectively, their piezoelectric constants have the opposite sign. Unlike poly(vinylidene fluoride), another popular piezoelectric polymer, PLLA does not exhibit pyroelectricity (ability to generate a temporary voltage on heating or cooling) (Tajitsu 2017).

Piezoelectric elements are key components of human-machine interfaces (HMIs) in new smart devices. A requirement for these materials is that they should not exhibit pyroelectricity. It is impossible to tell whether the signal comes from the pressure or the heat of the operator's hand if a piezoelectric sensor material displays pyroelectricity since it can instantly detect heat from a finger when it is used as an HMI. PLLA does not have intrinsic polarization, and hence it does not show pyroelectricity, and therefore it finds a place in developing HMIs. PLLA films also have a larger shear piezoelectric constant (~ 10 pC/N) compared to other polymers. Hence, they can sense bending and twisting motions with satisfactory sensitivity. If this unique function is utilized, PLLA can be used in sensor applications to allow intuitive control in HMI. Taking advantage of this special function, Murata Manufacturing and Mitsui Chemicals Inc. developed a TV remote control that combined a PLLA sensor with radio and power supply circuits, which could be controlled by the user's motion. The dye-sensitizing-type photoelectric cell fitted in this remote control produced enough electric power due to the high transparency of PLLA. The extra electric power generated by the photoelectric cell could be stored in a capacitor eliminating the need for batteries (Ando et al. 2012).

Murata Manufacturing Co., Ltd., also utilized piezoelectric PLLA films for designing piezoelectric PLLA fabrics having a strong antibacterial effect. This fabric is made of left-handed PLLA helical yarn (S-yarn) and right-handed PLLA helical yarn (Z-yarn). Application of stress on the fabric generates a strong electric field between the yarns which is caused by the reversal of the electric polarity of the yarns. The strong electric field resulting from the extension and contraction of the fabric is the reason for its antibacterial activity (Ando et al. 2017).

Wang et al. developed a visualized tactile sensing electronic skin (VTSES) made of poly(vinylidene fluoride-trifluoroethylene)/thin-film transistor/PLLA arrays. This device can detect static contact, dynamic force, and thermal transduction. The piezoelectric PLLA component of this device enables dynamic slide detection (Wang et al. 2022).

Dahiya and co-workers reported a wireless pressure sensing bandage based on inductor-capacitor resonant tank. This resonant tank is screen printed on piezoelectric PLLA nanofiber substrate which is connected in parallel with a planar inductor forming a LC circuit. The PLLA component provides a better conformal contact with the skin and increases sensitivity under the pressure due to its piezoelectric property. These smart bandages can be used for fast wound healing which is facilitated by the electroceutical arrangement due to piezoelectric PLLA substrate (Nikbakhtnasrabadi et al. 2022).

Conclusion

This chapter summarizes the properties and various applications in different fields. It is a promising candidate in many biomedical or industrial applications. Biodegradable, biocompatible, and bioabsorbable polymers have always attracted the attention of current researchers. Neat PLA and its blends and composites with its low cost and

excellent biocompatibility find applications in biomedical as well as packaging industry. It was observed that biomedical industry is the major area of research utilizing the features of PLA. Among the biomedical applications, tissue engineering is considered as the prominent one since PLA composites can be conveniently used to produce specific biodegradable body parts. It is expected that PLA composites will substitute conventional scaffolds in the near future. PLA and its composites owing to their exceptional properties are a promising research field in the future.

The chapter discusses the applications of PLA in numerous fields such as biomedical, automotive, textile, packaging, and sensing. Furthermore, enormous research is going on to design value-added products from PLA nanostructure. These efforts will establish the material in a wide range of applications which may throw back the sector of plastics in the near future.

Abstract

Facing the problem of excessive use of conventional petroleum-based plastic materials in a wide range of daily life applications is undoubtedly an urgent global issue. Researchers and organizations have driven much effort to develop novel materials such as coatings and films based on biopolymers which have emerged as a viable way to replace, at least partially, synthetic products. Biopolymers, like polysaccharides and proteins, can be obtained from marine or agro-industrial resources and also by food processing waste and by-products, which contributes to sustainability and a circular economy. Biopolymer films are pre-formed structures produced by solvent casting and extrusion procedures, while coatings are formed directly on the product surface by spraying, dipping, or spreading techniques. To enhance films and coatings properties, strategies including chemical modification, cross-linking, plasticizers addition, use of fibers and nano reinforcing materials, and blending of different biopolymers have been adopted. Although there is still much to be done in terms of mechanical and water barriers properties and large-scale processability, the incorporation of active agents into the biopolymer matrix, mainly natural antimicrobials and antioxidants, vitamins, nutrients, and growth factors, has emerged as one of the significant advantages in the design of novel functional materials. These active ingredients can prolong shelf life and provide many other additional characteristics of the final products. This chapter intends to cover the relevance and recent advances in biopolymer films and composite coatings, highlighting their applications in different sectors such as food packaging, medicine, textile, and agriculture.

Keywords

Biopolymers · Food packaging · Textile · Biomedical films · Mulching

Introduction

Owing to the scarce petroleum resources and the urgent need for more sustainable, eco-friendly, and cost-effective alternatives, biopolymers, due to their renewability and biodegradability, have emerged as promising raw materials for a wide range of materials and applications. Although a total replacement of conventional petroleum-based by bio-based plastics seems impossible, for some specific applications, the replacement looks evident and valuable, presenting huge business opportunities and benefits for a more sustainable production and economy. Bio-based materials showed a global market capacity of 2.4 million tons in 2021, forecasting an increase to 7.6 million tons by 2026 (European Bioplastics 2021). Packaging represents the greatest segment, with a 48% global production capacity in 2021. This scenario has also boosted the demand for biopolymers over the last years regarding technological innovations and commercial applications.

Biopolymers can be obtained from natural sources (starch, cellulose, alginate, chitosan, gelatin), biosynthesized by microorganisms (polyhydroxyalkanoate – PHA, polyhydroxybutyrate, PHB, bacterial cellulose), or chemically synthesized from agro-resources (polylactic acid, PLA). They are derived from renewable marine and agricultural resources and/or food processing wastes and by-products, and also natural fibers, which can provide reinforcement properties to the materials. Biopolymers and their combinations offer many possibilities and opportunities for various industries/sectors, including food packaging, paper, agriculture, medical, textile, and automotive (George et al. 2020).

Synthetic polymers have been extensively used over the years due to their easy processability, low price, high chemical and mechanical stress resistance, and great versatility. These molecules can be designed in a wide variety of physical and chemical characteristics by adjusting their molecular weight, chemical functions, and processing parameters. Biopolymers materials, such as films and coatings, usually exhibit lower mechanical properties and stability when compared to synthetic ones. To overcome such limitations and increase competitiveness, composite materials can be obtained by combining multiple biopolymers and/or micro/nano reinforcement components. These composites, which can display different phases, take advantage of pure materials' characteristics to attain enhanced structures. They can be classified into three categories: composites containing suspended reinforcing particles; multilayered structures of two different materials usually exhibiting strong physicochemical interaction between layers; and fiber-reinforced composites (George et al. 2020). The use of biobased nanoparticles and nanofibers usually impacts the mechanical properties, heat deformation temperature, gas permeability, and decomposition of the resulting biopolymer film. Blending different biopolymers to form films or coatings usually results in a material whose properties are expected to be a combination of those of the biopolymers alone.

Biopolymer films and composite coatings have various application possibilities in many different areas, boosting the interest of researchers and producers in developing novel alternative biodegradable materials. In this chapter, the relevance and recent advances in biopolymers films and composite coatings will be discussed, highlighting their applications in different sectors such as food packaging, medicine, textile, and agriculture.

Biopolymer Films and Coatings Preparation Methods

Despite sometimes being interpreted as synonyms, films and coatings present distinct producing processes. Films are produced as pre-formed structures, which are then applied over the product surface or between its components. On the other hand, coatings are formed by the direct application of the film-forming solution on the product surface (Falguera et al. 2011).

Biopolymer films can be formed by solvent casting (wet process) and extrusion (dry process). Casting is the most convenient method for producing biopolymer-based films. It consists in dissolving the biopolymer in an appropriate solvent (water

or other organic solvents), which may include additives and fillers addition, heating, and pH adjustment, and then pouring the solution directly into the support, followed by drying, forming a thin layer, usually 20–200 μm thick. The film thickness can vary with volume applied, solid concentration, final moisture content, and swelling characteristics (Bierhalz et al. 2020). Extrusion technology has gained much attention for the large-scale production of bio-based films since it can provide high productivity and use conventional plastic industry equipment. It uses thermoplastic biopolymers associated with plasticizers and low moisture levels and can be used for the large-scale production of films (Rajeswari et al. 2021).

Biopolymer coatings can be prepared by dip-coating, spread-coating, and spray-coating, and the chosen method determines the coverage efficiency and the cost of the process. The performance is also dependent on the selection of the coating solution (type, concentration, viscosity, and surface tension) (Bierhalz et al. 2020). Dip-coating involves dipping the product in the biopolymeric solution and then removing it at a constant rate, followed by solvent evaporation by drying. Layer-by-layer (LbL) technique is a variation of the dip-coating in which bi- or multilayered systems are formed by sequential application of the biopolymeric solutions. The thin layers formed are bonded together by physical or chemical interactions. In spread-coating, the coating dispersion is applied directly on the food material or packaging surface by using spreaders, brushes, rods, or spatulas. Spray-coating can be done using classical spraying methods, such as compressed air-assisted sprayer and knapsack sprayer, as well as electro-spraying method. One of the main advantages of spray coating is the possibility to be used on large and non-regular surfaces. A semi-permeable membrane is formed on the products by distributing the coating solution over the targeted surface through the formation of droplets. The droplet sizes usually reach about 20 μm for conventional spraying methods, while electro-spinning can result in much smaller sizes, around 100 nm (Tavassoli-Kafrani et al. 2016). Bio-based coatings technologies are promising for obtaining antimicrobial, hydrophobic, and self-cleaning surfaces, and numerous sectors can benefit from those technologies, such as the food, textile, pharmaceutical, agriculture, and paper and packaging industries. The biopolymer in the solution must constitute a sufficiently cohesive structural matrix. Other components can be added to the coating solution to enhance coating characteristics. Lipids and surfactants can be used to reduce hydrophilicity and water vapor permeability. In contrast, plasticizers, such as polyols and sucrose, can reduce the glass transition temperature and improve the flexibility of the polymeric matrix.

Food Packaging Applications

The increasing consumer demand for a diverse and constant offer of fresh produce and innovative and convenient food products has boosted the search for new food packaging solutions. Packaging that can maintain product quality and safety while minimizing environmental impacts associated with conventional plastic disposal imposes a great challenge to researchers and industries. Primarily, food packaging is intended to protect food from the external environment by avoiding or reducing

contact with microorganisms, exposure to oxygen, temperature, and humidity, therefore promoting the extension of the shelf-life. Other important features include communication, marketing, and convenience of use and storage (Kumar et al. 2020).

The relatively low cost, lightweight, versatility, and good barrier and mechanical properties make conventional plastics the most popular option for packaging food products. However, the intensification of consumers' concerns about environmental and health issues has brought focus on alternative bio-based food packaging materials. Such bio-based alternatives include as potential sources to produce edible films and coatings, mainly polysaccharides (e.g., cellulose, starch, chitosan, alginate, pectin, and agar) and proteins (casein, collagen, soy protein, whey protein, gluten, and zein). Besides biodegradability, biopolymeric films and coatings must ensure food safety, and mechanical, thermal, and barrier properties. The great diversity in chemical structure and functional groups provides possibilities for enhancing or tuning bio-based materials' properties by chemical and/or physical strategies. These include chemical modifications (esterification, grafting, and cross-linking), the addition of plasticizers, mixing with other biopolymers, nanofillers, and other substances that promote better miscibility (Garavand et al. 2017). Protein and polysaccharide films intended for food packaging usually exhibit higher performance through cross-linking the polymeric matrix. The main impact of cross-linking is the decrease in water sensitivity, one of the major drawbacks of biopolymers films and coatings causing swelling and disintegration. It also improves thermal, optical, and chemical stability (Azeredo and Waldron 2016). Cross-linking can be chemical or physical, involving the linking of the polymer chains by covalent or non-covalent bonds, respectively, forming tridimensional networks. Chemical cross-linking with some aldehydes (e.g., formaldehyde and glutaraldehyde) are very effective, especially with protein, but have been avoided due to the possibility of aldehyde residue migration. Calcium-induced physical cross-linking of polysaccharides results mainly from electrostatic interactions between calcium ions and uronate blocks in alginates and pectins chains, known as the "egg-box" model (Bierhalz et al. 2022). For food applications, it is essential to consider that the formation process of films and coatings must assure food contact requirements, such as pH, use of food-grade ingredients and solvents, enzymatic reactions, and thermal treatment.

The properties of films and coatings can be manipulated based on the characteristics of the biopolymers. Blending two or more carbohydrates and/or proteins is a common approach to improve matrix properties. Hydrophobic molecules, such as lipids, demonstrate strong moisture barrier properties, whereas hydrophilic molecules, such as polysaccharides and proteins, demonstrate efficient mechanical properties and good gas barriers such as oxygen and carbon dioxide. Such combinations can be achieved by the complexation of a hydrophilic layer with a hydrophobic layer or emulsion-based films by evenly distributing the hydrophobic component into the polymeric matrix.

Another important feature of biopolymeric films and coatings is their ability to act as a vehicle and promote the controlled release of active agents (antioxidants, antimicrobials, enzymes, probiotics, prebiotics, vitamins) that can act on the surface or be incorporated into the food bulk, improving quality and shelf-life (Kumar et al. 2020).

Fruits and Vegetables

Consumers' growing preference for a healthy and nutritious diet has driven demand for fresh fruits and vegetables free of pesticide residues and extended shelf-life. However, these products are highly perishable, and maintaining the post-harvest is complex. Quality loss occurs during harvesting, storage, and distribution until reaching the consumer, especially when long distances are involved. Losses along the supply chain are estimated at around one-third of world production (Gustavsson et al. 2011). Tropical fruit losses, for example, are estimated to be about 18–28% after harvest (Md Nor and Ding 2020). Among the main factors that affect the quality and, consequently, the shelf life of fruits and vegetables are biochemical modifications, post-harvest microbial deterioration, and physical damages during handling and transportation (Basumatary et al. 2022). Therefore, reducing losses and waste increases food availability for an ever-increasing population and reduces pressure on natural resources.

Fruits and vegetables are living tissues with high moisture content (60% to 95%) and water activity. After harvest, the respiration process continues using food reserves to produce carbon dioxide, heat, and water. Water is also lost to the surrounding atmosphere through the process of transpiration. These natural metabolic processes lead the fruit to senescence, with initial shrinkage and subsequent weight loss and deterioration of appearance (Flores-López et al. 2016). Chemical and biochemical processes; non-enzymatic browning; oxidation of chlorophyll, anthocyanin, pigments, and vitamins; and the conversion of starch to sugar are responsible for accelerating color deterioration, off-flavor, and loss of nutritive value of the fruits and vegetables (Basumatary et al. 2022). In addition, due to the high moisture content, low pH, and nutritional composition, fruits and vegetables are susceptible to microbiological damage. These deterioration processes have motivated the food and horticulture industry and researchers to obtain methods to maintain the quality, food safety, and freshness of these products. Films and coatings based on biopolymers have become prominent strategies for improving the shelf-life of several fruits and vegetables, such as apples, cherries, grapefruit, cucumber, strawberry, tomato, and capsicum.

Fruit and vegetable coatings change the atmosphere in the headspace, increasing the CO₂ concentration and reducing the O₂ concentration. This environment favors reducing respiration rate and conserving stored energy, prolonging the shelf life. The semi-permeable coating characteristic restricts the exchange of gases and water vapor but does not create an anaerobic environment that causes a loss of fruit quality. Therefore, barriers to water vapor and gas are the fundamental functional properties of edible films and coatings. It is also essential that edible films and coatings have a minimal impact on the color and gloss of the products and appropriate mechanical strength to prevent their tearing and protect the products from physical damage.

In addition to reducing moisture loss, gas exchange, respiration, and oxidative reaction, edible coatings are also suitable for incorporating several active

compounds, including antimicrobials, antioxidants, flavors, dyes, sweeteners, and vitamins, increasing the sensory attractiveness, and improving nutritional values. Edible films can also prevent fruits and vegetables from chilling injuries and storage disorders.

The components of edible coatings must be classified and recognized as GRAS (recognized as safe) because they are consumed with the product (Flores-López et al. 2016). Thus, polysaccharides and proteins have been extensively evaluated to produce films and edible coatings, used individually and together. The choice of coating material depends on the desired properties, as each polymer has unique characteristics. In general, polysaccharides are hydrophilic and result in coatings with poor moisture barrier but satisfactory mechanical properties. On the other hand, proteins have the desirable advantage of gas barrier properties without anaerobic conditions but also present a minimal moisture barrier (Md Nor and Ding 2020).

A wide variety of polysaccharides can be used as coatings for fruits and vegetables with proper adhesion, gas barrier, and mechanical properties. The most common are chitosan, starch, alginate, pectin, cellulose derivatives, carrageenan, and gums (Arabic gum, agar, guar, xanthan). As polysaccharides coatings have a poor moisture barrier, to delay moisture loss from fruits and vegetables, they can act as a sacrificial agent, in which the coating is dehydrated instead of the food.

Chitosan is widely used as coatings for fruits and vegetables because it lacks toxicity, biodegradability, excellent film-forming ability, gas barrier properties, and antimicrobial and antioxidant activity. In addition, chitosan is compatible with several compounds, such as vitamins, minerals, and antimicrobial agents, maintaining its nutritional and qualitative characteristics. Many studies support the potential role of chitosan coating in prolonging the storage life and controlling the decay of fruits and vegetables, such as papaya, apple, peach, broccoli, tomato, mango, carrot, and banana. The attributes of chitosan coatings for fruits and vegetables also include preventing the decrease in the content of natural antioxidants during post-harvest storage, delaying browning and suppressing fungal diseases, and inducing the production of enzymes that act in defense of plants, such as chitinase (Dhall 2013).

Antimicrobial activity is one of the most attractive properties of chitosan and depends on several factors, such as deacetylation degree, molecular weight, and concentration at which it is applied. Antimicrobial activity plays a significant role in the control of postharvest decay, accounting for 35–45% of coating effectiveness (Romanazzi et al. 2017).

Solubility, antimicrobial activity, and interaction capacity can be improved with chitosan in nano form. Chitosan nanoparticles exhibited higher antimicrobial activity due to the small and compact particle size and high surface charge. Divya et al. (2018) prepared chitosan nanoparticles by ionic gelation and confirmed its ability as a coating of material to improve the shelf life of tomato, chilly, and brinjal. For instance, the weight loss of tomato coated with 5% chitosan nanoparticles after 5 days of storage was 0.21%, while tomato coated with chitosan

presented a weight loss of 9.33%. For tomatoes without coating, the weight loss was 25%.

In addition to controlling postharvest decay of fruits and vegetables, chitosan has also been used to prevent plant diseases. Some examples of commercial formulations include Chitoplant (ChiPro GmbH, Bremen, Germany), Biochikol 020 PC (Gumitex, Lowics, Poland), Armour-Zen (Botry-Zen Limited, Dunedin, New Zealand); Biorend (Bioagro S.A., Chile), and Kendal Cops (Valagro, Atesa, Italy).

Cellulose derivatives such as methylcellulose (MC), carboxymethylcellulose (CMC), hydroxypropyl cellulose (HPC), and hydroxypropyl methylcellulose (HPMC) are also attractive for use as edible films and coatings for a variety of fruits and vegetables. They impart moisture and gas barriers, good adhesion to the food surface, retain the firmness and crispness, and can preserve flavor components (Nieto 2009). Commercial formulations based on CMC include Semperfresh™ (AgriCoat Industries Ltd., Berkshire, UK), composed of sucrose esters of fatty acids, sodium carboxymethylcellulose, mono-diglycerides of fatty acids, recommended for pear, melon, avocado, apple, cherry, plum, banana, and lime.

The use of alginate as an edible coating is closely related to its ability to form translucent, shiny, strong, and insoluble cross-linked structures with divalent ions such as calcium. An interesting aspect is that calcium chloride is a texture-firming agent since it can form complexes with low methoxyl pectin present in fruits and vegetables. Therefore, a similar benefit can be obtained with sodium alginate-calcium chloride (Alharaty and Ramaswamy 2020). Alginate- Ca^{2+} coatings have been used successfully to prolong the shelf life of fresh-cut Gala apples without causing fermentation due to undesirable anaerobic respiration. Applying calcium-alginate coatings on fresh-cut Gala apples has been demonstrated to reduce weight loss, browning, and mold growth and preserve firmness during storage (Alharaty and Ramaswamy 2020). This polymer has also been explored in fresh-cut fruits with high moisture surfaces, such as strawberries, melon, and watermelon.

Proteins such as gelatin, corn zein, casein, keratin, soy protein, wheat gluten, and collagen have been used for edible coatings for fruits and vegetables. Due to their hydrophilic nature, protein-based coatings are susceptible to moisture absorption, being affected by humidity and temperature. Incorporating fatty acids or using cross-linking agents can improve the water vapor permeability of protein-based films and coatings, but their edibility can be compromised (Dhall 2013).

Zein is one of the most explored proteins used as a coating in fruits and vegetables. This protein contains many hydrophobic amino acid residues, providing zein films with low water vapor permeability compared to most other proteins and good gas barrier properties. The benefits of zein coatings have been demonstrated on harvested fruits and vegetables such as pear, mango, apples, apricot, guava, and tomato.

Matrix formulations composed of polysaccharide-polysaccharide, protein-protein, and polysaccharide-protein have become an economical and versatile way to obtain new materials with better properties. The common objective of blends is to get material with better performance than individual polymers. The preparation of

films and coatings consisting of two or more biopolymers for application in fruits and vegetables is widely reported in the literature (Basumatary et al. 2022).

Nanomaterials such as nano-ZnO, nano-TiO₂, nano-silica, nanosilver, cellulose nanocrystals, and montmorillonite, owned to large surface area and high surface energy, are usually incorporated into biopolymers matrices to improve several properties, such as gas and water vapor barrier, thermal stability, and mechanical resistance.

Polysaccharide-ZnO nanocomposites, besides improving mechanical and barrier properties related to weight loss, respiration, and oxidation, also contribute to the inhibition of microbial growth of fruits and vegetables (Anugrah et al. 2020).

TiO₂ has been reported to exhibit antimicrobial and ethylene photodegradation activity when exposed to UV light by generating hydroxyl radicals and reactive oxygen species (ROS) on its surface, reacting with organic molecules. Nano-composite coatings of this nanoparticle in the chitosan matrix can delay the ripening process of tomatoes (Kaewklin et al. 2018) and reduce losses caused by decay and water dispersion of mangoes (Xing et al. 2020).

Nano-silver is widely used in films and coatings due to its antibacterial effect against 150 types of microbes. In a study on the preservation of quality of shiitake mushroom, alginate/nano-silver coating efficiently reduced the growth of mesophilic, psychophilic, pseudomonas, yeast, and molds and inhibited weight loss, softening, and browning after 16-days of storage (Jiang et al. 2013).

Non-climacteric fruits such as citrus fruits commonly receive lipid-based coatings (e.g., waxes and resins) to provide an attractive appearance, while reducing CO₂, O₂, and water vapor permeability. However, lipid-based coatings may encourage the accumulation of CO₂ and ethanol, causing the development of off-flavors (Flores-López et al. 2016). In this case, the association with polysaccharides provides appropriate gas and moisture barrier and mechanical strength.

Essential oils (EOs) are natural compounds obtained from plant materials and considered suitable natural preservatives due to their antimicrobial and antioxidant properties. Although they are generally recognized as safe (GRAS), the direct application of EOs to the surface of fruits and vegetables tends to be avoided due to the influence on the original flavor. Therefore, incorporating EOs into the polymeric matrix can reduce their impact on the flavor and prolong the action time of EOs through the slow-release effect. In addition, EOs can also improve the water vapor permeability of the films, which consequently influence properties such as weight loss, total soluble solids, acidity, and firmness (Yousuf et al. 2021).

The properties and shelf-life of fruits such as apple, peach, guava, mango, grape, banana, tomato, papaya, cucumber, cantaloupe, raspberry, and strawberry have already been evaluated with films and biopolymer coatings containing EOs. Oils from citrus sources (orange, lemon, lime, bergamot, grapefruit), cinnamon bark, and lemongrass are among the most common EOs used in coatings for fresh-cut fruits and vegetables.

The incorporation of active ingredients in films and coatings is considered a strategy of great interest to maintain the quality of fruits and vegetables. Antimicrobials, antioxidants, and anti-browning stand out among the primary agents used.

Enzymatic browning reactions negatively affect the appearance of products, especially fresh-cut fruits and vegetables, reducing consumer acceptability. Organic acids such as ascorbic acid, citric acid, oxalic acid, phenolic acids, and thio-containing compounds are often used to control excessive browning associated with edible films and coatings for fruits and vegetables. Coatings can also encapsulate aroma compounds, flavorings, colorings, and sweeteners enhancing sensory attributes. Functional coatings containing nutraceuticals like minerals, vitamins, and essential fatty acids can improve the nutritional value of fruits and vegetables. However, they may impart a bitter taste, and little information is available regarding the impact on mechanical and barrier properties (Panahirad et al. 2021).

Dairy Products

Dairy products are obtained by processing milk, which may contain food additives and other ingredients needed for processing. Within this category, cheese is one of the products in which edible films and coatings are applied to prevent quality losses. Many physicochemical, biochemical, and microbiological processes occur during cheese fabrication, so choosing the proper packaging can be challenging. Most degradation reactions are accelerated by light exposure and high moisture, such as lipolysis, proteolysis, and lipid oxidation, so packaging must provide low transparency and oxygen and water vapor permeabilities (Chen et al. 2019). Biodegradable films and coatings made from polysaccharides and proteins provide water vapor, oxygen, and carbon dioxide barrier, avoiding weight, flavor, and texture losses (Jafarzadeh et al. 2021). Kampf and Nussinovitch (2000) studied the physical and sensory properties of semi-hard and white-brined cheeses coated with alginate, gellan, and κ -carrageenan solutions. The most promising result was obtained by the κ -carrageenan coating, resulting in improved color and gloss and reduced weight loss along 46 days of storage, conferring a softer and less brittle texture. The barrier properties of packaging materials significantly impact the shelf life of cheese.

Furthermore, active components, such as antimicrobials and antioxidants, can be incorporated into edible films and coatings, hindering the release rates of such substances into the product surface, where microbial deterioration is more prone to take place and, therefore, the concentration of additives in the bulk can be reduced (Bierhalz et al. 2022; Jafarzadeh et al. 2021). Most studies concerning the use of edible films and coatings to protect cheese products include antimicrobial substances as a practical approach to inhibit deteriorating and pathogenic microbial growth. Cheese deteriorates during handling, ripening, and storage resulting in sensory and economic damages (Küçük et al. 2020). Fungi are a major cause of cheese spoilage, and besides quality impacts, some species produce compromising food safety.

Films based on alginate and/or pectin can exhibit distinguished properties by tuning the cross-linking and plasticization degrees (da Silva et al. 2009). Alginate films added with natamycin intended for cheese packaging displayed low O₂ permeability and adequate mechanical and moisture resistance (Bierhalz et al. 2014). Natamycin is a natural bacteriocin, Generally Recognized as Safe (GRAS), allowed

for use in different cheese and meat products. It has limited water solubility, so its addition to a biopolymeric matrix (film or coating) can guarantee a better distribution and antimicrobial action over the product surface (Santonicola et al. 2017). In vitro tests indicated the protective effect of alginate films containing natamycin against fungi species that usually contaminate cheese (Bierhalz et al. 2014). In recent research, Bierhalz et al. (2022) evaluated the effect of natamycin-loaded and natamycin-free alginate films applied over sliced cheese samples contaminated with *Aspergillus niger* and *Penicillium roqueforti* storage at 25 °C for 7 days. The samples covered with the active film showed a significantly lower microbial count (1 log cycle) than the control samples.

Chitosan films and coatings have shown great potential for application in cheese and other food preservation mainly due to the inherent antimicrobial properties associated with its cationic nature. Fajardo et al. (2010) found significantly lower mold and yeast counts for samples of Saloio cheese stored at 4 °C/27 days packed with chitosan films containing natamycin compared to control samples. Moreira et al. (2011) evaluated the antimicrobial effect of chitosan and chitosan/sodium caseinate coatings and films on cheese. They observed a reduced count of mesophilic, psychrotrophic, and yeast and mold in the range of 2 to 4.5 log CFU/g. Chitosan and nano clay nanocomposite exhibit antimicrobial action against spoilage and pathogenic microorganisms on Gouda cheese (Mohammadzadeh-Vazifeh et al. 2020). The shelf life of high-moisture mozzarella cheese was doubled in samples coated with carboxymethyl cellulose with and without natamycin stored at 8 °C compared to uncoated samples (Azhdari and Moradi 2022).

Protein-based films and coatings usually show lower oxygen and water-vapor permeabilities than polysaccharides. This trend can be attributed to the more polar and linear structure, reducing matrix-free volume. A whey protein isolate film was prepared with ginger EO and applied to Kashar cheese. After 30 days at 4 °C, active films showed appropriate water barrier properties and antimicrobial effects against *Escherichia coli* O157:H7 and *Staphylococcus aureus* (Kavas et al. 2016).

Polysaccharide-protein blends are increasingly used in cheese and other various food as they can enhance the functional properties of the proteins and polysaccharides alone. Positively charged chitosan can interact and form three-dimensional networks with opposite charges in proteins, such as caseinate. Antimicrobial films consisting of chitosan and blends of sodium caseinate/chitosan applied either by coating (dipping) the cheese sample with the film-forming solutions or wrapping with pre-formed films hindered mesophilic bacteria, psychrotrophic, yeasts, and molds growth. Sodium caseinate/chitosan films exhibited improved mechanical properties (tensile and impact strengths) and lower equilibrium moisture content compared to chitosan and caseinate neat films due to the strong electrostatic interactions between the two macromolecules (Pereda et al. 2014).

Fresh Kashar cheese samples inoculated with *Listeria monocytogenes* were covered with zein and zein/wax composite films containing natural antimicrobial agent (lysozyme) and natural antioxidants (gallic acid and catechin), and all films were able to inhibit bacterial growth for 8 weeks at 4 °C. However, zein/wax film

reduced the initial microbial load. Gallic acid and catechin in films proved to inhibit oxidative changes in the cheese samples (Ünalán et al. 2013).

Incorporating metal nanoparticles, such as zinc oxide (ZnO) nanoparticles (NPs) in biopolymeric films has been proposed as antimicrobial and photocatalytic systems. Carboxymethyl cellulose and chitosan films containing ZnO-NPs were applied on soft white cheese resulting in prolonged shelf-life (Youssef et al. 2016). For food packaging applications, migration and safety concerning the use of metal nanoparticles still need further investigation.

Eggs

Eggs are a source of high-quality protein, vitamins, and minerals. Its structural components include the shell and shell membranes, the albumen, and the yolk (Almeida e Silva et al. 2020). Several quality problems associated with storing fresh eggs, such as weight loss and changes in egg white, yolk, and pH, can significantly impact the sector. The use of biopolymeric coatings has been proposed to preserve quality parameters and extend the egg's shelf life. Xie et al. (2002) showed that coating eggshells with different biopolymers (soy and whey protein isolates, carboxymethyl cellulose, or wheat gluten) decreased eggshell breakage when compared to control (uncoated) samples. A coating solution composed of methylcellulose and hydroxypropyl methylcellulose added with polyethylene glycol-400 and a mixture of fatty acids was highly efficient in preventing egg quality deterioration stored under ambient conditions extending the shelf life of eggs by 4 weeks. The coating solution formulation was optimized regarding water vapor permeability and mechanical properties, and the lipid component, due to its hydrophobic nature, provided an extra moisture barrier to the coating. The moisture transfer across the eggshell determines the weight loss and albumen changes, so controlling the water vapor barrier of the biopolymeric film is extremely important (Suppakul et al. 2010). In a recent study, Rachtanapun et al. (2021) developed a novel egg-coating material composed of chitosan, carboxymethyl cellulose, and paraffin that successfully covered the egg surface, prolonging the shelf-life and quality parameters by 4 weeks at ambient temperature. The incorporation of paraffin was improved by blending carboxymethyl cellulose with chitosan, thus improving the mechanical properties of the coating. Paraffin acted as a plasticizer and hydrophobic component, enhancing coating flexibility and water resistance.

Concerning food safety issues, the egg production chain requires microbiological control since microfractures in the eggshell can lead to egg contamination by *Salmonella* and other bacteria. Salmonellosis is the most frequent foodborne disease, and eggs have been pointed as the main source of human contamination with *Salmonella* spp. in outbreaks. So, the sanitary quality of commercial eggs represents a bottleneck issue that relies on sanitizing procedures to ensure product safety over the whole production chain (Almeida e Silva et al. 2020). Different chemical compounds have been proposed to avoid contamination, e.g., washing with chlorine-based compounds, such as sodium hypochlorite solution. Due to the

possible toxic effects of chlorine solutions, quaternary ammonium salt components (QACs) are an alternative since they are bioactive surfactants with a broad activity spectrum for different microorganisms. However, the sanitizing effect depends on the chemical nature and concentration of the active agent, but also on the contact time with the product surface during storage. Eggshell coating with chitosan solution containing quaternary ammonium hindered the formation of *Salmonella Enteritidis* biofilm. The coating solution applied by dipping showed reduced surface tension and detergency, promoting an adequate physical and microbiological barrier, protecting eggs, and preventing moisture loss (Almeida e Silva et al. 2020).

Plasticizers are frequently required to enhance film flexibility and improve the mechanical resistance of brittle biopolymers. Besides, the preparation method also influences the efficiency of the coating. Chitosan coatings plasticized with glycerol, propylene glycol, and sorbitol were applied on eggshells by brushing, dipping, and spraying. The shelf-life of all chitosan treated was increased by about 20 days under ambient temperature and better internal quality parameters were obtained by samples coated by brushing and dipping (Kim et al. 2008).

Meat

The meat industry can suffer significant economic impacts from problems associated with lipid oxidation and microbial contamination during product processing, transportation, and commercialization (Domínguez et al. 2018). Pathogenic microorganisms such as *Salmonella Typhimurium*, *L. monocytogenes*, *E. coli*, and *Bacillus* spp. can easily contaminate processing and packaging lines. Biopolymer-based films and coatings can help prevent moisture loss and microbial growth, hinder the oxidation rate, and avoid flavor loss. The coating would act as a barrier to water and gases (CO_2 and O_2), thereby reducing weight loss, color deterioration, aroma deterioration, and maintaining quality (Falguera et al. 2011). So, the meat, pork, and poultry industries could surely benefit from using biopolymers films and coatings for fresh, frozen, and processed meat products.

Films of sodium alginate and agar, plasticized with glycerol, were produced by casting and tested on sliced salami samples stored for 3 months under refrigeration. Samples showed less variation in color compared to control (with conventional packaging) and higher microbiological quality, however, moisture loss was higher in samples wrapped by the bio-based films than in traditional packaging (Puscaselu et al. 2021). Three biopolymeric coatings based on gelatin, turmeric starch, and their blend were applied on fresh frankfurter sausages. All coatings exhibit increased antimicrobial activity over 30 days of storage and moderate mechanical strength. No changes were observed in product color, pH, and texture compared to uncoated samples (Tosati et al. 2017).

Reducing oxygen in contact with the meat product by vacuum or nitrogen packaging is among the most common strategies to prevent lipid oxidation. However, the maintenance of the red color of fresh meat requires high O_2 levels in the packaging. So, lipid oxidation can be delayed by active packaging containing

synthetic antioxidants, such as butylated hydroxyanisole (BHA) and butylated hydroxytoluene (BHT). However, the current demand for safe and more natural products highlights the growing interest in using natural antioxidants.

A great variety of plant extracts and EOs have been used as natural antioxidants for meat and other food products. They are incorporated into the biopolymeric matrix keeping a high concentration of active substances on the surface of the meat. However, the release kinetics of the active agent from the film is a crucial factor to be considered in choosing the biopolymer/antioxidant system (Gagaoua et al. 2021).

Whey protein films containing a mixture of cinnamon and rosemary EOs (2–5%) exhibit a great reduction in the lipid oxidation of pork salami samples (Ribeiro-Santos et al. 2018). Nisa et al. (2015) developed potato starch films with 5% green tea extract for application on fresh beef, while Qin et al. (2013) used chitosan films added with tea polyphenols to hinder the oxidation of cooked pork sausages. In both cases, wrapped meat had lower lipid oxidation ratios than the control and also increased stability of the red color.

In most cases, the incorporation of EO into edible films and coatings has been done through conventional emulsification, but the contact between the EO components and the polymer matrix could be improved with nano-emulsification. Nano-emulsions are a type of emulsion with reduced droplet size (20 to 200 nm) and would, therefore, reduce EO volatilization losses and enhance activity (Basumatary et al. 2022).

The addition of ginger EO in fish skin gelatin films containing ZnO-NPs caused an increase in the elongation and thickness and a decrease in tensile strength and moisture barrier of films. The active films showed antioxidant activity and reduced levels of total volatile bases nitrogen during fresh meat storage. Besides, the films exhibit strong antibacterial activity against food spoilage and pathogenic bacteria (Liu et al. 2020).

Seafood

Fish and fishery products are considered rich sources of protein, unsaturated fatty acids, vitamins, and minerals, and their consumption has increased in recent years. However, fresh fish can undergo fast spoilage because of its high moisture and solute concentrations, weak connective tissue, and neutral pH values, providing ideal conditions for microbial contamination and biochemical oxidation. In fish, lipidic oxidation leads to the formation of bad odors and flavors, harmful molecules, and color changes. Preservation methods like freezing, chilling, vacuum and modified atmosphere, salting, and drying are used in the fish processing industry but still do not guarantee complete microbial and lipid oxidation reactions. So synthetic preservatives such as phosphates, benzoates, nitrite, BHA, and BHT can help lipid oxidation, microbial contamination, texture, and color changes (Hussain et al. 2021).

Following the same trend of other food segments, there is a fast-growing interest in using natural plant and fruit extracts and EOs, bacteriocins, lactoperoxidase, and

bioactive peptides as antimicrobials and antioxidants for fish and seafood (Hussain et al. 2021). These natural components can be vehiculated by incorporating them into polysaccharides and/or proteins films and coatings. Coating solutions can be applied by dipping or spraying onto the fish product surface, enhancing the quality and consumer acceptability. Gelatin and its blends, due to their excellent film-forming properties, have been widely used in fishery products (Abelti et al. 2022).

Chitosan is one of the most promising biopolymers for producing films and coatings for fresh and frozen fish and seafood applications, as it possesses inherently antibacterial, antifungal, and antioxidant activities. The chitosan-free amine groups (NH_3^+) can interact with the negative charges of cell membranes of bacteria, causing microbial inactivation. Other polysaccharides used in fish packaging include cellulose, pectin, alginate, and κ -carrageenan. The antimicrobial effect of a composite coating of chitosan and fish skin gelatin on cod burgers was investigated. Microbial counts of the coated samples were 2 log cycles lower than uncoated ones (López-Caballero et al. 2005).

Biomedical Applications

Biopolymers have advantages that make them attractive for biomedical applications, with emphasis on biocompatibility, biodegradability, non-toxicity, and the possibility of chemical modification, which is highly beneficial for interactions between biomaterials and tissues. Biopolymer coatings are of special interest in implants for orthopedics, dentistry, and cardiovascular applications. These are used to modify surface properties and incorporate additional functionality such as the delivery of growth factors, antimicrobial agents, and drugs. Biopolymer-based films have wide applications as wound dressings and orally disintegrated films (ODFs).

Biomedical Coatings

Polymer assembly into coatings can be done using various physical and chemical methods. Physical methods based on the deposition of the biopolymer directly onto the substrate, such as dip-coating and spin coating, are simple and affordable (Nathanael and Oh 2020). Uniform coatings on substrates of varied sizes can be obtained by the dip-coating technique, which consists of immersing the substrate in the solution containing the biopolymer followed by removal to dry the coating by evaporation. In this technique, the coating thickness depends on several factors: immersion duration, sample removal speed, concentration and viscosity of the polymeric solution, and the number of coating cycles. The spin coating technique can also be used for flat substrates to obtain thin and uniform coatings. In this approach, the solution containing biopolymer is applied in the center of the substrate, which is then subjected to a high rotation speed. In this case, the main parameters are the rotation speed, surface tension, and solution viscosity. Due to the difficulty of rotating at high rates, this technique is more challenging to perform on large

substrates (Song et al. 2020). Other physical methods, including LBL, Langmuir-Blodgett (LB), and plasma-based coating methods, are more suitable for preparing very thin (up to monomolecular) layers of biopolymers.

Despite being straightforward and widely used, physical coatings may have poor stability against mechanical stress, representing a disadvantage in applications such as stents, artificial joints, or catheters. Coatings resulting from chemical bonds between the biopolymer and the substrate are particularly interesting in these cases. Chemical coatings with biopolymers use grafting-to methods, in which the whole molecule can be attached to the surface by creating suitable binding sites, either on the substrate or on the polymer (or on both) (Song et al. 2020).

Metals and metal alloys are used in applications where mechanical strength is crucial, such as hip implants, knee implants, dental implants, or stents. The most used metallic materials are titanium alloys, stainless steel, and cobalt-chromium alloys. In addition to mechanical performance, surface properties are very important for metallic biomaterials, including good cell adhesion, non-toxicity, corrosion resistance, and bacterial biofilm formation (Aydemir et al. 2021). Despite significant advances, the risks of infection can lead to implant failure and repeated surgical intervention, resulting in enlarged clinical and socioeconomic burdens and impaired quality of life for patients.

Coatings based on biopolymers show potential to address multiple issues related to biomedical properties of implants, such as enhanced wear and corrosion resistance, reduced toxicity, and better anti-microbial properties (Fig. 1). They also contribute to increased osteogenesis, improve their cell adhesion, proliferation, and differentiation performances, and carry desirable compounds on their surfaces. Metallic substrates have received coatings of several biopolymers, isolated or in combination, such as collagen, chitosan, alginate, and alginate-collagen.

Chitosan-based coatings on implant surfaces have been reported to enhance protein adsorption, cell adhesion, proliferation, bioactivity, mineralization, and corrosion resistance by incorporating inorganic particles. For dental implants, chitosan coatings can affect mechanical properties at the bone interface, such as elastic modulus, which reduces the mismatch between the implant surface and alveolar bone, reducing stress concentration areas. In an *in vitro* study of dental implants coated with chitosan, a high deacetylation degree of chitosan was shown to increase biomineralization and osteoblast cell formation (Alnufaiy et al. 2020).

Fig. 1 Biopolymer coating on dental metallic implant

Efforts have been directed toward increasing the corrosion resistance of magnesium alloys. These alloys are attractive because they are degraded autonomously in the biological environment, which avoids the second surgery in the case of fractures. However, they are susceptible to corrosion in the physiological environment, whose degradation products can damage cells. Multifunctional calcium phosphate and chitosan coatings can improve corrosion resistance, cytocompatibility, and antibacterial ability.

Collagen coatings have been proven beneficial for osteoblast activity, implant stability, and osseointegration, facilitating the mineralization of the extracellular matrix and the expressions of specific osteogenic markers. A study involving the implantation of titanium orthopedic screws coated with chitosan into the femurs of New Zealand white rabbits demonstrated that collagen coating enhanced bone fixation. The coating also created a more well-anchored and stable implant than the traditional hydroxyapatite coatings (O'Neill et al. 2021).

Duan et al. (2021) reported that the corrosion resistance of titanium implants and crowns used in dentistry is prone to be severely damaged in the presence of aggressive fluoride ions from toothpaste, prophylactic gels, and mouthwashes. These authors developed a chitosan-alginate coating with self-strengthening capability in artificial fluorine-containing saliva. The anticorrosion performance was improved by forming a calcium alginate gel in the presence of calcium ions in the corrosive medium.

Strontium ions can promote osteogenic activity and, as divalent ions can cross-link alginate, coatings of this biopolymer can be used as a delivery platform for sustained release. In this case, the slow release is favored by chelation with sodium alginate (Yuan et al. 2017).

Wound Dressings

The human skin is the largest multifunctional organ of the body and provides protection, thermoregulation, sensation, and immune functions. As a barrier organ, the skin is constantly susceptible to environmental risks, such as chemical, physical, and thermal injury. Skin lesions occur with disruption in the continuity of the epithelial line and can be categorized as acute and chronic according to the duration and nature of the healing process.

Wound dressings play a crucial role in the complex regeneration process of skin lesions. An ideal dressing must satisfy several requirements: provide a moisture environment, remove excess fluids from the wound, reduce pain, prevent microbial contamination, enhance epidermal migration, and promote angiogenesis and connective tissue synthesis. It is also important that the dressing is non-adherent and easy to remove, non-toxic, non-allergic, flexible to fit body contours, and able to deliver therapeutic compounds.

Some properties required for wound dressings are related to the wound characteristics. For example, the swelling capacity of a wound dressing must be high for lesions with high exudate production. Also, the water vapor transmission rate

(WVTR) of films and membranes depends on the type of wound, with minor injuries requiring low WVTR, while wounds with granulation tissue may require rates up to 20 times higher. Regarding mechanical resistance, it is essential to consider whether the injured area requires elasticity, such as joint regions (Bombaldi de Souza et al. 2020).

The use of biopolymers as a material for wound care has a wide scope due to their excellent biocompatibility properties, ability to support cell growth, regenerative potential, biodegradability, and durability. The most used biopolymers for wound healing applications are chitosan, alginate, bacterial cellulose, hyaluronan, collagen, silk fibroin, and gelatin. These biopolymers can be used alone or in combination and may also contain bioactive agents such as antibiotics, antimicrobials, and anti-inflammatories that will improve the therapeutic action. The films intended for wound dressing applications are obtained mainly by casting technique.

Polysaccharides have been extensively used as matrices for wound dressings, especially chitosan, alginate, hyaluronic acid, and bacterial cellulose.

Chitosan presents a hemostatic effect and stimulates macrophage activity, accelerating tissue regeneration. Chitosan and its derivatives play roles in wound healing, mainly in the first three stages. In the first stage, it helps to stop bleeding. In the second phase, called inflammation stage, chitosan contributes to cleaning the bacteria from the wound. In the third stage, chitosan contributes to the growth of granulation tissue and skin proliferation (Feng et al. 2021).

In addition to several studies related to the development of chitosan films and membranes for application as wound dressing, many chitosan-based dressings are commercially available, such as ChitoSorb (ChitoTech), KytoCel (Aspen Medical), Opticell (Medline), and Chitoflex (HemCon).

Alginates and their derivatives have also been explored for skin lesions treatments and reported to have anti-inflammatory effects, regenerative, and angiogenic properties. Alginate membranes cross-linked with calcium ions are attractive for wound healing, exhibiting good drug delivery and barrier properties, hemostatic, and highly absorbent character. As wound exudates are rich in sodium, there is an exchange of these ions with the calcium ions of the cross-linked matrix, resulting in a gel that contributes to maintaining a moist microenvironment. Therefore, the formation of granulation tissue and reepithelization is favored in the healing process. The list of commercially available alginate-based wound dressings is vast and growing fast. Some examples are Algicell (Derma Science), Kaltostat (ConvaTec), Tegaderm (3 M Healthcare), and Algisite M (Smith & Nephew).

Bacterial cellulose (BC) has outstanding properties that make it an important biopolymer for developing improved wound dressings, including severe wound healing. In addition to its porous structure, biodegradability, histocompatibility, and nontoxicity, BC is highly pure and can be used without prior treatments. BC films are easy to remove, reduce inflammation, and have a high capacity to retain moisture, which can vary from 60 to 700 times their dry weight, which aids in the absorption of exudates, prevents the dehydration of wounds, and promotes fast healing. Another advantage of BC is its transparency, which provides heat absorption and pain reduction in cases of burn wounds. The BC structure's microporosity

favors the drug's slow release to the wound. However, it does not impair the ability of the films to act as a physical barrier against external agents (Bombaldi de Souza et al. 2020).

Hyaluronic acid is found as a component of the skin's extracellular matrix (ECM) and is involved in the wound healing process, decreasing the inflammatory cells infiltration, improving the re-epithelization and granulation, as well as increasing the formation of blood vessels that are important for improving skin regeneration. Despite the biological attractiveness, high production costs, the possible presence of contaminants due to the extraction process, the low water stability, and weak mechanical properties have limited the application of hyaluronic acid films. The rapid degradation and high swelling of hyaluronic acid may require periodic dressing replacements and result in low biochemical functionality for cell attachment and proliferation. Therefore, different strategies have been studied to overcome these limitations, such as cross-linking, chemical modification, and/or conjunction with other polymers, such as methylcellulose, chitosan, and collagen. Commercial dressings based on a hyaluronan derivative, a benzyl ester of hyaluronan (HYAFF®), are available. For example, Hyalosafe® is a transparent film dressing indicated for superficial lesions with moderate exudate production, such as first and second-degree burns.

Proteins such as collagen, keratin, and silk fibroin, have promising potential in wound healing. Among these proteins, collagen is particularly interesting as it is the main component of the dermal extracellular matrix, playing a crucial role in the healing process. Dressings based on this protein have a highly absorptive and hydrophilic character and are indicated for many types of wounds, such as chronic wounds. Collagen films, however, have high permeability to bacteria and microorganisms, and daily dressing change is recommended in cases of wound infection. To improve mechanical stability and degradation rate, collagen-based films require cross-linking with chemicals (sorbitol, glycerol, glutaraldehyde, hexamethylene diisocyanate) or biological agents (transglutaminase and k-carrageenan).

Silk fibroin is of increasing interest in wound healing applications. In addition to excellent biocompatibility, this material has high water uptake, good air permeability, slight bactericidal properties, low immunogenicity, hemostatic properties, slow degradation, and remarkable mechanical properties. To induce crystallization and improve stability, films are crystallized in organic solvents such as methanol. However, this treatment makes silk fibroin films brittle in the dry state. The flexibility of the SF films can be improved by blending with other natural polymers or by incorporating plasticizers.

Zhang et al. (2017) performed an in vivo study using silk fibroin films to treat wounds in animals (rabbits and porcine) and humans. Compared with commercial dressings, the silk fibroin film reduced the incidence of adverse events and the average healing time. The films allowed visual observation of dermal wound healing, could be easily applied and removed, and showed excellent barrier and fluid absorption properties.

As the major protein of the outer epidermis, keratin has intrinsic wound healing efficacy involved in all stages of wound healing. Keratin-based dressings

demonstrate to stimulate keratinocyte activity and increase cell adhesion, migration, and proliferation. A clinical study with patients with superficial and partial thickness burns showed that keratin-based healing products facilitate healing with minimal scarring and presented several other advantages, such as ease of use, low cost, and good patient tolerance, with minimal pain and itching (Loan et al. 2016).

Keratin films and membranes are transparent, highly elastic, allow gas exchange and water penetration at the wound area, and prevent bacterial access. Limitations are related to low absorption exudate capacity and mechanical performance. Because of this, keratin is usually combined with other natural and synthetic polymers to create wound dressings. The challenge is to improve mechanical strength without sacrificing biological efficacy.

Proteins of non-animal origin are less common but also demonstrate potential for wound healing. Peles and Zilberman (2012) reported that the non-animal origin of soy protein eliminates the risk of transmissible diseases that pose a danger in products of human and animal origin. In addition, soy protein has good water resistance, long shelf life and stability, and degrades into natural components. These authors produced soy protein films and observed that the physical properties of the wound dressing (water absorbance and weight loss profile) could be controlled by the cross-linking process. Regarding water vapor permeability, the films presented values suitable for wound dressings ($\sim 2300 \text{ g m}^{-2} \text{ day}^{-1}$), and this property was not affected by the cross-linking method.

Combining two or more polymers to obtain blends and composites is a simple approach for tuning the properties of the wound dressings. Chitosan stands out as one of the most studied biopolymers for the formation of blends, which comes from its cationic nature that allows the formation of polyelectrolyte complexes with various anionic polymers such as alginate, pectin, hyaluronic acid, collagen, gelatin, silk fibroin, among others. In general, mechanical properties, moisture resistance, biocompatibility, and control of the release of active agents can be improved.

Regarding composites for wound dressing applications, the increase in mechanical strength and antimicrobial activity are the most desired goals. Therefore, Ag, ZnO, TiO₂, and CuO nanoparticles have been evaluated to form nanocomposite films with biopolymers. Several active compounds, such as antioxidant drugs, antibiotics, anti-inflammatory drugs, natural compounds with therapeutic activities, such as EOs, and growth factors can be incorporated into biopolymer matrices to maximize dressing efficiency.

Orally Disintegrating Films (ODFs)

Administering drugs orally is considered the preferred route by patients (Irfan et al. 2016). The use of biopolymer-based films for drug administration in the oral cavity has recently received increasing attention. These orally disintegrating films (ODFs) offer a precise dose administration and are easy to handle. An important advantage for patients with swallowing difficulties is that the administration of ODFs does not require water ingestion. In addition, drug absorption by the mucosa is a way to

prevent the degradation of active compounds in the gastrointestinal tract (Garcia et al. 2020).

The main requirement for a polymer film to be used as ODF is its rapid disintegration when in contact with saliva, releasing active pharmaceutical agents from the dosage form. Polymers used to produce oral films should be nontoxic, nonirritant, and have good wetting and spreadability. Among the most used are gelatin, pullulan, starch, sodium alginate, pectin, chitosan, maltodextrins, hydroxypropyl methylcellulose (HPMC), sodium carboxymethyl cellulose (CMC), and hydroxypropyl cellulose (HPC). The association of different polymers can contribute to better film properties, such as hydrophilicity, flexibility, mouthfeel, and solubility (Garcia et al. 2020).

The production of ODFs usually uses polymers (40–50% w/w), plasticizing agents (0–20% w/w), and active compounds (1–25% w/w). Other components, such as flavoring agents, sweeteners, and saliva stimulants, may be added in concentrations up to 40% w/w to improve acceptance. ODF properties can be modified by varying the polymer concentration used in the formulation, reaching up to 60–65% w/w. Regarding the methods, the main ones currently used are casting and hot extrusion to produce films having an area ranging from 5 cm² to 20 cm² (Irfan et al. 2016).

ODFs have been developed to treat various medical conditions such as allergies, pain, addiction, sleep difficulties, and Alzheimer's disease. ODFs have also shown potential for aesthetic purposes. For example, Lee et al. (2022) demonstrated that 22 women treated over 12 weeks with ODFs containing collagen had skin wrinkles reduced, and elasticity and density significantly increased.

Textile Applications

Functional textiles are one of the most important fields in textile science and industry. Functionalities can include antimicrobial activity, self-cleaning, antistatic, insect repellency, heat and cold resistance, anti-creasing, flame retardancy, and protection against ultraviolet radiation (Fig. 2). Biopolymers have played a significant role in obtaining these functionalities through coatings on the most diverse types of natural and synthetic substrates.

Well-established methods of textile finishing, such as exhaustion, impregnation, spraying, and LbL deposition, can be explored in the application of biopolymers coatings (Asif and Hasan 2018). Pad-dry-cure is one of the most industrially used methods to produce textile polymeric finishes. The process is accomplished by padding fabric through a biopolymer solution, squeezing between rolls at a pressure to control the pick-up, drying at moderate temperature, and curing at an elevated temperature (Malucelli et al. 2014).

A relevant disadvantage related to biopolymeric coatings is the poor adhesion to the fibers, which can result in gradual leaching with washing processes. Chitosan, for example, forms weak bonds with cellulose fibers based on hydrogen bonds and van der-Waals interactions. Cross-linking agents such as polycarboxylic acids can be

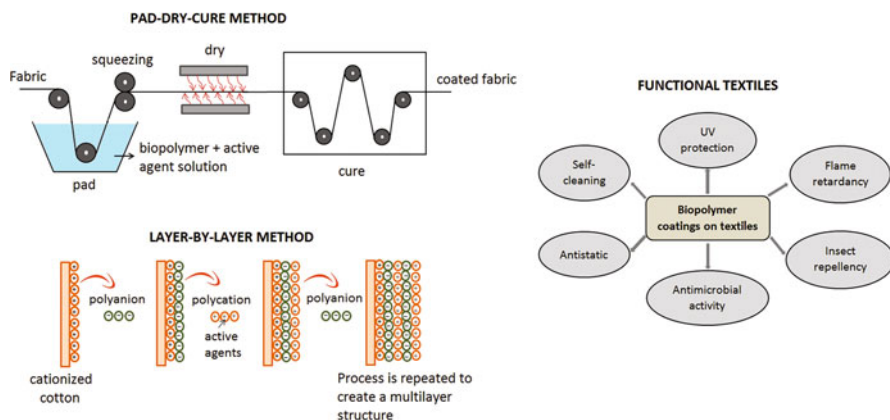

Fig. 2 Representation of pad-dry-cure and layer-by-layer coating methods for the development of functional textiles

used for stronger bonds, resulting in greater treatments' durability. In this case, the amine groups of chitosan and hydroxyl groups of cellulose can form covalent bonds with the carboxyl groups of polycarboxylic acid.

Coatings must not adversely affect the fabrics' feel, handling, and breathability. Therefore, nanocoating, which has thicknesses of less than 1 μm (Joshi et al. 2011), represents a promising alternative to provide functionality while preserving tissue characteristics. The LbL technique has been highlighted for obtaining nanocoating on textile substrates. The substrate surface is exposed to the polymer with a charge opposite to the substrate surface charge for times ranging from seconds to minutes. Multilayers are then constructed by the sequential adsorption of oppositely charged polycations and polyanions. Cotton inherently has an anionic character but is often subjected to modification processes, such as cationization or anionization, for more efficient electrostatic interactions.

Flame Retardancy

Halogenated and phosphorus chemical compounds are very efficient in obtaining textile materials with flame retardant properties. However, the fact that these materials are proven to be toxic has motivated the search for halogen-free substituents. Efficiencies even comparable to conventional phosphorus-based flame retardants can be obtained using biopolymer coatings under mild conditions (aqueous suspensions/solutions) with no volatile organic carbon (VOC) produced and with low human and environmental impacts (Malucelli et al. 2014).

Recently, alginate has emerged as an excellent candidate for eco-friendly and phosphorus-free coating flame-retardant textile. Alginates had inherent flame retardancy due to their ability to cross-link with polyvalent metal ions, such as calcium (Xu et al. 2021). For polyester fabric, Liu et al. (2018) demonstrated that

a coating with calcium-alginate/nano-calcium borate composite can improve flame retardant and anti-dripping properties.

LbL assembly method has been successfully used as a finishing technique to produce flame retardant fabrics by combining, for example, positively charged polyethyleneimine and negatively charged alginate with subsequent cross-linking. When comparing the cross-linking of alginate with barium, nickel, and cobalt ions, Pan et al. (2017) observed that cross-linked barium coating could protect the modified cotton fabric during a burning test resulting in a complete and stable char residue.

LbL technique can also be used to produce intumescent coatings with chitosan and phytic acid. An intumescent system consists of a carbon source, an acid, and a blowing agent. During heating, these components react to form an insulating layer that protects the fabric from flames. In this case, chitosan serves as a char-forming agent and acts as a blowing agent, releasing ammonia gas as it degrades. Swelling systems using chitosan with retardant activity were observed for cotton (Laufer et al. 2012) and polyamide 66 (Kundu et al. 2017). Protein coatings also demonstrate potential for developing textiles with flame retardant properties. The effect of several deposited proteins on the flame retardancy behavior of the surface of textile substrates was investigated, such as whey protein, egg white protein, casein, and soybean.

The use of casein is based on its high phosphorus content. In cellulose substrates, casein may favor dehydration, generating thermally stable carbonaceous structures, rather than the depolymerization of glycosyl units into volatile combustible species capable of further fueling the process. Consequently, the total burning time increases, and the total burning rate decreases, indicating an enhanced flame resistance. Carosio et al. (2014) compared flame retardancy of cotton, polyester, and polyester-cotton fabrics coated with caseins and observed self-extinguishment only for cotton. For polyester and polyester-cotton blends, the burning rate was strongly reduced (70% and 40%, respectively), but the melt dripping phenomena for polyester were not suppressed.

In addition to delaying or preventing thermal degradation, the water adsorption capacity of proteins could partially dissipate the heat during combustion and dilute the produced volatile species. For cotton, for example, whey protein coatings resulted in a long time for the combustion process to take place, but a self-extinguishment of the flame was not achieved (Bosco et al. 2013).

Proteins can also be combined with phytic acid using the LbL technique to form a flame retardant system arising from a synergistic effect of phosphorus (from phosphate groups of acid) and nitrogen (from amino acids from protein) that leads to high residue and time to ignition of fabrics (Liu et al. 2020).

Antimicrobial

Textile materials are susceptible to microbial growth, which can generate unpleasant odors, degrade mechanical properties, cause discoloration, and even dermal

infections in users. Besides aesthetic and hygienic purposes, an emerging segment of textile antimicrobials is medical textiles, which include surgical threads, gauzes, bandages, hospital clothes, and protective clothing (surgical masks, caps, gowns).

Chitosan is the biopolymer that has received the most attention due to its intrinsic antimicrobial action. Even if the main objective is antimicrobial activity, other benefits can be derived from this treatment for cotton fabrics, such as dyeing improvement, abrasion resistance, antistatic, and anti-crease properties. Yellow zein, rich in lutein and zeaxanthin carotenoids, has also demonstrated some intrinsic antimicrobial activity against *E. coli* in the treatment of cotton fabric (Gonçalves et al. 2020).

Nanoparticulate antimicrobial agents, such as silver, CuO, and ZnO are frequently used for antimicrobial functionalities. Biopolymer-based nanocomposite finishes act to prolong or make the effects of nanoparticles more prominent. For example, (Xu et al. 2018) demonstrated that the covalent binding of carboxymethyl chitosan onto the cotton fabric surface enhances the adhesion ability of the Ag nanoparticles. Antibacterial activity was maintained after 50 wash cycles, and the treatment did not affect properties such as tensile strength, water absorptivity, and vapor permeability.

The ability of alginate to form resistant films by cross-linking with divalent ions has been explored to entrap and release active antimicrobial compounds. In general, the release and antimicrobial activity from treated fabrics show a negative dependence on the amount of alginate and the cross-linker concentration.

UV Protection and Multifunctionality

The UV protection functionality is one of the most important for textiles used under prolonged sun exposure, such as sportswear and beachwear. For this purpose, TiO₂ and ZnO nanoparticles are among the most explored compounds thanks to their intrinsic property of UV protection. Other inherent properties of these nanoparticles include photocatalytic activity, antimicrobial effect, and flame retardancy, which can provide multifunctionality to treated fabrics. The use of these nanoparticles combined with biopolymer coatings, especially subjected to cross-linking, aims to prolong the durability of the functionalization in the face of successive washings.

Agricultural Applications

The expansion of the world population and industrialization have been accompanied by increased plastic consumption for the most diverse uses and applications. The versatility, attractive price, and stability of plastic materials have contributed to disseminating their use in almost every sector, including agriculture. Plastic in agriculture includes greenhouse covers, mulches, low tunnel films, drip irrigation tape, plant containers, nets, silage bags, trays, seedling bags, and seed tapes (Adhikari et al. 2016; Gamage et al. 2022). In 2020, the sector consumed about

11.7 million tons of plastic worldwide, comprising about 3.3% of the total plastic production (Plastic Europe 2021). In the majority of cases, conventional fossil-based polymers are used, which, in the long term, can affect soil properties and non-biodegradable residues accumulation. Therefore, biodegradable polymers have increasingly been considered as substitutes for plastics in many agricultural applications, such as mulching, plant containers, and seed coating owing their natural degradation and soil-enhancing properties (Santos et al. 2020).

Mulching

Plastic mulching films have advantages for crop production, from both agronomic and phytosanitary points of view. They contribute to weed management, reducing the need for chemicals, favoring the crop by conserving soil moisture and moderating its temperature, and avoiding direct contact of fruits and leaves with dirt and soil. The most commonly used material for conventional mulching is low-density polyethylene, which provides an effective moisture barrier and radiometric properties, and mechanical resistance. As already mentioned, despite all the benefits, the fate of non-renewable and -biodegradable polyethylene mulches after their use is a major environmental concern due to a large amount of waste generated. The mulches must be removed from the field after use, involving dispendious hand labor or specific machinery. Farmers often discard the plastic residues in a dump or burn them, generating toxic emissions to air and soil (Immirzi et al. 2009).

As an alternative to contour those effects, biopolymers can be used to develop novel materials. The ideal plastic mulch would stay intact in the soil until the end of the crop cycle and then undergo full biodegradation within a few months. Currently, great interest has focused on the polysaccharides such as starch, cellulose, chitosan, glucomannan, and sodium alginate for mulching purposes. Cellulose has gained considerable interest because it is the most abundant natural polymer and is easily available. Chitosan and alginate, mainly derived from aqueous resources, exhibit excellent film-forming properties and biocompatibility. Agroindustry wastes and by-products can be rich sources of these biopolymers, contributing to the sustainability of the production chains and cost reduction.

Biopolymer mulches can be processed by extrusion, casting, and spraying methods to form biodegradable films and coatings from biopolymers (Adhikari et al. 2016). Compared with conventional options, higher costs and poorer mechanical and barrier properties remain the main obstacles to bio-based mulches dawning. However, more strict environmental regulations regarding plastic production and disposal, allied to the increasing demand for more sustainable production processes, are pushing researchers and organizations in the race for the development of competitive, environmentally benign materials (Santos et al. 2020).

Several strategies to improve biopolymers' properties have been proposed, such as chemical modification, cross-linking, blending different biopolymers, adding plasticizers, and loading with reinforcement filler. Cellulose fibers, wheat bran, dry algae, and other natural components were added to the polymeric solution to

enhance mulch properties (Adhikari et al. 2016). Sprayable biopolymer formulations for soil coating are also gaining special attention. For mulching purposes, spraying the biopolymer solution in the soil to form a protective layer instead of applying a pre-formed structure represents an innovative approach (Immirzi et al. 2009).

Bio-based films and coatings can also vehiculate active agents as nutrients, pigments, and growth promoters. A chitosan solution sprayed on the soil surface of plant pots efficiently inhibited the growth of weed species for about 3 months when it began to biodegrade (Giaccone et al. 2018). Alginate and glucomannan mulching films enriched with sugarcane vinasse were produced and characterized, allowing the recycling of vinasse nutrients into the soil. Those films were cross-linked with calcium ions reducing drastically their water solubility (Santos et al. 2020). Starch and chitosan blend films with the addition of citric acid and black pigments showed potential for application as biodegradable mulching for short-cycle vegetables and flower crops (Brandelero et al. 2019).

Containers and Bags

Plant pots, seed trays, and bags are widely used in horticulture and nursery for growing, packaging, and transporting purposes. Considerable large amounts of plastic waste are generated from those applications (mostly single-use), which are often left in landfill or burned due to difficulty and high costs for proper disposal and recycling. Bio-based polymers have gained importance in this segment as alternatives to petroleum-based materials with the advantages of significantly reducing the amount of waste, labor costs, and environmental impacts since they can be planted with the seedling or young plant and undergo biodegradation direct in the soil, eliminating the need for transplanting and disposal. Biopolymers derived from agroindustry by-products and wastes such as starch, cellulose, soy protein isolate, alginate, and pectin, associated with natural reinforcement fillers such as wood pulp, coconut husks and fiber, and rice hull, can represent innovative and sustainable options for the development of new products. Pots of alginate and fibers from tomato and hemp were produced for transplanting plants, and field experiments showed adequate root and plant development with complete degradation of the pot structure after 2 weeks (Schettini et al. 2013). Blick et al. (2014) developed starch/polybutylene adipate terephthalate (PBAT) biodegradable seedling bags and showed that the material remained intact throughout the seedling production period (60 days) but was completely biodegraded after transplantation into containers (240 days). Agonomically, there were no significant changes in plant dry mass compared to control (with no bag).

Seed Coating

Seed coating is a kind of seed treatment in which polymers are used as carriers of nutrients, antimicrobial, and other active ingredients, favoring seed performance in

terms of physical, physiological, and health quality (Rocha et al. 2019). Biodegradable polymeric matrices can significantly reduce the amounts of agrochemicals through their encapsulation in super-low volumes and controlled release, avoiding exposure of the product to the external environment, as well as its evaporation (Pirzada et al. 2020). The use of biopolymers as seed coating has been highlighted in scientific research, such as chitosan, which promoted increases in soybean seed germination and seedling productivity (Zeng et al. 2012), cellulose acetate (Friuli et al. 2020), and in addition to biopolymer mixtures that favored corn seed germination (Vercelheze et al. 2019).

Conclusion

In the last years, much effort has been made to replace synthetic polymers with biodegradable materials for ever-expanding applications. Unique properties, such as biocompatibility, biodegradability, nontoxicity, and the possibility of chemical modification, make biopolymers attractive for many fields, including food packaging, biomedical, textile, and agriculture.

The shelf life and quality of fruit and vegetables, meat, dairy, and seafood products can be improved with edible films and coatings. There is a major focus on developing packaging systems containing antioxidants and antimicrobial agents, enzymes, or functional ingredients. In medicine, surface modification of implants to meet required or add specific functions, such as cell proliferation, tissue growth, repair, and delivery growth factors, active molecules, antimicrobial agents, and drugs, can be achieved by biopolymeric coatings. Orally disintegrating films have emerged as a route of drug administration that does not need water to be ingested, which is particularly useful for pediatric and geriatric patient populations. Biopolymers play a significant role in this application since film must be composed of a nontoxic and water-dissolving polymer. Biopolymer films also represent a versatile platform for improving skin healing due to the ability to remove wound exudate while maintaining a moist environment and minimizing bacterial infections. In textile applications, biopolymer coatings, mainly nanocoatings, provide products with high added value, with flame retardant, antimicrobial, and ultraviolet protection functionalities. One of the biggest challenges for this application is the durability of the treatment, which tends to be removed with successive washes if there is no permanent bond between the coating and the textile substrate. For agricultural applications, biopolymer films and coatings act to reduce the amounts of synthetic plastics and agrochemicals, enhance soil properties, and load active agents.

In general, incorporating nanofillers and combining different biopolymers have been proved to be an economical and versatile way to yield films and coatings with improved properties, overcoming mechanical and stability limitations. However, more studies must be done in terms of scaling-up processes to increase the competitiveness of biopolymeric films and coatings.

Abstract

Cellulose is a biomass that occurs abundantly in plants, animals, or bacteria. It can exhibit enhanced gas barrier performances due to their high degree of crystallinity and polar nature. Its linear polymer chain built out of β -D glucopyranosyl units linked via 1,4 positions and its fibrillar nature adds to its performance in slowing down diffusion of gases such as O_2 , CO_2 , N_2 , and vapor. During the last decade, this bio-nanomaterial was identified as a potential filler in composites to taper its reinforcement capacity. “Nanocellulose” refers to the cellulosic materials whose structure falls to the nanoscale regime. Its dimensions falling in nanoscale and formation of strong entangled nanofibrillar network and porosity, have inspired the evolution of novel applications. They may be cellulose nanocrystals, fibers, or bacterial cellulose. Nanocellulose is a non-hazardous, biocompatible, degradable

mass without side effects on health and environment. In previous years, as a result of advancement in research-based optimizations, its mode of synthesis has transformed a lot. New biosources, new mechanical processes, and new strategies and treatments have opened up a new realm in nanotechnology. Pharmaceutical packaging shows deadly demand for biocompatible oxygen barriers for retaining moisture and freshness, so do the need exist with electronic industry. Here we are focusing on nanocellulose-based gas barriers fabricated by itself via a suitable method such as layer-by-layer formation; nanocomposite was fabricated using extrusion, electrospinning, casting, or evaporation, where its primary role is reinforcement in those polymer matrices or as hybrid composite with prominent nanomaterials. The challenges in this realm are the water absorptivity and swelling or geometrical deformation of nanocellulosic films or composites and henceforth the failures in meeting material applications. In this chapter, nanocellulose-based gas barriers and its applications in various technological and industrial realms are discussed.

Introduction

Recent progression in science and technology coupled with an increased nature consciousness has moved the societal and industrial foci toward green mass and eco sustainable process. This agitation has been fueled by the depleted oil mines and the imbalance existing between the production of polymers and its recycling. As a driving force there is an option to replace oil-derived polymeric materials with renewable counterparts, preferably a biodegradable material. However, a complete replacement is not an easy task because the good material properties and excellent processability offered by these polymeric materials stabilize their market position. Common packaging materials and oil-based polymers possess good barrier properties, stability readiness to be processed, and high degree of transparency, which are just a glance of their desired qualities (Vermeiren et al. 1999). To catch oil-based polymers with renewable and bio-based materials, it is essential to reach at least similar application levels at a comparative cost. One mode to readily achieve this aim is to use naturally abundant biopolymers with existing industrial-scale production and processing protocols.

Moreover, huge amount of plastic packaging wastes produced yearly aggravate the pollution of marine and terrestrial ecosystem (Robertson 2013). Microplastics pose the menace of getting delivered to other organisms through food chain once it is ingested (Andrady 2011) because no organism can ever break it down or digest it. Along with this, materials of this kind induce excessive emission of gases that cause green house effect and henceforth lead to global warming. Global

environmental menaces due to petroleum-based plastics have become a serious concern. Apart from recycling used polymer packages, the fabrication of materials with biodegradability is the demand of the hour. On an environmental outlook, biodegradability is unavoidable apart from a functional requirement (Siracusa et al. 2008), especially considering that the bioplastics industry is growing at a rate of 20% per year (Peelman et al. 2013).

Gas Barrier Properties – Present Scenario and Green Barriers

By virtue of their barrier performance, thermoplastics, such as ethyl vinyl alcohol copolymers, polyvinylidene chloride, and aromatic polyamide, are used for extending food shelf-life by acting as barriers to small gaseous molecules. Compared to these, PVDC acts as better barrier to O_2 and water vapor in humid and freezing conditions. However, as shown in Fig. 1 (Nelson et al. 2016), the nanocellulose trends the highest oxygen barrier properties.

Copolymer of ethyl vinyl alcohol has more resemblance to nanocellulose (Fig. 1). The problem associated with both these barriers is that their resistance to passage of gases adversely diminished when freezing or high relative humidity (RH) is generated. Due to the plasticization mechanism, free volume increases owing to the swelling of $-OH$ groups present in their respective structures (Nelson et al. 2016). Copolymer of ethyl vinyl alcohol is a thermoplastic substrate which can be laminated in multi-layered hierarchical structures, whereas a neat nanocellulose is not

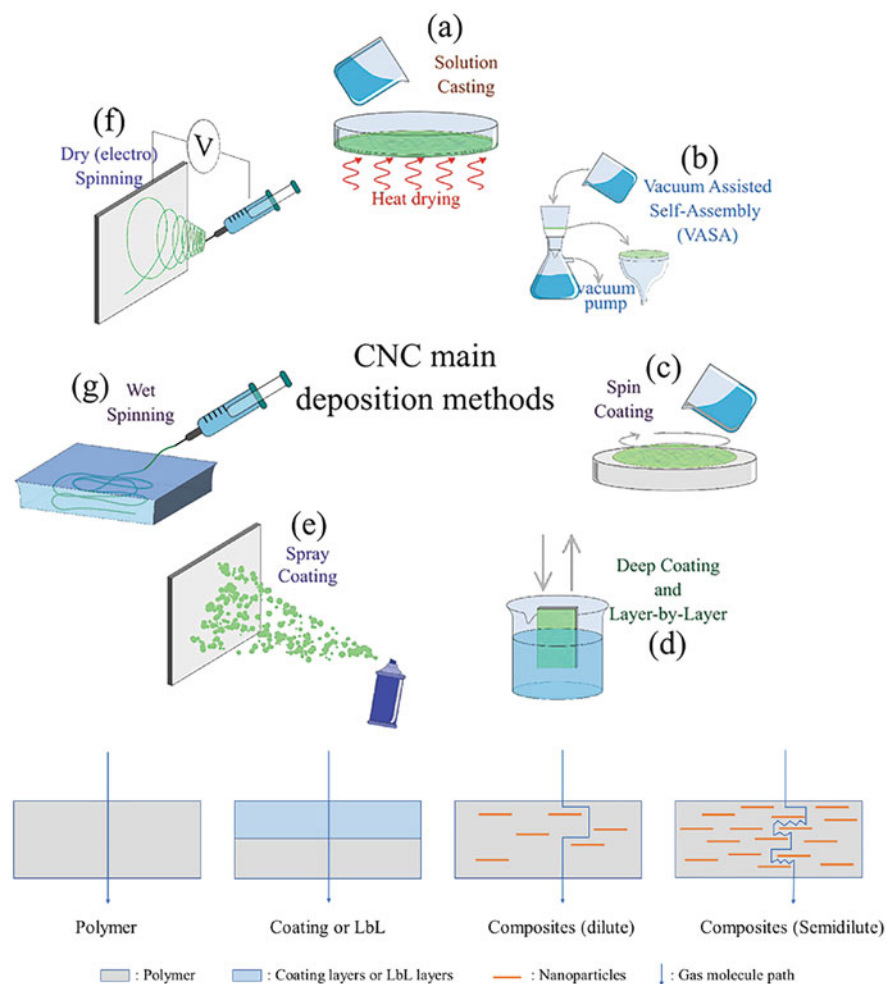

Fig. 1 Barrier properties of nanocellulose, synthetic plastics as well as bioplastics, and other bio-structures – their KPO_2 , KPW_2O (unit – $cm^3 \mu m/Pa \text{ day } m^2$ and $cm^3/day \text{ m } Pa$), respectively (from Nelson et al. 2016), oxygen and water vapor resistance coefficients focused

thermoplastic, so, need a blending with any combination of thermoplastics to fit their application as a packaging material. Lamination technique helps to alleviate the hydrophilicity of copolymer of ethyl vinyl alcohol and makes them fit to use in flexible materials. Nanocellulose improves the water vapor permeability (WP) of thermoplastics (Rhim et al. 2013) and cross-linked composites and restricts the swelling of hydrophilic polymer or nanocellulose at high humidity. It is known that water absorption weakens the high gas barrier as well as other beneficial properties for both nanocellulose films and composites. This poses the biggest menace as far nanocellulose-based materials are concerned. They possess perfect degree of orientation and mechanical strength but removal of water at pH ranging at four takes more than 4 h to making scaling-up a tough task. However, these findings are precious as they show the predominance of nanoscale structures and the trade-off between nanodimensions and processing time when focusing on overall properties. Aiming at enlarging the spectrum of biomaterials, several researchers have been focusing on novel bioplastics, compounds, and batches. A number of these polymers have been made available in a commercial scale for food packaging purposes such as aliphatic polyesters, poly(lactic acid) (PLA), starch, and cellulose (Siracusa et al. 2008), especially, chitin and chitosan. Polyesters are very crucial, as most are biodegradable and biomass based. Nanocellulose is a bio-based nano-polymer which is readily degradable, renewable, and eco-friendly material. It is made from a number of sources of natural origin such as plants, animals, and bacteria (Chen et al. 2011; Du et al. 2021). Usually reported forms of nanocellulose are of two: nanocrystals (CNCs) and nanofibrils (CNFs). CNCs (Foster et al. 2018; Moon et al. 2011) are rod-like particles, while CNFs are fiber-shaped ones (Chen et al. 2019). Other nanocelluloses are microcrystalline cellulose (MCC), microfibril cellulose (MFC) (Ewulonu et al. 2019), bacterial nanocellulose (BNC), and cellulose nanosphere (CNS). All these nanocelluloses consist of crystalline and amorphous regions (intermittently arranged). Usually, CNC has 72–80% crystallinity which is higher than that with 50–65% crystalline CNF, convincing the point that higher rigidity of materials and superior gas barrier potential is possible with these (Ferrer et al. 2017; Wu et al. 2021). Nanocellulose has strong hydrogen bonding interactions which influence physical–chemical properties and is hence hydrophilic. Nanocellulose, single CNF or CNC, shows strong mechanical strength and shows increased modulus and tensile strength. All these properties enhanced over the longitudinal direction of samples under study. Transparency is a property on demand in packaging applications due to requirement of content visibility. Nanocellulose films show high mechanical properties than the general spectra of polymers or synthetic polymers such as PET, LDPE (Aulin et al. 2012), and PS. The study of properties of filled polymer composites shows that incorporating nanocellulose into the polymer (generally called matrix) enhances their mechanical strength. Nanocellulose exhibits good optical performance. Optical transmittance value tops up to 90% (Aulin et al. 2010) and even close to 100%. Nanocellulose in the matrices does not deplete the optical texture of these materials (Espino-Perez et al. 2013). Mechanism of gas diffusion may be schematically shown as in Fig. 2.

Gas Barrier Performances of Different Nanocellulosic Materials

Cellulose Nanocrystals (CNC)

CNCs are rod-like dwarf materials with low degree of entanglement, particularly for CNC films with good degree of order, which leads to brittle (Chowdhury et al. 2019) films and are prone to large crack formation. The CNC film surface is much

smoother than that of CNFs. CNC-reinforced composites are more efficient as property enhancers in gas barrier performance due to their higher crystallinity. Films of CNC and CNF are good gas barriers as well. Water vapor permeability (WP) of films of nanocellulose is appreciably high due to good water uptake characteristics (Ferrer et al. 2017). The oxygen permeability of CNC films studied at different crystal orientations revealed that rod coater provided CNC films with unique order (Chowdhury et al. 2019). Ordered films are seen to exhibit a value of $0.2500 \mu\text{m}^2 \text{ day kPa}$, which is lower than the value shown by randomly arranged CNC films which comes as $219.00 \mu\text{m}^2 \text{ day kPa}$. Anisotropy affects gas permeability appreciably. In quest for creating gas barriers and active material for packing, a technique named LBL (layer-by-layer processing) has been practiced. In LBL, they interacted nanocellulose with some cationic polyelectrolytes. They may be selected from common cationic polyelectrolytes like chitosan and polyethyleneimine (Foster et al. 2018; Miao and Hamad 2013) and polydiallyldimethylammonium chloride or polyamidoamine resin. Combination of multilayers shows highly versatile coatings of ready-to-use structures such as boxes, plates, and bottles. The gas permeability of CNC films is superior to CNF or MFC films (Belbekhouche et al. 2011) and the CO_2 , N_2 gas permeability of CNC films is 1000 times higher than that of films of CNF, which owes to the lower entanglement between CNC and film brittleness. By adding minor amounts of CNF into these kinds of CNC films or increasing the degree of order of rod-shaped CNCs, permeability of CNC films decreases. It is due to the change in the packing density as well as the free volume of the system containing CNCs (Chowdhury et al. 2019; Fotie et al. 2018).

Cellulose Nanofibrils (CNF)

Numerous studies tried to solve water absorption-related problems, and few of them showed good results, but a few argue that not all methods could alter and affect the barrier property. The hydrophobic modification of quaternary alkyl ammonium salts in a study indicated that OP is directly proportional to molar ratio or chain length of quaternary alkyl ammonium salts. Modification is a solution that can certainly add hydrophobicity to films and delay water uptake, but it compromises the film density which directly induces an increased free volume of these CNF films, which initiate and propagate ready transport of the O_2 molecules and hence an increased OP. CNF films being developed as entanglement of nanofibers have good mechanical and gas barrier properties. This superior behavior owes its origin from high aspect ratio of these celluloses (Visanko et al. 2015; Herrera et al. 2014). Water vapor permeability of CNF films (Saengerlaub et al. 2019) is about 1000-fold higher than that of polymeric ethylene and ethylene glycol (Li et al. 2019). Hydrophobization by modification of nanocellulose can decrease the WP. An example for this is 10-undecylenoyl chloride (Li et al. 2019), which has superior water vapor resistance. However, hydrophobic modification has limitations in certain cases. It reduced the interaction between CNF chains (Solala et al. 2018), ending up in higher free volume of the films, which subsequently worsens water vapor barrier properties. Thermal

treatment reduces porous structure, and increase in crystallinity improves water vapor barrier properties, which is already a proven OP barrier. Other than oxygen, barrier to other gases is also significant. Carbon dioxide permeability of nanocellulose film is lower than that of low-density PE (Chowdhury et al. 2019). PP and PVC are in the same range of copolymer EVA. The CH_4 (Belbekhouche et al. 2011), CO_2 (Ansaloni et al. 2017), and N_2 gas permeate in a rate which is proportional to increase of RH.

Bacterial Nanocellulose

Bacterial cellulose (BC) is a useful cellulose nanostructure used either as reinforcing phase or as matrices for a wide range of variety of materials including films for food packaging applications. *Gluconacetobacter* synthesizes nanocellulose in a medium with C and N sources. Chemically, it is identical to plant cellulose; the bacteria synthesize cellulose and form group of nanofibrils and assembly of nanosized ribbon-shaped fibrils with <80 nm in width. It is also free from hemicellulose and lignin, reducing purifying costs and environmental damages of those derived from using harsh chemicals. It can form a pellicle membrane-like structure with a water retention capacity of nearly 700 times its dry weight. These membranes may be impregnated with polymer dispersions having reinforcing agents and antimicrobials. A bottom-up technique was used to self-assemble nanocomposites in which BC was grown in the presence of a biopolymer mixed in the medium. Works reported that these BC nanowhiskers (BCNW) filled in polyhydroxybutyrate-co-hydroxyvalerate (PHBV) matrices reinforced and had highly dispersed structure with better reduction in oxygen permeability without much change in mechanical performances.

Microfibrillar Cellulose (MFC)

From the pulp of bleached spruce sulfite, MFCs were synthesized and their oxygen permeability data were consolidated. They prepared MFC films without specific orientation using a 0.10% MFC suspension in a cylindrical mold, dried at room conditions. They were 20–33 mm thick, and their corresponding weight was found to be between 15 and 30 g/m². The OP values measured at 0% relative humidity were 17–18 mL/m² day. OP of the copolymer or PVDC-coated or -oriented polyester ones falls in the range of 3–5 mL/m² day and 9–15 mL/m² day. These films are therefore superior to several well-known synthetic polymer films due to their dense and nanostructure with porous network. After these observations, carboxymethylation pretreatment on MFC fibrils evidenced that they were highly charged and ready to liberate. This was evidenced at an RH of 50%; here the pretreated MFC films presented OP value of 0.085 mL mm/m² day atm. This is superior to the values for neat MFC which is between 0.3520 and 0.5050 mL mm/m² day atm (Aulin et al. 2010). This work also highlighted the impact of different parameters connected with synthetic strategy applied during MFC production. The films unlike the raw

low-charged MFCs had a tightly packed network formed by fibers with smaller and more homogeneous structural parameters. It was noticed that as the RH raised from 0% to 50%, a considerable increase in the OP values could be observed, from 6×10^{-5} to 0.0850 mL/mm m² day atm, respectively. The crystalline structure of MFC and its ability to form tightly packed dense interfibrillar network as well as intrafibrillar hydrogen bonds adds a lot to its ability to resist gas diffusion. At a low relative humidity, such an OP can be attributed to these structural features. At a higher RH of about 70%, the hydrogen bonds loosen, creating films that are less densely packed. Even at such a high RH, however, they provide better OP values that are superior to those of other biopolymers and films. Other parameters studied were the weight and the thickness of films which indicated that as the weight and thickness increased, the difficulty of the path that oxygen must traverse also increased which resulted in a decrease in the OP value. Moreover, the degree of OP also decreased with increased film thickness. Obviously, most pores are located at the surface of MFC films, the pores are scattered and thus contribute to the impermeability of films when they have proper thickness. The OP value of neat MFC films from kraft pulp was about 4 mL/m² day corresponding to a weight of 30–40 g m⁻². Higher OP values depending on the reaction time (from 6 to 11 mL/m² day) were seen for acetylated MFC films. Regardless of the treatment, whether it be acetylation or carboxymethylation or another one, under a given experimental condition to produce MFC films, they are seen forward as new biomaterials to realize the concept of good barrier food packaging. Compared to other renewable material including different cellulose and synthetic polymers, MFC films possess low barrier properties. The degree of crystallinity is high for MFCs that they even exhibit a OP that is much superior to that of cellophane. Fukuzumi et al. (2011) cast a TOCN/water dispersion to PLA film. It was a plasma-treated one and this methodology was found to modify MFC's affinity with water preserving its good gas permeability. The obtained TOCN-coated layer had 0.4 mm thickness on a 2.5-mm-thick PLA film. These ultra-thin MFC layers had a significant decrease in the oxygen permeability (from 7.4 to <0.001 mL/m² day kPa) between an unmodified PLA film and a PLA film. Similar conclusions have recently been reported, based upon the coating of PET films with TOCN dispersion, which decreased the OP value from 29.3 to 0.08 mL/m² day (Rodionova et al. 2011). The same year, a similar coating process for PET films and two kinds of TEMPO-mediated oxidation were proposed by Fujisawa et al. They prepared the usual TEMPO/NaBr/NaClO-treated cellulose nanofibrils (called TOCNs) with sodium carboxylate groups (COONa), and TEMPO-oxidized cellulose nanofibrils, HCl washed with free carboxyl groups (TOCN-COOH). The PET films were then coated with a thin layer of TOCN film in order to access their oxygen barrier properties. The oxygen permeability of these films decreased from 0.31 to 0.049 mL/m² day kPa when coated with modified form. Regarding the oxygen permeability, the combination of MFC with a polylactic film (Fukuzumi et al. 2011) and an amylopectin solution (Plackett et al. 2010) reported a decrease in this property. In this regard, two different MFCs with high amount of hemicelluloses and other with carboxymethylated MFCs (Plackett et al. 2010) were prepared, and amylopectin was added. Depending on the ratio of MFC to

amylopectin and also the type of MFC, the average OP (at 23 °C, 50% relative humidity) varied between 0.013 and 0.037 mL mm/m² day atm. The results obtained for amylopectin films with a 50 wt.% as well as 100 wt.% MFC films were similar. All the composites displayed reduced permeability values in the range 0.01–0.02 mL mm/m² day atm. These values are low on comparison with the oxygen permeability of amylopectin film which is 1.40 mL mm/m² day atm. Consequently, the addition improved this property, and the case repeats with the other combinations with MFC. So these combinations can lead to nanocomposite with good oxygen barrier. A nanopaper was prepared by coupling layered clay with MFC, which produced a strong and good gas barrier. When relative humidity was as high as 95%, a drastic increase of OP to 3.5 mL mm/m² day atm could be noted, whereas at 0% relative humidity and 50% relative humidity, low values were confirmed when half MFC and half clay combinations were studied (0.001 and 0.045 mL mm/m² day atm, respectively) and for 100% neat MFC films, the value showed an exponential increase from 0.048 to 17.5 mL mm/m² day atm.

Nanocellulose Hybrid Materials

A number of hybrid nanocellulose materials are explored which exhibit superior barrier properties. Excellent gas barrier film was fabricated by LBL using combination of polymer with nanoparticles or polymers having layer thickness in the range of hundreds of nanometers (Ariga et al. 2007; Hammond 2004). Nanoplatelet materials are promising barriers and hence are widely used as gas barrier layers due to the high surface area these platelets possess (Choudalakis and Gotsis 2009). The LBL technique is seen to improve gas barrier properties of these nanocellulosic materials. This is due to the concept that nanocellulose makes it feasible to be deposited as a very thin layer in a preferably parallel direction to the surface of the prospect film, leading to nanocellulose assembled in a perpendicular direction to the path of gas permeation and hence forms a barrier system. Materials such as (GO) graphene oxide, gibbsite (Chemin et al. 2019), Guar gum (Dai et al. 2017), alginate, clay, chitosan, and polyelectrolyte were prepared similarly with CNF (Li et al. 2013) or CNC to create gas barrier films (Halasz et al. 2015). By increasing the number of deposited layers, gas barrier properties of LBL materials can be tailored and enhanced barrier properties are observed after several bilayer depositions are executed. OP of gibbsite/CNC LBL films reaches 75% reduction by seven bilayers as in Fig. 3, and chitosan/CNC LBL films (Li et al. 2013) show 94.0% reduction at the 30 bilayer deposition (Chemin et al. 2019). It is reported as the oxygen permeability of polyethyleneimine/nanofiber film marks 94.0% deduction, whereas water vapor resistance reaches 52.0%. There is a 0% deduction by 50 bilayers when compared to the uncoated substrate (Aulin et al. 2013). This is mainly due to swollen structure, and hence, an improvement of WP ability is more significant as compared to the OP. In addendum to the increased number of bilayers, low air voids are used to achieve homogenous nano-coatings, which helps to improve barrier properties. For a given polymer cellulosic nanoassembly, there is an increase in film packing density

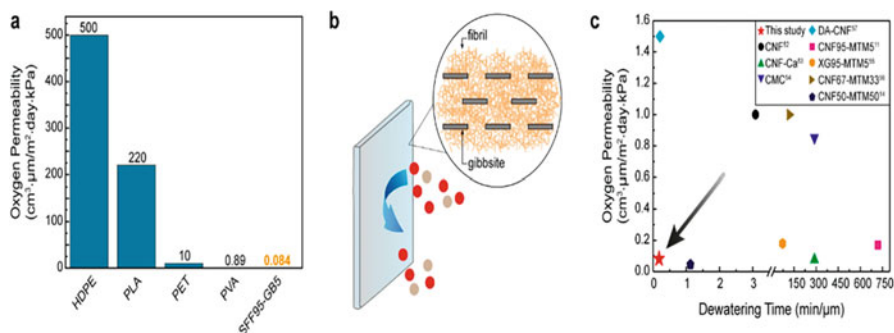

Fig. 3 (a) OP – SFF95–GB5 versus conventional plastics used in packaging (*HDPE* high-density polyethylene, *PLA* polylactic acid, *PET* polyethylene terephthalate, *PVA* polyvinyl alcohol). (b) Pathway for enhanced barrier properties. (c) Graph for oxygen permeability and dewatering time normalized by thickness for control and for wood-based materials. From literature, dramatic improvement in the OP of cellulose nanocomposite films is achieved with GO loading, as seen from Table 1

Table 1 Regenerated cellulose (RC)–graphene oxide (GO) films and their permeability to oxygen

Serial no.	Designation of composite films	PO ₂
1.	RC	$1.59 \times 10^{-12} \text{ cm}^3 \text{ cm/cm}^2 \text{ s Pa}$
2.	RC/1GO	$4.63 \times 10^{-14} \text{ cm}^3 \text{ cm/cm}^2 \text{ s Pa}$
3.	RC/5GO	$1.8 \times 10^{-15} \text{ cm}^3 \text{ cm/cm}^2 \text{ s Pa}$

by nanocellulose and polymer interactions between layers. The gas barrier property improves because a barrier effect is imposed on the polymer in the presence of partially impermeable semi-crystalline structure of nanocellulose. The LBL assembly alters OP much better than that of water vapor barrier properties as reported in earlier works (Dai et al. 2017). The nanoplatelet- and nanocellulose-filled polymers fabricated using LBL strategy show an excellent improvement of barrier properties. A previous work studied that LBL casts graphene oxide-CNF films – having 3.66 vol.% GO, which results in the OP coefficient of CNF film to decrease by about 40,000 times. Qin et al. reported that permeability of clay-filled CNF had permeability orders of magnitude lower than the neat substrate when 20 bilayers were deposited. Nanoplatelets in the meanwhile can also block water molecules when filled within such polymers that are capable of decreasing water absorption of the nanocellulose, resulting in high gas barrier properties even at high relative humidity conditions of operation. In a reported work, blending CNF/alginate to form films shows huge CNF aggregation and hence possesses poorer air barrier properties than bilayer or multilayer films fabricated with alginate itself. The same phenomenon could be observed with few other systems as can be seen in CNF/clay systems. In these, the blended composites of CNF/clay exhibit superior permeability values than the layered matrix of the same materials. Layered assembly can achieve nanoparticle arrangements that are well orientated in the polymer systems and thus

prevents aggregate formation of these nanoparticles and hence results in superior properties compared to the blended-type composites, as far as barrier capacities are concerned. However, these blending materials are readily processible and suitable for a wide range of polymers and nanoparticles than the former LBL materials. Nanocellulose consists of both polymeric part and nanoparticle part, which can play dual roles depending on the nature of different systems into which it is incorporated. Incorporation of different shaped nano's or varied components into the NC (nanocellulose) system yields various NC composites with different mechanical, optical, morphological, and barrier properties. Different particles such as clay, silica, layered double hydroxide–nanocellulose composites were studied for gas barrier properties. Nanocellulose composites with boron nitride nanosheets, halloysite structures, MWCNT, SWCNTs, nanographene, etc. were also studied. Silicates especially clay being a 1D nanoparticle of inorganic origin have a diameter of 30 nm to microns and about 1 nm thickness (Hu et al. 2020). The clay/nanocellulose films processing is done by simple mixing of these two raw materials in a suitable solvent, fixing it and filtered suitably and finally dried to obtain the final material. The layered structure of hybrid clay/nanocellulose composites is highly ordered and resembles platelet pack and have the nanocellulose matrix cover around it. The schematic nanostructure and SEM of the clay/NC composites are as shown in Fig. 3. The materials that resemble or imitate natural phenomena are drawing great interest since these hierarchical structures can yield superior, mechanical properties, stiffness and toughness, flame, heat retardant, and gas barrier abilities. Looking into the clay–NC composite films, there is markedly a continuous decrease in OP with clay content up to 50 wt.%. A reduction in OP in a range of about fourfold times could be seen with 1 wt.% clay, and this marks about 40-fold reduction when 50 wt.% clay was incorporated, all achieved at 0% relative humidity. Thus it's interesting to note that both barrier properties enhanced in a hand to hand mode with increasing the clay content in nanocellulose composites. In the case of CNF films, pure films show super high permeability when at a high relative humidity of 95%. This may be because at certain water levels, there will be disruption of hydrogen bonding and van der Waals interactions. On the other hand, as seen earlier the clay in clay/NC films helps to build barrier layers to water molecules and helps in reduction of the water absorption by nanocellulose. Though this is not an ultimate solution to water absorption-related issues, the composites still showed higher permeability at high humidity conditions compared to the dry conditions which is a ray of hope to futuristic prospects in application of these hybrids films. Crosslinking of or addition of positively charged additives produces more compact materials to generate even higher barrier materials. As seen with chitosan act as a flocculant in co-dispersion of negatively charged NFC owing to its positive charge and clay and/or surface modification with cationic groups as seen with CNF helps to self-assemble it with anionic clay forming composites with more densely packed structure. Gas permeability studies of reinforced composites (Fredrickson and Bicerano 1999) were published for all impermeable materials as plate-like, spherical, and tube-like nanoparticles. These helped to improve the microstructure of the clay/nanocellulose composites and exhibit the direction for futuristic research and technological aspects.

The barrier layer was composed of sheets, which significantly reduces the usable area parallel to the film and the compact structure promotes the formation of the large gas barrier layer of GO. Further it expands the gas diffusion path. As seen from Table 1, GO effectively suppress the penetration of O₂ into the composite films. Significantly, the OP of the RC (regenerated cellulose) film is as low and is almost 34 times higher than that of the RC/1GO film. As the GO content increases, a further steady decrease in OP is observed with increasing GO loading from 1% to 5%. The RC/5GO film shows about considerably 388 times reduction relative to the regenerated cellulose film and RC/1GO. Hence, the gas barrier performance of the NC film significantly improves due to the strong interfacial binding force between GO/NC (nanocellulose) matrix.

Nanocellulose-Reinforced Composites

Extrusion of nanocomposite is a general process where a continuous profile of the matrix is made into desired thickness by incorporating fillers into it by melting raw materials at a given temperature. The matrix made into desired thickness gives a modified polymer or composite of fixed shape on cooling once they are forced into a die. Recently, as a filler for the mechanical reinforcement of PLA adhesives and polymers, nanocellulose plays an important role. These matrices take the advantage of the very high specific surface area and aspect ratio of these nanocellulosics to boost their performances. The mechanical properties of low-density polyethylene when extruded with esterified CNCs grafted with acid chlorides of organic compounds found to improve, especially the elongation at break showed a marked improvement. Casting is a general operation of removal of solvent via evaporation from the NC at a given temperature to carry out evaporation in a controlled manner. Through this process, dried films of neat or modified NC are obtained. It is important to note that CNCs are brittle compared to CNFs which are flexible; but suitable plasticizers if incorporated can compromise the brittleness by improving the capacity of the CNC structures by reducing formation of hydrogen bonds which is seen reported for addition of sorbitol and glycerol. A composite melt is also made out of polymer by heating, either resistance heating or circulating fluids can be done. Fibers up to macrometric scale is prepared by electrospinning, which is a technique that uses the electrostatic forces of the fiber. In the past years, studies conducted showed that the pattern of orientation of the fibers that occurs during the ES alters the thermo-mechanical properties and crystallinity of the ES fibers; this very same concept has been successfully employed for exploring cellulose-based materials. CNC and MFCs were incorporated into PE and PVA via electrospinning method, and the respective electrospun complex matrices showed higher compatibility and improved mechanical properties. Very recently, similarly processed composite films of nanocellulose and poly (hydroxyalkanoates) showed good water impermeability. Clay-filled composites still show superior performance among different class of available fillers. Nanocellulose/montmorillonite composite films prepared from radical form of 2,2,6,6-tetramethyl substituted piperidine-1-oxyl (TEMPO)-oxidized

nanofibrils of cellulose (TOCN) with these filler nanoplatelets. The composite films obtained possessed good transparency and flexibility exhibiting superior mechanical strength and oxygen permeability resistances. By casting of a mixture formed of cellulose nanocrystals and plasticized starch, a nanocomposite material has been successfully obtained. The cast structure resulted had a remarkable enhancement of water resistance and mechanical properties such as tensile strength and Young's modulus from 3.9 to 11.9 MPa and from 31.9 to 498.2 MPa, respectively (Cao et al. 2009). Casting is not commonly used in packaging, but following the casting, CNC films were found to be transparent and denser.

Summarized Comparison of Barrier Performances of Nanocellulose

Frequent studies conducted as seen in literature regarding nanocellulose composites and majority of these concentrates on mechanical properties and extraneous applications. Only a few reports are found to study the barrier to gases and water vapor as well. Nanocellulose is directly added into the matrix of polymers, and the gas barrier properties of these nanocellulose composites are studied, the ultimate aim of which is to report a reduced OP of the polymer matrix. Polymer matrixes chosen are basically belonging to the group of thermoplastics and thermosetting plastics. Once filled in the appropriate matrix, the filler creates tortosity in gas permeation path creating harder diffusion roads for gas molecules and alters packing density inducing changes in crystallinity. These fillers also rearrange the water molecules in the matrix of the nanocellulose and hinder the plasticizing effect when present in polymers and thus increase matrix stiffness. The nanocellulosics generally employed to reinforce the polymer matrix are CNC and CMC having rod shape, fibrillar CNF and MFCs, and spherical CNSs. Thermoplastic matrices have been widely chosen as apt matrices to study the gas barrier properties of cellulose-filled systems. Nanocellulose-reinforced green biodegradable thermoplastics have become thrust area research subject, since these materials are best options as packaging and barrier materials for technical applications. Gas barrier properties of traditional thermoplastics reinforced with nanocellulose such as polymethylmethacrylate (PMMA), polyethersulfone (PES), polyvinyl alcohol (PVA), LDPE, polycaprolactone (PCL), polyester, and other class of thermoplastics such as sodium alginate, poly(butylene succinate), whey protein isolate, glutenin, gluten, polylactic acid, gelatin, thermoplastic starch, chitosan, agar, Guar, and collagen, all of biodegradable characteristics were analyzed. An increasing nanocellulose content in these filler-reinforced composites improves gas barrier properties on comparison with pristine polymers and the permeability decreased inversely proportional to the cellulose content. Gas permeability of PLA/CNC nanocomposites showed 31% and 67% reduction of vapor and oxygen permeability at a CNC loading of 3.0 wt.%. CNC and CNF particles are good in upgrading gas barrier properties of the polymers, even with low loadings of nanocellulose in these systems. To summarize recent papers, around 10–80% reduction of maximum permeability is observed with 1–20 wt.% nanocellulose.

Permeability shows the lowest point with a certain loading of nanocellulose and after that further loading of nanocellulose does not alter the resistance properties (Carvalho et al. 2018) in a noticeable manner. Guar/NC composites show decreased OP and increased WP (Dai et al. 2016) on increased addition of nanocellulose. OP and WP showing different trends may be correlated to water absorption or different RH values of the OP, that is, 40% RH and WP at 75% RH. It is possible that, at higher RH testing conditions, OP can also increase with the increasing nanocellulose content. Detailed studies are needed to explore the actual mechanism of this phenomenon. Other than the OP and WP, the permeability of other gases as CH₄, D₂, air, CO₂, and N₂ was also tested. The barrier properties of nanocellulose composites for these gases showed the similar trends as seen with OP and WP. Apart from all these fillers, modification of fillers was also found to be effective in affecting permeation. It was found that the silylation of CNCs in silicone rubber matrix works better than unmodified CNCs in reducing the polymer WP due to the improved affinity to the matrix. Silylation enabled crosslinking of otherwise less compatible CNCs into the matrix. However, some of the papers reported no gas barrier property changes or even increase of permeability of the thermoset composites filled with nanocellulose. The mechanism of gas barrier activity of nanocellulose-reinforced thermoset and that for thermoplastic are more or less the same, in which the nanocellulose creates tortuous paths for gas molecules passing through. If the nanoparticles are evenly dispersed to a good extent, it helps a lot in improving properties of thermoset materials. A poorly dispersed nanoparticle system on other hand may negatively affect the barrier properties. Henceforth, the gas permeability of these composites can be further improved by better dispersion of nanocellulose and improved inter-phase interaction between the nanocellulose and matrix.

Conclusions and Prospects

Nanocellulose is a bio-based polymer and hence a potential replacement to end plastic pollution due to packaging. To obtain super performing gas barrier materials from pure nanocellulosic materials, focus should be made on synthetic strategies and filler modifications. In combination with polymers as well as modified/unmodified fillers, even small amount of nanocellulose enhances gas barrier property and equips them to be more competitive with traditional pollutant packaging polymers. It can be used in pristine form or in combination with inorganic particles/polymers of bio origin. This chapter attempts to summarize recent studies on barrier properties of nanocellulose films, especially gas barriers, hybrid materials, and different composites. It concludes that nanocellulose-based matrices, films, and composites are useful for applications as packaging matrices or membranes based on their vapor, oxygen, and different gas permeation properties. However, application of nanocellulose materials is still challenged to overcome the hurdles as permeability, swelling in humid conditions, and improper dispersion of the nanocellulose in the polymer matrix. Some of the research papers recently published showed results concerning the rectification of these backdrops by modification or surface treatment of

nanocellulose. However, further studies and systematic strategies are needed to extensively use these materials in the industrial realms. The basic requirements of a matrix for packaging and technological applications are good tensile strength and better thermal properties. Apart from this, food packaging materials should meet some specific requirements, the ultimate function of which is to extend food stability, shelf-life, and to assure its quality/safety during that prescribed period. Barrier properties are so crucial as it focus on reducing gases and water vapor exchanges between the stored stuff and the environment outside it, decreasing the effect of physico-chemical factors and microbiological changes. Water vapor permeability (WP) and O₂ permeability (OP) have to be focused in depth and tailored for better performances. For a hydrophilic material, a decreased water solubility is of great importance, since a certain degree of water resistance is desirable for food applications to avoid film disintegration when in contact with humid food surfaces such as juices, meats, dairy foods, and fruit cuttings. Transparency is also usually desirable, so the consumer is satisfied with esthetics of the product. The objective of this chapter is to summarize observations and applications of cellulose nanostructures for packaging that are bio-based which can be extended to storing and coating purposes. A focus on the material properties related to packaging and barriers can be extended to superior levels using these advanced materials.

Abstract

Biopolymers are referred to as the materials which are synthesized or produced from natural sources, such as plants, animals, microbes, or any other living entity. The use of these polymers has increased considerably in recent years as the industry moves away from unsustainable fossil fuel supplies and comes toward a softer and more sustainable eco-friendly approach. The significant information about biopolymer-based nanostructures is included in this chapter. Electrospinning is a new fabrication technique that uses strong electric fields to make biopolymer-based nanofibers and nanomembranes. This approach enables broad tuning of material properties and functions by adjusting the solution composition. A summary of the significant biological uses of these biopolymer nanostructures

Introduction

Nanotechnology has become a new multidisciplinary field of study in scientific inquiry. Nanotechnology has transformed the fields of technology and science in the twenty-first century, with far-reaching implications for human life and the economy of the future (Barhoum et al. 2019). Nanotechnology is the study of materials with sizes ranging from 1 to 100 nm. Nanomaterials are nanotechnology advancements such as nanofibers, nanomembranes, nanowires, nanotubes, nanorods, nanocrystals, and so on (Almetwally et al. 2017). These diverse nanoparticles have potential distinguishing features. Nanomaterials have properties such as nano-size, porosity, high tensile strength, stability, surface modification ability, and permeability. They can also be useful in terms of physicochemical qualities, being nontoxic and biocompatible, and sensing and responding to environmental changes (Shahriar et al. 2019; Kenry and Lim 2017). The word nano is a Greek term that means “very small,” and fibers are structures that are longer in diameter than they are wide. As a result, nanofibers are structures that are smaller in diameter and have dimensions less than 100 nm when compared to normal fibers (Ramalingam and Ramakrishna 2017). Nanofibers have numerous applications, including health care (e.g., wound dressing, drug delivery, regenerative medicine tissue engineering), energy storage, and other environmental applications (Kenry and Lim 2017). Nanomembranes are quasi-2D structures with a macroscopic surface area and thicknesses that range from 10 to a few hundred nanometers. A freestanding or free-floating self-supported structure (Llorens et al. 2013) with a thickness of 1–100 nm and an aspect ratio of thickness and size greater than 10^6 is classified as a nanomembrane (Pérez-Madrigal et al. 2015). These had a variety of peculiar features that made them valuable in energy harvesting, optics, sensing, plasmonics, actuators, and other biomedical uses (Llorens et al. 2013).

Nanofibers and nanomembranes are manufactured from polymers which can be either biopolymers or synthetic or a blend of both polymers. But biopolymers have low immunogenicity, better biocompatibility, nontoxicity, biodegradability, etc. (Hu et al. 2014). So, biopolymers are used to fabricate nanofibers and nanomembranes for various medicinal and mechanical applications. Both biopolymer nanofibers and nanomembranes can be produced by various types of techniques, but electrospinning has recently attracted a lot of interest, owing to its cost-effective

setup. It has proven to be an efficient, easy, and versatile technology (Subbiah et al. 2005). This chapter provides an overview of the fabrication of biopolymer nanofibers and nanomembranes. The biopolymers that are used to make these nanofibers and membranes and their wide range of applications in different domains are also discussed.

Biopolymer-Based Nanofibers

Biopolymer nanofibers (BPNFs) are the natural polymeric materials that are produced by naturally occurring substances such as plants, animals, bacteria, fungi, shells or wood, etc. (Jain et al. 2020; Bai et al. 2021). Protein and polysaccharide nanofibers are the two most prominent types of biopolymer nanofibers on earth. Polysaccharide nanofibers include chitin fibers (Ifuku and Saimoto 2012) and cellulose fibers (Chen et al. 2018; Zhou et al. 2019) which contain intricate structural patterns and are employed to sustain living organisms' bodies and ensure their existence. Few of the protein nanofibers are found within organisms like keratin and collagen nanofibers (Yang et al. 2019); however, others include silk nanofibers which are produced by spiders and silkworms (Jin and Kaplan 2003).

BPNFs with varying structures and performances are produced by diverse manufacturing processes and raw materials. These nanofibers have captured the attention of scientists, because of their inherent nanostructures and capabilities, and have been extensively used in the energy, material, biological, and environmental domains (Ling et al. 2018). Nanofibers possess effective potential in various medical applications like drug delivery, tissue engineering, wound healing, and other medical devices because of their unique properties like large surface-to-volume ratio, flexibility, biocompatibility, excellent mechanical strength, high porosity, etc. (Jain et al. 2020).

Various techniques for the production of biopolymer nanofibers have been developed recently. Different types of BPNFs with varied morphologies, widths, lengths, degrees of nanofibrillation, crystalline structures, surface chemistries, and chemical constituents are fabricated through different sources using different strategies (Bai et al. 2021). The preparation methods of nanofiber include drawing, self-assembly, centrifugal spinning, template synthesis, phase separation, and electrospinning (Almetwally et al. 2017). But electrospinning is a highly acceptable and widely used method as compared to other techniques as shown in Table 1. This is because electrospinning is a cost-effective, simple, reproducible, continuous, and scalable process that has the property to manufacture continuous biopolymer nanofibers. It is flexible enough to control the dimensions of nanofibers based on shape, size, diameter, porosity, and surface area. The principle electrospinning process is based on the electrostatic fabrication of nanofibers (Yadav et al. 2019; Bognitzki et al. 2001). In 1934, Formhals was the one who published the first patent for the preparation of nanofibers by using the electrospinning technique (Jain et al. 2020). Electrospinning uses a high-voltage electromagnetic field to create electrically charged jets by polymeric solutions or melts, which on drying produces nanofibers when the solvent is evaporated. The more charged fibers are fields directed toward an

Table 1 Comparison between different techniques for nanofiber fabrication

Methods	Scalability	Control of nanofiber morphology	Merits	Demerits	Ref.
Template synthesis	No	Yes	Nanofibers with different diameters are obtained using various types of templates	Organic solvents are required Nonuniform distribution of size Problems of interconnectivity	Liang et al. (2012)
Self-assembly	No	No	Operated in water usually Bioactive functionality	Complex manufacturing process High cost Low mechanical characteristics	Liu et al. (1999) and Yan et al. (2001)

oppositely charged collector, which can be either a flat surface or a revolving drum to collect nanofibers. The fiber is subjected to a collection of gravitational, rheological, aerodynamic, tensile, and inertial forces in traditional spinning procedures. The spinning of fibers in electrospinning is principally accomplished from tensile stresses produced in the axial way of the polymer flow through generated charges in the applied electric field (Subbiah et al. 2005).

Applications of Biopolymer Nanofibers

Biopolymers are considered biodegradable substances because of their natural decomposition in the body due to physical environments. So, the requirement for their mitigation is removed. These biopolymers have biocompatibility and no toxicity. They can be made up into nanofibers due to these properties and can be utilized for various functions like drug delivery, tissue engineering, vascular graft implantation, wound healing dressings, biosensors, etc. (Fig. 1). The different merits and applications of the biopolymer-based nanofibers fabricated by the electrospinning technique are summarized in Table 2 (Jain et al. 2020; Hosseini Ravandi et al. 2013).

Biopolymer Nanofibers in Tissue Engineering Application

Tissue engineering is a multidisciplinary scientific and medical field that emphasizes the rebuilding and regeneration of injured tissues caused by illness, aging, or trauma. The extracellular matrix (ECM) and its function in diverse cell activities like proliferation and differentiation have recently gotten a lot of attention. The natural ECM is made up of fibrous interwoven structural proteins mainly collagen that forms a 3D network with a size of tens of thousands of nanometers (Nathanael and Oh 2021). Electrospinning is considered an efficient method in the tissue engineering discipline to fabricate biopolymer-based nanofibers with a structure related to ECM because of their flexible functional capability.

Because of its prevalence in the ECM, non-immunogenicity, and ease of separation from several sources, collagen has been used in a range of tissue engineering applications. But many of the biological and structural features of this natural scaffolding may be compromised by the normal processes required to separate and reprocess it into a manufactured material (Barnes et al. 2007). The collagen nanofibers have many important features which are useful for tissue engineering, i.e., they can release stress, avoid premature mechanical failure, scatter energy, and allow signals to reach neighboring cells that control functional responses in the body. Moreover, they have high water affinity, excellent biocompatibility, less antigenicity, and the capability to enhance the regeneration of tissues (Koláčná et al. 2007). All of these properties make collagen the deal biopolymer material for tissue engineering.

Electrospinning technology can manufacture collagen fibers that nearly resemble, and at some point may entirely reproduce, the biological and structural features of collagen ECM. The fibers of collagen type I showed a linear relation between fiber diameter and polymer solution when dissolved in hexafluoro-2-propanol (HFP) that ranged from 0.03 to 0.10 g/mL concentration and resulted in the formation of scaffolds which are made of fibers from 100 nm to 5 μ m in diameter (Matthews et al. 2002), whereas the fibers of collagen type III also exhibited a linear relation for collagen concentration ranging between 20 and 90 mg/mL and increased nanofiber diameter (115–612 nm).

Elastin is also gaining attention as one of the structural units of vascular extracellular matrix in the field of tissue engineering. It was studied that based on delivery rate, the human recombinant tropoelastin can be fabricated to nanofibers as well as microfibers by electrospinning (Li et al. 2005). The nanofibers of gelatin have also been lubricated by the electrospinning method using different solvents like formic acid, acetic acid, water, HFP, and ethanol. The gelatin scaffolds and gelatin with synthetic polymer scaffolds have been gaining popularity as tissue engineering scaffolds, with multiple studies demonstrating their effectiveness (Sell et al. 2009). The fibrinogen nanofibers have also been electrospun (Cigané et al. 2021) and have been used as a tissue engineering scaffold with effectiveness (Wnek et al. 2003). Chitin along with polyglycolic acid (PGA) has been fabricated into biocompatible and biodegradable nano-scaffolds for tissue engineering applications. The polymer PGA was used due to its biocompatibility and biodegradability. The diameter of these nanofibers is distributed between 50 and 350 nm, with an average diameter range of about 140 nm (Park et al. 2006).

Biopolymer Nanofibers in Drug Delivery

One of the most promising applications among the potential ones is drug delivery. A drug delivery system is utilized to increase the therapeutic effects of a pharmaceutical drug or a natural substance in a specific diseased region while minimizing the toxicological side effects. Nanotechnology is a multidisciplinary science that enables the synthesis of polymers at the nanoscale scale for a variety of medicinal purposes. The biopolymers show biodegradability, biocompatibility, and minimal immunogenicity in drug delivery as compared to synthetic ones (Jacob et al. 2018).

Electrospinning for drug delivery is interesting because of its excellent efficiency of encapsulation, low cost, ease of operation, greater loading capacity, and synchronized transfer of many treatments (Wang et al. 2010). To reduce toxicity and increase the therapeutic impact of standard dosage methods, many delivery strategies have been developed. Nanofibers have gotten a lot of interest in the last 10 years. Electrospun fibers were created using natural polymers. These biopolymers possess effective antimicrobial properties, good clinical functionality, less immunogenicity, and better biocompatibility. Natural polymers mostly include polysaccharides (chitosan, cellulose, dextrose, etc.), proteins (collagen, silk, gelatin, etc.), and a few biopolymer composites and derivatives (Schiffman and Schauer 2008). The properties of different polysaccharides, like chitosan, starch, cellulose, hyaluronic acid, dextran, chitin, alginate, etc., have been described which can be used for different biomedical uses like drug delivery, dressings of wounds, and enzyme immobilization (Lee et al. 2009).

Due to the polycationic nature of chitosan, they exhibited better anticancer activities. In vitro anticancer efficacy of quaternized chitosan derivatives against HeLa, Hep3B, and SW480 cells is well recognized (Toshkova et al. 2010). Chitosan is coupled with polylactic co-glycolic acid (PLGA) and polyethylene glycol (PEO) to create nanofibers that have been used as delivery methods for *Trichoderma viride* (Spasova et al. 2011) and *Bacillus* sp. (Zupančič et al. 2018).

Alginate and its derivatives are biodegradable and have controlled porosity, yet pure sodium alginate electrospinning is problematic. The use of another polymer is compulsory to control the viscosity and spinnability of alginate. Sodium alginate, in combination with PVA, has been electrospun into nanofibers that have worked as insulin delivery devices (Sharma et al. 2013). Fish sarcoplasmic proteins, as well as elastin silk, and collagen are the most used electrospun proteins for drug delivery applications. The sarcoplasmic proteins of Atlantic cod are elongated polymers with fiber diameters ranging from hundreds of nanometers to some micrometers. These properties, along with the potential health benefits of eating fish, make fish sarcoplasmic proteins appealing materials for electrospinning of nanofibers. As a result, these nanofibers can be employed to deliver antidiabetic medications like insulin (Stephansen et al. 2015). Some spiders, worms, and insects manufacture silk proteins, which are a distinctive family of naturally occurring fibrous biopolymers. Because of their self-assembly, controlled shape and morphology, gentle biodegradability, and biocompatibility, they are attractive materials for drug administration and tissue engineering applications (Elzoghby et al. 2015).

Biopolymer Nanofibers in Wound Healing Treatment

The wound dressings manufactured by electrospun nanofibers have excellent properties to speed up the process of healing. Their three-dimensional structure mimics the extracellular matrix architecture found in the skin, which performs a significant function in proliferation and cell adhesion (Miguel et al. 2019a). The porous structure of the nanofibrillary matrices is compatible with nutrient and gaseous exchanges, adsorption of injury exudates, and bacterial contamination prevention so that the architecture of the membrane will aid proliferation, differentiation, and adhesion of cells (Yuan et al. 2018).

Biopolymer nanofibers produced using a versatile electrospinning technology have some advantages, including efficient biodegradability, nontoxicity, ease of operation, effective biocompatibility, and even antibacterial activity while using chitosan (Ambekar and Kandasubramanian 2019). When employed in the formulation of electrospun nanofibers as wound dressings, biopolymeric macromolecules produced from polysaccharides have been shown to improve wound healing. The biomaterials based on polysaccharides from seaweed, specially alginates, have gotten much attention in the area of wound healing applications due to their cost-effectiveness, versatility, and abundance (Hao et al. 2020). The salts of chitosan nanofibers have been found to suppress the growth of *S. aureus* bacteria in the existence of very low fiber quantities. The negatively charged residues of macromolecules at the cell membrane surface are thought to interfere with the polycationic character of migrating glucosamine portions of chitosan, resulting in the death of microorganisms. As a result of their biodegradability and peculiar features that could help manage microbes, composite materials containing chitosan fibers can be used considerably in more applications (Torres-Giner 2011).

Due to its nontoxicity, antimicrobial activity, biodegradability, and biocompatibility, chitosan is one of the significant biopolymers for the manufacture of electrospun nanofibers. The physical, chemical, and ionic cross-linking techniques can be used to cross-link electrospun chitosan nanofibers with aligned or random fiber structures. The cross-linked electrospun chitosan nanofibrous membranes had better stability, biocompatibility, and mechanical properties, all of which are important for wound healing and other applications as shown in Fig. 2 (Cui et al. 2021).

Scientists are interested in plant-derived polysaccharides because of their biological properties like antioxidant, antidiabetic, and anticoagulant, as well as key traits such as biodegradability, nontoxicity, and environmental compatibility (Ghliissi et al. 2020). Plants are one of the most important suppliers of polysaccharides in terms of resources. Furthermore, their exceptional biological properties and inexpensive manufacturing costs make them suitable for wound healing treatment.

The starch-based nanofibers produced by electrospinning have a high porosity and a large surface area; also, they are biodegradable, biocompatible, and bioresorbable. As a result, these starch nanofibers have a lot of potential in the pharmaceutical industry, including tissue engineering and wound healing (Liu et al. 2017). In the area of the development of wound dressing, pectin, chitosan, and alginate are the most widely used ionic polysaccharides. The various molecular structures of these pectins

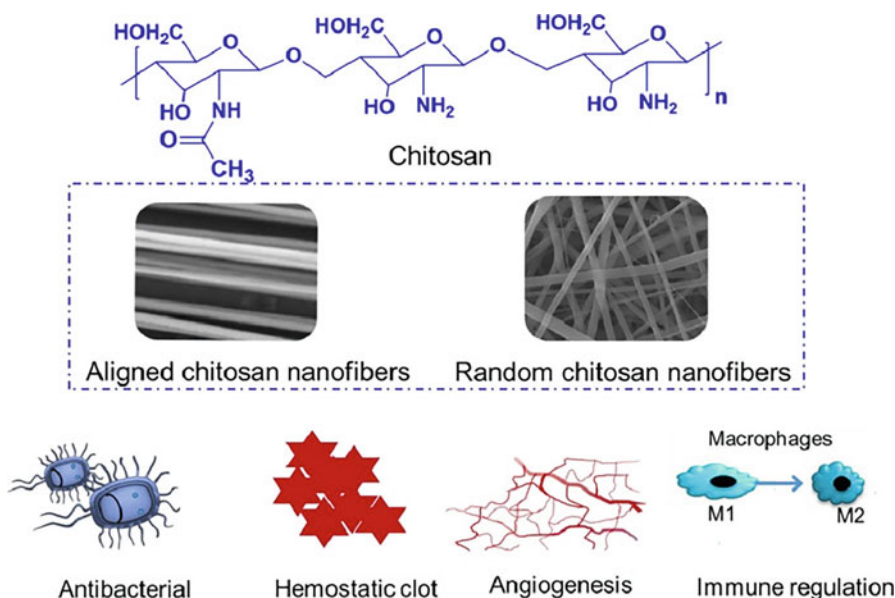

Fig. 2 Chitosan nanofibers for wound healing applications. (Reprinted from Cui et al. (2021) with the permission of (KeAi Publishing Ltd., China))

result in different properties of their nano-sized dressings, which are suitable for a variety of biomedical applications (Mogoşanu and Grumezescu 2014).

Chitosan is a natural substance that has been shown to have an important role in wound healing because of its unique properties, i.e., increasing hemostatic and analgesic effects, activating neutrophils, and better interaction with phospholipid membrane molecules, extracellular matrix formation, and activation of macrophage (Venkataprasanna et al. 2020). Chitosan and arginine were electrospun together to create hydrophilic and good porous wound healing dressings that copy the qualities of the natural skin. In contact with these membranes, human fibroblasts attached and multiplied, indicating biocompatibility. Bacteriostatic activity against *Staphylococcus aureus* and *Escherichia coli* was also found in these nanofiber mats. In comparison with pure chitosan nanofibers, in vivo administration of these nanofiber mats on Wistar rats revealed better wound healing and regeneration of tissues (Wani et al. 2017).

Biopolymer Nanofibers as Biosensors and Analytical Systems

Many disciplines rely on the identification of biological molecules at low quantities, which necessitates high sensitivity. For these applications, highly conducting biosensors are now being developed. They are often made of biofunctional materials and have a high level of sensitivity and selectivity. These biosensors are used in a variety of applications, including the environment, food, and medicine (Rezaei et al. 2015).

Nanofibers permit enzymes to be immobilized and can be developed into sensitive electrochemical biosensors due to their large surface area, porous nature, and spatial structure. By immobilizing genetically modified acetylcholinesterase inside electrospun chitosan and PVA nanofibers, a highly sensitive electrochemical biosensor was effectively produced. Then, this enzyme-immobilized system was effectively designed to detect pirimiphos-methyl in olive oil. The biosensor functioning for detection of pirimiphos-methyl enhanced to a low value of detection limit which is 0.2 nM as compared to already internationally existing defined value which is 164 nM (El-Moghazy et al. 2016). The Hg^{2+} ions may be detected in various analytical samples using fluorescence sensor systems which are composed of rhodamine B-adorned chitosan-based nanofibers. When the spirolactam ring of the rhodamine unit is opened, these rhodamine-based chitosan nanofibers permitted the particular detection of Hg^{2+} ions. These mats are improved as sensitive sensing probes due to the large specific surface area provided by nanofibers. This strategic formation offers the ability to arrange and build good functioning sensing materials for the environmental identification of multiple metal elements (Wani et al. 2017). By grafting DNA on cellulose nanofiber, a double-function cellulose nanofiber-based bionic biosensor with effective biocompatibility was produced for detecting silver ions (Ag^+) and acetylcholinesterase (AChE). These silver ions served as recognition sites for the detection of AChE (Wang et al. 2021).

Natural polymer nanofibers are used in chromatographic analyses as well. Electrospinning was used to make chitosan-iron nanofiber composites, which were used to extract a small quantity of 9-tetrahydrocannabinol from blood samples after it was detected by ultraviolet detectors. The substantial surface area of these natural nanofiber composites showed that an analyte and adsorbent had a robust contact. This innovative sorbent might provide a higher analytical role in terms of detection limit, repeatability, and recovery while using less toxic organic solvents and sorbent materials than the adsorbent in C18 columns (Wani et al. 2017).

Filtration

Nanofibers can be used as filters to capture small particles. Generally, filter efficiency is improved linearly by decreasing the thickness of the filter membrane and increasing the applied pressure. Electrospinning is the technique that can lessen filter diameters to smaller than 0.5 μm , which results in enhanced filter efficiency when pressure is increased (Rezaei et al. 2015). When regenerated cellulose nanofibers are used which are formed from the alkaline analysis of nanofibers of cellulose acetate with diameters ranging from 200 nm to 1 μm , then a filter membrane was created. The nanofibers were heated for 1 hour at 208 $^{\circ}\text{C}$ to increase their mechanical characteristics and structural stability. In order to isolate biomolecules such as bilirubin and bovine serum albumin, a filter membrane was surface revolutionized with Cibacron Blue F3GA. Furthermore, when compared to conventional microporous membranes, this filter membrane had a better water permeability (Ma et al. 2005). Similarly, the affinity membrane was produced from a regenerated cellulose nanofiber. This membrane was functionalized with protein A/G and showed a high

affinity for immunoglobulin G (IgG) which makes it applicable for the purification of IgG (Ma and Ramakrishna 2008).

Another composite membrane was produced whose top layer was made of cellulosic nanofibers, the middle layer was made of a polyacrylonitrile electrospun scaffold, and the supporting substrate was made of polyethylene terephthalate nonwoven. When compared to the identical membranes without cellulose-based nanofibers, the efficiency of this filter membrane rose by nearly five times (Ma et al. 2014).

The chitosan-based nanofibers also exhibit desirable filtering features. It was employed in a huge range of filtration uses, including purification of water and air filtration. The blend solutions of chitosan and PEO are electrospun onto a nonwoven polypropylene substrate to create a nanofibrous filter medium. They proved the effectiveness of filter media of chitosan-based nanofibers for the mitigation of pathogenic microorganisms, contaminated particle media, and heavy metal ions from air and water. The antimicrobial, heavy metal binding, and physical filtration effectiveness of chitosan-based filter media were investigated and connected with the physical features and surface chemicals of nanofibrous filter media (Jayakumar et al. 2010; Desai et al. 2009). The metal adsorption of chitosan electrospun nanofiber mats of diameter 235 nm in aqueous environments was investigated. These nanofiber mats counterbalanced with potassium carbonate in water have demonstrated better stability of water erosion and greater adsorption affinity for metal ions (Haider and Park 2009).

Biopolymer-Based Nanomembranes

Nanomembranes (NMs) are the primary building block of probably all living creatures – life as we know it would not be conceivable (Jakšić and Jakšić 2020). NMs establish nowadays fascinating matter thus in the broad area of nanotechnology. They fit the definition of self-sufficient, independent, or free-floating freestanding architect whose length-to-width and also breadth-to-wideness characteristic proportions both overdo 100 nm (Jiang et al. 2004). A class of intriguing nanomaterials includes nanomembranes and nanosheets, which are anticipated to offer sophisticated industrial applications in addition to fundamental scientific advancements (Watanabe et al. 2009). Due to their recyclability, high-performance and functional bio-nanocomposites are attractive examples of biologically generated materials well with hierarchical management platform because of their flexibility, bioactivity, biocompatibility, and availability of multiple active sites on the surface for adding unique functionalities (Xiong et al. 2018). Biopolymers are covalently linked long chains of monomeric units that make up polymeric biomolecules. The three main categories of biopolymers are polynucleotides, polypeptides, and polysaccharides. Due to their biocompatibility, biodegradability, and processability, biopolymers are hypothetical synthetic biomolecules that might be used in a range of industrial fields (Jayan et al. 2021).

Because of their exceptional mechanical tenacity, effective stacking transmission, and unique flexible properties, extremely thin nanomembranes possess the capability to be used in place of a variety of elastic useful devices (Shi et al. 2014). By executing a bulging test and an AFM (*atomic force microscope*) bending experiment, the flexibility characteristics of reduced graphene-oxide cellulose nanocrystal nanomembranes were explored. The results reveal better interfacial contacts that improve the robustness and elasticity of reduced graphene oxide-cellulose nanocrystal nanomembranes (Kim et al. 2016). These characteristic nanomembranes are made of biopolymers that have several uses. Different nanomembranes can be created using a variety of approaches. Among the important strategies are surface modification, nanotechnology, nanofabrication, layer-by-layer deposition, chemical vapor deposition, 3D printing, sol-gel processing, and others (Ciganè et al. 2021). The other techniques include wet-phase transposition (Chen et al. 2011), dry/wet-phase transposition (Khan et al. 2020), electrospinning method (Jin et al. 2019; Miguel et al. 2018), etc.

Applications of Biopolymer Nanomembranes

A focus of the analysis is on engineering and biomedical applications (Albisa et al. 2017), such as supercapacitors (Bhushan et al. 2014), solar cells and batteries (Anjaneyulu et al. 2005), separation technologies and wastewater treatment (Benson et al. 2019), catalytic sensing (Albisa et al. 2017), wound dressing (Ariyoshi et al. 2021), cancer therapy (Ariyoshi et al. 2021), tissue engineering (Aliyu et al. 2018), and drug delivery (Albisa et al. 2017). These systems have definite benefits, such as positive impacts on post-injury recovery (such as the restoration of injured cerebral, vertebral, and periphery nerves, tendons and ligaments, and epidermis) and no lasting fitness threats.

Molecules' Selective Separation

Membrane-based segregation of nanomaterials and macromolecules such as proteins and polypeptides is becoming more common because it is an inexpensive and scaled-up technique. Trimethylsilyl cellulose (TMSC) was regenerated to create a self-supporting cellulose membrane with pore dimensions reaching from 1.5 to 3.5 nm that help the separation of tiny molecules based on size and charge and exhibit excellent anionic molecule differentiation (Puspasari et al. 2016). By combining cellulose nanofibers with poly(dimethylsiloxane) (PDMS), robust, nanometer-thick semipermeable membranes were created (CNF). Spin coating is a repetitive process that produces multilayered nanocomposites. Through a fault-free PDMS sheet of almost 17 nm width, a durable PDMS-CNF nanomembrane provides exceptional penetration of 50,000 GPU. The asymmetrical configuration of PDMS and CNF had an impact on the nanomembrane's capacity for gas permeation; the CNF layer's sides showed reduced gas permeability, while the PDMS composite layer functioned as a direct air-capturing medium (Ariyoshi et al. 2021).

Wound Dressing

Wound healing is a well-defined yet intricate chain of processes generally consisting of five overlapping steps: hemostasis, inflammation, migration, cell growth coupled with matrix healing, and epithelialization coupled with modification of the scar tissue (Maver et al. 2015; Boateng et al. 2008). Chitosan membrane was manufactured by utilizing techniques of dry/wet-phase inversion and sterilized with ethylene dioxide and gamma radiation and characterized regarding thickness, tensile strain, morphology, strain break percentage, and Vero cell cytotoxicity in vitro that was not affected, hence appropriate for wound dressing material (Marreco et al. 2004). Fish scale collagen peptides are combined with chitosan oligosaccharide to form fish scale collagen peptides/chitosan oligosaccharide nano-fibrous membranes (FSCP/COS-NFM), and fiber-forming capacity is increased by using polyvinyl alcohol through electrospinning technique. FSCP/COS-NFM exhibited antimicrobial efficacy toward *Escherichia coli* and *Staphylococcus aureus*. It supported the proliferation of human skin fibroblasts and was used in wound dressing (Wang et al. 2011; Jayakumar et al. 2011). Chitosan-based membranes were synthesized through immersion-precipitation phase inversion using a casting method by using the acetic acid aqueous solution as solvent. It showed strong inhibition to bacteria penetration of *Pseudomonas aeruginosa* and *Staphylococcus aureus*. It demonstrated outstanding oxygen permeability, restricted evaporation, and enhanced fluid drainage capacity. Chitosan membrane acted as a hemostatic agent and stopped bleeding when applied to the wound. On the 35th perioperative day, the wound's collagen fiber deposits were neatly structured and aligned along one axis parallel to the skin's surface, indicating that the injured tissue had been perfectly repaired. The outcome suggested that the chitosan membrane is asymmetrical and may have an application as potential material for wound dressing as shown in Fig. 3 (Mi et al. 2001).

To meet the conditions (oxygen permittivity, regulated evaporation phenomenon, and the discharge of injury metabolic byproducts) is required for such membrane to be employed as a wound bandage; an AgSD-assimilated chitosan membrane along

Fig. 3 Demonstration of the major characteristics of asymmetrical membranes used to enhance the healing of wounds. (Reprinted from Miguel et al. (2019b) with the permission of Elsevier)

with constant antibacterial efficiency has been generated through a dry/wet-stage inversion process. The asymmetrical chitosan membrane contains AgSD, which works like a rate-controlling wound bandaging to release sulfadiazine and silver ions during the time (Mi et al. 2003). A unique thermo-responsive hydrogel membrane consisting of poloxamer 407, sodium alginate, platonic F-127, and polyvinyl alcohol (PVA) was developed to speed up the wound healing process. The created hydrogel membranes had exceptional inflammation capabilities, surface permeability for sustained drug release, and strong mechanical qualities as well as ultimate tensile to endure external frictional forces despite sealing the injury (amikacin). According to antibacterial data, *S. aureus* and *P. aeruginosa* were significantly more inhibited by amikacin-loaded hydrogel membranes. Our innovative alginate-based hydrogel membrane showed great promise in the rigorous assessments as an effective wound healer for quicker wound healing (Abbasi et al. 2020). Alginate-based mats with or without zinc oxide nanocomposites were electrospun and afterward subjected to a rinsing process to develop exceptionally stable products with thinner, homogenous nanofibers with 100–30 nm diameter. Along with the easiest and harmless manufacturing process, except for often used animal collagen-extracted methods, the suggested alginate-based solutions could result in safe and economical surgical coverings as well as wound covering membranes (Doderio et al. 2019).

Tissue Engineering

Transmittance, bidirectional oxidation, redox stabilization, bioactivity, lipophilicity, 3D structure, and surface morphology are a few of the desirable characteristics for tissue engineering applications (Ramalingama and Tiwari 2010). The carboxymethyl chitin (CM-chitin), 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide (EDC) reagent, and 2-aminoethane sulfonic acid were combined to create sulfated chitin. The biospecific breakdown of the sulfated chitin has intriguing implications for tissue engineering and medication delivery (Jayakumar et al. 2008). In bone tissue engineering applications, biomaterials play a crucial role since they can replicate the structure and chemical composition of bone tissues at the nanoscale level. In particular, natural polymer composites with chitin, chitosan, or collagen are preferable because they exhibit properties like biocompatibility and biodegradability that are necessary for bone tissue engineering (Li et al. 2014).

Wastewater Treatment

Wastewater from most home and industrial processes contains undesired harmful pollutants. Many physical, chemical, and biological technologies have been reported over the previous three decades, including flotation (Afzal et al. 2019), precipitation (Mavhungu et al. 2021), oxidation (Li et al. 2021; Deng and Zhao 2015), solvent extraction (Hall et al. 1990), evaporation (Sharshir et al. 2020), carbon adsorption (Chai et al. 2021), ion exchange (Kansara et al. 2016), membrane filtration (Hube et al. 2020), electrochemistry (Smith 1972), biodegradation (Yu et al. 2020), and phytoremediation (Hu et al. 2020), but here our concern is biopolymer-based nanomembrane filtration. Because of its great effectiveness and lesser energy

utilization as compared to distillation processes, membrane desalination technology is widely seen as a solution to the problem of water scarcity (Aliyu et al. 2018). Cellulose from agricultural waste is mixed with chemicals to form two biopolymer-based nanomembranes (ramie and sisal cellulose nanomembranes) of varying pores ranging from 120 to 230 nm and from 20 to 80 nm, with thermal decomposition at 230 and 450 °C, pH range from 6.7 to 7.2, and TDS (total dissolved solids) of 368 and 523 mg/L, respectively; by using these nanomembranes, we can purify the wastewater (Hassan 2020). ZIF-8@CM composite membranes were made by synthesizing ZIF-8 in situ on a cellulose matrix using an alkali/urea method. This membrane might be designed for the purification or filtration of dyes, and it has been shown to have high failure rates for rhodamine B and good renewability, providing the potential for a useful application in the treatment of wastewater (Chen et al. 2020). The state inversion approach was employed to create the plane membranes by combining cellulose acetate with polyethylene glycol (additive) and N-methyl-2-pyrrolidone as solvent. Additionally, membrane's pure water penetration flux was examined (Mohammadi and Saljoughi 2009). The electrospinning technique is used to create alginate-based membranes that contain ZnO NP (nanoparticles), which were then used as biosorptive constituents. The membranes have a homogeneous structure that is made up of linked cavities that are an average size of 140 nm and nanofibers having a diameter of 100 nm on average. UV-vis spectrophotometric studies were carried out to assess membrane uptake/release capabilities using Congo red (CR) and methylene blue (MB) dye solutions in water, which were selected equally as ideal probes for basic or acidic categories, respectively. Additionally, after a few quick washing procedures in deionized water, good reusability was attained for MB. Surprisingly, desorption efficacy under physiologically analogous circumstances is designated quite great for MB but lowered for CR, showing ionic associations have an impact on the release process. The outcomes indicate that the electrospun membranes were employed in drug supply and decontamination processes (Doderio et al. 2020). Figure 4 portrays the wastewater treatment through membrane filtration.

Drug Delivery

The term “drug delivery systems” (DDS) refers to several different drug carriers that are used to carry medications to specific muscles, organs, subcellular organs, and cells for drug discharge or absorption (Li et al. 2019). The technique and route by which an active pharmaceutical ingredient (API) is supplied to increase its desired pharmacological impact and/or convenience and/or to reduce undesirable effects are how drug delivery (DD) is defined. This can be summed up as “improving drug efficacy” (Bae and Park 2020). Bacterial cellulose (BC) is a pure kind of cellulose that is manufactured by several numbers of bacteria that can control how quickly model pharmaceuticals are released through the skin. The positive results of the 24-hour patch test on the skin confirm the potential utility of bacterial cellulose membranes as carriers for transdermal drug delivery (TDS) and topical drug delivery (Almeida et al. 2014). Semipermeable membranes, commonly made up of cellulose acetate (CA) through a variety of flux boosters, regulate the pace at which

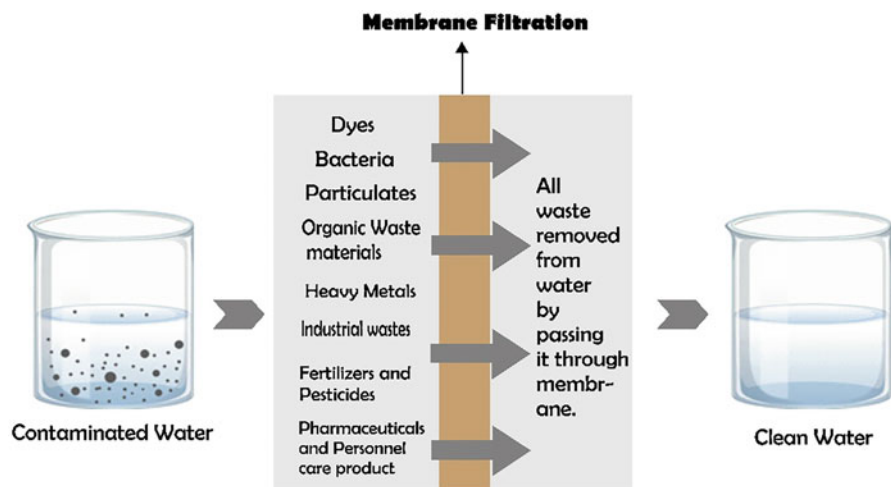

Fig. 4 Wastewater treatment through membrane filtration

medications are released from OROS[®] (orderly discharge osmotic delivery technology of ALZA Corporation). An effective substitute was found to be cellulose acetate butyrate (CAB). The CAB membrane was equally durable as the CA membrane but had greater drying abilities, providing benefits, particularly for compositions that are thermolabile. It has been shown that osmotically regulated drug administration is possible with CAB-based membranes. The examined membranes were as durable as CA membranes, showed high stability, and could have their membrane permeability changed by adjusting the film's thickness and flux enhancer levels (Shanbhag et al. 2007). To create membranes for various biomedical applications, carboxymethyl cellulose (PVA-PEO) and poly(vinyl alcohol)-poly(ethylene oxide) blends were created using two methods: solvent casting and freeze-drying. The porous architecture of the FD membranes, which are three-dimensionally linked, provides routes for fluids to exit the wound. The membranes' overall porosity was discovered to be between 89% and 92%. The WVTR (water vapor transmission rate) for the FD membranes was discovered to be between 2000 and 3000 gm^{-2} per day. Ciprofloxacin hydrochloride, an ideal medication, was as well included in the matrices, and medicine discharge was investigated. A zone of inhibition approach was used to assess the membranes' antibacterial capacity against *E. coli* (Agarwal et al. 2013). The fabrication of four distinct alginate-based membranes, along with other copolymers (e.g., Carbopol, Tween, and polyvinylpyrrolidone) and other elements with various functions, is introduced. Thermogravimetric techniques (TGA) and Fourier transform infrared and ultraviolet spectroscopic techniques, as well as the scanning electron microscope, are utilized to examine membranes and binary blends generated among the elements utilized in membrane production and methotrexate. The transdermal delivery of methotrexate can be accomplished using the A-MTX (sodium alginate glycerol methotrexate) and AGP-MTX (sodium alginate glycerol polyvinyl pyrrolidone methotrexate) membranes (Bajas et al. 2021).

Conclusion

Biopolymer-based nanofibers and nanomembranes due to their recyclability, adaptability, biodegradability, biocompatibility, and accessibility of numerous reactive sites for introducing novel functionalities are appealing representatives of high performances and functions. The domain of synthesizing and fabricating biopolymer-based nanofibers and membranes is so vast that several areas require improvement. Until now, utmost research has been directed toward the development of new synthetic nanofibers and nanomembranes for effective wound healing materials that mimic the extracellular matrix architects present in the epidermis. They have definite benefits, such as positive impacts on wound healing such as repair of damaged spinal, cranial, and peripheral nerves, connective tissues, and skin and have no long-term health risks. Currently, scientists are attempting to construct NFs and NMs from biopolymers to reduce the toxic effects of chemicals considering their effective use in wastewater treatment due to their antimicrobial properties, tensile strength, biodegradability, and recyclability. All categories of NFs and NMs have their peculiar functionalities and significance accompanied by certain limits. To eliminate these shortcomings, diverse biopolymers are now introduced as promoters to NMs and NFs and are usually favored in medical application like tissue engineering, drug delivery, wound healing and dressing, sensors, and purification as well as filtration. There must be a need to devise more appropriate methods to enhance the effectiveness of these NFs and NMs which can be organized by introducing biopolymers that improve various properties to be used in biomedical applications. They should necessarily be facile, nontoxic, cost-effective, efficient, and excellent materials, and their exposure to the human body must not be harmful. Most of the recent research has been done on chitosan- and cellulose-based NFs and NMs, and researchers need to be focused on producing other biopolymer-based nanofibers and nanomembranes which must be efficient for various medical and nonmedical applications.

Abstract

Starch is a relevant biopolymer since it is easily modifiable and can be used as an alternative material to several petrochemical-based nonbiodegradable materials. The physicochemical characteristics and subsequent uses of starch are dependent on their botanical origin, which has a big impact on the granule structure and amylose to amylopectin ratio, which ranges from 15:85 to 35:65, with the

exception of waxy starch and high amylose maize starch. The amylose to amylopectin ratio has a momentous effect on the biochemical, physicochemical, mechanical, and thermal properties of native and modified starch. The chapter provides a comprehensive understanding of the effect of amylose to amylopectin characteristics of starch on their physical and biochemical properties of starch, including the digestibility, dispersibility, rheological, and reinforcing properties.

Keywords

Starch · Amylose/amylopectin ratio · Crystallinity · Rheological properties · Modified starch · Gelatinization · Heat moisture treatment (HMT)

Introduction

A solid polysaccharide with no flavor or color, starch is made up of the components amylose and amylopectin, which are in turn each made up of multiple glucose monomer units. Along with cellulose and glycogen, starch is one of the three main biorenewable natural compounds that may be found on Earth. Despite sharing the same monomer component, glucose, the various stereochemical linkages cause a completely distinct conformation, and as a result, diverse physicochemical characteristics (Al-Assaf et al. 2007). A polysaccharide called starch is made up of glucose molecules linked together by – (1–4) and – (1–6) connections. It is made up of two different types of substances, amylose and amylopectin. Amylose is a linear polymer made up of glucose units connected by -D-(1–4) glycosidic bonds, making up around 20–30% of all starch. Amylopectin, on the other hand, is a branched-chain polymer with around 5% of -D-(1–6) links in the branched chain and -D-(1–4) glycosidic linkages in the linear chain.

Structural differences existing in the starch constituents' deliver starch granules a semi-crystalline structure, where amylose contributes to amorphous and amylopectin contributes to crystalline regions. These semi-crystalline starch granules are highly species-specific (Singh et al. 2008a) and thus have different size, shape, and morphology depending on the biological sources, topology, geographical conditions of the cultivated locations, and cultural practices (Laurentin and Edwards 2013). It can also be affected by environmental factors such as climate, temperature during growth, harvest date, water stress, and storage temperature (Singh et al. 2008b).

According to Robyt (2008), the molecules of amylose and amylopectin generate various degrees of intramolecular and intermolecular hydrogen and hydrophobic bonds that keep the molecules together and produce a granule that is insoluble in water. The process of granule biogenesis involves irregular starch production, which is greatly influenced by both genetic characteristics and environmental factors (Jane 2007). A starch granule's amylose and amylopectin structure varies from the center to the edge (Pan and Jane 2000). Starch appears as a white, soft powder that is insoluble in water but is sometimes seen in a colloidal state that settles over time. Due to its large relative abundance, ease of isolation in a highly pure state, enzymatic hydrolysis to glucose and/or other maltodextrin products, corresponding chemical modification, and ease of solubilization, starch is an important substance. Because

starch is an environmentally acceptable, nonpolluting, and biodegradable material, it has undergone substantial research in the creation of packaging materials to replace dangerous plastics.

Granule Structure of Starch

Granule structure of starch is a microscopic structure that possesses its constituent molecules of amylose, amylopectin, and small amount of water, organized in micelle within a durable and morphologically identifiable form (Imberty et al. 1991). The chains of the amylopectin molecules along with amylose stack on top of each other that can be considered two-dimensional molecules. It gives radially oriented crystallites, which is 9 nm in size. Within the micelle, there are normal chains, chain terminations, and branches. Starch chains that enter and exit the micelle create the amorphous phase of the starch granule (French 1984).

The starch granule, which has an entire morphology dimension (Fig. 1) in the micrometer range, contains a complex hierarchical structure that can be considered on various separate length scales, including molecules (scale factor: 1), lamellae (scale factor: 9 nm), growth rings (scale factor: 100 s nm), etc. To date, little is known about the three-dimensional lamellar and growth ring structure of starch. There are currently two models for the lamellar structure of potato starch. The first model

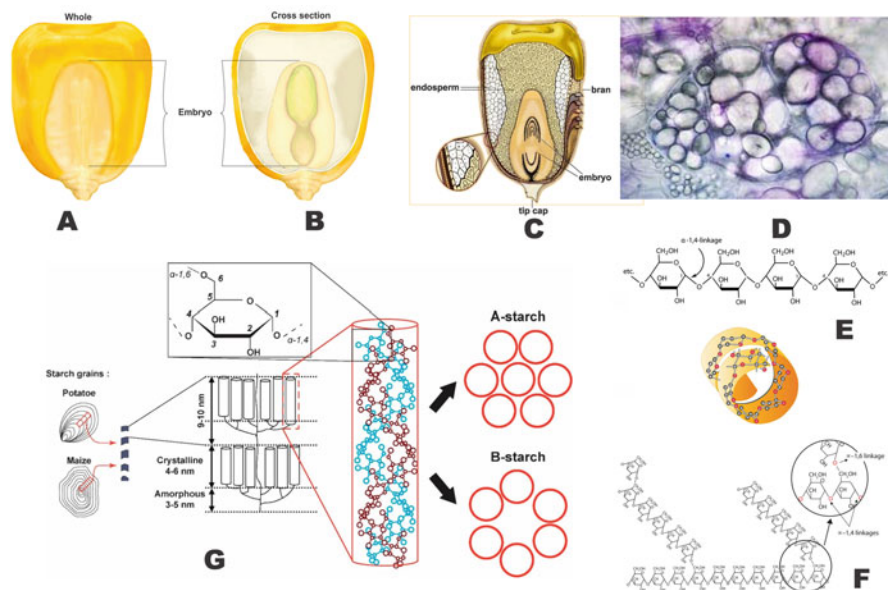

Fig. 1 The starch's hierarchical structural levels of organization, which demonstrate a seed arrangement from cm to m range (a–c). The circles represent the double helices visible from the top of a hypothetical granule with amorphous and semi-crystalline growth rings extending from the hilum (d), amylose component of starch (e), and amylopectin double helices generating the crystalline lamellae of the blocklets (f) (g)

predicts that the lamellae will be twisted into helical structures that converge side by side, and the second model includes helical lamellae that form “blocklets” with restricted lateral coverage. Depending on the source plant, these blocklets have a spherical shape and come in sizes between 20 and 500 nm. A single-crystalline growth ring is thought to consist of two end-to-end blocklets on average (Fig. 1) (Waigh et al. 1999).

Because starch is insoluble in water, its granules are incredibly easy to separate. Granules of starch or amyllum, which are produced by biosynthesis and are composed of densely packed polysaccharides and a little amount of water, are semi-crystalline. Utilizing techniques such as NMR spectroscopy, small-angle X-ray microfocus scattering, X-ray microfocus diffraction, and others, it has been discovered that the natural starch granules’ annular growth ring structure is made up of alternating crystalline and semicrystalline lamellae. The developing rings surround the hilum core and are both crystalline and amorphous (Lin et al. 2011). Crystalline lamellae are formed when amylopectin branches interlock to form double helical structures. Due to its greater interaction with amylose, amylopectin has reduced crystallinity but still predominates in the double helical form in the semi-crystalline lamellae. The starch granule’s multiscale structure is depicted in Fig. 1 and includes (a) the granule itself (2–100 μm), (b) growth rings (120–500 nm), (d) blocklets (20–50 nm) formed of super-helical lamellae (9 nm) both amorphous and crystalline, (c) amylopectin, and (h) amylose chains (0.1–1 nm) (Dufresne 2014; Bertoft 2017).

In most situations, amylose, which is essentially unbranched, accounts for the remaining 25–28% of the starch in cereal grains, while amylopectin, which contains many branched chains, makes up the majority of the starch, accounting for 72–75%. Waxy starches are those that include less than 5% amylose, high-amylose, or amylo-starches are those that contain more than 35% amylose, and normal starches are those that contain 20–35% amylose. (Tester et al. 2004) Amylose, which is thought to be robust in nature, makes up the amorphous region. The crystalline component of the starch granules with a high amylopectin content is easily susceptible to melting at low temperatures because of a disruption in crystallinity (Yuryev et al. 2004).

Starch granule crystallinity is maintained even after amylose has been leached off (Zobel and Stephen 1995). It is obvious that a significant portion of the crystalline growth rings must be formed by amylopectin. According to Imberty and Pérez (1989), the amylopectin branch connections that form the crystallites are clustered and have many exterior chain segments with 15–20 glucose residues entwined into double helices. All chains are arranged in arrays, and the parallel stranded double helical structure is found in pairs. With a pitch of 2.1 nm and six glucose residues on each turn of each strand, two chains bind together to form a double helix. These double helices measure 4–6 nm in length (Bertoft 2017).

Due to differences in their amylose to amylopectin ratios, different sources of starch have varied characteristics. The structural compactness of amylopectin, which is generated in endosperm during grain formation, determines the size and shape of the starch granule. The shape of amylopectin is determined by the ratio of long-chain to short-chain branches, which also affects the starch compactness and starch granule size (Jane 2007). The amount of phospholipid, phosphate-monoester, lipids, granular

architecture, distribution of branched chains in amylopectin, amount of amylose, and crystalline structure all have a significant impact on the starch's functional qualities (Singh and Kaur 2004; Singh et al. 2003). The starch granules can be as small as a few sub-microns to as large as 100 μ m, and they can be spherical, lenticular, oval, elliptical, disc-shaped, etc. (Zhou et al. 2013). Additionally, they can be found as flat thin plates, irregularly formed polygons, and circular pancake shapes with different thicknesses (Jane et al. 1994). Some of the granules' surfaces include tiny holes or apertures, and the degree of porosity varies correspondingly. When exposed to amylolytic enzymes in the human stomach, these pores may represent the site of the first enzyme attack, a way for the enzymes to enter the hilum, or they may be useful for controlling the conversion of starch during germination (Fannon et al. 1992).

Chemistry of Starch–Amylose and Amylopectin

Starch present in granular form in the amyloplasts of tubers and grains and chloroplasts of green leaves have semi-crystalline structure, composed of both amorphous and crystalline rings. The function of both amylose and amylopectin is to store energy in plants and make up the structure of the plant starch granule as a storage unit. There are high- and low-level branching areas in the branched amylopectin molecules. The side chains of amylopectin in the highly branching regions are grouped together to generate the crystalline zones. Thus, short branching chains of amylopectin are the predominant crystalline component in granular starch, while amylose and the branching points of amylopectin add up to the amorphous portions.

The X-ray diffraction pattern of starch depends upon the water content of the granules during the evaluation. Therefore, water can be termed as one of the components that affects the crystalline organization of starch. However, the crystalline to amorphous transition occurs at 60–70 °C in water and the process is coined “gelatinization” (Dufresne 2014). Starch is categorized based upon the X-ray diffraction pattern produced due to the variation in amylopectin chain length and nutritional characteristics as given below (Bashir and Aggarwal 2019).

- (a) Type A: Having amylopectin of chain length 23–29 glucose units and possessing densely packed crystallites with monoclinic lattice, e.g., cereal starch.
- (b) Type B: Having amylopectin of chain length 30–44 glucose units with hexagonal lattice, e.g., potato starches, banana starch, some tropical tubers, and amylose-rich starches.
- (c) Type C: Intermediate between A and B or mixture of type A and B, comprising amylopectin with chain length of 26–29 glucose molecules, e.g., legume starch.
- (d) Type V: Present in swollen granules and is formed upon gelatinization. It is a characteristic of amylose, fatty acids, and mono-glycerides (Gallant et al. 1997).

It is attributed that higher proportions of short and long side chains of amylopectin have a higher crystalline nature. In other words, higher content of longer

amylopectin chains is more crystalline than those with lower content of the long-chain fractions (Singh et al. 2006). The branched amylopectin molecule contains regions with low and high degree of branching. In highly branched regions, side chains of amylopectin are grouped, forming crystalline zone clusters. These crystalline regions are not susceptible to hydrolysis.

The heat of gelatinization (ΔH gel) of such highly crystalline starch is higher than that of high amylose starches. This is due to the increase in double helix content, which increases with higher concentration of long side-chain amylopectin, i.e., the disruption of the double helices rather than long-range disruption of crystallinity increases the ΔH gel. In addition, the higher X-ray diffraction intensities and transition temperature are also higher than that of more extended amorphous region due to higher degree of crystallinity, which provides structural stability and makes the granules more resistant to gelatinization (Singh et al. 2008a).

Amylose varies with a degree of polymerization (DP) in the range of 50–6000 glucose residues. It is now well recognized that a fraction of the amylose molecules is slightly branched by α -(1,6)-linkages (Fig. 2). On the other hand, amylopectin is a very large, highly branched chain molecule with a DP ranging from 30,000 to 300,000 glucose units. Thus, the molecular weight of amylopectin is about 100 times larger than that of amylose. A strand of amylose and amylopectin are respectively reported to have molecular weights in the range of 104–106 and 107–108 Daltons, respectively.

Fig. 2 (a) An amylose molecule made up of a few occasional branch chains and linear, long chains of glucose monomers interconnected by α -(1,4)-glycosidic linkages. (b) A highly branched amylopectin molecule having linear α -(1,4)-glycosidic linkages and branches connected by α -(1,6)-glycosidic bonds

Although amylopectin molecules are shorter than amylose molecules in length, they are more hefty than amylose because of their extremely branched structure. Amylopectin's side chains are A, B, and C, with the C chain serving as the principal chain to which the B branches are connected. The B chain participates in several clusters and is categorized as B1, B2, B3, etc., according to their participation in the side-chain clusters. The subscript indicates how many chains are involved in the development of the cluster. Branched molecules have a chain that creates a α -(1–6) bond to B1 chains at their exterior (Robin J et al. 1974). The features of high amylose starches have been thoroughly investigated. Wu et al. (2006) investigated the ethanol fermentation efficiency of several starch sources and discovered that starches with more than 30% amylose have a negative impact on the efficiency of ethanol conversion. As the amylose content grew, the conversion efficiency dropped. Starch must be gelatinized since it cannot be digested by enzymes in its natural state. This causes it to change into an amorphous mass and make itself more accessible to the glycosidic enzymes.

Native Versus Modified Starch

Starch can be categorized into three major groups: native starch (which is not subjected to any treatment), modified starch (in which few original properties of the native starch has been changed or modified by enzymatic, chemical or physical treatment), and hydrolyzed starch (which causes the polymeric chains to break down into simple sugars like maltose) (Chung and Liu 2009). The primary goal of starch modification is to change the physicochemical properties of native starch in order to enhance functional properties such as gelling, adhesiveness, binding, thickening, and film formation. Because of superior functional qualities than native starches, modified starches are employed in a wide range of processed foods. Many physical modification methods, such as heat moisture treatment (HMT) and annealing, lead to physical alteration of starches without gelatinization or degradation to the starch granules, and have no effect on the granule's birefringence, sizes, or shapes. Treatments affect the interior granule structure in quite distinct ways (Chung and Liu 2009).

Native starch is the pure form of starch occurring in nature, obtained from wheat, corn, rice, potato, tapioca, etc. The components of starch contribute to its water-holding capacity, and swelling in hot water at different temperatures depends on their genotypic diversity and growing conditions, but they are usually insoluble in cold water.

The stability of native starch under different pH values and temperatures varies adversely. Native starch granule is insoluble in water at room temperature and is extremely resistant to hydrolysis by the amylase enzyme. Due to their limited functionality under ordinary circumstances, they have to be modified in order to enhance their properties and functionalities such as solubility, texture, viscosity, and thermal stability. Such modifications are desired for the product development as well as their potential role in the starch industry. Most native starches are semi-crystalline

with crystallinity of about 20–45% (Zobel 1988). For commercial applications, starch is extracted from plants to get a flour-like tasteless and odorless white powder, insoluble in cold water. This powder, which contains native starch, consists of microscopic granules with diameters depending on the botanic origin, ranging from 2 (for wheat and rice) to 100 μm (for potato), and with a density of around 1.5 g. cm^{-3} . This extracted flour is modified by refining through wet grinding, sieving, and drying methods (Buléon et al. 1998).

Starches require modification since they are indigestible and lack the ability to contribute to the structure of many foods. The modification processes involve chemical, physical, or enzymatic treatments, irradiations, etc. In addition, they are modified to acquire different properties that are desirable for different applications such as preparation of packaging material, thickeners, binders, emulsifiers, food, pharmaceuticals, etc.

Physical modification can be brought about by attrition methods such as milling whereby the smashed or “damaged” starch granules are easily dispersed in cold water to provide pastes or gels, which are digestible. “Pre-gelatinized” starch is obtained by the simultaneous gelatinization and drying of aqueous starch dispersions for commercial applications. Enzyme hydrolysis is employed to obtain starches particularly for food-grade materials such as the production of dextrans and glucose. α -Amylase and amylo-glucosidase are most often used in this respect to make glucose syrup, but maltodextrins and crystalline glucose (dextrose), specialist dextrans and maltose may be obtained with β -amylase action. Chemical and physical properties can be appreciably altered by chemical modification of starch, and the chemical modifications usually enhance desirable characteristics of starches. These include “cross-linking” to provide chemical and thermal resistance and the addition of specific chemical moieties to prevent retrogradation of starch gels on cooling (Tester and Karkalas 2002). Chemical modifications include acid modification of starch granules, oxidation, formation of ester derivative, and etherification. These treatments help to improve hydrophilic character, introduce hydrophobic character, introduce positive or negative charges, cross-link the starch chains, and introduce color to the starch. The properties of modified starch depend on the nature of starch source, the amylose to amylopectin ratio, the nature of the substituents that are added, the degree of substitution, whether it is pre-modified by acid hydrolysis, and whether the starch is granular or gelatinized (Robyt 2008).

Starch chain interactions, gelatinization temperatures, granule swelling, acid and enzyme hydrolysis, viscosity, amylose leaching, and retrogradation were all affected by physical modification methods such as in osmotic pressure-treated starches (Pukkahuta et al. 2007). The cross-linking method alters some of the functional characteristics of starches, allowing for a wide range of uses. Because of significant features such as low gelatinization temperature, high swelling and solubility, storage and good cooking durability, acetylated starches with low degree of substitution (DS) have been widely employed in the food industry for several years (Wang and Wang 2002). Acetylated starches are less susceptible to retrogradation because the amylose fraction, which is predominantly responsible for starch retrogradation, is altered. Acetylation appears in all amorphous regions even in the outer lamella of

crystalline areas, resulting in an increase in the specific surface area of starch granules, which is consistent with Biliaderis' (1982) assumption for acetylation in starch granules. Chemical structures, DS, and acetyl group distributions, all influence the physicochemical characteristics of acetylated starches. The DS improved as the size of the starch granules decreased. Taro starch had the greatest DS level and the smallest starch granule dimension, while potato and corn starch had the opposite dimensions. The DS of isolated amylose populations of various granule fraction sizes remained unaltered.

Heating cassava starch at low temperature (45–65 °C) leads to minor variation in structure of starch and amylose–amylopectin ratio (Wicaksono et al. 2016). The number of freeze–thaw cycles increased when starch is heated to a high temperature (59–79 °C) accompanied by freezing and defrosting. It altered starch rheological properties and increased swelling power, heat stability, and viscosity. It also impacted the starch granules' surface characteristics (Lawal 2019). A high pH causes partial breakdown of cassava starch granules, resulting in a reduction in molar size and gyration radius while low pH causes starch to hydrolyze especially in the amorphous region of granules and also lowers the molecular weight of the starch (Wicaksono et al. 2016). Addition of carboxymethyl substitution of hydroxyl groups in starch leads to the addition of the hydrophobic groups on the starch molecule. This increased the starch stability in aqueous media, decreased the ability of recrystallizing, and also prevents the damage due to heat and microorganisms (Lawal 2019). Amini et al. (2015) reported that the granular crystallinity and morphology of surface of the corn starch improves when microwave radiation is applied at various moisture and temperature ranges. This also improved the solubility, emulsifying activity, gelling ability, water and oil-holding capacity, and swelling ability. Pasting temperature and viscosity were found to be increased while the degree of relative crystallinity, gelatinization, and peak viscosity decreased. Another study on modified corn starch by Pukkahuta et al. (2008) showed that the starch granules' shape was distorted, crystallinity was changed from B-type to A-type, and gelatinization temperature was increased when corn starch was heated in a sodium sulfate hypertonic solution at 100–120 °C. Berski et al. (2011) showed that amylopectin depolymerization occurs due to increase in linear molecules when oat starch was chemically reacted with sodium hypochlorite. Rice starch when treated with ultrasonic waves resulted in distorted starch granules, reduced pasting ability and starch digestibility, whereas the viscosity, granules' swelling capacity, and solubility were increased after the treatment (Yu et al. 2013). Thirumdas et al. (2017) treated rice starch with glow discharge or low-temperature plasma leads to free radical generated starch cross-linking and increased leaching of amylose. It increased the viscosity and pasting and decreased the tendency of retrogradation. The same study also showed that the reaction between the acetyl group and hydroxyl group of polymeric rice starch prevents the starch granules from crystallizing and retrograding and also decreased the solubility and pasting temperature. The treatment leads to an increase in swelling capacity and viscosity of starch granules. Another study revealed that there was alteration in the starch reactivity and its physical properties when starch was co-polymerized with synthetic polymers like polyvinyl chloride,

polyethylene, and polypropylene, which change the starch structure from homo to heteropolymer (Hernández 2018). Rice starch when treated with pullulanase (debranching enzyme) resulted in the formation of linear short-chain molecules that were easier to align and aggregate and associate to form double helix. The gelatinization temperature was found to be more in comparison to native rice starch and crystalline structure was also changed from A-type to V-type. Treatments also increased the resistant starch content and water-holding capacity of rice starch (Cao et al. 2020).

Application of ionizing radiation such as gamma radiations to starch also improves their properties such as viscoelastic properties, emulsion stability, etc. Usually application of gamma radiation to polysaccharides results in their degradation, but in the presence of an alkyne such as acetylene enables their cross-linking, leading to the formation of products with enhanced functionality (Al-Assaf et al. 2007).

Amylose to Amylopectin Ratio of Native Starch Species

The ratio of amylose to amylopectin and the structural variations are highly influenced by the source of the plant material. Waxy starches contain less than 10% amylose, whereas high-amylose starches contain amylose greater than 40%. Regular starches consist of 20–30% amylose and 70–80% amylopectin (Tester et al. 2004). Table 1 lists several common native starch species along with the % composition of amylose and amylopectin.

The amount of amylose and amylopectin in the starches of different species and the same species developing under various conditions varies greatly. When scientists examined the starch content of various cultivars of a single species, they discovered clear differences in the species' characteristics. Native starches, picked from suitable cultivars with special qualities, have been proposed as a possible replacement for chemically altered starches. Singh et al. (2008b) investigated the structural, thermal, and viscoelastic characteristics of potato starches isolated through selective breeding of various plant varieties. Additionally, there were significant differences in the distribution of amylopectin chains across the starches, with polymerization levels ranging from 6 to 30. They discovered that changes in genotype and environmental factors had no effect on the amylose content. Thus, the crystalline and amorphous areas of the starch granules are significantly impacted by this variation in the amylose to amylopectin ratio. According to research by Barichello et al. (1990), starches with higher levels of crystallinity had higher transition temperatures and gelatinization enthalpies than those with higher levels of amorphity (Singh et al. 2003).

The amylose/amylopectin ratio's impact on glass transition temperature (T_g) was examined by Liu et al. (2010) since it is relevant to both science and industry. In their experimental work, they used corn starches with various amylose/amylopectin ratios. T_g was discovered to increase from 52 °C to 60 °C with an increase in amylose concentration from 0 to 80 for samples with roughly 13% moisture. T_g rises

Table 1 Percentage composition of amylose and amylopectin and the corresponding ratio in some common native starch species

S. no.	Native starch species	Amylose (%)	Amylopectin (%)	Ratio (amylose/ amylopectin)	References

for the same type of starch as the amylose level does. As a result, T_g rises along with the amylose/amylopectin ratio value.

Effect on the Morphology of Starch Granules

The characteristics of starch related to the morphological structure primarily resolve the significance and applications of starch. The biochemical mechanisms of starch accumulation and the grade and quality of the raw material play a major role in determining the characteristics of starch shape. The genotype of the plant and the

metabolic characteristics of the chloroplast or amyloplast determine the form of the starch granules. The size of the granules varies depending on the temperature of growth. Greater granule size and lower pasting and transition temperatures are created in starch tubers grown in lower-temperature regions compared to those grown in higher-temperature locations. The fluctuation in binding moisture, amylose, and phosphorus content at higher growth temperatures is to blame for this (Tester et al. 1999). Smaller starch granules swell worse and require a greater temperature to gelatinize, in addition to being more difficult to store and tasting worse than larger ones (Zabolotets et al. 2019). It has been noted via scanning electron microscopy (SEM) micrographs that some starch granules, such as those made of rice, corn, wheat, etc., have less smooth surfaces than those made of potato, which have very smooth surfaces. These uneven and smooth surfaces could have tiny pores (Martens et al. 2018).

From an evolutionary standpoint, the creation of various biochemical and physiochemical features of the starch molecule is directly influenced by granule form. The morphological variance among the various starch molecules was primarily controlled by the ratio of two -glucan chains (amylose and amylopectin), as well as their molecular architecture. According to reports, there are numerous factors that contribute to the differentiation and morphological variation of starch granules, including numerous, complex genetic controlling factors, plastid size and number, environmental factors at the time of seed germination, intricate biochemical cascades, and the availability of malto-oligosaccharides (Shapter et al. 2008). According to earlier research, the botanical origin from which starch is obtained has a significant impact on the starch granule's form. Starch granules are created in the plastids known as amyloplasts during the formation of the endosperm. Because of the existence of the surrounding granules, the formation of numerous granules in a single amyloplast causes smaller granules to take on a polyhedral structure. Low magnification reveals that these polyhedral starch granules eventually compacted and appeared as a single granule in the amyloplast. On the other hand, the individual amyloplasts' starch granules of the *Panicoideae* family form a big, simple granular structure. According to Rahman et al. (2000), *Triticeae* exhibit a distinctive bimodal structure in the endosperm where giant lenticellular A-type granules (16–26 μm) interact with small spherical or ovoidal granules (2–10 μm in diameter). The distinctiveness of each starch molecule is typically primarily observed through granular appearance. For instance, compared to legume starches, cereal starches have a lower amylose percentage and smaller granules. Rice starch granules are very small (3–10 μm), have a unimodal size distribution, and are polygonal or angular in shape, but legume starch granules range in size (4–80 μm) and can be oval, spherical, elliptical, or irregular depending on the source plant (Acevedo et al. 2022).

According to evidence on the effects of different amylose/amylopectin ratios on starch morphology, acylation is one chemical modification that stimulates morphological changes, which in turn introduces different functional groups into the starch granule and alters the physical and biochemical properties of starches (Zhu et al. 2017). Wang et al. (2018) emphasized the contribution of starch branching enzyme I (SBEI) and SBEII, one of the genetic regulating variables, to the formation of

morphologically distinct (heterogeneous) starches in some mutant rice. According to this study, gradually lowering the levels of SBEI, SBEIIa, and SBEIIb in transgenic resistant starch rice line (TRS) primarily increases amylose formation and decreases amylopectin content by creating more room for amylose biosynthesis and decreasing amylopectin synthesis or branching degree. Additionally, Verma et al. (2018) used SEM and FTIR to investigate the morphological characteristics of various cereal starches with variable amylose/amylopectin ratios and ended up finding that Basmati and IRRI rice varieties have polygonal, irregular shapes with shiny surfaces, which largely depends on the biochemistry of the chloroplast or amyloplast, as well as plant physiological conditions. According to a report by Waleed et al. (2021), fermentation directly affects the molecular and morphological characteristics of barley starch from the Chinese highlands. The starch granules of fermented barley starch FHB72 and FHB42 were reported to have damaged and cracked structural features without any growth rings, which may be the result of superficial erosion of the starch granules. According to Han et al. (2020), starch granules are made up of amylopectin fragments with large molecular masses in the outer section and a gel-like structure with empty spaces in the inside part. As a result, starch granules produced as a result of high hydrostatic processing pressure (HHP) have severely distorted interior structural morphology. In a similar manner, Liu et al. (2016a) demonstrated that the morphology of the starch granules in sorghum remained unaltered with HHP of 120–360 MPa, but when 480 MPa pressure was applied, the starch granules swelled and collapsed to demonstrate deformation and fusion following application of 600 MPa HHP. These results were also supported by Liu et al. (2016b) in mung bean starch, Deng et al. (2014) in rice starch, Liu et al. (2012) in corn starch, Liu et al. (2008) in potato starch, and Liu et al. (2008) in rice starch. These results made it abundantly clear that the amylose/amylopectin ratio and degree of branching have a significant impact on the granular morphology. Another study by Dhull et al., published in 2021, examined the effects of physical and chemical alterations on the morphological characteristics of the starch in black rice (*Oryza sativa* L. *indica*). They discovered that native rice starch had smaller irregular forms with sharp angles, edges, and no pores on the surface before heat moisture treatment (HMT).

HMT, however, has a considerable impact on the shape of rice starch granules, and starch fragment aggregation has also been noted. Similarly, the surface of starch granules modulated by octenyl succinate anhydride (OSA) was observed to be rough and dotted with pores. The primary way the OSA functional group affects surfaces is by generating many holes and channels. Al-Ansi et al. (2022) also suggested that as germination progressed, amylose percentage increased from 22.81% to 26.63%, while starch content decreased from 45.70% to 31.67% (24 h, 48 h, 72 h). The increased amylose/amylopectin ratio during germination supported the theory that the grains' starch had been mobilized. Amylase was more accessible to the non-reducing ends of amylopectin than to those of amylose, which contributed to the greater amylose/amylopectin ratio. These findings have consequently drawn attention to the fact that the morphological characteristics of starch granules have the potential to enhance the quality of starch-based meals and other uses.

Effect on the Structure of Starch Crystallinity

As in section “[Granule Structure of Starch](#),” starches are divided into three crystalline forms known as A, B, and C depending on the XRD results. The assembly of amylopectin double helices into crystalline lamellae, interspersed with amorphous lamellae made up of -(1–6) branch regions of amylopectin and amylose in waxy starches, is what causes crystallinity in starch granules. It is evident that the alternating crystalline-amorphous lamellae serve as the foundation for semi-crystalline (or “dark”) growth rings, which consist of about 16 crystalline lamellae and are roughly the same width as the interspersed amorphous (or “light”) growth rings (–140 nm), in high-amylose starches, where amylose forms double helices and crystalline domains accordingly (Tester et al. 2004). While nanocrystals made from B-type starches created round-like particles, those made from A-type starches adopted square-like particles. The various packing arrangements of the amylopectin chains for A- and B-type starches provided an explanation for this. Starch produces a compact semi-crystalline shape in order to increase the concentration of energy stored and decrease the amount of storage energy used. Additionally, a number of integrated enzyme systems are used in this biochemical process.

According to a variety of terminologies, such as starch molecular fine structure, structures formed by amylose–amylopectin fine structure, and starch aggregate structure, structures formed by amorphous lamellae, crystalline lamellae, fractal structures, and ordered aggregates, have all been thoroughly investigated (Chi et al. 2018). Therefore, a fundamental understanding of the starch hierarchical changes is important in order to evaluate the impact of starch crystallinity on the food processing industry as well as other applications. Using chain length distributions (CLDs) and full molecular size distributions, Tao et al. (2019) emphasized the molecular fine structure of starch from this perspective. Additionally, they used a variety of technologies to reveal the hierarchical branches of CLDs, such as size-exclusion chromatography (SEC) or its coupling with multi-angle laser scattering (SEC-MALS), asymmetrical flow field-flow fractionation coupled with MALS (AF4-MALS), fluorophore-assisted capillary electrophoresis (FACE), and high-performance anion-exchange chromatography (HPAEC). Molecular fine structure is primarily framed using a biosynthesis-based model, highlighting changes throughout starch biosynthesis, according to a different study by Nada et al. (2017). Additionally, using various technologies like X-ray diffraction (XRD), SEM, atomic force microscope (AFM), confocal laser scanning microscope (CLSM), transmission electron microscope (TEM), primarily by small-angle neutron scattering (SANS), and small angle X-ray scattering (SAXS), starch aggregate structures of 1–100 nm size are interlinked with lamellar structure, fractal structure, as well as nanoscale reassemble (Blazek and Gilbert 2011). While AFM/SEM/TEM focuses on specific positions of starch nanoparticles, XRD unravels crystalline and amorphous structures on a small scale. Starch structures that are hundreds or thousands of nanometers in size are also interpreted using SAXS and SANS. As a result, a thorough analysis of each approach gradually discloses all of the structural characteristics of starch crystallinity. Additionally, the fundamental -D-glucan chains of starch ultimately control structural organization (Wang et al. 2019).

Previous research (Shi and Seib 1992) identified a number of starch self-assemble structures with reduced DP and amylopectin chain length. First, DP 10 chains were predicted to form double helical structures far less frequently than chains with DP 14–24 or DP 12–22. Additionally, double helices are once more organized in order to create native crystalline structures of the A-type, B-type, and C-type, while another V-type crystallinity is created after being processed with a variety of guest molecules (lipids, glycerol, DMSO, etc.) (Krishnan et al. 2020). However, according to a few studies (Bertoft 2017), while tuber starches have B-type crystalline structure because of their long-chain amylopectin chain length ($DP > 20$), cereal starches have very short amylopectin chain length (DP20), which results in the formation of A-type crystalline structure. The simultaneous existence of both A- and B-type crystalline structures is represented by the C-type crystalline structure, which is primarily found in legumes, roots, fruits, and other stem starches. Furthermore, it is confirmed in a study by Rodriguez-Garcia et al. (2021) that while B-type crystals have hexagonal structures, which lead to more open structures and packing with 36 water molecules within crystallinity, A-type crystals have polymorphic crystals that are packed with eight water molecules, resulting in orthorhombic structures. Since amylose–amylopectin arrangements in the starch sources are finally deciphered by the type of crystallinity and thorough indexing of orthorhombic as well as hexagonal structures, it is important to understand these factors. According to Jane et al. (1997), A-type starches generate thinner crystalline lamellae than B-type starches because they have very short amylopectin chains (Chi et al. 2017). Due to the inclusion of “weak places” into the structure of crystalline lamellae, it is also extremely vulnerable to acid and enzymatic treatments. This suggests that starch hierarchical structures are thus intrinsically linked and driven by starch intermolecular interactions with various characteristics. This principle of starch multiscale structures also has a direct influence on starch digestibility, targeted food preparation, and in other aspects.

Effect on Biochemical Properties

The solubility, gelatinization, retrogradation, glass transition, hydrolysis, oxidation, esterification, digestibility, and reinforcing qualities of starch are just a few of its physical and biological characteristics. The amylose to amylopectin ratio, molecular weight, and extent of branching, among other factors, have a significant influence in predicting the functions of a specific starch sample, including pasting, texture, rheological properties, digestibility, etc. (Egharevba 2019). By removing flaws in its natural qualities, various adjustments to these starch traits improve their functional applications.

Digestibility

Starch crystals are less prone to being digested because they contain bonded liquid. This explains why A-type starch dissolves more quickly than B- and C-type starch

crystals. Smaller granules digest more quickly than larger ones because they have more surface area to interact with digestive enzymes (Franco et al. 1992). Since amylopectin is easier to digest and amylopectin presence slows down the rate of starch digestion, amylose is known to contribute more to resistant starch (RS) or slow-digesting starch (SDS). Therefore, greater crystallinity is linked to easier digestion, while amorphous fraction decreases digestibility. High amylose content in starch is resistant to digestion, slowing the rate at which blood sugar levels rise. As a result, it has a low glycemic index and is less likely to gelatinize (Magallanes-Cruz et al. 2017). Consequently, the glycemic index lowers when the amylose to amylopectin ratio rises. This suggests that amylopectin is readily digested and hydrolyzed, which is harmful to diabetics since it releases reducing sugars into the bloodstream (Dipnaik and Kokare 2017). Higher amylopectin content starches break down more quickly, earning the moniker “rapidly digested starch” (RDS).

Digestion and cooking are positively correlated with each other. Cooking, presumably by gelatinizing it, increases the starch’s availability for enzymatic hydrolysis (Snow and O’Dea 1981). The digesting process is also impacted by the starch granules’ surface shape. The surface of starch granules might be smooth like rice or squishy like a potato, and the amount of holes is thought to affect how well starch is digested. As a result of these channels, it was thought that enzymes would break down starch granules from the inside out, resulting in a quicker digestion. However, Martens et al. (2018) found that the positive correlation between the number of pores and the digestion kinetics could only be applied within a single botanical source and not across botanical sources.

High amylose starches have been found to have high gelatinization temperatures and to produce tougher gels (Shi et al. 1998). In the presence of water, a gelatinization process occurs that facilitates digestion (Tester et al. 2000). The granules of native starches undergo a characteristic structural reformation that is unique to their botanical origin when heated in excess water. They inflate and gradually lose their ordered or crystalline structure, turning into a basically amorphous mass. Eventually, a thin paste or gel is created and the granule structure is completely gone. Due to the heating of the extra water, the double helices at this point are hydrated and begin to unravel. It is believed that this process starts at about 45 °C (onset temperature, or T_o), peaks at 60 °C (T_p), and is finished about 75 °C (T_c). Amylases and amyloglucosidase, starch-hydrolyzing enzymes, eventually cause starch to be totally digestible. However, starch is fermented in the human colon and produces short-chain fatty acids, which are subsequently absorbed and used as a source of energy.

Dispersibility

Reconstitution of flour or flour mixtures in water is known as dispersibility. It has been said previously that the better the dispersibility, the better the flour will reconstitute in water (Kulkarni et al. 1991). To put it another way, it is the starch’s capacity to swiftly form tiny granules when mixed with water in the spray tank to produce a fine particle suspension. For products made from starch, starch

dispersibility in organic solvents is essential because it impacts the production procedures, which in turn affects the final product's attributes. The finished product is stable, consistent, and has high physicochemical qualities thanks to a well-dispersed powder, which supports its use as a thickening, stabilizing, and binding agent in many dishes, such as soups, sauces, gravies, baked goods, etc. Particle sizes, z-potential, moisture, and other variables can all affect how well starch granules dissolve in organic solvents. In their 2009 study, Akanbi et al. compared the dispersibility of breadfruit and cocoyam starches and discovered that cocoyam starch had a higher dispersibility value (86.500.18%) than would breadfruit starch (40.6670.5774%).

The Kulkarni et al. (1991) approach, as updated by Akanbi et al. (2009), can be used to measure the dispersibility of starch. A 10 g sample of starch is precisely weighed into a 100 ml measuring cylinder with a stopper. Also, 100 cc of distilled water should be added, stirred thoroughly, and then left to stand for 3–4 hours to develop the pure and sediment layers. The dispersibility is determined by subtracting the upper layer meniscus from the lower layer meniscus or by subtracting the volume of settled particles from the final volume (Jacob and Adeleke 2019). Both biomaterials and biological applications depend on dispersibility, with monodispersed materials frequently being the most desirable (2013) (Ha, S., et al.).

Che et al. investigated the dispersibility of Cassava starch particles of various sizes in liquid paraffin (2007). They claimed that compared to the native cassava starch, the micronized cassava starch dissolved more easily in liquid paraffin. This demonstrated how accurately reducing granularity increased dispersibility. Native cassava starch's large granule size resulted in decreased dispersibility. The particles' intrinsic gravity caused them to settle swiftly. During starch suspension heating, the enormous variation in granule size and swelling power amongst blended starches results in an uneven distribution of moisture. As a result, the behavior of the combination deviates from what may be predicted based on the behavior of the particular starches. There were significant variations ($P < 0.05$) in the values of dispersibility for the control starches and their respective blends, according to Ashogbon's (2014) research on bambarra groundnut (BBS) and cassava (CS) starches and their blends. As was already indicated, the reconstitution of starch flour will work better the higher the dispersibility value. In this investigation, the 30BBS/70CS mixture's value of dispersibility was significantly higher than that of the other starches, and the results are consistent with the dispersibility values published by Ashogbon and Akintayo for rice starch (87.01%) (2013). Additionally, all of the dispersibility values found in this study were superior to those found in Akanbi et al.'s (2009) analysis of breadfruit starch (40.67%).

For their long-term stability and ease of preparation, starches are modified and dried or pre-gelatinized. Compared to untreated starch, which forms gel at room temperature and is more prone to deposition, it absorbs more water and disperses easily in water. When starches are handled in an alkaline environment, cationic starches are created, and they have a higher dispersion than untreated starches (Omorieghe Egharevba 2020). Ren et al. (2018) investigated the chemical, wettability, thermal, and structural characteristics of cross-linked starch nanocrystals (SNCs),

which were modified by cross-linking modification using citric acid in aqueous medium. They discovered that cross-linked SNCs had lower polarity, stronger hydrophobicity, and dispersion stability, which allowed them to be used as reinforcements in hydrophobic polymer matrices.

Rheological Properties

Because they can change the technical and mechanical qualities of the starch, starch rheological properties are extremely important for the quality of products associated to starch (Zhang et al. 2017). Amylose/amylopectin ratio, particle size, and amylose-lipid composition and interactions, particularly lipids and proteins that prevent the interaction of starch and heat, have an impact on pasting profiles (Liu et al. 2003). Two corn flours, Kassai, which is white, and Atp-Y, which is yellow and has a different amylose/amylopectin ratio, were examined by Dongmo et al. (2020) under unroasted, roasted, and unfermented conditions. The tested flours' pasting temperatures ranged between 74.50 and 77.77 °C and were influenced by the variety and treatment; the yellow variety demonstrated a higher pasting temperature value than the white variety. This is because the yellow variety has a large concentration of lipids, which interact strongly with the amyloidosis and reduce its swelling. Similar to this, the untreated flours had higher pasting temperatures than the treated ones due to the significant lipid and protein content, as well as the strong connectivity between these components that serve as a temperature barrier. The decreasing concentration of lipid and protein following the treatment and the beginning of hydrolysis of the minimal energy interactions that maintain the crystalline structure of the starch are what cause the drop in pasting temperature in various treatments. The peak viscosity value of the untreated and unfermented flours was greater. The stronger hydrolysis of the starch constituents during heat treatment, loss of phosphorus ions, and reduction in interactions that maintain the starch's crystalline structure could all be contributing factors to the lower peak viscosity values (431.50 Cp and 895.50 cP for Atp-Y and Kassai, respectively) in roasted flours. The setback value varied from 356 to 3198 cP with a decline following the various treatments, which may be caused by the untreated maize flours' high amylose/amylopectin ratio and the yellow variety's high lipid content (Mishra and Rai 2006). According to Casthana et al. (Castanha et al. 2021), the peak apparent viscosity of several starches with differing amylose contents was ordered as follows: potato (amylose 28%), cassava (amylose 20%), waxy maize (amylose 2%), maize (amylose 28%), and high amylose maize (amylose 72%). This behavior was greatly influenced by the inherent characteristics of starch, granule size and shape, amylose/amylopectin ratio, and their individual chain lengths (Tester and Morrison 1990). Amylose content of maize starch is adversely connected with peak viscosity, final viscosity, trough viscosity, setback value, and breakdown viscosity, according to Karakelle et al.'s (2020) study of the rheological properties of the maize starches that varied in their amylose content. The pasting temperature was seen to decrease along with the reduction in amylose level (from 70% to 0%). The samples with a 20% or lower amylose content, however, did not

significantly differ in pasting temperatures. According to the kinetic modeling of pasting curves, all starches had starch coefficients greater than 1, indicating that water absorption into the starch granules increased the rate at which the granules swelled. In comparison to normal maize and rice starches [82.0 and 79.9 °C, 152 and 113 rapid viscosity unit (RVU), respectively], waxy maize and waxy rice starches had lower pasting temperatures (69.5 and 64.1 °C, respectively) and higher peak viscosities [205 and 205 rapid viscosity unit (RVU)], respectively. The primary component of starch, amylopectin, is really responsible for the ability of starch to expand and the development of viscosity during cooking, whereas amylose, particularly in the presence of lipids, appears to interact with amylopectin and limit starch granule swelling. As a result, normal maize and rice starches displayed higher setback values (74 and 64 RVU, respectively) than their waxy counterparts (16 and 16 RVU, respectively) (Ai and Jane 2015). Due to the depolymerization of starch molecules, acid-thinned sorghum starch had less viscosity (Singh et al. 2009). Due to the starch molecules' depolymerization and charge repulsion, oxidized cassava and barley starches have poorer gel strength than the corresponding control starches (Sangseethong et al. 2010). In comparison to their control starch, annealed mung bean starch (Chung et al. 2000), HMT rice (Hormdok and Noomhorm 2007), or potato (Eerlingen et al. 1997) starch typically forms a stronger gel. The rising effect also appears to be more pronounced for native starches with high swelling capacities, such as potato starch. HMT, however, has been demonstrated to prevent the gelation of sweet potato and rice starch. According to Pimpa et al. (2007), sago starch treated with 10/15 kGy electron beam radiation results in a stiffer gel than their control starch, but when treated with 20–30 kGy dosage, the gel becomes softer. This demonstrated how radiation therapy has an effect on the cross-linking and depolymerization of starch granules (Bao et al. 2005). When Hussain (2020) compared the rheological characteristics of chickpea and rice starch, he discovered that rice starch had lower values for the corresponding final, peak, and setback viscosities. All starches displayed shear-thinning non-Newtonian behavior when the parameters of steady shear were investigated (n1). Another study on modified potato starch revealed that when acetylated composite potato starches were compared to their unmodified counterparts, the majority of the pasting properties, such as breakdown, setback, peak, and final viscosities, were found to be decreased (Bolade and Oni 2015). The rheological characteristics of potato starch in their natural, HMT, microwave-treated, ultrasonicated, and synergistic forms were examined by Nadir et al. (2015). When native potato starch was treated with HMT or the microwave, the initial pasting temperature increased (from 61 to 63 and 65 °C, respectively). The initial pasting temperatures were reduced from 56 and 55.2 °C, respectively, with the other two treatments (ultrasonication and syneresis). In comparison to the original potato starch, the setback value of modified starches was found to be lower for all treatments with the exception of the microwave treatment. In comparison to the native approach, the breakdown values of the HMT method were higher. Starches are highly stable during continuous heating and agitation, as evidenced by the drop in breakdown value caused by HMT.

The rheological characteristics of starches with various amylose to amylopectin ratios (80/20, 50/50, 23/77, and 0/100) were investigated by Xei et al. (2009) using samples that had first been pre-compound with water. Under a slit capillary die, the shear stress and apparent melt viscosity properties of sample pellets were studied as functions of moisture content (19–27%) and extrusion temperature (110–140 °C) at various shear rates. Six points were typically recorded for each sample using the cutting and manual entering measurement mode, with the screw speed varying between 30 and 180 points per minute.

Using the equation, apparent shear rates are determined:

$$\dot{\gamma} = \frac{6Q}{WH^2}$$

where $\dot{\gamma}$ is the shear rate, Q is the volumetric flow rate (in cm³/s), W is the slit width, and H is the slit height.

The values of shear stress are determined by the following equation:

$$\tau = \frac{H \cdot \Delta P}{2L}$$

Here, τ is the shear stress, ΔP is the pressure drop over the capillary, and L is the slit length. In the work, the rheological properties of various corn starches with different amylose/amylopectin ratios are studied using a Haake rheometer.

The melts demonstrated shear thinning behavior in all circumstances, and the power law index n ($0 < n < 1$) tended to rise with increasing temperature and moisture content while falling with increasing amylose content. The consistency (K) value increased with increasing amylose while reducing with increasing moisture content and extrusion temperature. Because of their higher levels of gelatinization, increased molecular entanglements between linear polymer chains, and lower levels of gel-balls and super-globes, which are much easier to move than long linear chains, the amylopectin-rich corn starches exhibited lower viscosity and higher Newtonian behavior (Xie et al. 2009).

The energy stored in and recovered from it every cycle is measured by the storage dynamic modulus (G'), and the energy lost or dissipated per cycle of sinusoidal deformation is measured by the loss modulus (G'') (Ferry 1980). Tan can be used to represent the energy storage to energy loss ratio for each cycle. In the dynamic rheometer, the value of G' for starch rises with temperature, reaches a maximum, and then falls as the temperature is raised further. This change results from the granule enlarging and disintegrating due to the melting of the crystalline areas (Evans and Haisman 1979). Thus, the rheological properties are significantly influenced by the granular structure. For example, huge and irregularly shaped potato starch granules displayed higher storage and loss modulus and lesser tan than the smaller, oval-shaped granules (Singh and Singh 2001). Protein content raises the pasting temperature, while damaged starch and protein content lower the peak viscosity value

(Singh et al. 2003). Additionally, the levels of G' , G'' , and \tan decrease with an increase in amylose and increase with an increase in amylopectin (Kaur et al. 2002).

Reinforcing Properties

Because starch is widely available, inexpensive, renewable, biocompatible, biodegradable, and nontoxic, the usage of starch-based materials is drawing a lot of attention. These qualities make them a top candidate for both drug carriers and implant materials. It has also been discovered that starch nanocrystals make good reinforcements. However, the starch's botanical source may have an impact on its ability to reinforce. LeCorre et al. (2012) investigated how the botanical origin of starch nanoparticles affected the starch-natural rubber nanocomposite's reinforcing characteristics. When employed as filler, starch nanoparticles extracted from different types of potato, maize, and wheat improve the material's reinforcing characteristics. With the exception of potato starch, the reinforcing effect diminished as the amylose level rose.

Reinforcing properties are one of the key biological aspects of starch molecules that make them useful for a variety of applications. Recently, Bangar et al. (2022) published a work in which cellulose nanocrystals (CNC) from the Kudzu (*Pueraria montana*) vine were used to reinforce starch-based nanocomposites. In this study, kudzu CNC was used to reinforce pearl millet starch, which enhances crystallinity, heat and moisture-barrier characteristics, and tensile strength following reinforcement. Nanocomposite films were developed utilizing solution-casting procedures. Due to the strong compatibility of intermolecular H-bonding contacts, chemical similarity, enhanced dispersion, and adhesion capabilities of Kudzu CNCs in the PMS matrix, the stability performance of PMS/Kudzu CNC nanocomposites is significantly higher. Another study by Campos et al. (2022) focused on the impact of adding fine bagasse microparticles (FBM) to foamed materials made from cassava starch, which had a substantial impact on the foam's physical and mechanical characteristics following reinforcement. Additionally, it should be emphasized that starch has demonstrated a strong capacity to function as the best reinforcing agent in a variety of contexts recently. Starch-based biodegradable polymers' manufacture, difficulties, and prospects for the future were explained by Siqueira et al. in 2021. They continued by saying that while this way of producing polymers is more involved, time-consuming, and sophisticated than the conventional method using petroleum-based materials; it has significant advantages from both a biodegradability and a business standpoint. Moreover, Lin et al.'s (2011) study demonstrated a reinforcing mechanism using starch nanocrystal filler in polymer matrices to improve intrinsic stiffness, mechanical performance, thermal characteristics, solvent absorption, and barrier properties. It has been discovered that starch nanocrystals' structure is less resilient than cellulose nanocrystals', which restricts their use in the biomaterials sector and would considerably increase their practical utility in the near future. The combination of citric acid, cellulose fibers, and active phenolic extract were utilized as cross-linkers, reinforcement agents, and antioxidant materials,

respectively, in Li's (2020) study on three main techniques of starch films for food packaging. After being strengthened with cellulose fibers, starch's performance was improved in terms of stress resistance and adequate flexibility. It may also be utilized as the ideal coating material to stop the oxidation of lipids in foods like nuts and cereals. According to Liu et al.'s (2020) work on thermoplastic starch film, thermoplastic starch (TPS) was made from cassava starch, glycerol, and nano-SiO₂ using a straightforward film-blowing approach. Tensile strength and thermal stability of starch greatly increased while starch crystallinity simultaneously decreased after the addition of glycerol and nano-SiO₂. Waxy maize starch nanocrystal reinforcement has also been used to describe pea starch films. Tensile strength of the composite films increased with the addition of 5% of nanocrystals, and it was discovered that additions of more than 7% of nanocrystals primarily caused nanocrystals to aggregate on the surface of the composite films and produce longitudinal fibrous structure (Li et al. 2015). According to Lopez-Gil et al. (2014), there are a number of ways to use natural fibers like barley straw and grape trash to enhance the mechanical properties of composites made of thermoplastic starch. Comparatively to oil-based polymers, such as polypropylene (PP), polyethylene-terephthalate (PET), and a biodegradable polymer, Polylactic acid, those starch-based products are appropriate for food packaging trays (PLA). The production of thermoplastic arrowroot starch (TPAS)-based composite films through the insertion of arrowroot fiber (10–15%) into glycerol plasticized matrix utilizing solution casting process was emphasized by recent works by Tarique et al., (2022). After fiber reinforcing, mechanical qualities are improved, and reinforced films show tremendous promise for the food packaging sector. In a similar vein, another study looked at the production of biodegradable plastic using maize starch powder and orange peel powder, which led to an increase in the starch film's mechanical stability and biodegradability. Additionally, it improved the ability of water to absorb moisture and the solubility of water and oil (Chhatariya et al. 2022). In one study, Doan et al. (2019) described how to characterize rice starch gels and how to strengthen them with resistant starch made by enzymatic means. The amylosucrase-modified resistant starch reinforcing procedure resulted in an increase in rice starch gel hardness of up to 60%, but a considerable decrease in gel cohesiveness, which was found to be consistent with the reinforcement. Haaj et al. (2016) compared the reinforcing properties of amorphous starch nanoparticles (SNPs) obtained from ultrasound treatment with those of starch nanocrystals extracted from waxy maize starch through an acid hydrolysis and discovered that the former has better reinforcing properties even though the latter is produced using an environmentally friendly or green methodology.

The reinforcing properties of starch nanocrystals in a matrix of unvulcanized natural rubber were investigated by Mele et al. in 2011. Nonlinear dynamic mechanical experiments were used in their investigation to emphasize the Mullins and Payne effects as well as the starch nanocrystals' substantial reinforcing effect. Two models – the Maier and Goritz model and the Kraus model – were used to forecast the Payne effect. The Maier and Goritz model was used to show that the nonlinear viscoelastic characteristics were controlled by the adsorption and desorption of natural rubber

chains on the filler surface. However, the Kraus model showed that for filler amounts of more than 6.7 volume %, a percolating network formed. Overall, it was noted that adding reinforcement with other materials to the starch components led to both increased functionality and texture. Therefore, the future development of new technologies in the food industries was influenced by the qualities of starch that reinforce other components.

Conclusions and Future Perspective

It has been demonstrated that the crystallinity and granule structure of starch influence both its chemical and physical properties. Both of these depend on the amylose to amylopectin ratio in the starch sample, which in turn depends on the type of plant used and the environment in which it was grown. As a result, the variability in the configuration of amylose and amylopectin as well as their branching distribution within a starch granule accounts for the majority of the variation in the characteristics of starch samples from various sources. The values of various parameters, including Tg, pasting temperature, gelatinization temperature, etc., to name a few, increased as the amylose concentration increased. Therefore, it is ideal to either manage the plant's development conditions or adjust the starch sample to meet a certain requirement in order to obtain starch for a particular use.

Starches are increasingly gaining more attention as a raw material in the production of biodegradable polymers as a result of environmental concerns and the scarcity of fossil fuels (Arvanitoyannis 1999). Since starch is a naturally occurring, biodegradable polymer, it is frequently combined with other substances to improve its physical, chemical, mechanical, and functional properties. There are a wide variety of uses for starch nanoparticles, such as a medicine carrier, emulsion stabilizer, fat substitute, and adsorbent for wastewater treatment (Haaj et al. 2016). It is also widely employed in the food, sweetener, glue, paper, textile, and textile sectors. These uses depend on the characteristics of starch, such as viscosity, swelling volume, solubility, and clarity. Because starch dissolves in water, it can be used as a vehicle to transfer solid active chemicals to a target organism (Jacob, and Adeleke 2019).

As a result of developments in chemical and biotechnology, starch has been widely modified for a variety of uses, and even if its physicochemical qualities have changed, they are still simple to handle. Starch will soon prove to be a predecessor to “green plastic” materials. As a flexible, ecologically friendly resource, starch can be used to replace harmful petroleum-based products in fields such as material science, biotechnology, industry, medicine, and engineering.

Acknowledgments We thank the University Grants Commission, Government of India, for the financial support of the UGC Major Research Project (No. F. No. 42-300/2013(SR)). Dr. Bejoy expresses gratitude to the Department of Science and Technology for supporting the college's Fund for Improvement of S&T Infrastructure (FIST) program.

Abstract

Material synthesis procedures of advanced materials such as nanomaterials and superconductors utilize traditional chemistry processes accompanied by high ecological footprint. These synthesis processes involve high energy, utilize toxic solvents and chemical reagents, and demand complex reaction conditions. Due to the growing demand of such advanced materials in several modern-day commercial applications, there is a strong need for developing sustainable reaction systems that involve lesser costs and energy, minimal environmental toxicity, and ease of large-scale manufacturing. In this chapter, we discuss the importance

Superconductors · Nanomaterials · Green chemistry · Biopolymers · Environmental sustainability

Introduction

Biopolymers are long repeating chains of the monomers of sugars (polysaccharide-based biopolymers) or proteins (polypeptide-based biopolymers) sourced from animals, plants, or microorganisms.

The polysaccharides-based biopolymers are composed of glucose units covalently bonded together using glycosidic linkages. The process of polymerization of polysaccharides is accompanied by loss of a water molecule for each glycosidic linkage. Polysaccharides based biopolymers are diversely found in nature which may differ in their overall charge and could be polycationic (chitosan), neutral (dextran), and polyanionic (alginate) (Harding et al. 2015). They can also be classified as homogeneous and heterogeneous polysaccharides if the monomer units are the same or different; for example, glycogen is a homogenous polysaccharide chain, and xanthan gum is a heterogeneous polysaccharide chain (Johnson-Green 2002).

Polypeptide-based biopolymers comprise amino acids as monomer units that covalently bind with repeating units using amide linkages accompanied by loss of a water molecule for each amide linkage. Polypeptide chains further form specialized structures (secondary, tertiary, and quaternary) using molecular interactions like hydrophobic and hydrophilic interactions, disulfide and salt bridges, and hydrogen bonding causing polypeptide chain folding to form beta-plated sheets, alpha-helical structures, and even complex three-dimensional quaternary structures (Enna and Bylund 2007). Some examples of polypeptide-based biopolymers are collagen, elastin, silk-like proteins (SLPs), keratin, albumin, and gelatin.

Polymers obtained from biological sources (renewable resources) have gained enormous attention and are industrially produced as an alternative to fossil-fuel based (a non-renewable resource) polymers. Traditional material synthesis offers several limitations in terms of minimizing carbon footprint. The innate biodegradable nature of biopolymers has reduced the cumulative carbon footprint of any chemical reaction system wherever they are employed.

Polymers made from renewable resources minimize environmental pollution as they are biodegradable and reduce carbon footprint and the risk of global warming. Moreover, biopolymers have found a wide range of applications such as fabrication of photovoltaics and photodetectors, manufacturing of biomaterials, for formulating

food coating and packaging materials, cosmetics, tissue engineering, drug delivery, etc. In the field of material science, the production of biopolymers has gained enormous interest among industry and academic researchers owing to their potential to replace polymers made from non-renewable sources. Biopolymers have also increasingly been used in the green synthesis of advanced and emerging materials like superconductors and nanomaterials. Biopolymers are used as templates, reducing agents, and stabilizing/capping agents for synthesis of *advanced materials: superconductors* and *nanomaterials*. Environmentally benign material synthesis processes are extensively being explored due to adverse environmental impact of conventional synthesis methods and growing demand for materials with unique physical properties in several modern-day applications.

Superconducting materials play an important role in several fields such as medical diagnostics using MRI imaging systems, a study of subnuclear particles like taus and neutrinos using particle accelerators, and operation of magnetic levitation high-speed trains. Another class of advanced materials, that is, *nanomaterials* have found their application in wide areas such as catalysis, drug delivery, electronics, oil recovery, antibacterial textiles, paints and medical surfaces, corrosion inhibition, etc. These advanced materials (superconductors and nanomaterials) are typically synthesized using physical and chemical methods like thermal decomposition, chemical reduction, UV irradiation reduction, laser irradiation, ultrasonication, etc. All these methods employ high energy-consuming machines and specially designed devices to achieve material synthesis conditions such as high-temperature calcination and sintering, exposure to ultraviolet light, reduction process assisted by ultrasonic waves, and use of pure inert gas or high-power intense laser beam. The chemical methods for the synthesis of nanoparticles and superconductors present several limitations such as the use of organic solvents and surfactants which are toxic for environmental disposal. For example, hydrazine hydrate and sodium borohydride are not safe for direct disposal in the environment but are extensively used as reducing agents to prepare nanoparticles such as AgNPs. Besides, methods like hydrothermal synthesis demand extreme precision of experimental conditions such as the amount of surfactant, precursor concentration, and solvent volume and influence the structure of nanomaterials due to variation in different batches of experimentations (Zhang et al. 2022).

The ecofriendly synthesis of advanced materials has gained momentum among researchers due to advancements in green chemistry and the rising need towards sustainability by adopting less toxic synthesis procedures. The biopolymer-assisted green synthesis of advanced materials including nanoparticles and superconductors has gained momentum owing to its facile nature, cost effectiveness, and minimum environmental impact. Biopolymer assisted synthesis allows the control of the nanomaterial morphology due to the presence of specific chemical interactions among biopolymer chains and the precursor substances (in the bottom-up nanoparticle synthesis approach). Besides, biopolymer-based synthesis of superconducting material like Lu123 provides homogeneity of precursor materials at atomic level without the requirement of mechanical grinding which is otherwise done for over 150 h in physical method of synthesis. Moreover, the biopolymer (dextran) backbone provides a microstructure that efficiently controls nucleation and crystal growth of superconductors (Dedman et al. 2010).

Synthesis of Superconductors Using Templated Biopolymers

Superconductors are known for carrying tremendously high currents below the transition temperature. It is the capability of high T_C (transition temperature) superconductor to persist and allow extremely high current density (J_C) (Rajput et al. 2006) at relatively high temperature (normally higher than 40 K) that has made these a sought-after material viz., YBCO, BISCO, and MgB_2 (Chauhan and Chaudhary 2010; Rajput 2017). J_C is affected by defects, grain boundaries, impurities, and their size as well (Rajput and Chaudhary 2008). For a given high T_C superconductor, thus enhancing J_C needs attention toward its fabrication processes under various required morphologies (Rajput and Chaudhary 2010). Additionally, most of the technologically important high T_C superconductors are oxides viz., YBCO, BISCCO, etc., and need to be calcined under a flowing oxygen atmosphere. Epitaxial growth or stability of high T_C phase of a superconductor has also been a constant objective of researchers to enhance J_C and H_C (critical magnetic field) (Gogia et al. 1991).

Achieving the Meissner effect (diamagnetism) is challenging in nano dimension owing to the suppression of T_C due to a decrease in electron density of states (DOS) at fermi level (Brihuega et al. 2011), in agreement with Anderson criterion (Reich et al. 2003). From the application point of view, J_C and upper critical field (H_{C2}) are of utmost importance in granular type II superconductors. According to WHH (Werthamer–Helfand–Hohenberg) theory (Werthamer et al. 1966),

$$H_{C2} = 0.69 T_C \frac{4ecK_B}{\pi} N(0)\rho_N \quad (\text{in “dirty limit” } L_{\text{eff}} \ll \xi_0)$$

L_{eff} – means free path

ξ_0 – intrinsic coherence length

e – electron charge

K_B – Boltzmann constant

$N(0)$ – DOS at fermi level

From above it is clear, that with a decrease in size and, in turn, increasing disorder and hence large ρ_N , H_{C2} would monomerically increase, provided T_C and $N(0)$ do not decrease with decreasing size. With a decrease in particle size both $N(0)$ and mean free path L_{eff} decreases. A decrease in $N(0)$ would reduce H_{C2} , whereas decrease in L_{eff} would enhance H_{C2} . The above formula forms the basis for increasing H_{C2} by introducing non-magnetic impurities or by preparing nano superconductor provided T_C does not change appreciably.

Biopolymers are effective sequestering agents for metal cations to prepare nanoparticles. Biopolymers form growth – restricting “cocoon” during calcination process. When polymer is taken as a template agent, its concentration is important for controlling the shape (Alikhanzadeh-Arani et al. 2014) (Hall 2006). Different sizes and morphologies result from using different amounts of polymer because of nucleation and embedding of nano particles in the polymer matrix. There are only a few reports on the size dependence of critical magnetic fields in superconductors, and these are mostly

on typical elemental superconductors viz., Al and Pb (Bose et al. 2006). Biopolymer-mediated synthesis of high T_C superconductor is evolving into an important research area with recent attention toward the sol-gel method in presence of biopolymer likes, chitosan (Alikhanzadeh-Arani et al. 2012), sodium alginate (Schnepf et al. 2008), and dextran (Walsh et al. 2007) (Wimbush et al. 2012). Researchers have successfully prepared superconducting nanowires (Hall 2006; Zhang et al. 2012) porous superconducting foams (Walsh et al. 2009) and ordered porous bodies using biopolymers during the sol-gel method. Biopolymer-mediated synthesis of superconductors could overcome difficulties in the preparation of long superconducting tapes.

Accordingly, there are reports of (i) an enhancement in H_{C2} of Al (Cohen and Abeles 1967) and $PbMo_6S_8$ (Niu and Hampshire 2003) with decrease in grain size, by 60% and 100%, respectively; (ii) high yield of superconducting nanoparticles without considerable change in T_C , even with high Ir addition in Y123 (Wimbush et al. 2012); and (iii) improved synthesis time of $LuBa_2Cu_3O_{7-\delta}$ of 48 h compared to 500 h for solid-state synthesis method (Dedman et al. 2010a). At the same time, none of these systems showed a decrease in T_C .

Sol-gel synthesis of superconductor using biopolymer also facilitates easy introduction of dopant (Walsh et al. 2007). Walsh et al. (2007) have studied the effect of varying Ag concentration on J_C and demonstrated silver as a flux pinning agent to enhance J_C in Y123. Walsh et al. (2007) have demonstrated controlled crystal morphology in Y123 by incorporating biopolymer into sol-gel synthesis protocol (Table 1). These authors (Walsh et al. 2007) have shown the different morphologies: (i) sponge like when prepared with biopolymer; and (ii) typical poly dispersing in Y123 prepared without dextran. Authors have attributed the observed high J_C to its small crystallite size as well as the surface pinning of the porous structure.

Self-sacrificial biopolymer templates can be used to create superconducting sponges. These sponges exhibit higher thermal shock resistance with comparative uniform cooling (Noudem et al. 2004; Noudem et al. 2003), such sponges are of practical interest for their application as fault current limiter (FCL) superconducting bearings.

Synthesis of Nanoparticles Through Biopolymer Template

Nanoparticles are particles in the range of 1–100 nm and typically below 10 or 20 nm. Richard Feynman introduced the concept of nanomolecular level in the year 1959 through his famous talk titled “There’s plenty of room at the bottom” (Richard 1960). Since then, researchers have found wide applications of nanoparticles in various fields such as medicine, therapeutics, dye treatment (Sheshmani et al. 2014), photocatalysis, water treatment, and many more. The reaction conditions and precursor materials determine the shape, size, and physiochemical properties of the nanoparticles (Dedman et al. 2010). Besides, the use of solvents and reducing agents during synthesis impact environmental sustainability due to their non-biodegradable and toxic nature (Sheshmani et al. 2014). As the technological advancement of society cannot be stopped, it is important to develop synthesis procedures that are simple and environmentally benign (Hu et al. 2010). In this direction, biopolymers have shown promising results to be used as capping/ stabilizing and reducing agents for the synthesis of nanoparticles.

Biopolymers are either used as stabilizers and capping/reducing agents in the synthesis of nanoparticles. The morphology of gold nanocrystals is controlled using

bovine serum albumin (a single polypeptide chain of 583 amino acids) in combination with a small amount of silver nitrate additive to form Au octahedrons with an average edge length of 73 ± 9 nm. Normally, polymers containing carbonyl and tertiary amine groups such as poly (vinyl pyrrolidone) play an important role in the regulation of the shape of noble metal nanomaterials. The amide groups present in BSA protein act as surface regulating polymer like multiple tertiary amides of PVP. Cui et al., reported a method of synthesis of nanoplates in which hyaluronic acid (polysaccharide based natural biopolymer) acts as both a reducing and stabilizing agent. This study focuses upon differences in the shapes and morphology of nanoparticles led by aging of HA and AgNO₃ solution employed in the synthesis. Interestingly, a distinct morphology of spherical NPs is obtained using fresh solution and a morphology of triangular nanoplate using an aged solution in a short duration of 15 min (Cui et al. 2008). In another strategy, surfactant free PLGA nanoparticles are made to avoid the extra purification step for removing excess surfactant. It is also important to effectively replace the role of surfactants (zwitterionic, cationic, anionic, and nonionic) in controlling the structure of nanoparticles in aqueous phase. This is achieved by grafting Alkaline lignin (ALGN) and lignosulfonate (SLGN), two forms of lignin (hydrophilic natural biopolymer), upon poly (lactic-co-glycolic acid) (PLGA, a hydrophobic synthetic polymer) using covalent interactions to form (A/S)LGN-PLGA biopolymer template. The ALGN-PLGA nanoparticles are made by self-assembly and emulsion-evaporation process. The diameter of the synthesized nanoparticles ranged from 100 to 200 nm. The varied LGN/PLGA ratio was an important factor in controlling the shell thickness and core size of the synthesized nanoparticles (Astete et al. 2020).

In this section, we discuss the application of chitosan, cellulose, sodium alginate, and hemicellulose to assist the synthesis process of nanoparticles.

Chitosan

Chitosan is a class of semisynthetic polymers originated from the alkylation of chitin in its natural form in crustaceans. It is a copolymer of β -[1 \rightarrow 4]-linked to *N*-acetyl D-glucosamine and D-glucosamine units. Being a non-toxic biodegradable polymer, chitosan polymer is being explored for various applications including templated synthesis of nanomaterials. Sheshmani et al. (2014) reported a facile chemical route for the synthesis of nanocomposite graphene/Fe₃O₄/chitosan using the solvothermal method. The composite was used as a nano adsorbent material for dye degradation of acid orange-7 dye in wastewater treatment. Ceria nanoparticles were synthesized using chitosan as a template to obtain porous ceria-chitosan nanospheres with an average size of 4 nm and BET specific surface area of 105 m²g⁻¹. It was concluded that stable residue of the nanoparticles can be obtained after two weight loss steps owing to the evaporation of water and decomposition of chitosan (Sifontes et al. 2011). Chitosan/chitin film has been used as a seed for silver nanoparticle synthesis. These silver nanowires were used for the synthesis of nanowires using the drop cast method (Chandran et al. 2018). Similarly, tungsten nanoparticles can be synthesized

using chitosan as template. In this technique, ammonium metatungstate was encapsulated in chitosan biopolymer using calcination at temperature within 400–600 °C. The nanoparticles produced using this reaction were used for electrochemical hydrogen evolution and showed four times higher activity than bulk WO_3 (Ganesan and Gedanken 2008).

Navarro et al. reported a synthetic procedure using chitosan for preparing a hybrid nanostructure with narrow particle size distribution (1.2–8 nm). Magnetic nanoparticles of MFe_2O_4 (M-Mn or Mg) were synthesized from the polymeric solid solution of cations chelated within a chitosan matrix (Garza-Navarro et al. 2010). Hu et al. reported a method of synthesis of chitosan-acetic acid nanoparticles, wherein, the ratio of chitosan and acetic acid played an important role in controlling the size of the nanoparticles. The synthesis was done by polymerization of the monomer using acetic acid. In addition to the content of the chitosan, the role of pH was also investigated and a correlation between the pH/content of chitosan and the size of nanoparticles was reported (Hu et al. 2010).

Cellulose

Cellulose is the most abundant biopolymer in nature obtained from sources such as plants, animals, algae, and fungi. The plant originated cellulose is accompanied by small quantities of hemicelluloses and lignin. The applications of these polymers in the synthesis of nanoparticles are discussed further. The cellulose structure contains D-glucopyranose ring units in the 4 C1-chair configurations linked via β -1,4-glycosidic bonds (Heinze 2015). Cellulose biopolymers are used as scaffolds to facilitate the seeding of nanoparticles. However, they also facilitate the synthesis process. On a similar front, Li et al. reported the synthesis of spindle-shaped TiO_2 nanocrystals. These crystals showed high efficiency heavy metal adsorption (Li et al. 2015). Padalkar et al. used cellulose nanocrystals (isolated from tunicates) to synthesize a series of metallic nanoparticles: Ag, Au, Cu, and Pt. The synthesis was done in three steps: extraction of cellulose; sulfuric acid hydrolysis of cellulose pulp (for obtaining sulfate-functionalized tunicate CNCs); followed by sulfation (Zhong and Jin 2009) (Padalkar et al. 2010). Along with synthesis, the usage of cellulose also plays an important role in controlling the morphology of the nanoparticles. Liu et al. (2012) reported a method of using regenerated cellulose films as a template to synthesize monodispersed Fe_2O_3 nanoparticles, achieving an average particle size from 28 to 42 nm without a size selection process.

Sodium Alginate

Sodium alginate can be used as a template during synthesis to reduce the toxicity of nanoparticles. Gao et al. (2008) prepared Fe_3O_4 nanoparticles using sodium alginate as a reducing agent in a redox based hydrothermal synthesis. The reaction was carried out using $\text{FeCl}_3 \cdot 6\text{H}_2\text{O}$ and urea as starting materials. The average size

obtained was 27.2 nm. Similarly, Kuzmanović et al. synthesized manganese doped cadmium sulfide nanoparticles of diameter 4 nm using a sodium alginate template. The doping of manganese with cadmium sulfide was present throughout octahedral sites. The chemical synthesis led to the chemical bonding between Cd^{2+} ions and alginate showing low toxicity as compared to CdS nanoparticles. These particles were reported to have applications in bioimaging due to the distorted crystal field instigated by manganese showing high photoluminescence properties (Kuzmanović et al. 2017).

Alginate based TiO_2 nanospheres were reported in 8–11.6 nm range according to the synthesis temperature ranges (Dutta et al. 2012). These particles showed high photoconductivity against the dye, Rose Bengal, due to enhanced photon to electron conversion.

Hemicelluloses

Hemicelluloses are one of the most abundant polymers present in the cell wall of plant cells, covalently linked with lignin and physically intermixed with cellulose. Hemicelluloses are complex heteropolysaccharides made up of xylose, mannose, galactose, arabinose, uronic acid, and glucose. Hemicelluloses consist of reducing aldehyde groups and hydroxyl groups and may exist as random coil chains in aqueous solution or helical chains in aqueous solution (Mazeau and Charlier 2012). The hemicelluloses from bamboo along with glucose are used to synthesize silver nanoparticles by reducing silver nitrate in an aqueous medium. The presence of hydroxyl groups on the hemicellulose polysaccharide matrix enables the complexation of silver ions with strong non-covalent interactions. The aldehyde groups of the glucose reduce the silver ions to elemental silver causing nucleation of silver and formation of nanoparticles. Also, the helical structure of hemicelluloses prevents agglomeration of silver nanoparticles. However, at higher concentrations of silver nitrate, hemicelluloses are not able to effectively cap silver nanoparticles resulting in nanoparticle aggregation (Peng et al. 2013).

Green Solvents Can Make Biopolymer Assisted Material Synthesis More Environmentally Sustainable

Green chemistry has revolutionized the field of material science which in retrospect consists of large-scale industrial synthesis of materials using environmentally toxic solvents, chemicals, and reagents. The use of aromatic chlorinated solvents (toluene, benzene, phenol, etc.) causes ozone layer depletion, results in environmental toxicity, and requires appropriate alternatives like biodegradable ionic liquids (ILs) to ensure a greener synthesis process. Several nanomaterials including gold, silver (Wang et al. 2016), copper (Gawande et al. 2016), and superconducting materials like MgB_2 (Xu et al. 2008) are synthesized using the aromatic chlorinated solvents like toluene.

The solvents used in the material synthesis processes significantly contribute to environmental pollution necessitating a strong need for green solvents with properties such as low environmental toxicity, low vapor pressure, biodegradability, and high boiling point. Green solvents with such properties include polyethylene glycols (PEGs), water, ILs, and supercritical (SC) fluids. ILs are organic salts, composed of a polyatomic inorganic anion and an organic cation, and are commonly preferred green solvents. ILs possess environmental compatibility along with good operational safety. They are environmentally benign with negligible vapor pressure and suitable to be used as a solvent in sustainable synthesis processes. There are notable pursuits of using green solvents for NP synthesis, for instance, imidazolium IL that has been used to synthesize metal nanoparticles such as silver and gold. The long alkyl chain of imidazolium enhances the stability of AuNPs, lowers aggregation, and increases solubility (Safavi et al. 2012). Imidazolium based IL acts as both stabilizer and solvent for the nanoparticle synthesis process. Silver nitrate (AgNO_3) is reduced to AgNPs by imidazolium halide ionic liquids along with H_2 (hydrogen gas). A significant advantage of this synthesis process is that it does not require the removal of excess reducing agents left in the reaction system (Patil et al. 2020). ILs are faced with the limitation of structure- biodegradability relationship in which pyrrolidinium ionic liquids are more readily biodegradable than imidazolium ionic liquids (Neumann et al. 2014). Glycerol, also called “Organic Water,” provides several advantages besides being a green solvent such as immiscibility with aliphatic hydrocarbons, solubility with organic and inorganic compounds using hydrogen bonds, and polar nature. The concentration of glycerol controls the size of AuNPs in the green synthesis procedure without involving toxic chemical reagents.

Synthesis procedures of materials based on traditional chemistry approaches do not minimize hazardous environmental impact and also require high energy instrumentations. The synthesis of advanced materials (nanoparticles and superconductors) using physical and chemical methods involves the use of hazardous chemicals, reagents, and solvents (Zhang et al. 2020). Besides, these synthesis processes are associated with high energy consumption (Horwat et al. 2011) like pulsed laser deposition of $\text{LuBa}_2\text{Cu}_3\text{O}_7$ and $\text{LuBaSrCu}_3\text{O}_7$ single-phase superconducting thin films (Schwab et al. 1993) and pulsed laser deposition of oxide nanoparticles (Oxide NPs: Y_2O_3 , Gd_2O_3) (Amans et al. 2011). The physical methods also comprise high temperature and pressure conditions such as spark plasma sintering based synthesis of high-density MgB_2 (Dadiel et al. 2021) and Co/Ni-doped BaF_2As_2 superconductors (Zaikina et al. 2018) consisting of step-wise exposure of high pressure and temperature conditions. In chemical methods, expensive and environmentally toxic stabilizers (surfactants like CTAB), organic solvents (aromatic hydrocarbons, chlorinated solvents), and reducing agents (sodium borohydride) are used. Green chemistry altogether attempts to minimize the environmental impact of the overall reaction system so that the economic feasibility and environmental sustainability does not limit the synthesized material’s translational application. Besides, the use of biopolymer-assisted growth of superconductors and nanomaterials should be combined with an appropriate choice of a green solvent.

Abstract

Biomimetics, an interdisciplinary field of science denoting synthetic methods which mimic biochemical processes in nature, has contributed to the invention of many novel technologies and designs. In this chapter, we discuss the various nature-inspired biomimetic polymers, its advantages and limitations, applications, and future prospects. Classification of biomimetic materials is broadly based on function, process, structure, and molecular aspect of material, which is the source of biomimicry. Biomimetic materials find its applications in various fields like architecture, robotics, superhydrophobic, self-cleaning materials, adhesives, nanotechnology, and biomedical. Biocompatible and bioactive substances from biological sources fulfill various functions that are critical for the sustainability of life. Significant research based on architecture of biological materials and their tissue interaction has been carried out toward engineering revolutionary bioinspired structures that show superior biocompatibility and bioactivity. Advancements in biomimetic research makes way for the creation of novel nature inspired biopolymers which sustainably meet design challenges.

Biomimetics · Biopolymers · Therapeutics · Tissue engineering

Introduction

Scientists and inventors study characteristics of things in nature and come up with amazing technologies and products invented as a result of studying nature. Biomimetics, an interdisciplinary field of science relating to or denoting synthetic methods which mimic biochemical processes in nature, has fascinated humans for generations and inspired the invention of many novel technologies and designs.

Biomimetics is defined as the study of biologically synthesized materials and biological mechanisms and for the purpose of reproducing analogous products by artificial means which imitate natural ones, and the investigation of nature and its models to emulate, in order to solve human problems (Fratzl and Weinkamer 2007). Parallel terms include bionics and biomimicry. As Vincent et al. (2006), quote, “The term biomimicry, or imitation of nature, is defined as copying or adaptation or derivation from biology” (Vincent et al. 2006).

The term “biomimetics” originates from the Greek words “bios” and “mimesis” which decodes as “life” and “to imitate,” respectively. In 1969, Otto H. Schmitt devised the term biomimetics (Schmitt 1969). This emerging field of biomimetics is multidisciplinary and has advanced as new technologies based on biologically inspired engineering at infinitesimal levels. The sustainability basis of this field is that nature follows the path of minimum expenditure of energy, utilizing the most common materials to achieve a task.

Innovative Products from Nature-Inspired Biomimetics

Biomimetics is not a new idea – historiographic considerations of the science of biomimetics clearly manifest that this has been practiced much earlier. “*Codex on the Flight of Birds*,” inscribed by Leonardo da Vinci in 1505–1506, ventured that air travel by humans could be modeled on avian flight mechanics (Zanon 2009). In 1903, the first successful airplane flight by the Wright brothers occurred. The Wright brothers modeled the wings’ control mechanism based on the technique birds uplift and change direction manipulating air currents. In 1851, landscape designer Joseph Paxton built the Crystal Palace for the Great Exhibition, the first international expo of manufactured products in London. The palace’s unique architecture with crisscrossed iron girders, to support nearly 300,000 panes of glass, was inspired by the leaf of a water lily, where interconnected ribs aid the plant support substantial mass in water. Swiss engineer George de Mestral patented Velcro in the year 1955. During a hunting trip in the Alps, his dog became covered in burs. Cockleburrs got gripped to clothes readily due to hooks. Mestral found that their hook-and-loop construction, can be gripped and ungripped with force. Inspired by the seeds’ tiny hooks, de Mestral proposed a fabric product: one with hooks and the other with loops (WIPO 2016). In 1960s, when NASA used Velcro in space shuttles to prevent food, equipment, and other items from floating away in zero gravity, it became widely known.

American biophysicist Otto Schmitt (1969) used the term “biomimetics” (Patterson 2009). No stranger to bioinspired technology, Schmitt had invented an electrical circuit modeled after the neural impulse systems of squids in 1934. Bioinspired technology-driven Schmitt, stirred by neural impulse systems of squids, had invented an electrical circuit in 1934.

A technology that resembles the grooves found on shark skin was tested by NASA in 1986. Inspired by self-cooling mounds of African termites in 1996, Architect Mick Pearce created the Eastgate Centre in Harare, Zimbabwe. The building uses chimneys that draw in cool air to maintain a temperate environment as it does not have mechanized heating and cooling system. The ventilation costs one-tenth of that in a comparable, air-conditioned building. Also, it uses less energy (35%) (Scobey-Thal 2014).

In 2006, Richard Bonser published a study that assesses the growth of biomimetic innovation (Bonser 2006). Accordingly, between 1985 and 2005, the number of patents worldwide containing the word “biomimetic” or “bio-inspired” augmented by a factor of 93, which is supremely high. The United States-based firm, Biomimicry 3.8, consults for and empowers companies about ways to incorporate bioinspired innovation into their practices (Scobey-Thal 2014). In 2012, Sorensen and Galvez, founders of NBD Nanotechnologies United States, produced a successfully tested concept for a water bottle which was inspired by the Namib Desert beetle. Like the insect, which draws water from air by collecting condensation on microscopic bumps on its back, the bottle would harvest air moisture. The device could store up to 3 liters of water every hour (Scobey-Thal 2014). In 2014, an article in *Nature*, on metal-free battery, was published on carbon-based molecules called

quinones (naturally abundant) analogous to those that accumulate energy in animals and plants (Huskinson et al. 2014). This technology delivers the accumulation of renewable energy in large grid systems.

Humans have been turning at nature for being guided for answers to problems throughout their lives. One such example is the honeycomb structure of the beehive. Bees and wasps build nests which are made of hexagonal cells, both space saver and strong. Stacked together, hexagons fill spans in an offset arrangement with six short walls around each “tube,” giving structures high compression strength. Beehives are efficient in dissipating heat well, which prevents the waxy structure from melting on hot days. Efficiency, strength, and controlled heat loss are all important for human structures as well, so it is no wonder that honeycombs inspire human design. Structures inspired by honeycombs in bee nests are widely used to build airplane wings, light-weight building materials, flexible panels for bridge construction, and packaging and acoustic dampening materials.

Other examples of biomimetics include the development of superhydrophobic surfaces based on the lotus leaf, the “shark skin” drag-resistant swim suit (Hwang et al. 2015), and Velcro fasteners modeled on burrs (Velcro 1955). Shape of airplanes developed from the design of birds, wings, and their feathers – was the result of numerous years of biomimetic research on the structure and design of birds.

The whole idea of this chapter is a detailed discussion about the various biomimetic materials used, its advantages and limitations, applications, and future prospects.

Biomimetic Materials: General Classification

The symbiotic relationship between humans and nature has been crucial in our coexistence in this world, and this science of biomimetics opens up many examples for innumerable applications. Designing innovative products by the application of the rules of biomimetics plays a significant role in industries where it offers human convenience in inter disciplinary fields (Benyus 2009). Many researchers pointed out the significance of understanding these examples for providing revolutionary applications using the science of biomimetics.

Bioinspired materials have attracted a lot of attention in the recent decades with an increased interest in identifying nature-refined biological products that can be used as a source to develop innovative advanced materials. The excellent mechanical and functional properties exhibited by biological materials are coincidentally important in many engineering industries. The fundamental aspect in many of these biological materials, which are simple in composition but efficient in performance, is contributed by the hierarchical structure, i.e., the organization of building blocks. Being durable, reliable, and nontoxic, these materials present inspirations for designing advanced materials applying biomimetics (Wang et al. 2020).

Glaser and Viney (2012), reported that the character of new biomimetic materials lies in understanding the structural and functional aspects of hierarchical structures in nature and remodeling them for our use. Most of these hierarchical structures were

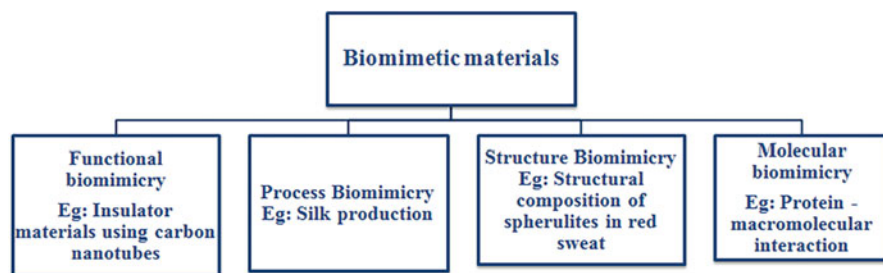

Fig. 1 Schematic illustration of the broad classification of biomimetic materials based on the biomimimery which has inspired the production of the (bio)materials

constructed from small building blocks which later on attain a complex polymeric structure, and fine-tuned by adaptation and optimization to yield excellent performance.

A typical example is the bone toughness which is extraordinary, due to the presence of collagen fibrils at micro/nanometer levels, which also ensures the assembly of several types of bones with varied functions (Fratzl et al. 2004). The changes in functionality of a material can be attained by hierarchically structuring a material in different ways, rather than finding a new material. Many examples in nature inspire researchers to discover new materials which mimic nature and adapt their properties for a wide range of applications.

To throw more light on the science of biomimetics and nature-inspired biopolymers, it would be convenient to differentiate between various classes of biomimimery, on the basis of which natural trait is being imitated (Fig. 1). Classification of biomimetic resources can be done broadly based on functions, process, structure, and molecular aspect of materials, which is considered as the source of biomimimery.

Functional Biomimimery

Physical and/or chemical properties of a biomaterial are inspired from natural sources which can be exploited for making a biomimetic material. Functional biomimimery concentrates on acquiring information from the way living things execute specific functions which can be extrapolated in making a new biomimetic material. In every successful biomaterial, there is some element of functional biomimimery (Glaser and Viney 2012).

An example for functional biomimimery is the development of insulator materials mimicking the functionality of the fur of polar bear which is hollow and keeps them warm. Functionally, bear's fur insulates or conserves heat provided by its features. This property of fur is used as a model to create an insulator (Cui et al. 2018). Inspired by the polar bear hair, waterproof and lightweight, thermal insulating carbon tube material is created. It finds application in outerwear and in insulated buildings. The evolutionary adaptation of polar bear to prevent heat loss in cold and humid conditions has turned out to be an excellent model for engineers to design synthetic heat insulators (Cui et al. 2018).

Another aspect of functional biomimicry is when a natural material is taken from an organism and replaced for damaged material in a host. A simple example for this is provided by false teeth made from ivory of elephant, walrus, or hippo in earlier times, which were used to make dentures.

Process Biomimicry

In process biomimicry, a natural process is copied, like photosynthesis in the leaf of green plants. Photovoltaic systems were created which takes up solar energy, the first footstep at imitating a leaf which uses up energy (Benyus 2009). Research is undergoing to make highly efficient solar cells that imitate nature as artificial leaves – water-gel-based – that combine plant chlorophyll with carbon materials, resulting in cost-effective and flexible solar cell (Mcclure 2019).

Many invertebrate animals like spiders, several insects, and myriapod species (an arthropod group that includes centipedes, millipedes, and related animals) use the silk they produce for varied essential functions, for their survival, i.e., prey capture, for habitat construction, and for egg protection. Adult weaver ants which live in trees are known for their unique nest-building action where workers construct nests by weaving together leaves which are glued together by larval silk. The natural silk made by spiders and some insect larvae is turned from aqueous solution, and it forms a water-insoluble final product. This alteration in solubility is accompanied by changes in the conformation of the integral protein chains, but the chemical nature of the chains remains unaffected. As quoted by Viney (1997), “The water-soluble protein molecules secreted by the silk glands are globular; they aggregate into a processable liquid crystalline fluid within the ducts leading from the glands to the spinnerets, and thence undergo shear nucleated reorganization into a solid fiber stabilized by water-insoluble crystal.” Nature thus provides a proposal for sustainable and environmentally gentle dispensation of polymer fiber.

Biomimicry in construction is the practice of designing buildings and products that simulate processes that occur in nature. In simulating process that is shown by natural materials, a good example is the manufacture of wood glue which is formaldehyde free and nontoxic, inspired by the way blue mussels firmly attach under the water using flexible, thread-like tentacles (Messersmith 2013).

Structure Biomimicry

Structure means “the arrangement or formation of the tissues, organs, or other parts of an organism.” Structure biomimicry ensues once nature inspires the atomic and molecular association at nano/micro structure levels in a biomaterial. However, Darwin’s Principle of “natural selection” plays inevitable role making nature’s choice an accepted model, and this has been tested and proved to be the best choice in the long course of evolution and survival. While designing biomimetic material, a perfect understanding of the polymeric blends is essential to attain the structural

integrity of the nature's model. Visual inspiration in architecture is a more easily adaptable mode of structure biomimicry, for example, a "picture of sea turtle shell can be used to shape a reinforced concrete for a large span roof structure in an exhibition building" (Kshirsagar 2017).

Nature is skillful in achieving multifunctionality, by the use of hierarchical structure, and thereby optimizing many characteristics in its building block. This permits autonomous control of properties that are a result of structure at different dimensions. The best example of multiple action and thereby function is by the "red sweat" (red-colored oily secretion) of Hippopotamus (Reed et al. 2009). "The fluid sweat contains two types of liquid crystalline spherulite (spherulites (from Greek sphaira = ball and lithos = stone) are spherical semicrystalline regions inside non-branched linear polymers)." Some of the spherulites are efficient in light scattering due to their structural characteristics so that the sweat shows sunblock property; the other spherulites, which are coarser at microlevel, provide the characteristics to spread on skin due to lessening of viscosity (Saikawa et al. 2004). Both these assets of red sweat along with molecular biomimicry of the red sweat are useful in the making of better skincare products that are potentially useful as sunscreens (Reed et al. 2009).

Another instance of structure biomimicry can be observed in spider's silk; the fibers form the "major component of the drag line and the radial threads of a web" are secreted by major ampullate glands (Trancik et al. 2006). Silks are natural polymers consisting mostly of the amino acid, alanine, serine, and glycine, and are produced by arthropods in the class of Insects, Arachnida, and Myriapoda (Bini et al. 2004). Biologically, silk fibers provide structural support, defense, and assist in food capture. The nanostructure reveals "a bimodal size distribution of crystalline regions" which consists of larger and smaller crystals. "The larger crystals promote the high initial stiffness of the fiber when it is deformed in tension; however, their imperfect internal structure prevents them from acting prematurely as stress concentrators that could accelerate failure. The smaller crystals do not contribute significantly to initial stiffness, but they provide stability to the material during plastic deformation" (Turner and Karatzas 2004). Biomaterials mimicking this microstructure of spider silk which shows optimal combination of mechanical properties could have tremendous applications.

Molecular Biomimicry

Molecular biomimicry happens when a biomaterial is produced by atoms and molecules available from natural sources. A typical case is that of "filamentous bacteriophage," due to its adaptability, modifying potential, and sturdiness as a promoter of liquid crystalline phase formation (Reed et al. 2009). This property aids in self-assembly of building blocks in a bottom-up approach. Filamentous phage or genetically engineered phagemids (a DNA-based cloning vector, which has both bacteriophage and plasmid properties), at the right phase of its life cycle, can guide the self-assembly of complex structures in perfect symmetry and alignment. "Genetically modified fusion phagemid accomplishes molecular biomimicry by stabilizing liquid crystalline order in the same way that a native filamentous phage would" (Reed et al. 2009).

These filamentous phages are biodegradable, and thus used as a disposable constituent of the repaired tissue. “Recombinant filamentous bacteriophages are successfully encapsulated in biodegradable polymeric microparticles (MP) for stimulation of innate and adaptive immune responses.” Microparticles (MPs) are made of poly (lactic-co-glycolic acid) (PLGA) to encapsulate bacteriophage and retain their immunogenic properties. Bacteriophage-encapsulated PLGA microparticles serve as a vehicle for vaccine delivery (Jamaledin et al. 2020). Molecular biomimetics is thus an evolving field in which nanotechnology along with molecular biology principles can be hybridized to provide solutions to scientific problems.

Applications of Biomimetic Materials

Biomimetic materials show similar characteristics with biomaterials and are modeled with a means to reproduce the functions and traits of a material that is naturally produced by living organisms. The principles and accomplishment of a biomimetic material depends on the restoration of natural structure and function which is environmentally stable. Biomimetic materials find their applications in various fields like architecture, robotics, superhydrophobic, self-cleaning materials, adhesives, nanotechnology, and biomedical applications (Fig. 2).

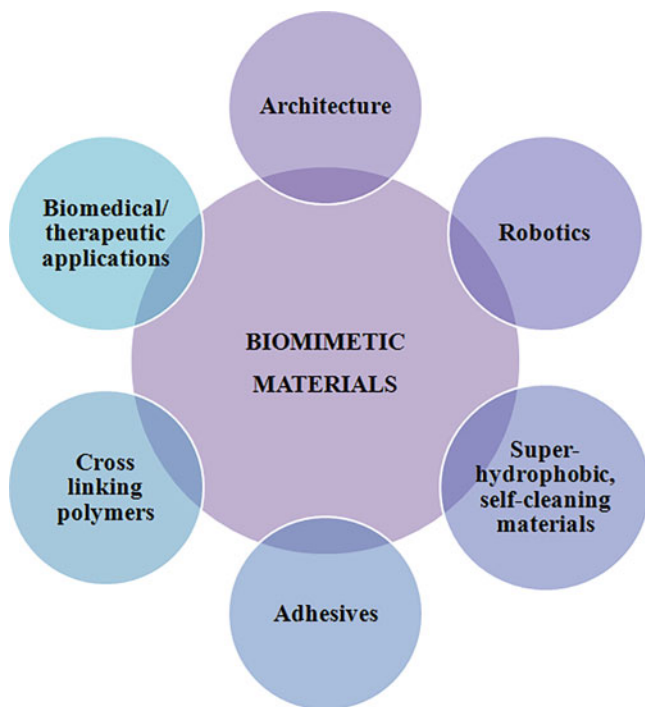

Fig. 2 Schematic representation of the applications of biomimetic materials

Biomimetics in Architecture

Biomimetic architecture seeks sustainable solutions to resolve architectural problems concerning building various structures. Understanding the principles governing the inspiring natural forms or natural materials will provide immense source for sustainable designs. One such example is buildings designed mimicking the hierarchical structure of organic bone which can withstand tremendous force of earthquakes. Biomaterials like bone and teeth are nanocomposites with a hierarchical structure that shows excellent mechanical properties. This is because bones are produced by composites in complex, layered structures with ordered architecture that spans nanoscale to the macroscale (Meyers et al. 2008). This structural composition provides great high mechanical strength, which can be mimicked in the construction of buildings.

Another example is Gecko's Climbing feet-inspired climbing pads. Gecko's feet have minute hair coverings on their toes which aid to climb up any vertical surface with great grip that prevents fall off (Arzt 2006). This biomechanics of feet of gecko is imitated in making a pair of climbing pads that support human weight. Those climbing pads are layered with polymeric adhesive tiles and covered with an array of polydimethylsiloxane (PDMS) and are attached to an independent degressive elastic element and are sawtooth-shaped (Hawkes et al. 2015). When these pads, which are about the width of a human hair, are pulled upon, they create adhesion forces (Fig. 3a).

Another occurrence of application of biomimetic architecture for human use is the bullet train made by Japan scientists which model was inspired by the shape and sleekness of the kingfisher. This led to upgradation of bullet trains which showed reduction in tunnel boom ("irritating noise created by these trains when they displace the surrounding air") and thereby aided in avoiding tunnel damage. The overall aerodynamics needed to be modified, which made the train more streamlined, inspired by the beak of the Kingfisher bird (Fig. 3b).

Humpback of whales provided the design for highly efficient wind turbines. Propulsion for steering in water is done by bumpy tubercle fins. Biomimetic fins ("a flattened appendage on various parts of the body of many aquatic vertebrates, including fish and cetaceans, and some invertebrates, used for propelling, steering, and balancing") reduced the drag and also improved lift. Another versatile application is antimicrobial film which emulated shark skin. The skin of a shark is covered with dermal denticles which are like minute teeth creating an antimicrobial zone. This biomimetically acting film coating prevents growth of microorganisms and other marine life on ship hulls. These dermal denticles create low-pressure zones which reduce the drag during motion, and this design of sharkskin is incorporated in swimsuit design (Wen et al. 2014).

Another example is that of Woodpeckers, which are excellent excavators and are also known for their shock-absorbing beak. As the woodpeckers strike the wood, the bird's head shows shock-absorbing phenomena. This inspired the making of shock-resistant black boxes and micrometeorite-resistant spacecraft (Lee et al. 2014).

Termite mounds are another model of biomimetics in architecture. They are huge structures built by small insects and offer temperature-stabilized habitats that protect

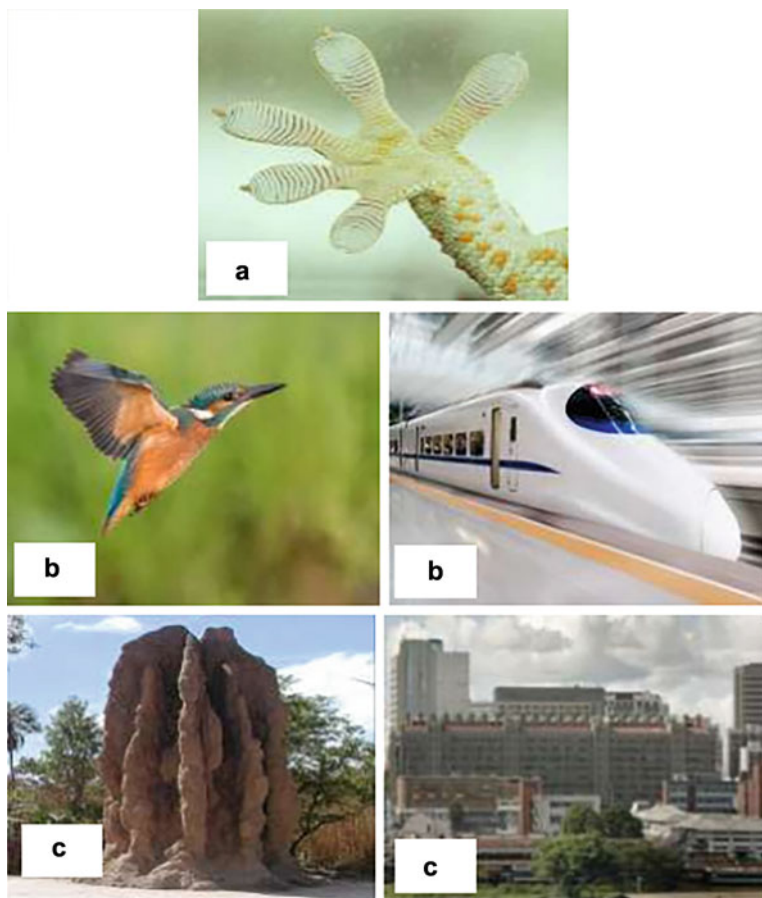

Fig. 3 Examples of nature-inspired ideas in architecture. (a) Gecko feet. (b) Kingfisher beak (left), Bullet train (right). (c) Termite mound (left) and mound inspired building (right) in Eastgate Centre, Harare Zimbabwe

the organism from extreme environmental fluctuations and allow them to cycle energy and matter, and communicate information with the world outside. Termite mound-inspired ventilation system works on the principle of convection. Termites are experts in modeling an intricate ventilation system for cooling, which consists of air pockets. Buildings have been designed mimicking the termite mound, which maintains temperature without any mechanical systems (King et al. 2015) (Fig. 3c).

Biomimetics in Robotics

Biological intelligence and the field of biomimetics in robotic science show advanced trends toward successful research. Robots, are synonymous with synthetic

animals with senses, intelligence, perception, and motor skills desired to operate in the world in ways that are highly beneficial for human use. As Wang et al. (2021), defined, “Biomimetic robotics is the development and integration of biomimetic mechanisms by imitating biological structures or behaviors.” Biomimetic robotics find wide range of application where robots are created with characteristics seen in organisms and functions, such as “humanoid robot in the home environment, quadruped robot in the field, and bird-like flying robot in the sky” (Wang et al. 2021). A crucial feature of biomimetic robots is their competence to acclimate to the natural environment. Bioinspired intelligent control systems work in robotics to physically interact with the world.

Biomimetic robotics are empowered by biomimetic intelligence, which aids it to be exploited for practical purposes. “The biomimetic multi-legged robot simulates the structure of living creatures’ legs and the way they move, such as human-like biped robot, tetrapod-like quadruped robot, and spider-like hexapod robot. The advantage of the multi-legged robots is their adaptability to various terrains which can overcome the site constraints so that they are suitable for tasks like search-and-rescue and environment detection” (Shigemi et al. 2018).

The “biomimetic flapping-wing robot” emulates the flight principles of birds and insects in nature which use their “fast-vibrating wings” to perform soaring, revolving, and other movements shown by birds and insects (Wang et al. 2021). “Compared with non-bionic flying robots, biomimetic flapping-wing robot exhibit excellent flight performance and maneuverability and agility of biomimetic flapping-wing robot are better than that of the fixed-wing and rotary-wing flying robots” (Breuer 2019). For underwater salvage operations and deep-sea survey, underwater biomimetic robots which show travel efficiency and mobility are employed that surpass the outdated robot used in underwater robot (Dong et al. 2020).

Biomimetics in Superhydrophobicity

Several bioinspired biomimetic superhydrophobic surfaces recently developed were stimulated by natural organisms like wings of butterfly, leaves of lotus, which display excellent superhydrophobicity. Xu et al. (2016), report in-depth studies on “self-cleaning ability” due to superhydrophobicity shown by biostructures like duck feathers, skin of shark, and feet of gecko. Lotus’ flowers and leaves unfold and stayed clean even when emerging from mud and muddy waters. Water droplets acquire a spherical shape on lotus leaves that removes the dirt and impurities on the leaves when the surface is slightly sloped, showing self-cleaning function (Fig. 4). Due to this asset, it is widely replicated because of its latent advantages in multidisciplinary fields such as biomedical, environmental safety, aeronautics, polymer, textiles, rain wears, upholstery which never accumulate dirt, umbrella, etc. (Liu et al. 2014).

As Stegmaier et al. (2008) report, “self-cleaning textiles could be prepared via two approaches. One is addition of nanoscale coarseness on textile using silver nanoparticles, ZnO nanorods and carbon nanotubes, or by physical surface modification methods such as laser or plasma together with introduction of low surface

Fig. 4 “Water droplets on lotus leaves. (a) leaf surface microstructure formed by papillose -(small nipplelike projection, such as a protuberance on the skin, at the root of a hair or feather, or at the base of a developing tooth) epidermal cells covered with epicuticular wax tubules on the surface” (b) which create nanostructure” (Zhang et al. 2006)

energy materials which convey hydrophobicity.” Another method is “treatment of fabrics having micro- or nanostructure, like silicone coated on microfiber polyester fabric to introduce superhydrophobic polyester with self-cleaning properties” (Gao and McCarthy 2006).

Glass beads coated with paraffin were widely tested on the bases of lotus leaves for the property of hydrophobicity. “Recent addition to this includes the achievement of nano-microscale surface topography by fibre-attached nanoparticles that enhance surface roughness. Silicate and fluorocarbon nanoparticles when used serve the purpose commercially. This could be applied in fabrics, especially in cotton fabric using a homogeneous silica-copper hybrid nano-composite fabric to attain super hydrophobicity” (Liu et al. 2014).

Anticorrosion coatings bioinspired by lotus leaf were developed and are also replicated in paints industry, which could reduce the use of chemical detergents and costly labor in order to clean paints. As wetness damages concrete and metallic structures due to scaling caused by salt content and other chemical reactions which deteriorate the infrastructures, protective coatings inspired by biomimetics extend the life span of such structures due to repellency of water and self-cleaning action. “Many lotus-leaf-inspired biomimetic coatings like SiO_2 , polymethyl methacrylate – PMMA-ZnO nanocomposite, are UV-durable and thus would enhance the performance of materials and products used in outdoor conditions, as they can remain robust and stable to maintain their hydrophobicity with increasing UV exposure time” (Vazirinasab et al. 2018).

Inspired by the nonwetting phenomena of duck feathers, the microstructures of the duck feather showed a multiscale structure responsible for their superhydrophobic behavior. Chitosan, a biopolymer, when used as building blocks through a “novel surface solution precipitation (SSP) method and further modification with a silicone compound can achieve low surface energy.” Textiles treated with this material exhibit super water-resistant property, thus providing an automatic way to create hydrophobic surfaces on soft substrates using flexible material as building blocks. “Compared with lotus leaves, duck feathers are soft and flexible, and the water repellent characteristic of duck feathers is durable, thus it provides an ideal model for the fabrication of super hydrophobic surfaces on soft substrates” (Liu et al. 2008).

The lustrous feathers of *Anas platyrhynchos* drakes are due to “unusual arrangement of two-dimensional photonic crystals and further exhibit a superhydrophobic surface.” This property was recreated in a nanocomposite structure “fabricated by a typical top-down iterative size reduction method,” which showed enhanced hydrophobicity. As Khudiyev et al. (2014) reports, “It is prepared in 3 steps (1) fabrication of PC (polycarbonate) rod as a core component, which in turn is prepared using a hollow PC preform with an initial diameter of 30 mm, (2) A PVDF (polyvinylidene difluoride) polymer film is then wrapped around this rod until a total diameter of 12 mm is reached, and (3) a PC film is wrapped around the PC/PVDF core until the total diameter exceeds 20 mm (the complete architecture therefore has a final diameter ratio of 10: 2: 8 for PC: PVDF: PC). These 2D solid core photonic crystal fibers strongly resemble drake neck plumage in structure and fully polymeric material composition (Fig. 5) and can be produced in a wide array of colors by minor alterations during the size reduction process” (Khudiyev et al. 2014).

Fig. 5 Increased hydrophobicity in feather of drakes and feather-inspired photonic crystal structure. (a) Neck feathers exhibit super hydrophobicity due to the presence of structural hierarchy. (b) contact angle measurement of a single mallard feather. (c) enhanced intrinsic hydrophobicity of PVDF film by increasing surface roughness. (d) the nanoscale surface pattern observed on structures and the alignment of the fiber arrays both contribute to surface super hydrophobicity. (e) the water contact angle (CA) is measured to exceed 165° for this particular array. (Source: Khudiyev et al. 2014)

Biomimetics in Adhesives

Natural adhesion seen in biological organisms and natural materials has characteristics which the synthetic adhesive could not achieve. Examples include Velcro inspired by burdock plant, adhesive properties of insects which aid in climbing walls, and plants (“Ivy plant”) which show strong adhesion onto substrate-like buildings and those shown by barnacles (animals related to crustacea) with adhesion in “underwater habitat,” which help them to grip to ship hulls (Favi et al. 2014). Biobased adhesives have tremendous manufacturing industry applications due to their properties like biodegradability, renewability, and economical sustainability and do not pollute the environment.

Velcro (a popular brand of hook-and-loop binding), the finest example which works on imitating the principle of adhesion from a Burdock plant, is the “hook-and-loop fastener” developed by Georges de Mestral in the 1950s (Barthlott et al. 2017). Burdock is the “Velcro” of wild plants, whose seeds are inside the flower head, making its clinging characteristics an excellent mechanism for seed dispersal. Velcro, a good example of biomimetics, revolutionized multidisciplinary fields, which finds its application in routinely used things like buckle of shoes, curtain fasteners, fabric fastener, etc.

Another fine example is delicate adhesion shown by hairs in insects and lizards which aids them in climbing effortlessly without falling off. “Weak van der Waals interactions between the fine hairs on the adhering surface and the target surface paves way to adhesive property.” Geckos would stick to any surface, and this uncommon feature has created great curiosity to analyze the mechanism and fine structural characteristics of Geckos feet. “The gecko-feet have thousands of keratin fibers called setae which branches into hundreds of smaller and thinner fibers (Fig. 6). These micro and nano fibers ensure good adhesion with smooth and rough surfaces. This branch structure of the setae is important to adapt a large number of spatulas to rough surfaces and provide close contact with the substrate and induce intermolecular forces for the adhesion. Van der Waals forces and capillary forces play a dominant role in fibrillar adhesion” (Kim and Sitti 2006).

Fig. 6 (a) Gecko Toe-Seta arrangement which helps in adhesion; (b) carbon nanotube adhesive tape/gecko tape /nano tape

Scientists were enthused to imitate the gecko feet structure to make adhesion materials.

Synthetically made polymeric substances have been invented grounded on adhesive keratin fibers on geckos' feet (Shah and Sitti 2004). Apart from polymeric adhesion material synthesis, carbon nanotubes were also tried out, but firm adhesion is hard to achieve, and none were performed under water. "Studies indicated an improvement in the average shear strength of the adhesion with multi-wall carbon nanotubes" (Hsiao et al. 2003).

Study of adhesion properties shown by spiders and insects has also facilitated the development of synthetic adhesives, which led to evolve a designer foot for a "spider-inspired scaler robot," and further studies threw light on the factors which contributed to adherence property on different surfaces. These climbing robots find a wide range of application which would be used to reach unfathomable places for humans, "ranging from automatic cleaning systems for windows and exteriors of buildings, to the inspection of hazardous environments and autonomous vehicles for space applications."

"English ivy plant (*Hedera helix*, is an evergreen perennial) exhibits an excellent adhesion mechanism aided by secretion of a yellowish sticky substance when it climbs vertical surfaces." The superglue-like secretion, which comprises spherical nanoparticles, aids the plant to firmly grip onto surfaces as it creeps. Nanoparticles are composed of "arabino-galactan proteins," which aid in adhering strongly (Huang et al. 2016). Those nanoparticles displayed low-inherent viscosity in solution, and this gives a satisfactory wetting behavior to this adhesive. "Nanoparticles are thought to penetrate easily into any surface irregularities, further promoting intimate interactions with the substrate onto which the plant clings" (Chun 2016). Chun (2016), reports that "when the nanoparticles, pectin and calcium ions were combined, the bio adhesive characteristics were reproduced, further validating the adhesion mechanism."

Another entrant that shows excellent adhesion property is the algae named "*Prasiola linearis*," which is based on "non-specific protein folding and subsequent aggregation" which is the general property of polypeptides under certain conditions. This type of protein folding which leads to formation of "proteinaceous crossed β -sheet amyloid fibrils" is reported in neurodegenerative ailments like Alzheimer's disease. This "protein folding property" which provides mechanical strength could be extrapolated in new adhesives and other materials owing to their many valuable mechanical and self-assembly properties (Mostaert and Jarvis 2006).

Biomimetics is in close association with bionanotechnology, which has been described by Alvarado et al. as "the use of biological systems or its derivatives to manipulate the world at nanoscale" (Alvarado and Baudrit 2013). As Kaboorani and Riedl (2011), report, wise use of nanotechnology, besides imitating biological adhesive structures, is a breakthrough for the adhesive industry to create a new cohort of adhesives. Ramirez et al. (2019), show that "application of nanotechnology helped to design adequate alternative to old methods of wound closure, such as sutures and staples."

Biomimetics in Nanotechnology as Cross-Linking Polymers

Polymers are large molecules containing numerous small building blocks – or monomers – merged to form a chain-like structure which shows characteristics based on their component parts. Biopolymers are polymers that are produced by or derived from living organisms. Biomolecules like polysaccharides, proteins, and nucleic acids (NAs including DNA and RNA) are natural polymers which play key role in living systems owing to their intricate structures thus providing astonishing properties. Natural polymers provide a spur for biomimetics in creating artificial polymers which show explicit functions like “flexibility, non-toxicity, self-healing, adhesiveness, super hydrophobicity.” One way of growing these polymeric chains is through radical polymerization process, “where a free radical initiate chain growth by adding to a monomer unit, generating a new radical that in turns adds to monomer.”

Biomimetic polymers show wide range of applications like specific cell-focused drug delivery, modified biomaterials with enhanced tissue interaction like “transplants or prosthesis.” “The flexibility, ease of fabrication and low weight of polymers makes them suitable for extensive applications” (Camargo et al. 2009). Biomimetic synthetic polymers have the benefit of compounding chosen purposes with custom-made structure and stability at chemical and physical level. Translation of biological principles to synthetic polymers results in the fabrication of materials with greatly enhanced mechanical properties which finds its application in diverse fields.

In recent years, “the synthesis of biopolymers, particularly, the naturally available degradable polymers such as chitosan, hyaluronan, collagen and gelatin are used in the preparation of scaffolds, and these natural scaffolds are the total extracellular matrixes (ECMs) of decellularized tissues or organs” (Kohane and Langer 2008). “Biomimetic materials share characteristics with biomaterials in that they serve to restore natural function where the original material is absent or unable to perform properly.” “Biomaterials play a pivotal role as scaffolds to provide three-dimensional templates and synthetic extracellular-matrix environments for tissue regeneration” (Ma 2008). In the tissue-engineering field, biomimetic polymers can serve as scaffold materials via imitating the process seen in nature.

Due to properties like “biodegradability, biocompatibility and non-immunogenicity” of biopolymers like sodium alginate, chitosan, they are widely employed for medical and pharmaceutical applications (Motwani et al. 2008; Dang et al. 2012). Chitosan is “a derivative of chitin which contains N-acetyl-d-glucosamine residues and β -(1,4)-2-amino-2-deoxy-d-glucopyranose units.” Sodium alginate is a polysaccharide made from brown sea weed which consists of repeating units of α -l-guluronic acid and (1,4)- β -D – mannuronic acid. These two biopolymers have high end applications in biomimetic polymer synthesis. “Wound dressings derived from natural polymers such as Alginate and chitosan-based wound dressings have plentiful advantages as they can take up several forms such as sponges, foams, nanofibers, films, and hydrogels” (Huang and Fu 2010; Mndlovu et al. 2019).

However, natural polymers are usually insufficient due to their disapproving mechanical characteristics. Synthetic polymers, when used in combination with

natural ones, seemed to show “enhanced physical properties, degradation patterns, and overall antimicrobial properties” (Almeida et al. 2011). Recently, using the “solvent casting technique,” Balu et al. (2020), fabricated “biomimetic nanocomposite scaffolds which contain chitosan–sodium alginate blended with three different TiO_2 concentrations (used as fillers).” The nanobiocomposite showed decreased cytotoxicity and better antibacterial activity which showed positive results. Hybrid nanobiocomposites, made from inorganic metal oxide nanoparticles as fillers with large surface area, interact effectively with polymer chains at molecular level. As per existing reports, “nanostructured Au, SiO_2 , CdS, ZnO, TiO_2 , etc. based bionanocomposites are widely used in biomedical applications” (Moura et al. 2016). Biocompatible and bioactive substances from biological sources fulfill various functions that are critical for the maintenance of life.

Hydrogel and Lipophilic Polymers

Wisely created biomimetic polymers, for biomedical use and tissue engineering or as implants, show successful interaction with “cells/multiple cells or even whole tissues.” “The polymers used can be divided into two major classes based on their physicochemical properties; hydrogels- composed of hydrophilic polymers which swell in water, from solid lipophilic materials which demonstrate little water uptake when brought into an aqueous environment” (Langer and Peppas 2003).

Hydrogels allow increased oxygen, drugs, and nutrients dispersion rates (Lee and Mooney 2001) and can be administered with or without cells, allowing for a less invasive implantation. Their fluidity allows ease of shape flexibility and stiffens via gelation (Drury and Mooney 2003). Cross-linking makes hydrogels acquire mechanical firmness. “Cross linking either physically or chemically gives hydrogel a 3D network structure, making it insoluble. This insoluble cross-linked structure allows effective immobilization and release of active agents and biomolecules. Hydrogels appear similar to natural soft tissues because of their high-water content” (Hubbell 1995).

Hydrogel polymers used in tissue engineering range from “naturally derived to synthetic materials” which show better biocompatibility and diminished cytotoxicity. “Alginate, gelatin, agarose, fibrin, chitosan are examples of naturally derived polymers, whereas poly(ethyleneglycol) (PEG), oligo(poly(ethylene glycol) fumarate) (OPF), poly (acrylic acid) (PAA) derivatives, and poly(vinyl alcohol) (PVA) represent synthetic polymeric materials” (Drotleff et al. 2004).

Alginate is a “linear polysaccharide copolymer of (1–4)- linked beta-D-mannuronic acid and α -L-guluronic acid,” due to its features like reduced toxicity and ease of accessibility, and is altered with peptides with free carboxylic acids on the polymer backbone under minor gelation settings. “Alginate gels can be cross-linked using divalent cations (Ca^{2+} , Ba^{2+} , or Sr^{2+}) or by covalent chemical cross-linking techniques” (Lee and Mooney 2012). Arginylglycylaspartic acid (RGD), the “peptide motif responsible for adherence of cell to the extracellular matrix (ECM), is exhibited in most organisms. Cell adhesion proteins called integrins – “principal receptors used by animal

cells to bind to the extracellular matrix” – function as “transmembrane linkers, fix to this sequence, which is found within many matrix proteins, including fibronectin, fibrinogen, vitronectin, osteopontin, and several other adhesive extracellular matrix proteins” (Plow et al. 2000). The unearthing of RGD and illumination on how it interacts to integrins paved way for the invention of advanced therapeutics and diagnostics. “The peptide itself is used ubiquitously in bioengineering” (Alipour et al. 2020). “Cell-alginate interactions is enhanced by covalent linking to integrin binding peptide sequence RGD or its derivatives to the polymer backbone. The free carboxylic groups of the latter are activated using EDC/NHS (ethyl(dimethylaminopropyl)carbodiimide / N-hydroxysuccinimide.) and reacted with the terminal NH₂-group of the peptide” (Rowley and Mooney 2002) (Fig. 7a).

Chitosan is an excellent polymer used as a suitable substrate in creating biomimetic polymers, due to its organizational resemblance to glycosaminoglycans found in native tissue and presence of easily alterable free amino groups in the polymer backbone (Drury and Mooney 2003). Wang et al. “covalently bound WGA (Wheat

Fig. 7 An illustration of examples of biomimetic polymers. “Materials derived from **natural** hydrogel type polymers: (a) alginate-RGD; (b) chitosan-WGA. Materials derived from **synthetic** hydrogel type polymers: (c) PPF-PEG-RGD; (d) (PEG-RGD. Materials derived from **lipophilic** polymers: (e) PMMA-Insulin; (f) PEG-PLA-Somatostatin” (Image Source: Drotleff et al. 2004, European Journal of Pharmaceutics and Biopharmaceutics 58 (2004) 385–407)

germ agglutinin), a lectin molecule, to chitosan to enhance cell–biomaterial interactions by first activating WGA using EDC and afterwards reacting these products with the amine groups of chitosan to form stable amide linkages” (Wang et al. 2003) (Fig. 7b).

A commonly employed synthetic polymer in the biomedical field is Poly ethylene glycols (PEG), owing to nontoxic and nonadhesive property to protein which results in excellent products. “PEG can be processed into a hydrogel by modifying with acrylates or methacrylates, which are sensitive to photo-cross-linking” (Drury and Mooney 2003). To enable selective cell attachment, PEG is attached to RGD-sequences (Drumheller and Hubbell 1994; Burdick and Anseth 2002) (Fig. 7d).

Another synthetic hydrogel-forming material for drug conveyance applications is “an amphiphilic triblock copolymer derived from a low molecular weight poly (propylene fumarate) (PPF) with two terminal PEG units.” It results in a product being minimally invasive, due to its property like being decomposable due to hydrolytically cleavable ester groups in the polymer backbone and thermo-reversible gelation. Jo et al. synthesized “a triblock copolymer consisting of two terminal carboxymethyl PEG units and one PPF block in the middle of the copolymer” (Jo et al. 2000). The end free carboxylic group which is unrestricted allows for conversion to succinimidyl esters using N-Hydroxysuccinimide/ dicyclohexyl carbodiimide (NHS/DCC) chemistry resulting in polymers, easily modified with RGD sequences (Fig. 7c).

Current research shows that in addition to hydrogels, lipophilic water-insoluble polymers are also employed to make biomimetic polymers. Degradable materials are typically used for biomedical applications during gradual reabsorption of the material thereby replacing the defect in living tissues. Nondegradable materials have been explored, to accomplish increased biocompatibility and tissue incorporation of medical implants. Many nondegradable materials like polystyrene (PS) or polyacrylate have furthermore been modified to yield biomimetic materials. Polystyrene (PS) offers a good model system for lipophilic surfaces. Park et al. synthesized a “sugar-bearing PS derivative with RGD grafted to the polymer backbone using carbodiimide chemistry to investigate the changes in the behavior of hepatocytes on these modified polymer surfaces” (Park 2002).

Poly (methyl methacrylate) (PMMA) is another material which can easily be altered by the hydrolysis of methyl ester groups in a basic environment. PMMA surfaces can be bound with peptides through “subsequent reaction of the obtained acid residues with amine groups of peptides using EDC chemistry” (Ito et al. 1996). A substitute constitutes the fastening of the bioactive molecule to an acrylate anchor and grafts it to the PMMA backbone using UV-irradiation. Schaffner et al., for example, used this method to covalently link insulin to PMMA surfaces (Schaffner et al. 1999) (Fig. 7e).

PLGA – (Poly (lactic-co-glycolic acid) and PLA – poly (lactic acid) materials are persistently used for biomedical applications because of their exceptional biocompatibility to form firm scaffolds for cell cultivation (Quirk et al. 2001). Free carboxyl group at the terminal of PLGA chains aids in modification of the polymer. In one type of PLGA modification, “a galactose derivative was bound directly or via a PEG

spacer to the acidic end of the molecule” (Yoon et al. 2002). “Using NHS/DCC chemistry, an amine containing galactose derivative or PEG diamine was tethered to the polymer. Lactobionic acid was then grafted to the remaining free amine group of PEG using carbodiimide chemistry. An alternating block copolymer of lactic acid and lysine was used to provide free reactive amine groups in the polymer backbone.” RGD peptides were then covalently attached to the resulting free amine groups (Cook et al. 1997).

Tessmar et al. (2003) created a new group of PLA derivatives. “To reduce uncontrolled protein adsorption to the lipophilic PLA, a diblock copolymer with hydrophilic PEG was synthesized, starting from PEG and D, L-lactide in the presence of stannous 2-ethylhexanoate” (Tessmar et al. 2002). The amine group at the terminal end of PEG chain showcases a modification site. By employing linkers like L-tartaric acid or succinic acid, the polymer was activated for protein binding by converting amine group to a reactive carboxylic group. “Alternatively, a thiolreactive group was introduced via β -alanin and maleic acid anhydride resulting in a thiol reactive maleinimide. Insulin, as an amine containing protein, and somatostatin, a substance with a cleavable disulfide bridge, were shown to attach to these activated polymers” (Tessmar et al. 2003; Drotleff et al. 2004). For wide application in tissue engineering, Hacker et al. developed a method for producing scaffold which maintains its binding capacity resulting in forming cell carriers which are easily modified with proteins (Hacker et al. 2003).

Thus, as discussed previously there are enormous examples of polymeric materials which act as hydrogel and lipophilic polymers used in tissue engineering and serve greater purpose in the biomedical field. Specific type can be chosen based on the purpose.

Polymeric Synthetic Pathogens

Another contribution in the field of biomimetic polymer is creation of polymeric synthetic pathogens where “the features of pathogens, in particular viruses, which possess diverse geometry and surface properties are exploited.” Viral properties are simulated in “bio-inspired non-viral polymeric systems for high efficiency drug/gene delivery and other therapeutic applications.” Polymeric nanoparticles which embed DNA have been made with variance in geometry to biomimic the structure of natural viruses. The “constructs are composed of a cationic co-polymer and anionic DNA that, through bottom-up self-assembly in solvent with varying polarity, can form nanocomplexes” (Jiang et al. 2013). These polymeric nanostructures specifically target cells or tissues which can possibly modify target cells – immune system cells and stem cells – and induce them to act based on information encoded via nucleic acids incorporated in those nanostructures. This method ensures safety without being infectious. Better immunization against pathogenic diseases is achieved via this method. “Lipid-coated polymeric particles which display antigen on the surface” are one such approach of creating polymeric synthetic pathogen (Hanson et al. 2014). This approach permits “individual tuning of the core-shell structure.” To

mimic pathogens for better antigen presentation to stimulate immune cells for antibody production, better ways of tuning the properties of the polymeric particle are needed. Ajithkumar and Pramod (2018), established “a virus system with a core-shell structure for targeting tumor tissues with a simple and predictable self-assembly technology.” They incorporated doxorubicin – a specific anticancer drug – and DNA into the core of artificial virus and a folate-bound albumin as outer layer. As folate receptors are persistently over-expressed in cancer cells and normal cells show limited expression, as per Lu and Low (2002) this allows specific adherence of artificial viruses to cancer/tumor or any type of abnormal cells. As Zheng et al. report, “The outermost layer of the artificial virus is a polypeptide complex of poly (L-lysine) and poly (G/L-glutamic acid), which dissolves in acidic pH. Hence, when an artificial virus is introduced in vivo, it reaches the tumor tissue, the complex dissolves and the drug releases ensuring targeted drug delivery” (Zheng et al. 2021).

Biocomposites

Ebrahimi and coworkers 2019, reported “biomimetics in the field of tissue engineering, which focuses on mimicking the biological process during biomaterials synthesis to produce materials similar to natural tissues” (Ebrahimi 2019). These materials have wide range of application in the biomedical field. From biomimetic point of view, “natural tissues are composite materials with a structural unit based at the nanoscale.” Attempts on development of new materials should be based on the complex design and characteristics as well as its scale at micro- or nanolevel. “An exceptional example is 3D printing of organs.” Abouzeid et al. (2018) reported “the preparation of bioactive scaffolds for bone tissue engineering by combining 3D printing and a biomimetic mineralization process.”

3D printing of bones aided by biomimetics is studied by Lopes and coworkers (Lopes et al. 2018). The “biomimetic mineralization” of bones encompasses development of hydroxyapatite (HAp) by the presence of calcium ions and phosphate ions in replicated body fluid on the scaffold surface. This allows uniform dispersion of HAp in the scaffold. “This modification is analogous to chemical structure and material properties of natural bone minerals and has got higher biological activity and promotes cells proliferation and growth” (Lopes et al. 2018). This method’s demonstrations enhanced mechanical properties to encounter the requirements of bone tissue repair, while “scaffolds without biomimetic mineralization are soft and prone to collapse.”

As per Hopkins et al. (2015), “due to complexity of its structure and function, the central nervous system (CNS) is challenging to mimic.” There is increased occurrence of neurological diseases. As neurons are cells that cannot be regenerated under any conditions, a ground-breaking approach toward construction of neurons and auxiliary cells would be highly valuable to mankind. A biomimetic approach toward spinal cord shows that, “the types of cells and their arrangement has a highly controlled spatial distribution which is the key to mimic the spinal cord architecture.” Recently, Joung et al. (2018), “fabricated a heterogeneous bioinspired spinal

cord by multi-material 3D bioprinting in which clusters of spinal Neuronal Progenitor Cells (sNPCs) and Oligodendrocyte Progenitor Cells (OPCs) can be accurately positioned in different parts of the scaffold during assembly” (Fig. 8). These “bioinspired spinal cords successfully showed differentiation of functionally mature neurons during in vitro culture, which allows for further differentiation of neuronal

(g) Schematic of induced pluripotent stem cell (iPSC) reprogramming and differentiation into spinal neuronal progenitor cells (sNPCs) or oligodendrocyte progenitor cells (OPCs). These progenitor cells are 3D bioprinted into the scaffold and cultured in vitro.” (Source: Joung et al. 2018)

progenitor cells into neurons projecting axons and oligodendrocytes that myelinate the axons, respectively. This biomimetic approach provides a novel technique for treating neurological diseases which aids to prepare scaffolds with better bioactivity for mimicking the central nervous systems” (Joung et al. 2018).

Dentistry

In dentistry, application of biomimetics includes repair of dentition by inculcating possible ways of regenerating and replacing affected dental tissues by biomimicking natural tooth in properties and morphology. Curative dentistry offers a varied variety of applications like reestablishing defects in tooth by polymeric biomimetic peptides to attain remineralization (Bazos and Magne 2011). As per Tirlet et al. (2014), “adhesive restorative materials have demonstrated tooth morphology and aesthetics mimicking natural teeth. Biomimetic dental implant coatings of calcium phosphate and hydroxyapatite have been investigated to improve osseointegration of dental implants to achieve therapeutic benefits (Galler et al. 2010). “The tissue-engineering approaches resulted in regeneration of lost or damaged dental tissues mimicking their natural counterpart” (Zafar et al. 2020). This therapeutic method endeavors preservation of intact tooth structure and restores the role of natural teeth. For example, “Biomimetic endodontic regeneration includes the formation of dentin barrier by pulp-capping agents, root formation during apex genesis and apexification, apical healing by root-end fillings, and pulp regeneration by cell-homing strategies” (Kaushik et al. 2016).

Advantages and Limitations of Biomimetic Materials

The science of biomimetics provides opportunity to learn various strategies for survival and energy efficiency showed by different life forms and apply them to bring sustainable solutions to the challenges faced by mankind in innumerable fields. Apart from imitating biological materials or services, biomimetics requires thorough study of organisms and where they inhabit along with how they function. Without further acquiring knowledge about such works, the utility of mechanisms cannot be accurately understood.

Biomimetics is based on the properties that ensure some integral advantages observed in the biological world. It helps create products and processes that are sustainable, cost effective, energy efficient, and high performance and that redefine and eliminate waste. As Bar-Cohen (2006), reports, “assistance from the study of biomimetics can be seen in many applications, including stronger fibre, multi-functional materials, self-cleaning super hydrophobic biomaterials, improved drugs, superior robots, sustainable architecture, strong adhesives, restorative dentistry, bioengineered spinal cord, energy harnessing structures which run on sun’s energy.” In spite of all these advantages, the science of biomimetics offers many drawbacks and limitations at application level. As Shimomura (2010), states, “the combination of newly revealed materials with biomimetics research will be a key to

understand their applications and limitations.” The structural and purposeful usages of new biomimetic products must be perceived together with positive and negative characteristics study.

A challenging segment in biomimetics is the identification and selection of the initial source of biological information which serves as solution for a scientific problem. This primary source of bioinspiration must not be highly specific, comprising several organizational levels of the biological domain which allow a vast variety of biological phenomena covered, and must not be too complex, to facilitate the process of understanding for those investigators without a biology background.

Identification of functions of organisms along with their various adaptive mechanisms in response to environmental factors based on energy optimization is an ongoing field of research which forms the basis of biomimetics. The supreme encounter faced by biomimetics is to elucidate the association of fine structures in biological sources and its relationship with the organism and its habitat, if they are not wholly studied. “The designation ‘nature made’ does not provide intrinsic superiority.” Shimomura (2010), showed that “finding substantial examples through the integration of biology, natural history, and materials science is the next step in biomimetic research.”

Adhesion characteristics of various biopolymers are a matter of great concern as they have wide range of applications in various fields. Even though strength of adhesion property is better in synthetic/nonsynthetic adhesives, in the biomedical field they have limitations like low absorption rate, high toxicity unsafe for life, and less adhesiveness on wet materials. Most of the adhesiveness shown by natural materials is due to their nanostructures, and hence research has to be focused on new adhesives based on nanostructural level. However, to develop an appropriate adhesive for different surface types is still not possible.

Another limitation in biomimetic polymer design is the constraints in manufacturing technology currently practiced. In nature, organization of building blocks into specific patterns or geometry occurs with incredible integration. But to recreate or add the property in a bioinspired product is highly complex, and such intricacies need to be standardized primarily. In addition, some of the high-performance products synthesized in laboratory occur with restricted size and quantity and are minimal, and the characteristics are analyzed without following uniform standards which draw back further work. Time and cost investment in the process also adds to the limitation when large-scale production is concerned. As per Wang et al. (2020), “the inherent efficiency of biological materials is difficult to duplicate, as the microstructure involves engineering complex architectural details that are beyond the capability of most current nanotechnologies.” Therefore, in summary, such bioinspired biomimetics cannot be replicated at an industrial scale and technological mapping of the process is over whelming at the moment.

In the forthcoming times, several biomimetic polymeric materials, which can be used as implants which can be applied clinically, will be developed regarding the current scenario of research works. In dentistry, “the reinforcement and completion of the tooth structure by biological regeneration will be evident in few years” as per Zafar et al. (2020). But due to the complexity of tooth structure, limitations and challenges for application clinically need to be overcome.

Knowledge acquisition on the various natural phenomena and detailing of natural materials may not always solve difficulties or challenges faced during biomimetic polymer production; nevertheless, possibilities and potential of further research work are tremendous. As Reed et al. (2009) cite, “Today’s biological curiosity can become the object of tomorrow’s biomimicry.”

Future Prospects

Currently, different types of biomimetic polymeric materials are widely employed for variety of functions. However, as new mechanisms for the production of nature-inspired polymeric materials are formulated, progression of biological bodies and the mechanism of how they evolve over a time period also need to be distinguished. As the scientific community’s awareness of how various life processes occur, various biomaterials’ involvement and their hierarchy in structure and better knowledge about working code come to light, and interdisciplinary research can be carried out to imitate their technology for innovative products. Biocompatibility of presently used polymeric materials also needs improvement, and hence, extensive research needs to be carried out.

Biomimetic polymers offer great promise to actively modulate biological systems. Numerous challenges need to be overcome in the area. The knowledge sparsity about structure and functioning of the biological system, which is the source of biomimicry, is the biggest challenge in this field of biomimetic polymers. Strong perception of principles ruling biological organisms and phenomena of various life processes is a significant aspect in biomimicry. The various biomimetic materials discussed in this chapter are useful tools to explore and illuminate biological principles. The competences of biomaterials beneficial for use in biomedical research develop drastically during the period when exploration can move toward understanding of how such materials interact with the biological system both locally and systemically.

Recently, biomimetic polymers in the biomedical field, specifically the immune system, are a focus for manipulation. Using polymeric materials to target precise immune system constituents in combination with drug delivery has the latency to pointedly increase the capability of cancer immunotherapies to better target tumors. This would be revolutionary as it expands the disease resistance. It is anticipated that exceptional biomimetic models created based on the knowledge of different biological bodies will enhance the life and application of polymeric biomaterials. Presently, the biomimetic process is moving at a slow pace in revealing the full potential of biomimicry.

Conclusion

Nature has shown evolution and augmentation of different kinds of biomaterials with exceptional characteristics. Deep thoughtful investigation into the mechanism behind this creation aids to recreate useful products which serve human beings.

Biomimetics and fabrication of nature-inspired polymers has been the driving force for many innovative ideas and research for years. The commercial applications of biomimetics are widespread including devising new nanomaterials, devices, and processes. With the fast progress of research and knowledge built up, biomimetics accelerates the biomedical field forward to introduce new biomaterials which mimic nature. Imitating the characteristics will likely lead to innovative products; nevertheless, it has boundaries which need to be overcome, which brings greater impact in biomedical field which would solve many snags at the application level. With the simple idea of imitating nature, now biomimetics has touched many sophisticated and delicate areas of science and technology with amazing results. Advancements in biomimetics and nature-inspired biopolymers hold the key to more sustainable technological developments.

delivery of cosmetic ingredients. The present work discusses the cosmetic applications of biopolymeric materials which include the interaction of materials with the skin and important characteristics of topical delivery of bioactives, safety measures of albumin materials in cosmetics, various design formulations of albumin, and the particular applications in the field of cosmetics. Albumin plays a critical role in the health as it is one of the major proteins in the living organisms.

Albumin · Cosmetics · Application · Skin · Proteins · Biodegradability

Introduction

The use of cosmetics is not a modern part of application because ancient women used Kohl to darken the eyelashes and Cleopatra used milk to whiten and soften her skin. Now in today's world, cosmetics are billion dollar industry which uses a wide range of materials like minerals, polymers, emulsifiers, preservatives, color, flavors, thickeners, and pH stabilizers. Use of biopolymers in cosmetics is widely classified into proteins and polysaccharides. Use of albumin in cosmetics became more advantageous because they are biologically derived, biocompatible, biodegradable, and eco-friendly. Proteins from animals, fungi, and algae are widely used as source of protein. In recent times, plant-derived proteins are also used in cosmetics. The safety and effectiveness of proteins/peptides in cosmetic formulations is well established for skin and hair care. In the moisturizer, peptides are known to improve the appearance of facial skin. The polysaccharides are inexpensive and readily available because of their natural sources, and they have been used in cosmetics for a long time. The polysaccharides widely used in various cosmetic applications are cellulose, xanthan gum, hyaluronic acid, chondroitin sulfate, guar gum, chitin, dextrans, pectin, carrageenan, agar, and alginates (Luo and Wang 2016; Mota et al. 2020a).

A cosmetic material is defined as a constituent or preparation proposed for placement in contact with any external part of the human body, including the skin, mouth, and teeth. We use cosmetics to protect, cleanse, perfume, and change the appearance of our skin or to alter its odors. Various biopolymers such as proteins and polysaccharides were used to increase the aesthetics of the product and to improve the effect on the body. These are used as emulsifiers, thickeners, whitening agents, antiwrinkle agents, etc. (Mota et al. 2020b). Usually, cosmetics contain a mixture of water, emulsifier, preservative, thickener, and stabilizers of color, fragrance, and pH. Apart from these ingredients, some active formulations called cosmeceuticals that impact the natural function are also included in the products to give some pharmaceutical effect. Common classes of ingredients used in cosmetic formulations are specified in Table 1 (Augustine et al. 2013).

Cosmeceuticals is the integration of cosmetics along with the pharmaceutical industry. They are selected by real effectiveness, and they contain active ingredients

Table 1 Class of ingredients used in cosmetics

Function	Common classes of ingredients
To promote the emulsion formation	Emulsifiers
To change the consistency of product	Thickeners
To increase the hydration	Moisturizers
To decrease the surface tension of the product	Surfactant
To give enjoyable aroma to the product	Fragrances
To provide an pleasing color to the product	Colors
To regulate the pH of the product	pH stabilizers

Table 2 Class of ingredients used in cosmeceuticals

Function	Common classes of ingredients
To maintain a youthful appearance	Antiaging agents
To prevent the lines and wrinkles	Antiwrinkle agents
To eliminate localized hyperpigmentation and lighten the general skin tone	Whitening agents

at high concentration with their prevention and inherent treatment features. They are manufactured with a greater scientific evidence than the normal cosmetics and hold a lower therapeutic value than the pharmacological product. Like cosmetics, cosmeceuticals are topically applied but they contain ingredients that influence the biological function of the skin. Cosmeceuticals deliver the necessary nutrients for improving the appearance for healthy skin. Cosmeceuticals improve the skin tone, radiance, and texture, by reducing wrinkles which forms the increased growth section of the personal care industry. The most popular cosmeceuticals are given in the Table 2 (Pandey et al. 2022; Patravale and Mandawgade 2008).

Albumin is a blood protein that is mostly produced in hepatocytes and it acts as a reservoir for the transport of many substances such as nutrients, hormones, metals, and toxins. They are produced in the hepatocytes; the molecular weight of albumin is 66.5 kDa and the half-life is 19 days. The albumin is available in different variants such as bovine serum albumin, ovalbumin, and human serum albumin (HSA). HSA plays an important part in the drug delivery system because of its biodegradable nature. The ovalbumin is easily available, low cost, and bioavailable, and they are used in food, cosmetics, and drug delivery applications. This albumin can be able to associate through covalent or noncovalent attachment, covalent conjugation, and ligand mediated interactions with the bioactives or encapsulation of the bioactives (Foulke 1992). The traditional method uses the albumin in egg white that have been widely used as a wrinkle remover for centuries, and when the egg white is applied to the skin, it provides tightening of the skin and smoothens the wrinkles. After the egg white is applied to the skin, the tightening effect of the skin is produced within 5 to 10 mins, and albumin gets dried on the skin. Usually after applying the egg masks the face has to be kept without any movements, otherwise the mask would crack and

the tightness of the skin gets lost. Most of the skins will get benefitted from the egg pack and it is one of the age-old cheapest form of beautifying treatment method. The method involved is to separate the white from the yolk of the egg and beat the white till it gets fluffy. Lemon juice is added to the beaten white which is then applied to the clean face, and it should remain on the face for about 20 min. Then the pack is removed with warm water which is followed by washing with cold water and finally a piece of ice is applied over the skin. These egg mask or egg pack treatments include astringent and cold water or ice to sustain the tightness of the skin (Gadomska and Katarzyna Musiał 2021; Yusuf and Fatmawaty 2017).

Another example is the use of bovine serum albumin (BSA) as a wrinkle smoothening agent. In this method, they have formulated the BSA with the film forming agents, plasticizers, and preservatives. The film forming agents such as sodium silicates and carboxymethyl cellulose help deliver the uniform film with a matt finishing so that it is less visible. The plasticizers such as glycerine or propylene glycol increase the flexibility of the film so that it prevents from scaling, cracks, and flakes. These ingredients together improve the smoothening of the wrinkles which simultaneously increases the visual effectiveness of the skin (Zhu et al. 2008).

In a study, they made an albumin solution and applied on the facial skin and found a tightening sensation on their skin because the solution dries within few minutes, and reduction of wrinkles and smoothing effect was observed within 3–8 mins. They have performed a microscopic examination to visualize the facial skin after application of albumin solution and observed that even the finest wrinkles became invisible. The expression lines around the eyes and mouth are not altered much but when larger amounts are applied there are reduction in the fine lines. When larger amounts are applied it reduces minor wrinkles and also it leaves a transparent film which later turned into scale flakes. By applying it repeatedly leads to peeling after it dried off and the effect is about 2–6 h depend on its facial motion. The time extends for the person whose face showing little emotion, inexpressive and poker faced. When the face gets dried, it is remoistened with a few drops of water to make it restored. With the wetting of water, it reduces the fine wrinkles even after 8 h, and also it is said that completely washing the face with soap and water will completely eradicate the smoothening effect. This anti-wrinkling effect is not cumulative with the repeated dosage daily and there is improvement from the first to last day of use. After the applied solution gets dried, applying the facial creams did not alter the effect and also no adverse effects and side effects were observed. This chapter will provide a highlight on the structure, molecular association of albumin, and role of albumin in the formulation design for the cosmetic applications (Li et al. 2016; Hu 2011).

Albumin-Based Tissue Scaffolds

In this method they have used a new process in which it is converted into an albumin polymer from the liquid albumin solution and then into a tissue scaffold by freeze drying-based molding method. The yield is about 75% with respect to

volume and for single 500 ml of blood, the yield of albumin tissue scaffold would be 105 ml. So, the availability of this material will be adequate for the tissue engineering applications, and it showed an excellent biocompatibility. Normally, the albumin is used as an additive in the tissue culture medium because the cell responses are associated with this protein. Moreover, albumin is the major protein present in the animal blood and the plasma albumin binds with the fatty acids, nutrients, steroids, and metabolites in the circulation. For maintaining pH, osmotic stress, and reducing the power of human blood, the plasma albumin plays a major role. In this method, they have mentioned that albumin-based tissue scaffold is considered as a useful substrate because it plays a structural support in the cell and tissue engineering applications (Ong et al. 2019). The physical and mechanical properties revealed that the prepared albumin scaffolds were similar to that of the collagen tissue scaffolds. The albumin tissue scaffolds and the collagen tissue scaffolds have exceptional water binding capacity. In addition, they also have good cell binding characteristics which support cell growth because they are peptide-based biomaterials. In this study, they have found that the albumin tissue scaffold didn't change in the dimensions even after 28 days of MSC culture. The albumin tissue scaffolds are difficult to degrade by MSCs because the degradation behavior of cross-linked albumin is very different from the other biopolymers. Because of this unique characteristics, the albumin will decrease the complexity by avoiding the interactions between the cell and scaffolds. This albumin tissue scaffold is a good substrate for tissue culture and tissue engineering applications (Li et al. 2014) (Fig. 1).

Blood and tissue are collected from an adult and an albumin tissue scaffold is developed, seeded with stem cell and with biologics to form biologic scaffold composites. Albumin tissue scaffold forms an artificial tissue with a living cell scaffold

Albumin Protein from Rice Bran

The most important crop is rice in most parts of Asia and it gives more than 20% of energy source and it is the very significant crop in nutrition. During the polishing process of the rice, the by-product obtained from the manufacturing process is said to be “Rice Bran” which is about 10.5% of whole grain. This rice bran is rich in nutrition with high value of protein when compared to other parts of grain. Rice bran consists of vitamin B, Vitamin E, minerals, dietary fiber, and rice bran oil which contains unsaturated fatty acids. The protein in the rice bran are albumin, globulin, prolamin, and gluten which nourish the body with protein, peptides, and essential amino acids. Moreover, it also helps to build immunity and is an important component in food and medicine. It has outstanding biological properties more than any other cereals which is very useful for the beauty and cosmetic industry (Li et al. 2014) (Fig. 2).

The rice bran with the fats is cold pressed to extract albumin protein which has both nutrients and biological activity used as an ingredient in various cosmetic, beauty, and also in the food products. It has an excellent antioxidant property which makes it useful for the cosmetic products. In addition, it stimulates the collagen creation, nourishes the skin and face, reduces wrinkles, and moisturizes and nourishes the hair to make it smooth and shiny (Zheng et al. 2019; Phongthai et al. 2017) (Fig. 3).

Fig. 2 Extraction of albumin from rice

Fig. 3 Properties of albumin protein: (a) moisturizer, (b) antioxidant, and (c) anti-aging

Albumin and Skin Smoothing

Albumin causes a tightness on the skin with skin smoothing effect because it fills the cracks like putty; the refractive index of the albumin softens the wrinkle lines. The facial skin can be easily stretched by a slight force because of their loose and flabby nature. This nature of the skin is due to the degeneration of the connective tissue, and the network of elastin and collagen fibers is highly altered. The collagen fibers in the dermal structure are degraded heavily whereas the elastic tissue is increased greatly. As the solution gets dried the contraction of the skin occurs which lifts the grooves to the normal level and thereby reduces the wrinkles as that of the surrounding skin (Maidhof et al. 2019).

Dermal Delivery of Albumin in Cosmetic Products

The dermal route of protein administration has various advantages, and they avoid first-pass metabolism, bypass the absorption, avoid the effect of pH and enzymes, and transit time. They can also be made into controlled delivery of proteins and also has an excellent biocompatibility. In this study, they have used inorganic nanoparticles (NPs) such as calcium phosphate nanoparticles (CaP-NPs) and zinc oxide nanoparticles (ZnO-NPs) as enhancers (Kianfar 2021). CaP with a molecular weight (MW) of 310.176 g/mol contains calcium and phosphate and they are essential nutrients as well. ZnO with a MW of 81.408 g/mol acts as an antioxidant, heals the wounds, and also treats other skin disorders (Shokri and Javar 2015). These two inorganic particles have excellent biocompatibility, nontoxic, and cytoprotective, and they are also inexpensive. These inorganic nanoparticles used in this study were not used as drug carriers, rather they are used as enhancing agents. Here, the albumin protein is not attached or loaded into the NPs but they are positioned to the skin layers in which it helps the albumin to pass into the skin. Therefore, the NPs were used as the penetration enhancers and not as the carriers of albumin. Moreover, in this method they have added organic solvents as chemical penetration enhancers (CPEs). They have used six organic solvents as CPEs such as coconut oil (Co), olive oil (Ol), sunflower oil (Su), dimethylsulfoxide (DMSO), liquid paraffin (LP), and tetrahydrofuran (THF). The oils and the rest of organic solvents were used because they can be used safely as they are FDA-approved dermal CPEs. The enhancing mechanism of inorganic NPs and the CPEs were chosen because they have a combination effect to obtain an improved and highest permeation of albumin (Shokri 2014).

Effect of CaP NPs and Solvents Permeation

The albumin is a globular protein with high MW hydrophobic compound which hinders to pass the skin. Lipids present in the subcutaneous (SC) prevents the dermal permeation of molecules. So the enhancing agents such as CPEs and the inorganic

Fig. 4 Permeated amounts of albumin coconut oil (Co), olive oil (OI), sunflower oil (Su), dimethylsulfoxide (DMSO), liquid paraffin (LP), and tetrahydrofuran (THF)

NPs can dissolve and soften the lipid structure and thereby improve the permeation of albumin (Desouza et al. 2013). THF is highly volatile and it has low ability to dissolve albumin and lipids. Su is a mixture of oleic acid (omega-9) and linoleic acid (omega-6) group of oils and 10% of terpenes. OI is the combination of 55–83% of oleic acid and palmitic acid. Co is 91% of saturated fatty acids. These oils slightly increase the permeation of albumin due to their weak capability to dissolve lipids. Also, the albumins can bind to fatty acids which helps in albumin permeation with the presence of solvents. The DMSO increases the albumin permeation more than that of oils because of their ability to dissolve lipids in spite of its volatile nature. When compared to all the solvents used, LP has the increased permeation ability of albumin because it dissolves and softens the lipids much better than the other solvents. Moreover, the LP consists of hydrophobic hydrocarbons which penetrates and deposits in between the hydrophobic chains in the lipid layer of SC and also it improves the albumin permeation by decreasing the consistency of SC lipids (Sahdev et al. 2013). In this study, LP was selected as the best solvent CPEs for the permeation of albumin (Fig. 4). The results of this study indicate that simultaneous use of CaP NPs with each and every one of the solvent leads to increased permeation of albumin than the individual solvents alone. This also exhibits that the increase in the albumin permeation by CaP NPs is proportional to that of each and every solvent. It is specified that the CaP NPs augmenting action was to make stronger the effect of each solvents. Among all the combinations, the combination of CaP NPs and LP increases the permeation of albumin which leads to increase of about 86 mg of albumin (Sun et al. 2010).

Effect of ZnO NPs and Solvents Permeation

Similar to CaP NPs, the ZnO NPs and LP increases the permeation of albumin than other combinations of solvents. ZnO NPs and LP combination leads to increase of about 103 mg of albumin which is considered as the most effective combination.

They have also found that the triple combination such as CaP NPs, ZnO NPs, and LP did not increase the permeation of albumin than the combination of ZnO NPs and LP (Fig. 5). The two combinations were considered to be more effective with the combination of two enhancers ZnO NPs and LP. This enhancing capacity of CaP NPs, ZnO NPs is referred to the nanosize range and also its crystalline state (Shokri et al. 2014). The microscopy images clearly show that it is not only be referred to their penetration into the skin and also it retains on the skin layers for a specified period of time. This particular phenomenon disorders the microstructure of the skin layers and it makes the skin permeable to albumin. The same phenomenon makes the skin permeable to the solvents which in turn improves the permeation of albumin. The triple combination such as CaP NPs, ZnO NPs, and LP leads to a saturation state of permeation of albumin which means it possess the improved enhancing effect but it was not significantly more effective than the combination of ZnO NPs and LP. The combination of the inorganic NPs and LP used in this study can be attributed to the two different mechanisms. Seemingly the two mechanisms could be able to complete the enhancing the effects of permeation of albumin. Figure 6 shows that the

Fig. 5 Permeated amounts of albumin CaP NPs and LP, ZnO NPs and LP and CaP NPs, the ZnO NPs and LP

Fig. 6 Histomicrographs of mice skin (a) CaP NPs, (b) ZnO NPs, and (c) untreated skin

skin distribution of CaP NPs spreads in all the layers of the skin whereas the ZnO NPs mostly deposited in the SC and epidermal layer. The concentration of ZnO NPs in the SC layer was more than the CaP NPs and thus the ZnO NPs alter the SC layer than the CaP NPs which in turn enhance the permeation of albumin more than that of CaP NPs. In this study, the results suggest the combination of ZnO NPs and LP to enhance the permeation of albumin effectively in the skin and this dermal delivery of albumin protein is useful in the formulation of cosmetic products (Shokri and Javar 2014).

Human Serum Albumin Cell Carrier Solution for Skin Regenerative Application

Several hours are required for transportation of produced cells to reach the application sites. Here, they have examined four candidate solutions for transporting human keratinocytes. The solutions are normal saline, Saline and human serum albumin (saline with 2.5% HSA), keratinocyte with pituitary bovine extract (PBE-media), and xeno free keratinocyte media. One million keratinocytes were collected from three donors which were suspended in each solution and preserved at 4 °C for 24 h. The cells preserved in the saline and HSA displayed higher viability after 1, 3, and 24 h and the viable cells were seeded in the collagen matrix and cultured it for 48 h. Colonization and adhesion were higher in the cells placed in the PBE media. They have reported saline and HAS as a suitable cell transportation solution to use clinically, and the PBE media is considered to be the alternative one for the transportation of cells (Shahin et al. 2020).

The cellular therapy is the developing and emerging field for the burns and chronic wound management in the clinical therapy. Faster healing and better skin quality are obtained by saline and HAS cultured keratinocytes. The cell therapy field is considered as the Advanced Therapy Medicinal Products (ATMPs) as there a various regulations were updated. The cells have to be manufactured and processed according to the GMP (Good Manufacturing Practice) which is specific to Advanced Therapy Medicinal Products. An example is in the patients who suffer from major burns, the keratinocytes are sprayed on the surgically excised burn wounds and this skin is used for harvesting autologous skin grafts. The medical union has stringent regulations for ATMPs, which include cells cultivation should be fully taken with the GMP compliance (Sarkar et al. 2020). Accordingly, the cells were transported to the clinical site which will administer the cells, and this transportation process takes several hours from the manufacturing place to the clinical site (Burke and Mi 1994). Moreover, the readiness of the patient and team for surgery may need more time and it can also be extended for a period of 24 h. It is always preferred to transport the cells as fresh cells because freezing of cells are associated with decreased number of cells and phenotypes. The keratinocyte cells were kept in the cell carrier solution at 4 °C for 24 h, and the cell count and viability were estimated after 1 h, 3 h, and 24 h. After 24 h, the viable cells and the viability were high in the saline and HSA group compared to other groups. About 2.5% of HSA is added to saline as it is prepared in

the microencapsulated form in poly lysine alginate, and this is considered as a protective cell carrier. In their studies, they have used this HSA as a preservative solution for smooth and endothelial muscle cells and also investigated that 2.5% of HSA is the optimum concentration to preserve the cells at 4 °C for 24 h and 48 h. The HSA overcomes the infectivity problems and is widely used as carrier solution in more complicated drug delivery systems. Albumin is incorporated in the cell culture along with the peptides and growth factors. HSA binds to the outer surface of the cell membrane by adsorption and provides high protection to the cells. The albumin prevents the damage of the cells caused by hydrodynamic stress and is taken by the cells through endocytosis clathrin-coated pits (Lee et al. 2005) (Fig. 7).

The cell culture media was used as the transfer solution for 48 h for the avulsed teeth and after reimplantation the periodontal cells were viable for 12 months. In another experiment they have used four different media to transport keratinocytes for 12 h and found that the morphology was similar before and after transportation. These results confirm that the cells transported at 4 °C for 24 h and 48 h were viable and they can adhere to the cell culture. After 24 h in the transport solution, the cells have equal number of viable cells when resuspended at 37 °C and 5% CO₂ for 48 h. The cells were then stained with the crystal violet solution, and they have the ability to form colonies and also adhere to the cell culture surface. The elution of the stain displayed higher absorbance for the cells in the PBE than the other groups and there was no difference in the CDM and saline + HSA solution. The keratinocytes were characterized by immune staining of the marker CK-14 (Cytokeratin 14) and they were fixed after 48 h. The cells from all the groups look positive for the skin and no difference was observed in the groups. This study recommends the usage of 2.5% HSA in saline solution as the cell carrier for up to 24 h at 4 °C for clinical use. Based on the clinical trial the cell transportation and the cell viability were preserved for use in patients with burn wounds and chronic burn wounds (Xu et al. 2013; Kent and Bomser 2003) (Fig. 8).

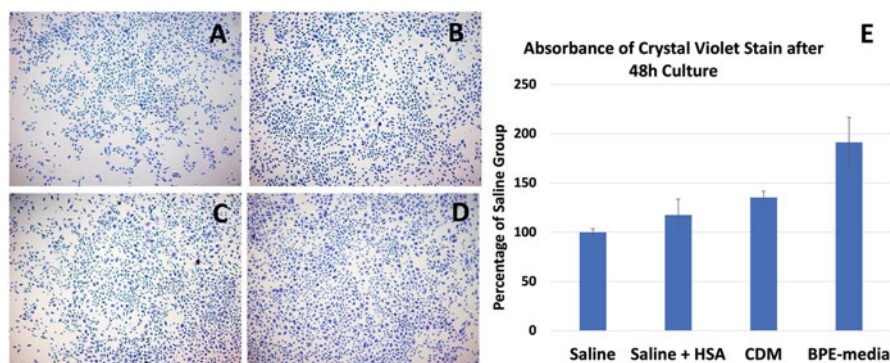

Fig. 7 Crystal violet staining showed adherence and colonization, following 24 h incubation at 4 °C, of keratinocytes kept in saline (a), saline + HSA (b), CDM (c), and BPE-media (d). The elution of the stain (e) was higher in the BPE-media in comparison to the rest of the groups. Also, CDM had higher intensity than saline group. (Reproduced with permission from scientific reports)

Fig. 8 Immunocytochemical staining for cytokeratin 14 (a–d) and involucrin (e–h). Keratinocytes kept in saline (a, e), saline + HSA (b, f), CDM (c, g), and BPE-media (d, h) showed comparable positive staining for the studied markers. Scale-100 μ m. Transdermal Perfusion of Nanoformulation Containing BSA for Cosmetic Applications

It's very challenging to perfuse the large molecules such as proteins in the transdermal route because of the lipophilic nature of the skin. The main barrier function of the skin responsible for the perfusion is stratum corneum which is the outer protective layer and it consists of flat dead cells. They are filled with the corneocytes and lipid bilayers which are impermeable to the large molecular weight compounds. The protein/peptide molecules that are hydrophilic are made into dispersion formulations by making the external layer hydrophobic and thus this dispersions are permeable to the SC layer. Protein nanodispersions with the size range of 210–260 nm of 27 and 40 kDa showed poor permeation into the skin layer. In another study they have used small sphere size of the nanodispersions of about 190 nm which improves the transdermal delivery. This spherical size nanodispersion is useful in improving the permeation of larger proteins for skin vaccination (Martins et al. 2013).

In this study they have used a 66 kDa of bovine serum albumin to attain the size of 162 nm nanodispersion. The albumin (BSA) – fluorescein isothiocyanate (FITC) nanodispersions were manufactured using solid-in-oil technique. They have adopted three different steps in which the sucrose ester surfactant is dissolved in chloroform and BSA-FITC using high pressure homogenization. Then this sample is subjected to lyophilization to remove the water and chloroform to obtain a surfactant–protein complex. After lyophilization, the sample is dispersed in isopropyl myristate by ultrasonication of about 20 kHz to form nanodispersion (Fig. 9). The figure explains the physical appearance of BSA-FITC in the presence and absence of nanodispersion (Martins et al. 2013).

The in-vitro permeation of the prepared BSA nanodispersions in the pig skin was examined using Franz diffusion cells system. The pig skin specimens were collected and the thickness is 66–72 μ m; the follicular structure, collagen fiber arrangement, and content of glycosphingolipids and ceramides of the pig skin resemble that of the

Fig. 9 (a) Schematic preparation method of BSA nanodispersions, (b) appearance of nano-dispersion without sucrose ester, and (c) chemical structure of sucrose ester surfactant

human skin. The specimens of the pig skin were placed between the two compartments in the Franz cells, the donor and the receptor. Then the pig skin was kept for incubation at 37 °C for 48 h and then washed many times to remove the excess particles which had not permeated the skin. The samples were taken for the histological studies, and using confocal laser microscopy the permeation of the skin were studied (Moser et al. 2001). The extent of penetration and BSA nanodispersion localization are illustrated in the 2D and 3D images (Fig. 10). By the image acquisition technique which is the result of acquiring the images multiple times per second for the analysis of diffusion kinetics. From the confocal analysis it is clearly demonstrated that the fluorescence intensity of the BSA nanodispersions is much higher in the SC and the epidermis and as it gets lesser it crosses to the dermis. The permeation results were attained mainly because of the small particles and the hydrophobic coating on the outer layer of the particles. The rate controlling step of permeation to the skin is that it passes through the hydrophobic region of the skin. This study proves that the high molecular weight BSA coated with the surfactant which is hydrophobic can easily penetrate the skin. It gives lot of benefits to the cosmetic industries as it transdermally delivers the large proteins across the skin membrane (Huzil et al. 2011; Schreiner et al. 2000).

Bovine Serum Albumin Loaded Niosomes for Cosmetic Applications

Bovine serum albumin is a biological protein that is widely used in cosmeceuticals and delivery applications, as a suitable carrier because of its non-toxicity, non-antigenicity, and biodegradability. BSA is used as combination with other

Fig. 10 Confocal images of pig skin crossed by BSA nanodispersion: upper 2D illustration FITC images correspond to the green color with emission maxima at 520 nm emits from FITC-labelled BSA protein and TRICT correspond to the red color with emission maxima at 576 nm emits from TRICT-labelled IPM oil. The Merge images (FITC + TRICT) combine green and red fluorescent signals emitted from the same sample. 3D images represent reconstruction of z-stack confocal images. These images demonstrate a piece of skin marked with blue; the left image represents a particles reconstruction (green particles represent FITC-BSA and red particles TRICT-IPM oil). The central image combine green and red channels (FITC-BSA green and TRICT-IPM oil red channel) and the yellowish color symbolizes the overlapping of both. The right 3D image demonstrates the view of the skin piece from the side where the penetration of FITC-BSA and oil-TRICT is easily detected. ingredients/polymeric systems mainly for increasing the stability and prolonging the effect. The niosomes are vesicles that have high biocompatibility, low toxicity, and is useful for targeted drug delivery and skin tissues. Hydrophilic, hydrophobic, and biomacromolecular agents such as proteins and peptides were encapsulated in the vesicles. The surfactants such as Span and cholesterol are added as additive stabilizing agent, and these are the main components that acts as the nanocarrier for the formulation of niosomes. Encapsulated proteins and growth factors are required greatly in the pharmaceutical and cosmetic industries. The BSA-loaded niosomes were synthesized by the reversed phase evaporation method. The Span 60 with different percentage weights were dissolved in diethyl ether. Simultaneously BSA was dissolved in the deionized water and it is added to the flask by mixing them with the formation of vortex for 60 s. Then it is emulsified using sonication method for

Fig. 11 BSA loaded niosomes. (Reproduce with permission from AAPS PharmSciTech)

3 min in a water bath at 10 °C. The emulsion was kept for evaporation process to remove the excess organic solvents at 40 °C with a rotation speed of about 60 rpm (Fig. 11) (Moghassemi et al. 2017; Mahale et al. 2012).

The in-vitro release profile of BSA-loaded niosomes showed that 30–50% of the loaded BSA was released within the first hour because of the BSA molecules present on the surface. The niosomes with 80% showed a slower release profile because it has created a lower entrapment efficiency which created a difference in the two sides of the niosomes when compared to others. This type of release profile is also obtained for the niosomes containing span 85 and span 80 in which the BSA (30%) released after 3 days. Then the BSA was treated with the MO with a mixture of acidic buffer (pH = 4). BSA along with MO causes a change in color from white to orange, and the colored BSA niosome formulation indicates that the encapsulated BSA niosomes through the optical microscopy studies. They have also studied the absorbance of albumin-MO at 560 nm with different pH values. They have also analyzed using surface plasmon resonance (SPR) analysis to study the binding of MO-albumin and it is stated that one or two MO molecules bind to the albumin molecules at pH 3.6–7.2 (Fig. 12). The sustained release of BSA niosomes were particularly useful for cosmetic, drug delivery, and tissue engineering applications (Nasir et al. 2012; Chaikul et al. 2019).

Chitosan-Ovalbumin Nanogels for Cosmetic Applications

Chitosan and ovalbumin are the two natural macromolecules that are used to formulate nanogels for cosmetic applications. Chitosan and ovalbumin solutions were mixed and pH of the solution was adjusted. Then the solution was stirred and heated till the ovalbumin gets gelled to form a nanogels. In the nanogels formulation, the nanogels core is partly entrapped by the chitosan chains and the remaining chitosan chains form the shell of the nanogels. The prepared chitosan ovalbumin nanogels exhibited excellent stability and didn't dissociate in the pH of 2 to 10.5

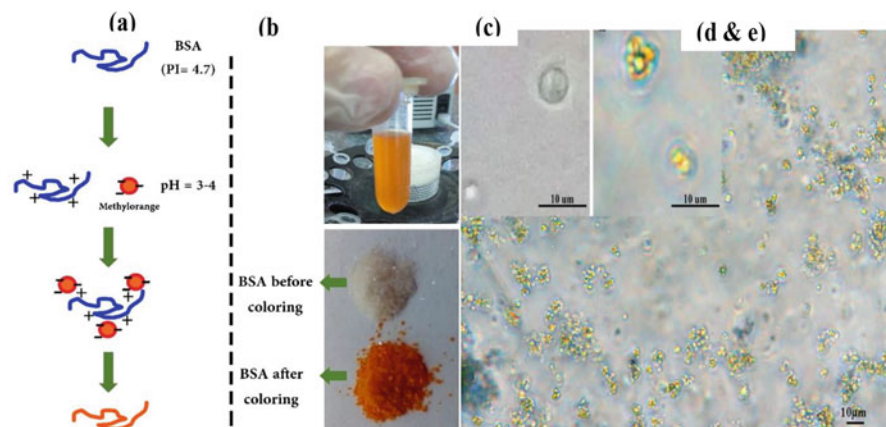

Fig. 12 (a) Scheme showing the mechanism of dyeing of BSA by MO, (b) final colored BSA with MO and light microscopy images of uncolored BSA-loaded niosomes (c) and colored BSA-loaded niosome (d and e)

Fig. 13 Chitosan-ovalbumin nanogels for cosmetic applications

(Fig. 13). The size, dispersibility of the preparation, and hydrophilicity and hydrophobicity of the nanogels are pH dependent. The shell structure of the chitosan in the prepared nanogels gives appealing properties. The main advantage of this system is that the nanogels are formed by a convenient and green method of preparation, and there is no separation procedure required. Such exceptional properties make the chitosan-ovalbumin nanogels good candidates for cosmetic industry (Yu et al. 2006; Yin et al. 2012) (Fig. 14).

Protein Formulations for Cosmetic Applications

The protein formulations based on emulsions and dispersions were the most investigated area in the cosmetic industry. The formulations can be used for the delivery of cosmetic agents, transdermal perfusion, and cosmetics application. Various methods have been used to formulate proteins and they are emulsification, self-assembly, coacervation/desolvation, and solid-in-oil dispersions. For the preparation of protein formulations in the micro- and nanoscale, emulsification and dispersibility methods are the commonly

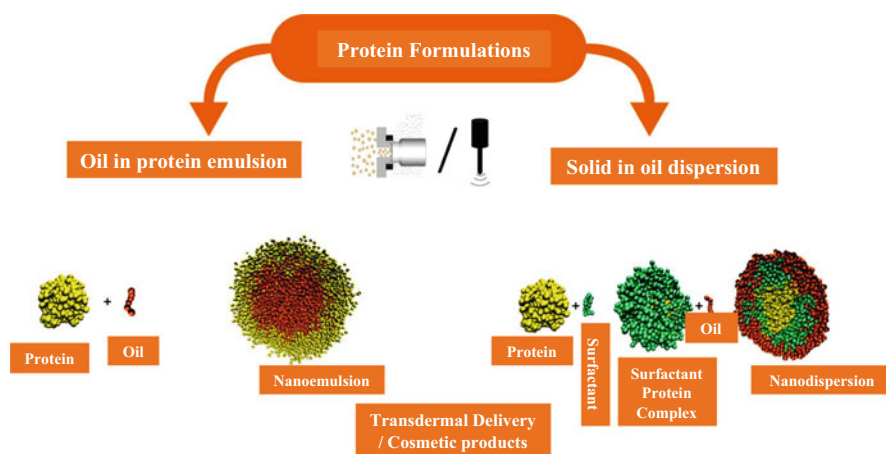

Fig. 14 Protein formulation showing microemulsion and nanoemulsion prepared by mechanical high energy methodology for cosmetic applications. (Reproduced with permission from Trends in Biotechnology)

used approaches. These protein formulations can be used for delivering the constituents through skin permeation (Ye et al. 2013). There are certain factors that impact the behavior of the protein preparations and they are particle size distribution, solubility, temperature, surface tension, ionic strength, and type of emulsifier and concentration of emulsifier. It is a very important step to select the type of emulsifier for the formation of an emulsion and the effective emulsifiers are nonionic, ionic, or mixtures of nonionic surfactants. These emulsifiers lower the interfacial tension and stabilize the emulsion against flocculation and coalescence. The concentration of emulsifiers play a crucial role in obtaining homogeneous emulsions and the protein molecules have spherical and regular surfaces and it has good mobility in the emulsion interface. The penetration into the aqueous phase leads to solvate the hydrophobic portion and it gets adsorbed at the fluid interfaces. The adsorption of proteins on the oil water interface stimulates the changes in the conformation of the structures in the protein solution (Martins et al. 2016). These changes leads to a very structures of albumin in solution. Fig. 15a shows the spheres of BSA prepared at high shear forces by the sonication method, and these high shear forces are responsible for the conformational changes in the protein at the interface of solvent and water. Figure 15b depicts the inner portion of the BSA spheres changes when the RNA is encapsulated with the BSA and it turns more hydrophilic. For the preparation of nanodispersion, sucrose and fatty acid were used as nonionic surfactants in which the hydrophobic part is the outer layer. Because of the high monoester content it forms a hydrophilic sucrose ester and the high esterification leads to lipophilic sucrose ester. The sucrose ester has the low hydrophilic-lipophilic balance (HLB), they have the higher hydrophilic part, and the HLB varies with the rate of esterification of the sucrose. The sucrose ester has a HLB value range from 0 to 20 and this low HLB value designates that they are more hydrophobic in nature (Fig. 15c). They have excellent biocompatibility, biodegradability, and low toxicity and are potentially used in cosmetic formulations (Li Zhai et al. 2013).

Serum Albumin for the Treatment of Various Skin Disorders

An invention which has the composition of serum albumin used to treat various skin disorders and it can also provide improved skin protection for the extreme climatic conditions. The amount of albumin used for treating various skin conditions depends on the specific category of the composition. Usually the concentration of albumin used ranges from 1 mg/ml to 90 mg/ml of the gel base. 20 mg/ml of recombinant serum albumin with 10–75% alcohol solution is used as sanitizing solution which is

used for treatment during postoperative incision. This albumin sanitizer is useful in providing antimicrobial protection to the skin. Another albumin preparation used for UV blocking gives sun protection and the ingredients required are serum albumin, para amino benzoic acid, titanium dioxide, zinc oxide, cinoxate, and dicamphor salicylate.

The composition contains recombinant human serum albumin of about 20 mg/ml used as freeze dried form and it is dissolved in the alcohol-gel base which contains propylene glycol, vitamin E, hydroxy ethylcellulose, and sodium hydroxide. It is used as a potential agent for the topical use as per the clinical study. The same composition is used for treating psoriasis which is studied clinically, and this albumin alcohol-based gel was applied in the skin areas. Scaling was followed by the formation of new skin and then after 3 weeks the skin became normal because the psoriasis condition has not reappeared. The same formulation is tested clinically for treating acne and the albumin alcohol gel is supplied with 40 ml tubes. The patients applied the albumin alcohol gel over the acne areas which showed improved skin conditions.

10 mg/ml of recombinant human serum albumin was added to the lotion base and studied clinically by applying this ointment topically on the hands for the treatment of dry skin. Their hands became soft, smooth texture giving a good conditioning and moisturizing of the skin without the presence of oil or greasy nature. The composition contains 10 mg/ml of recombinant human serum albumin, theobroma cocoa, almond oil, cetosteryl alcohol, vitamin E, and sodium hydroxide. 1 mg/ml recombinant human serum albumin was added to the lip balm base which contains bees wax, castor oil, lanolin, and vitamin E. When tested clinically, all of them got a protective effect over the application of lip balm in the chapped lips and found a huge improvement in their lips. This lip balm showed a long-lasting effect by moisturizing and conditioning the lips with soft supple nature (Patent 1988).

Conclusions

In conclusion, albumin has numerous cosmetic applications such as skin regeneration, transdermal delivery, skin lightening, antiaging, anti-wrinkling, antioxidant, moisturizing and conditioning, protection and treatment of dry skin, acne, psoriasis, sagging, elasticity, pigmentation, sun burns, etc. The albumin has numerous skin functions in which it retards the skin aging by various mechanisms, and it directly inhibits the catalytic action of tyrosinase, scavenging of ROS, inhibition of ROS synthesis, improves the cellular antioxidant capacity, maturation of tyrosinase and other melanocytic enzymes, and decrease in the inflammatory responses of the cells. The future studies are needed to improve the clinical efficiency of albumin and its cosmetic formulations, thereby increasing the content in the cosmetic products which in turn can be attained by improving the skin permeation through optimization process. The improved efficiency can be achieved by the combined use of active ingredients albumin derivatives along with different target components for the better treatment of skin pigmentation. During that process, the intracellular melanosome

transfers from the melanocytes to the keratinocytes. Therefore, further studies are very important to identify their analogs and its metabolites action more in clinical aspects.

Abstract

Biodegradable biopolymers have gained much attention over synthetic non-biodegradable petroleum-based polymers. Petroleum-based nonbiodegradable polymers are produced in large amounts globally, which end up in the landfill. Their accumulation in the environment can be a major threat to human health and ecology. Shifting to biodegradable polymers can reduce the waste disposal problems associated with conventional petroleum-based polymers. Various biopolymers from natural sources are highly used in many applications, including agriculture, packaging, biomedical, and environmental remediation applications, due to their biodegradability, eco-friendliness, biocompatibility, low cost, and availability. This chapter discusses the type of various biodegradable polymers in terms of classifications, mechanisms, chemical structures, and biodegradability of various biopolymers. This chapter mainly covers the natural biopolymers, including starch, cellulose, pectin, chitin, gellan gum, gelatin, polylactic acid (PLA), and polyhydroxyalkanoates (PHAs).

Keywords

Biodegradability · Biopolymers · Cellulose · Chitin · Gellan gum · Polyesters · Polysaccharides · Starch

Introduction

Petroleum-based nonbiodegradable synthetic plastics, such as polyethylene (PE), polypropylene (PP), polystyrene (PS), polyethylene terephthalate (PET), and polyvinyl chloride (PVC), are produced globally in large amounts, and only 9% have been recycled. These nondegradable conventional plastics dumped in landfills have accumulated in the environment, and the fragmentation of these plastics into microplastics (less than 5 mm) causes serious ecological and health problems (Agarwal 2020; Ahmed et al. 2018; Maraveas 2020). Microplastics found in the environment can be transported through the food chain and accumulated in plants, animals, and humans. The presence of microplastics in many food products has been reported in literatures, including shellfish, algae, sea salts, fish, drinking water, and few mentions in other foods, milk, beer, fruit, honey, tea bag, chicken, and animal food (Kwon et al. 2020; Pironti et al. 2021). Recycling of plastic waste is also not preferable due to the potential risk of leakages of toxic and synthetic chemicals, such as antioxidants, plasticizers, and stabilizers (Maraveas 2020). Furthermore, the depletion of petroleum and increasing

demand for polymers emphasize the importance of biodegradable polymers from renewable sources (Siracusa and Blanco 2020).

Therefore, there is an increasing demand for natural biodegradable polymers as a substitute for nondegradable petrochemical-based polymers to combat the adverse effect. Biopolymers have many advantages, including complete biodegradability/compostability, recyclable, eco-friendly, noncorrosive in nature, nontoxic, low cost, and abundantly available (Ramesh Kumar et al. 2020; Ray et al. 2021). Biodegradable polymers are generally classified into two groups: natural polymers and synthetic polymers (Godavitame et al. 2017). Natural polymers, including polysaccharides, proteins, etc., are derived from renewable or biological sources (plant, animal, microbial, and marine sources). Synthetic polymers, including polyesters and aliphatic polymers, are chemically derived materials from renewable resources (natural) or nonrenewable (petroleum-based) resources (Balaji et al. 2018; Ramesh Kumar et al. 2020).

Biodegradation of biopolymers undergoes fragmentation or breakdown of polymers into monomers and oligomers through the effect of enzymes and/or other factors (heat, moisture, sunlight) and then complete mineralization of fragmented compounds by the microbial activity, which produces carbon dioxide, water, ammonium, nitrogen, hydrogen, and biomass (Folino et al. 2020).

However, the use of biodegradable plastics has been limited by their higher cost, narrow processing windows, moisture sensitivity, and poor mechanical and barrier properties (Laycock et al. 2017). Generally, polymers are modified or blended with other polymers to enhance the properties of biopolymers, which would change the overall biodegradability.

The present chapter discusses the various types of biodegradable polymers, applications in various fields, mechanisms of the biodegradation process, and biodegradability of various biopolymers. This chapter mainly discusses about polysaccharides (starch, cellulose, pectin, chitin, gellan gum), protein (gluten), microbial polysaccharides (PHAs), and bio-based synthetic polymer (PLA).

Types of Biodegradable Polymers: Classification of Biodegradable Polymers

Biodegradable polymers are generally categorized into two groups: natural polymers and synthetic polymers. Natural polymers can be produced from renewable biological sources, whereas synthetic polymers can be produced from biological resources (renewable resources) or petroleum resources (nonrenewable resources) (Balaji et al. 2018; Doppalapudi et al. 2016).

Biopolymers can also be classified according to the source of raw materials and manufacturing methods (Fig. 1) (Cheng et al. 2021; Ferreira et al. 2016; Ghanbarzadeh and Almasi 2013; Nair et al. 2017).

1. Natural polymers from vegetal or animal biomass – polysaccharides (plant sources: starch, cellulose, hemicellulose, lignin, guar gum, pectin; animal

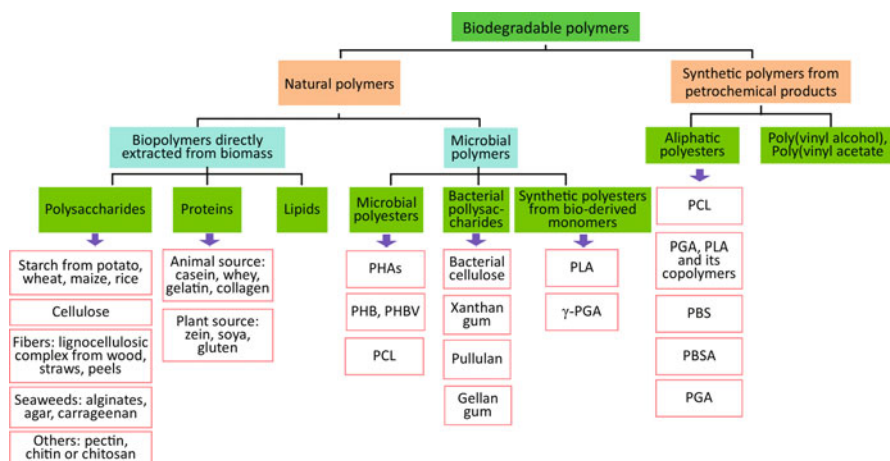

Fig. 1 Classification of biopolymers

sources: chitin and chitosan; marine sources/seaweeds: alginates, carrageenan, agar), proteins (animal sources: collagen, gelatin; plant sources: gluten, soy protein, zein), and lipids (cross-linked triglycerides)

2. Microbial polymers – polyhydroxyalkanoates (PHAs), polyhydroxybutyrates (PHB), poly(hydroxybutyrate-co-hydroxyvalerate) (PHBV), poly(γ -glutamic acid) (γ -PGA), and bacterial cellulose, cellulose, xanthan, gellan, and pullulan
3. Synthetic polymers (chemically synthesized from renewable bio-based monomers or petroleum polymers) – polyesters, such as polycaprolactone (PCL), polyglycolide (PGA), polylactic acid (PLA), and poly(glycolic acid) (PLGA); polyvinyl alcohol (PVA); poly(butylene succinate) (PBS); polybutyl succinic acid-butyl adipate (PBSA); and poly(butylene adipate-co-terephthalate) (PBAT)

Many natural and synthetic biodegradable polymers have gained much attention over the recent past decades. Natural polymers, including polysaccharides (cellulose, starch, pectin, chitosan, gellan gum, alginates, carrageenan, agar), proteins (gluten, gelatin), lipids, and polyesters (PHA, PHB, PHBV, PLA monomers) from various plant, animal, and microbial sources, as well as synthetic polymers, including PLA, PVA, PCL, PBSA, and PBAT, have been widely used to construct many biodegradable materials (Cheng et al. 2021; Ruggero et al. 2020; Udayakumar et al. 2021). Petroleum-based polymers, including PCL and PBS, can also be synthesized by microorganisms (Nair et al. 2017).

Applications of Biodegradable Polymers

Biodegradable polymers have a wide range of potential applications in various fields, including food packaging, agriculture, environmental remediation, and bio-medical (Mohapatra et al. 2017).

Environmental Remediation

Due to the rapid growth in industrialization, various contaminants, such as heavy metals (Ni^{2+} , Cu^{2+} , Co^{2+} , Cd^{2+} , Cr^{6+} , As, Hg, etc.), pesticides, herbicides, fertilizers, oil spills, industrial effluents, sewage, organic pollutants (aliphatic and aromatic hydrocarbons, pharmaceuticals, volatile organic compounds), toxic gases (CO , SO_2 , NO_x), particulate matter, and microbes, have polluted the environment, consequently affecting human health (Briffa et al. 2020; Guerra et al. 2018).

Various biopolymers, including cellulose, lignin, starch, chitosan, alginates, gelatin, guar gum, and their composite films, are used as adsorbents, membrane-filtration, coagulants, and flocculants to remediate the environment (Udayakumar et al. 2021). Nanomaterials such as inorganic (metal and metal oxides, such as Ag, TiO_2 , zerovalent iron NPs [nZVI], etc.), carbon-based (carbon nanotubes [CNTs], graphene), and polymeric-based materials have been used to remove various contaminants from the environment (Guerra et al. 2018).

Chitosan can be used as a flocculent, coagulant, and adsorbent to remove the contaminants, such as heavy metals (Ni, Cr, Zn, Cu, As, Cd, Pb, etc.), dyes, antibiotics, biological contaminants, herbicides, pesticides, and pathogenic microbes, from wastewater and soil (Pal et al. 2021).

A wide variety of biopolymer nanocomposites with a high adsorption capacity, made by incorporation of clay into polymers, including starch, cellulose, alginate, chitosan, gelatin, collagen, and PLA, has been used in the removal of heavy metals, reactive dyes, pesticides, and bisphenol A (BPA) in water and in soil remediation (del Mar Orta et al. 2020).

The incorporation of fillers or reinforcements from natural sources improves the mechanical and thermal properties of starch polymers. Thermoplastic starch incorporated with filler kraft lignin showed improved mechanical and thermal properties of the starch polymer. Furthermore, the presence of kraft lignin polymer was reported to slow down the biodegradation process of thermoplastic starch, which ensures the stability of the polymer. Thermoplastic starch/kraft lignin film can be a suitable material for the removal of methyl orange in wastewater by absorption (de Freitas et al. 2021).

Water streams polluted by dyes affect the availability of safe drinking water. Water contaminated with dye can be a threat to human health due to its long-lasting and resilient properties. Cellulose, chitosan, starch, hemicellulose, and lignin have been reported for their potential to be used as dye adsorbents to remediate industrial dye effluents and contaminated water bodies (Bhatia et al. 2021; Dassanayake et al. 2021). Biopolymers, such as chitosan and alginates, and their blends, in bulk or in nanoparticle (NP) form, can be used to remove heavy metals (As^{5+} , Au^{3+} , Cr^{6+} , Pb^{2+} , Cu^{2+} , Mo^{5+} , etc.) from contaminated water and soil (Almutairi et al. 2021). Chitosan and alginate NPs with *S. linifolium* extract-phycosynthesized Fe NPs exhibited high efficiency as adsorbents for the removal of Cr^{6+} from contaminated water (Almutairi et al. 2021).

Biopolymers, such as chitosan, cellulose, alginate, and many others, incorporated with ZnO nanofillers can be used as bio-adsorbents or photocatalysts for water remediation (Mallakpour et al. 2021).

Relatively high content of different functional groups in lignin, such as aliphatic carboxyl and hydroxyl groups, can act as adsorption sites for dye molecules, including Safranin O, Basic Red 2, methylene blue, Remazol red, Congo red, methyl orange, and many others, through forces, such as electrostatic interactions, dipole-dipole interaction, polar bonds, hydrogen bonds, and π interaction (Bhatia et al. 2021).

Packaging Materials

Biodegradable polymers and their composites incorporated with nanoparticles or other additives (e.g., essential oils, plant extracts) are widely used in food packaging with various functions, including edible packaging film/coating and active (antimicrobial, antioxidant) and intelligent packaging.

Biodegradable bio-nanocomposite film produced from gellan and xanthan gum incorporated with ZnO NPs was shown to improve the mechanical, water vapor and UV barrier, hydrophobicity, and antimicrobial properties against pathogenic bacteria *S. aureus* or *E. coli* (Rukmanikrishnan et al. 2020).

Multilayer antimicrobial film was prepared from gellan gum and chitosan incorporated with thyme essential oil coarse emulsion or nanoemulsion. In comparison with the coarse emulsion, nanoemulsion of thyme essential oil was shown to increase the mechanical flexibility (elongation at break) and UV blocking, as well as the antimicrobial (against *E. coli*) properties of the developed antimicrobial film (Zhang et al. 2021).

The application of natural fibers from hemp and flax fibers as fillers in PHBV was shown to improve mechanical properties. In contrast, wood fibers had no significant effect on PHBV composite (Frącz et al. 2021).

Coffee and rice husk are good sources of cellulosic materials, which were reported in the range of 34–35%. Cellulose fibers and cellulose nanocrystals from coffee and rice are the potential sources of cellulosic reinforcing material which can be used in many applications including food packaging (Collazo-Bigliardi et al. 2018). Brown rice starch-based chitosan film can be a suitable candidate for sustainable food packaging (Hasan et al. 2020).

Films developed using gliadin-rich fractions showed higher transparency and disintegrated when immersed in water and, thus, can be used for edible packaging material. In contrast, the glutenin-rich film had higher tensile strength and water barrier properties, which can be used for packaging of low- and intermediate-water activity foods (Hernández-Muñoz et al. 2003).

Gellan gum-based film was developed with 2-hydroxyethyl cellulose (HEC) and lignin to study the effect of lignin incorporation on the properties of gellan gum film. The incorporation of lignin at 10% considerably improved the tensile strength, elongation at break, contact angle (or surface hydrophobicity), and water vapor permeability properties of the gellan gum/lignin and gellan gum/HEC/lignin-based composite film. Moreover, the incorporation of lignin in gellan gum exhibited high ultraviolet (UV) protection, excellent radical scavenging activities, and non-cytotoxicity (Rukmanikrishnan et al. 2020).

Shen et al. (2022) studied the effect of the incorporation of lipids, such as paraffin wax, beeswax, paraffin oil, and oleic acid, on improving the water resistance of wheat bran cellulose/wheat gluten composite biodegradable film. Incorporation of paraffin wax, beeswax, and paraffin oil at 5–20% was reported to increase water vapor permeability and surface hydrophobicity. In contrast, oleic acid addition was shown to reduce the moisture barrier properties.

Functional ingredients, such as plasticizers and emulsifiers, can be incorporated into the pectin matrix to improve the properties of pectin-based edible films, where plasticizers improve the mechanical properties of pectin and emulsifiers increase stability and adhesion (Espitia et al. 2014).

Chitosan incorporated with apple peel polyphenols at 0.05% exhibited good water barrier, mechanical, antioxidant, and antimicrobial properties, thus having the potential to be used in antimicrobial active food packaging (Riaz et al. 2018).

Adding bio-nanocomposite of Roselle calyx extract (RE) and ZnO NP to chitosan/guar gum film improves the tensile strength and elongation at break and the barrier, antioxidant, antimicrobial, and sensory properties. Therefore, these antimicrobial and antioxidant films by chitosan/guar gum/RE-ZnO bio-nanocomposite can be used to coat Ras cheese for preservation (El-Sayed et al. 2020).

The addition of ZnO nanoparticles in gellan gum/polyacrylamide film improved mechanical, thermal, and barrier (UV and water vapor) properties as well as decreased hydrophilicity. This film also exhibited antimicrobial properties against pathogenic bacteria, including *Bacillus cereus*, *Staphylococcus aureus*, *Cronobacter sakazakii*, *Escherichia coli*, *Salmonella enterica*, and *Salmonella typhimurium* (Balasubramanian et al. 2021).

Paper is a biodegradable, highly recyclable, and compostable material and has been used in many primary and secondary packaging. The porous structure and hydrophilicity of paper material result in low barrier properties for moisture, gases, and aromas, thereby limiting its application in food packaging (Lo Faro et al. 2021). Paper materials are generally coated with PE to improve the barrier properties, which makes them difficult in recyclability and biodegradability. Biopolymers, such as PHBV and PCL, can be used as paper coating material (Lo Faro et al. 2021).

Agriculture

Biodegradable polymers are also highly utilized in agricultural applications, mainly mulching films and plant pots. Mulching films help to increase the crop's yield and quality, improve weed control, and reduce the requirement for water irrigation and pesticides in modern agriculture (Havstad 2020). Various biodegradable biopolymers, including starch, PBAT, PLA, PBS, and their blends, can be used in the production of biodegradable mulching films (Havstad 2020; Serrano-Ruiz et al. 2021).

Plant tissue culture technology, gellan gum, and agar are commonly used gelling agents in culture media. The type and concentration of gelling agents can affect the physical and chemical characteristics of the tissue culture media. The study on the effect of various gelling agents, such as gellan gum and agar, on three different

stages of rice regeneration revealed that medium solidified with gellan gum was most favorable for callus induction and higher root regeneration over agar medium, while shoot regeneration was not affected by the type of different gelling agents (Mohamed et al. 2021).

Biomedical Applications

Many natural and synthetic biopolymers have significant applications in the field of biomedicine, including controlled drug delivery, wound healing, tissue engineering, and organ substitution (Bhatia 2016; Song et al. 2018). Biodegradable polymers derived from natural sources are highly used in biomaterials due to their biocompatibility, low immunological response, low cytotoxicity, nontoxic by-products, and ability to support cell adhesion, proliferation, and regeneration of new tissues. Moreover, degraded products should be nontoxic, easily metabolizable, and excreted from the human body. Various natural polymers, polysaccharides (hyaluronic acid, chitosan), and proteins (collagen, collagen, gelatin, fibrin, elastin, chitosan, hyaluronic acid, and polypeptides) have been utilized to construct scaffolds in tissue engineering (Klimek and Ginalska 2020; Song et al. 2018; Xue et al. 2021). Fibrin and collagen are frequently used as cartilage and other orthopedic repair materials in tissue engineering. The combination of chitosan and alginate in wound dressings. Furthermore, PHA (microbial polyesters), PLA, PGA, and PLGA co-polymers are the most commonly used synthetic polymers in tissue engineering (Bhatia 2016). These synthetic polymers are widely used in various surgical procedures, wound closure (sutures, staples), and orthopedic fixation devices (ligaments, pins, rods, screws, tacks) (Velu et al. 2021). Natural and synthetic polymers, including chitosan, alginates, gelatin, hyaluronic acid, polyester-based polymers (PLA, PGA, and their co-polymer PLGA), and PCL, have also been extensively used in the applications of drug delivery (Jana et al. 2021).

Low-acyl gellan beads were studied for their potential to be used as carriers for oral delivery of meloxicam in the treatment of colorectal cancer. Low-acyl gellan beads showed pH-dependent behavior in swelling and degradation. At low pH, protonation of COO^- groups in low-acyl gellan results in the suppression of electrostatic repulsion between chain and stabilization of gel and vice versa at high pH. Thus, low-acyl gellan beads can be used as carriers for oral delivery of meloxicam, which is intended to release in the distal parts of the gastrointestinal tract by omitting the stomach (Osmalek et al. 2017).

Table 1 shows the applications of various biodegradable polymers.

Mechanisms of Biodegradability

The “biodegradation process” is defined as the decomposition of materials into CO_2 , CH_4 , H_2O , inorganic compounds, or biomass (del Rosario Salazar-Sánchez et al. 2019). Biodegradable plastics can degrade via various mechanisms. Some

Table 1 Different biodegradable polymers in various applications

Polymer	Applications	Characteristics	References
Starch from corn, wheat, rice, and potato/glycerol	Thermoplastic starch film for food packaging	Maximum tensile strength (4.48–8.14 MPa), Young's modulus (116.42–294.98 MPa), elongation at break (35.41–100.34%), water solubility (27.88–32.57%)	Domene-López et al. (2019)
Tapioca starch/glycerol/polyvinyl alcohol (PVA) liquid/glycerol/bamboo fibers	Reinforcement in tapioca starch to improve the mechanical properties	Tapioca starch with chemical treated or untreated bamboo fibers: tensile strength (1.6–4.0 MPa), tensile modulus (61.4–282.6 MPa)	Yusof et al. (2019)
Lignin-based nano-adsorbents	Water treatment	Adsorption of dye, such as Safranin O, Basic Red 2, methylene blue, Remazol red, Congo red, and methyl orange	Bhatia et al. (2021)
Corn starch/cellulose fillers (cellulose fibers or cellulose nanocrystals from coffee and rice)	Potential cellulosic reinforcing material for food packaging	Cellulose nanocrystals from rice (186%) and coffee husks (121%) improved the elastic modulus of thermoplastic corn starch films Tensile behavior such as elastic modulus, tensile strength, and percentage deformation at break of corn starch films, containing or not cellulosic reinforcing agents, was 258–740 MPa, 8.1–13.0 MPa, and 1.9–13.4%, respectively	Collazo-Bigliardi et al. (2018)
Date palm leaf fibers/PVA/corn starch	Food packaging	Addition of fiber (30 wt %) to the composite film increases the tensile, flexural, and impact strength	Ray et al. (2021)
Brown rice starch/chitosan plasticized by palm oil	Food packaging	9.3–15 MPa tensile strength	Hasan et al. (2020)
Gliadin-rich and glutenin-rich fractions of wheat gluten	Food packaging: edible coating and nonedible film	Glutenin-rich films: higher tensile strength, less extensible, low water	Hernández-Muñoz et al. (2003)

(continued)

Table 1 (continued)

Polymer	Applications	Characteristics	References
		vapor permeability – suitable for nonedible packaging films for low- and intermediate-water activity foods Gliadin-rich films: higher transparency, disintegrated in water, lower tensile strength – suitable for edible coatings	
Wheat gluten/xylans	Biodegradable composite film	Xylan can be used as an additive up to 40% (w/w) in wheat gluten films Mechanical and solubility properties are influenced by wheat gluten/xylan ratio, xylan type, drying conditions, and pH	Kayserilioğlu et al. (2003)
Wheat bran cellulose/ wheat gluten film incorporated with lipids	Hydrophobic biodegradable food packaging	Composite film containing 15% bee wax had the lowest water vapor permeability (0.76×10^{-12} g/cm ² ·s·Pa) and acceptable mechanical properties	Shen et al. (2022)
Whole potato flour/ whey protein isolates or bovine gelatin or chicken gelatin	Biodegradable, edible bioplastic materials	Increased the tensile strength (4.43–5.67 MPa), tensile modulus (97.98–127.65 MPa) and elongation (5.63–20.50%)	Omrani-Fard et al. (2020)
Gellan gum (G)/2-hydroxyethyl cellulose (HEC)/lignin (L)	Food packaging applications	Tensile strength (35.5 and 39 MPa), elongation at break (26.1 and 32.5%), contact angle (57.8 ° and 70 °), water vapor permeability (2.40 and 2.18×10^{-9} gm/m ² ·Pas) in G/L- and G/HEC/L-based composite film (L 10 wt %), respectively Also enhance the UV barrier and radical scavenging activities, with a non-cytotoxicity effect	Rukmanikrishnan et al. (2020)

(continued)

Table 1 (continued)

Polymer	Applications	Characteristics	References
Gellan gum-treated sand	Effective removal of Ni^{2+} from contaminated water	Gellan gum (1%) increased the Ni^{2+} adsorption of sand by 150% or greater	Tran et al. (2021)
Gellan/xanthan gum/ZnO NPs	Food, pharmaceutical packaging applications	Incorporation of ZnO NPs increased the tensile strength (22.1–35.5 MPa), thermal stability (82.5–96.2 °C), glass transition temperature (69.9–74.8 °C), contact angle (54.1–60.8 °), and UV barrier and decreased water vapor permeability ($3.83\text{--}2.31 \times 10^{-9}$ g/m ² Pas). Antibacterial activity against <i>S. aureus</i> or <i>E. coli</i>	Rukmanikrishnan et al. (2020)
Chitosan/apple peel polyphenols (APP)	Antimicrobial active food packaging	CS/APP film with 0.25–1.00% APP exhibited good water barrier (14.65–10.01 g·m ⁻¹ s ⁻¹ Pa ⁻¹), antioxidant, and antimicrobial activity against <i>E. coli</i> , <i>B. cereus</i> , <i>S. aureus</i> , and <i>S. typhimurium</i> . In contrast addition of APP decreases the tensile strength	Riaz et al. (2018)
Chitosan/guar gum/Roselle calyx extract and ZnO NP bio-nanocomposites	Antimicrobial film for Ras cheese	Improved mechanical properties and water vapor and oxygen barrier properties. Higher antioxidant and antimicrobial activities against <i>Escherichia coli</i> , <i>Listeria monocytogenes</i> , <i>Aspergillus terries</i> , <i>Aspergillus flavus</i> , <i>Salmonella typhimurium</i> . No significant changes in pH and acidity; enhance the shelf life of Ras cheese coated with developed film	El-Sayed et al. (2020)

(continued)

Table 1 (continued)

Polymer	Applications	Characteristics	References
Gellan gum/polyacrylamide/ ZnO NP	Food packaging	The addition of ZnO nanoparticles increased the glass transition temperature (from 181.8 to 196.3 °C), thermal stability (87.8–96.5 °C), tensile strength (33.5–43.8 MPa), elongation break (24.6–32.8%), contact angle (58–65.6 °), and UV blocking properties (99.2% protection against UVB) and reduced the water vapor permeability ($2.2\text{--}1.6 \times 10^{-9} \text{ gm/m}^2\text{Pas}$) Improved antimicrobial properties against <i>Bacillus cereus</i> , <i>Staphylococcus aureus</i> , <i>Cronobacter sakazakii</i> , <i>Escherichia coli</i> , <i>Salmonella enterica</i> , and <i>Salmonella typhimurium</i>	Balasubramanian et al. (2021)
Low-acyl gellan beads/ meloxicam/Tween®80	Targeted drug delivery	Showed the pH-dependent behavior in swelling and degradation Potential carriers for oral delivery of colon-targeted meloxicam in the treatment of colorectal cancer	Osmalek et al. (2017)
Gellan gum/chitosan/ thyme essential oil coarse emulsion or nano-emulsion (TEON)	Multilayer antimicrobial film for food packaging	In comparison, nano-emulsion of thyme essential oil improved the elongation at break (14.05%) and UV blocking, as well as the antimicrobial properties against <i>E. coli</i> . In contrast, it decreased their water vapor barrier properties and tensile strength	Zhang et al. (2021)
Gellan gum/heat-treated soy protein isolate/ Clitoria ternatea extract	Active and intelligent packaging film seafood freshness	Incorporation of heat-treated soy protein isolates significantly changes hydrophobicity,	Wu et al. (2021)

(continued)

Table 1 (continued)

Polymer	Applications	Characteristics	References
		water vapor permeability, tensile strength, and swelling capacity Antioxidant and antibacterial properties, freshness indicator of seafood based on pH-sensitive color change of anthocyanin	
PHBV/hemp, wood, and flax fibers		Natural hemp fibers in PHBV increased Young's modulus (about 167% increase), tensile strength value (about 21%), and tensile strength (about 62%)	Frącz et al. (2021)
Paper/PCL or PHBV/polyethylene glycol (plasticizer)	Cellulose-based food contact materials/paper coating	In PCL- and PHBV-coated paper: increased water barrier than uncoated and fluorinated paper PCL showed higher grease resistance than uncoated paper	Lo Faro et al. (2021)
Chitosan/alginate NPs Chitosan/alginate/Fe NPs	Removal of Cr^{6+} from aqueous environments	Both were good adsorbents for Cr^{6+}	Almutairi et al. (2021)

biodegradable polymers, including polysaccharides and polyesters (PHAs), can be directly biodegraded by microbes (enzymatic degradation), whereas others are aided and enhanced by natural factors, such as UV, oxygen, and heat (Folino et al. 2020).

Biodegradation of polymers mainly involves chain cleavage, called depolymerization, through enzymatic and nonenzymatic hydrolysis. Depolymerization of polymer produces water-soluble low molecular weight oligomers, dimers, and monomers, which are then assimilated by microorganisms into biomass or mineralized to CO_2 , H_2O , CH_4 , inorganic compounds, and other metabolic products (Ahmed et al. 2018; Laycock et al. 2017). Biodegradation reactions involve both aerobic (produces CO_2 and H_2O) and anaerobic mechanisms (produces CH_4 and CO_2) (Ahmed et al. 2018; del Rosario Salazar-Sánchez et al. 2019).

Moreover, biodegradation occurs by two mechanisms: surface and bulk erosion. Surface erosion, a faster method, occurs by decreasing the thickness of the material when the surface hydrolysis rate is greater than the diffusion rate of water into the polymer. Since enzymes are larger particles than other catalysts like chemicals and free radicals, it is difficult to penetrate the bulk polymers. Thus, enzymatic degradation involves a surface erosion mechanism. Bulk erosion takes place when the water diffusion rate exceeds the rate of the hydrolysis reaction. The typical

Fig. 2 Schematic diagram for the mechanism of biodegradation

mechanism in polyesters, such as PCL, PGA, and PLA, is bulk degradation. Factors including the chemical nature of the chain, molecular weight, distribution, and crystallinity influence the biodegradation mechanism (Brdlik et al. 2022; Haider et al. 2019; Laycock et al. 2017). Degradation of polymers can occur alone or in combination of surface and bulk erosion mechanisms. Figure 2 illustrates the basic schematic diagram for the mechanism of biodegradation.

Some of the hydrolytic enzymes that are involved in polymer hydrolysis are amylolytic enzymes such as α -amylase and lysozyme (hydrolysis of starch and chitin, respectively), lipase (hydrolysis of ester bonds and aliphatic and aromatic polyesters [PHAs, PCL, PLA, and a PET]), PHA depolymerase (hydrolysis of PHAs), pronase, proteinase K, bromelain (hydrolysis of α -ester bonds such as in PLA), and β -glucosidases (conversion of cellobiose into glucose) (Laycock et al. 2017).

Various blends and composites of biopolymers have been used over the last two decades to counteract the weaknesses of pure polymers, such as rapid degradation rate, poor mechanical and barrier properties, and moisture sensitivity (Jiang et al. 2020; Rosseto et al. 2019). However, the biodegradation rate varies based on the composition of the blend and the compatibilizer added (Dammak et al. 2020). Furthermore, the biodegradability of a material depends on the polymer characteristics (molecular weight, size and shape, crystallinity, surface properties, type of functional groups, additives, biosurfactants) and the environmental or exposure conditions, such as type of microorganisms, enzyme characteristics, nature of pre-treatment, UV radiation, oxygen content, humidity, moisture content, temperature, and pH under which the degradation occurs (Ahmed et al. 2018; Folino et al. 2020; Ruggero et al. 2020).

Biodegradability can be evaluated by various methods depending on the conditions of the test system, measuring weight reduction, CO_2/CH_4 /biogas production, O_2 consumption (biological oxygen demand [BOD] or the ratio of BOD/ThOD [theoretical oxygen demand]), disintegration (loss of visibility in the final compost), loss of mechanical properties, surface erosion, observing surface morphological

changes using microscopic techniques, and reduction of molecular weight using spectroscopy (Folino et al. 2020; Ruggero et al. 2020).

Biodegradation of Biopolymers

Polysaccharides

Various polysaccharides from different sources, such as plants (guar gum and gum acacia), animals (chitosan), microorganisms (xanthan gum), and seaweeds (alginate), are used to prepare hydrogels for various food and nonfood applications (Das and Giri 2020). Cellulose and starch are the primary polysaccharides in the applications of various materials. Other than these, more complex polysaccharide-based polymers, including xanthan, curdlan, pullulan, and hyaluronic acid, produced by bacteria and fungi, also have drawn increasing attention nowadays (Ghanbarzadeh and Almasi 2013).

Starch-Based Biopolymers

Cellulose and starch are the main polysaccharides highly used in many applications. Starch is a hydrocolloid biopolymer, and it is the cheapest and abundantly available polysaccharide (Vroman and Tighzert 2009). Starch is a heterogeneous polysaccharide-based polymer that is composed of two types of molecules: amylose and amylopectin. Amylose is a linear, crystalline polysaccharide made up of α -1,4-D-glucopyranose units, whereas amylopectin is a branched and amorphous polymer made up of short chains of α -1,4-D-glucose units linked by α -1,6 glycosidic bonds (Fig. 3) (Jiang et al. 2020; Olatunji 2016; Vroman and Tighzert 2009).

Starch is a storage carbohydrate synthesized in both lower and higher plants and stored in leaves, roots, tubers, and seeds. Typically, starch is accumulated as water-

Fig. 3 Chemical structure of starch molecules: (a) amylose and (b) amylopectin

insoluble particles known as starch granules. The internal structure of the starch granules is conserved between organs and species. The molecular weight of amylopectin is higher (10^6 – 10^8 gmol^{-1}) than the amylose molecules (10^5 – 10^6 gmol^{-1}). Amylopectin is the most abundant polysaccharide, accounting for 70–80%, which varies with plant species and organs (Balaji et al. 2018; Compart et al. 2021; Ghanbarzadeh and Almasi 2013).

Though starch is generally insoluble in water and alcohol, it can be irreversibly dissolved in the presence of heat through a process called gelatinization (Olatunji 2016). Thermoplastic starch (TPS) is a gelatinized starch-based material used in many applications (Jiang et al. 2020). The gelatinization process involves granular swelling, destruction of crystalline structure, partial separation of amylose and amylopectin, and molecular solubilization at high temperatures (Jiang et al. 2020). Gelatinized starch can recrystallize or retrograde at low temperatures (Vroman and Tighzert 2009).

Starch can be extracted from various plant sources, mainly from maize, corn, wheat, potato, cassava, barely, and rice (Balaji et al. 2018; Domene-López et al. 2019). Starch has been used in adhesives, paper, clothing, cosmetic creams, food thickener, packaging, and environmental remediation (Mallakpour et al. 2021; Olatunji 2016).

As shown in Fig. 4, biodegradation of starch takes place through hydrolysis at the α -1,4 and α -1,6 acetal link by enzymes and yields nontoxic products. Amylases hydrolyze the α -1,4 link, while glucosidases hydrolyze the α -1,6 link. Chemical modification of starch, such as acetylation and plasticization (substitution of hydroxyl groups) or blending with other molecules, may influence biodegradability (Nevoralová et al. 2019; Vroman and Tighzert 2009). Amylopectin degrades faster than amylose due to the branched structure (Olatunji 2016).

Cellulose-Based Biopolymers

Cellulose, $(\text{C}_6\text{H}_{10}\text{O}_5)_n$, is the main component of the plant cell wall, which has rigid nature and is the most abundant polymer globally (Olatunji 2016). Cellulose is a linear homopolymer of β -D-glucopyranose linked by β -(1,4) glycosidic linkages (Fig. 5). The number of repeating units in a cellulose chain varies with the origins: about 10,000 units in wood while 15,000 in cotton (Rosseto et al. 2019).

Modified cellulose by physical and chemical methods is used in many applications, such as fillers, coating films, laminates, papers, packaging, textiles, optical films, sorption media, viscosity regulators, and building materials, as well as advanced functional materials (Heinze 2016; Motaung and Liganiso 2018).

Fig. 4 Hydrolysis of starch

Fig. 5 Chemical structure of cellulose

Cellulose chains stack parallelly via intra- or intermolecular hydrogen bonding and aggregate into microfibrils (5–50 nm in diameter and several microns in length). Arrangements of cellulose chains form two regions in microfibrils: (1) highly ordered (crystalline) and (2) less ordered (amorphous) regions. These microfibrils are further aggregated to form cellulose fibers (Moon et al. 2011; Shahabi-Ghahfarrokhi et al. 2020).

Cellulose is a highly crystalline structure and high molecular weight polymer and possesses distinct properties, including high tensile strength and insolubility in most solvents. Due to the infusibility and insolubility, cellulose is generally modified into various derivatives to improve its processability. The most widely used cellulose derivatives are ethers, methylcellulose (MC), hydroxypropyl methyl cellulose (HPMC), and ester carboxymethyl cellulose (CMC) (Shahabi-Ghahfarrokhi et al. 2020; Vroman and Tighzert 2009).

Wood, cotton, straw, coffee husks, rice husks, bamboo pulp, stalks, pineapple leaf fiber, coconut husk, mango seeds, banana peels, flax, hemp, and many other materials are good sources of cellulose (Collazo-Bigliardi et al. 2018; Olatunji 2016). Plant or vegetal cellulose is generally accompanied by hemicellulose, lignin, and other molecules. Apart from these plant sources, cellulose can be produced by seaweed, fungi, and some species of bacteria, genera *Gluconacetobacter*, *Agrobacterium*, *Pseudomonas*, *Rhizobium*, and *Sarcina*, and notably by the species of *Komagataeibacter* spp. (formerly *Acetobacter* and *Gluconacetobacter*). Bacterial cellulose is an extracellular polymer, although it is chemically equivalent to plant cellulose, found in pure form, that is free of by-products such as lignin, pectin, hemicellulose, and other lignocellulosic compounds. Bacterial cellulose has a high degree of polymerization and a highly crystalline structure. The high purity of bacterial cellulose enables its direct utilization with minimal processing in biomedical and other applications, such as drug delivery systems, wound dressings, surgical materials, scaffolds, and tissue/organ regeneration (Heinze 2016; Swingler et al. 2021). Both vegetal and bacterial cellulose is widely exploited for various applications, including food, paper, packaging, biomedical, and environmental remediation (Collazo-Bigliardi et al. 2018; Olatunji 2016; Swingler et al. 2021).

Pectin

Pectin is a gel-forming polysaccharide found in the plant cell wall at a higher level (up to 30%). Pectin is a heteropolysaccharide, mainly, at least 65%, comprising galacturonic acids linked at the O-1 and O-4 positions. Three major pectic polysaccharides have been identified: homogalacturonan, rhamnogalacturonan I, and

rhamnogalacturonan II. About 65% of pectin is homogalacturonan, having a linear homopolymer of α -1,4-linked galacturonic acids, in which some carboxyl groups are esterified with methanol at C-6 and/or acetyl groups at C-2 and/or C-3 hydroxyl group (Fig. 6). About 20–35% of pectin is rhamnogalacturonan I, which contains repeating units of α -D-1,4-galacturonic acids and α -L-1,2-rhamnose in the backbone. The side chains of arabinans, galactans, or arabinogalactans are attached at C-4 of the rhamnose residues. Rhamnogalacturonan II is the most structurally complex pectic polysaccharide that makes up about 10% of pectin, which consists backbone of galacturonic acids with complex side chains attached at C-2 and C-3. These side chains may consist of arabinose, galactose, apiose, fucose, rhamnose, acetic acid, glucuronic acid, galacturonic acid, and xylose. It is assumed that all these three pectic polysaccharides are covalently cross-linked as they are difficult to separate without using chain-cleavage agents such as enzymes and chemical treatments (Wusigale et al. 2020; Zdunek et al. 2021) (Fig. 7).

Fig. 6 Chemical structure of pectin

Fig. 8 Mechanism of pectin gelation: (a) LMP (egg-box model) and (b) HMP. 1, hydrophobic interactions; 2, the hydrogen bond between hydroxy groups; 3, the hydrogen bond between carboxylic acid groups

Galacturonic acids and rhamnose are the backbones of each major pectic polysaccharide. DE, acetyl esterification, and molecular weight of pectin vary with the source and extraction methods. Some galacturonic acids are partially esterified with methanol at the C-6 carboxyl group and occasionally with acetyl groups at C-2 or C-3 hydroxyls (Fig. 8). Degree of esterification (DE) is the percentage of carboxyl group esterified with methanol, i.e., methyl-esterified galacturonic acid units. Pectin can be categorized into two types based on the DE: high methoxyl pectin (HMP) (DE > 50%, that is, more than half of the carboxyl groups are esterified) and low methoxyl pectin (LMP) (DE < 50%) (Martău et al. 2019; Rubio-Senent et al. 2015; Shahabi-Ghahfarrokhi et al. 2020).

DE has significantly influenced the solubility, gelling, and film-forming properties of pectin. HMP gelation occurs in conditions of reduced electrostatic repulsions and water activity. HMP forms a thermally reversible gel in the presence of co-solutes such as sucrose or glucose at acidic pH. In HMP, the cross-linking of two pectin chains involves a combination of hydrogen bonds and hydrophobic interactions between the methyl esters. Sugars reduce water activity due to their hydrophilicity, thus promoting hydrophobic interactions between pectin macromolecules. On the other hand, LMP gel formation is independent of pH and sugar conditions. LMP forms a thermally

irreversible gel in the presence of cations (Ca^{2+}), which act as a bridge between two carboxyl groups of different adjacent pectin chains via electrostatic interactions. This mechanism is known as the egg box model, similar to the alginates gel (Basu et al. 2017; Espitia et al. 2014; Ishwarya and Nisha 2022).

Pectin is the most extensively studied polysaccharide, mainly obtained from citrus peel, apple pomace, and sugar beet (Zdunek et al. 2021). Furthermore, pectin can be extracted from food industry by-products, such as fruit and vegetable pomaces, coffee pulp, olive oil by-products, and many others (Martău et al. 2019; Reichembach and de Oliveira Petkowicz 2020; Rubio-Senent et al. 2015).

Pectin hydrogels are widely used in the applications of food ingredients/additives, food packaging, biomedical, controlled bioactive delivery, health management, and many other applications (Ishwarya and Nisha 2022).

Chitin

Chitin is a structural polysaccharide, naturally found in the exoskeleton of insects and mollusks, the shell of crustaceans (shrimp, crab, and lobster), and the cell wall of fungi, mainly in the classes of Basidiomycetes, Ascomycetes, Zygomycetes, and Deuteromycetes. Chitin is also a highly hydrophobic linear polysaccharide of animal origin (Abo Elsoud and El Kady 2019; Olatunji 2016).

After cellulose, chitin is the second most abundant biopolymer in nature. The chemical structure of chitin and chitosan is similar to that of cellulose. The hydroxyl group at C-2 of cellulose monomer, β -(1-4) linked D-glucose, has been replaced with the acetamide group in chitin and chitosan. Chitin is a linear nitrogenous polysaccharide consisting of β -(1,4)-linked-N-acetyl-D-glucosamine (N-GlcNAc) monomers. Chitosan is the derivative of chitin. Chitosan is a linear biopolymer of β -(1-4)-linked-D-glucosamine (GlcN) units. Chitosan is the modified form of chitin, which is obtained from partial alkaline N-deacetylation (Figs. 9 and 10) (Abo Elsoud and El Kady 2019; Gonil and Sajomsang 2012; Martău et al. 2019).

Chitosan is a natural, water-soluble derivative of chitin. Chitosan, a deacetylated form of chitin, can be obtained from chitin by deacetylation through alkaline hydrolysis. Chitin and chitosan can be differentiated by the degree of acetylation (or degree of N-deacetylation). In general, a polymer having a degree of acetylation above 50%, containing more than 50% of N-acetyl-D-glucosamine units, is called as chitin. The polymer with less than 50% N-acetyl-D-glucosamine units, a degree of acetylation less than 50%, is referred to as chitosan. Commercially available chitosan is composed of homopolymers containing various fractions of N-acetyl-D-glucosamine and D-glucosamine residues and has a degree of N-deacetylation between 70 and 100% (Gonil and Sajomsang 2012; Rosseto et al. 2019). Moreover, hydrolysis of chitin under severe conditions, such as of HCl or chitosanase enzymes, breaks the β -(1-4) glycosidic linkages (depolymerization) and produces low molecular weight oligosaccharides. Repeated hydrolysis with HCl (Francis et al. 2021; Martău et al. 2019). Repeated acid hydrolysis transforms the chitin into chitin nanoparticles (Elsabee et al. 2020).

Commercially, chitin is obtained from shellfish sources such as crabs and shrimp (Gonil and Sajomsang 2012). Marine wastes, such as by-products of seafood processing skin, head, tails, shells, scales, and spine, are potential materials for

Fig. 9 Chemical structure of (a) chitin and (b) chitosan

Fig. 10 Chemical preparation of chitosan from chitin

extracting chitin and chitosan. Chitin, chitosan, and their derivatives are used in a wide range of applications, including food, food packaging, biomedicine, pharmaceuticals, cosmetics, agriculture, personal care products, textiles, and the environmental sector (Elsabee et al. 2020; Rosseto et al. 2019).

Gellan Gum

Gellan gum is a linear, anionic water-soluble exopolysaccharide secreted by the bacterium *Sphingomonas elodea* (previously known as *Pseudomonas elodea* or *Aeromonas elodea*). Gellan gum is a high molecular weight (around 5×10^5 Da) compound, which is composed of linear tetrasaccharide repeating units of β -1,3-D-glucose, β -1,4-D-glucuronic acid, and α -1,4-L-rhamnose in the molar ratio of 2:1:1

with two acyl groups, acetate and glycerate, which are bound in the same glucose adjacent to glucuronic acid (Ferreira et al. 2016; Prajapati et al. 2013; Rukmanikrishnan et al. 2020). Furthermore, gellan gum is available in two forms: (1) high-acyl gellan gum, native form, and (2) low-acyl gellan gum. Low-acyl gellan gum can be obtained by deacetylation of native gellan gum through alkaline hydrolysis at high temperatures (Fig. 11) (Das and Giri 2020; Ferreira et al. 2016).

The gel-forming mechanism of both high-acyl and low-acyl gellan gum is associated with disorder-order transition, that is, gellan gum forms a disordered coil structure at high temperature and ordered double helix structure on cooling. Further aggregation of helices forms a three-dimensional network. Aggregation and gelation of helices are inhibited by electrostatic repulsion between the helices due to the presence of negatively charged glucuronate carboxyl groups. Reduction of electrostatic repulsion can be achieved by reduction of pH and/or salt (Morris et al. 2012).

High-acyl gellan gum forms weak gels when cooling a hot solution at low pH. Aggregation of helices is determined by the presence of acyl group or degree of deacetylation. Low-acyl gellan gum forms gel in the presence of cations, such as Ca^{2+} , Mg^{2+} , Na^+ , and K^+ , and promotes the aggregation of double helices of gellan molecules to form a three-dimensional network. Compared to monovalent cations, divalent cation ions greatly promote the aggregation and gelation process. High-acyl gellan gum produces soft, elastic, and thermo-reversible gels ($<100^\circ\text{C}$), while low-acyl gellan gum produces harder, nonelastic brittle, and thermostable gels

Fig. 11 Chemical structure of gellan gum

Fig. 12 Schematic diagram for the gelation of gellan gum

(Bacelar et al. 2016; Ferreira et al. 2016; Sworn and Stoubly 2021). The pH, sugars, acyl substituent, ion type, and ion concentration influence the gel formation and its properties (Kang et al. 2015). Figure 12 shows the schematic diagram for the gelation mechanism of gellan gum.

Gellan gum has wide applications in many fields, including food, cosmetics, pharmaceutical, biomedical, tissue engineering, and environmental bioremediation, due to its biocompatibility, nontoxicity, stability, and biodegradability. They are used as a stabilizer, gelling agent, thickening agent, binders, carriers for controlled drug release, coagulants, lubricants, and film formers for packaging and hydrogel-based filters (Das and Giri 2020; Prajapati et al. 2013; Rukmanikrishnan et al. 2020; Zia et al. 2018).

Proteins: Glutens

Gluten has drawn much interest in nonfood applications due to its viscoelastic properties and low water solubility (Lagrain et al. 2010). Wheat protein consists of functional (albumins, globulins) and storage protein, which is also known as prolamins. Gluten is the primary storage protein of wheat grains. Wheat gluten proteins consist of monomeric gliadins (28–55 kDa) and polymeric glutenins (500–1000 kDa). Glutenin represents 40–50% of wheat endosperm protein, and 40–45% is gliadin. Gliadin proteins are a complex mixture of polypeptides and are classified as α/β -, γ -, and ω -gliadins on the basis of mobility at low pH in gel electrophoresis. Glutenin has two subunits: high molecular weight (HMW) and low molecular weight (LMW) glutenin subunits. Gliadins, such as α/β - and γ - gliadins, have casein in their amino acid sequence and form intrachain disulfide bonds. In contrast, ω -gliadins lack in cysteine residues. Glutenins consist of aggregated proteins linked by the formation of intrachain and interchain disulfide bonds (Dybka-Śtepień et al. 2021; Kuktaite and Ravel 2020; Mahan et al. 2018; Wieser 2007).

Considering the secondary structure, α/β - and γ -gliadins mainly consist of α -helices and β -sheets, while ω -gliadins mainly contain β -turns (Kłosok et al. 2021).

The secondary structure of LMW glutenin is similar to α -/ β - and γ -gliadins. However, not like gliadins, LMW glutenin can form intermolecular disulfide bonds. HMW glutenins have three distinct domains: non-repetitive N-terminal, repetitive central, and C-terminal domains. The N- and C-terminals contain α -helices, and the repetitive central domain consists of overlapping reverse β -turns that form a loose spiral structure. HMW glutenins form extended rodlike confirmation (Johansson et al. 2013).

Glutenins and gliadins are interacted with each other to form a gluten network via covalent (intra- and interchain disulfide bonds) and noncovalent bonds (ionic bonds, hydrogen bonds, hydrophobic bonds, and van der Waals forces) (Abedi and Pourmohammadi 2021; Kłosok et al. 2021). Structural variation of gluten constituents (glutenin and gliadins), amino acid composition, and their interactions determine the unique characteristics of gluten. Gluten consists of high levels of glutamine and proline amino acids and low levels of charged amino acid residues (Abedi and Pourmohammadi 2021; Lagrain et al. 2010). Since nonpolar glutamines are found in gluten proteins in higher amounts, they represent a high noncovalent hydrogen-bonding potential between glutenin and gliadin (Lagrain et al. 2010). Covalent disulfide bonds between gluten proteins play an important role in further polymerization and rheological properties. Despite the fact that cysteine residues are found in lower amounts in gluten (about 2% of the total amino acid composition), they play a major role in gluten network formation by promoting cross-linking by disulfide bonds (SS bonds) and disulfide/sulfhydryl (SH/SS) interchange reactions which increase both tensile strength and elasticity of gluten (Abedi and Pourmohammadi 2021; Lagrain et al. 2010). A small increase in the number of disulfide bonds can have a significant structural effect and enlarge the gluten network (Lagrain et al. 2010).

The processing of film coatings or other protein-based materials mainly involves three main steps: (1) breaking noncovalent and covalent intermolecular bonds using physical or chemical modifications, (2) arranging and orienting mobile polymer chains, and (3) formation of new intermolecular bonds and interactions stabilizing the three-dimensional network (Lagrain et al. 2010).

The process of gluten network development involves hydration, depolymerization, and re-polymerization. Hydration of gluten along with mechanical forces is essential to unfold and modify the initial conformation of gliadin and glutenin chains (increasing β -turns and hydrated extended structures). Hydrated gliadins contribute to the viscosity and extensibility of the dough, and hydrated glutenins contribute to dough strength and elasticity. Generally, gluten is considered a “two-component glue,” in which gliadins act as a “plasticizer” or “solvent” for glutenins (Kłosok et al. 2021; Wieser 2007).

Mixing/shearing and temperature play a crucial role in forming a three-dimensional protein network stabilized by the interchain disulfide bonds, hydrophobic, or isopeptide bonds. Shearing or mixing causes protein denaturation, changes in secondary structure, and increases the molecular mobility of gluten protein, which enhances the exposure of reactive sites and consequently increases the cross-linking reactivity of gluten proteins. Mechanical stress also causes depolymerization by cleavage of disulfide covalent bonds resulting in increased free sulfhydryl group (SH) groups. Heating below the gelation temperature (up to 70 °C) facilitates the formation of the gluten gel network through hydrogen and ionic bond disruption and enhances

hydrophobic interactions. Heating at critical temperatures leads to higher disulfide (SS) bond formation in glutenin by oxidation of the sulfhydryl group (SH). Further increase in temperature leads to glutenin-gliadin interaction by SS bond formation through SH/SS interchange reactions (Abedi and Pourmohammadi 2021; Lagrain et al. 2010). Fig. 13 depicts the gel schematic diagram of gluten network formation.

Wang et al. (2017) investigated the chemical interactions and protein conformation in the heat-induced wheat gluten gelation mechanism. The study also showed that wheat gluten unfolds during heating and aggregates at temperatures of 80–90 °C. The ionic bond and hydrogen bond, and free SH content, were shown to decrease when the temperature was increased from 25 to 90 °C. A decrease in SH

Fig. 13 Schematic diagram of gluten network formation

content can be attributed to inter- and intramolecular disulfide bond formation by oxidation upon unfolding of gluten protein and exposure of SH groups. Random coil content increased at 50 °C, whereas intermolecular β -sheets increased at 90 °C due to gluten aggregation. This study suggested that wheat gluten is unfolded and reorganized during heating, resulting in exposure of hydrophobic and SH groups. Upon further heating gluten network is formed by disulfide and hydrophobic bonds, while ionic and hydrogen bonds have little effect (Wang et al. 2017).

Both nucleophilic and radical reactions were hypothesized to play an important role in gluten aggregation (Auvergne et al. 2008). Mechanical cleavage of the SS bond in gluten leads to the formation of thiol radicals (Fig. 14d) (Abdel Aziz et al.

Fig. 14 Reaction between gluten chains: (a) mechanical cleavage, (b) oxidation and disulfide bond formation, (c) SS/SH exchange reaction, and (d) free radical formation

2018). The influence of mixing on thiol and disulfide groups in the wheat gluten network was studied. During mixing, a transient increase in free SH (thiols) groups was recorded, but the formation of total free SH groups dropped with increasing temperature. The free SH group formation may result from the reduction or scission of disulfide bonds. Moreover, when mixing continues at a particular temperature, the result indicated an irreversible loss in thiol equivalent groups, i.e., a net decrease in SS groups higher than free SH increase. This may be attributed to the formation of sulfoxyl compounds by oxidation of thiyl radicals (S^\bullet) that might form during mechanical scission of disulfide bonds (Morel et al. 2002).

Gluten is a plant protein that can be obtained from the by-product of starch fabrication. Among other proteins, gluten has a unique feature, viscoelastic properties. Due to the thermoplastic properties and its potential for chemical modification, gluten can be used to develop a range of materials for food and nonfood applications, such as composite materials, foams, edible film, food packaging material, and films for agricultural uses (Abedi and Pourmohammadi 2021; Domenek et al. 2004; Dybka-Śtepien et al. 2021; Kuktaite and Ravel 2020). Protein films, including wheat gluten films, have good oxygen barrier properties at low relative humidity (Hernández-Muñoz et al. 2003; Pirsá and Aghbolagh Sharifi 2020). Protein films can be used to pack many foods, especially beans, fruit kernels, and cashews (Pirsá and Aghbolagh Sharifi 2020).

Since gluten is a thermoplastic material, gluten polymer can be processed through the extrusion technique, a well-established technique used in commercial synthetic plastic films (polyethylene). This makes them suitable for industrial application (Jiménez-Rosado et al. 2019).

Synthetic Polymers from Bio-derived Monomers: Polylactic Acid (PLA)

Polylactic acid (PLA) is a thermoplastic, biodegradable synthetic polymer widely used in many applications. PLA is a linear, aliphatic polyester polymer obtained through the polymerization of the D-/L-lactic acid monomer produced by bacterial fermentation of polysaccharides or through chemical synthesis (Grujić et al. 2017). The ratios of L- and D-isomers influence the properties of PLA (Garrison et al. 2016) (Fig. 15).

Lactic acid-based biodegradable polyesters have gained much attention, mainly in medical applications, as they are degradable in the human body and then eliminated by kidney filtration and bioassimilation, as well as in the environment by

Fig. 15 Chemical structure of PLA

microbes (Elsabee et al. 2020, p. 1). PLA has also been used in agriculture (sustained delivery of pesticides and fertilizers, seed protection), drug delivery, tissue engineering, and packaging (Vert 2015).

The lactic acid precursor is obtained from renewable resources and fossil oil (Vert 2015). Lactic acid can be produced from renewable sources, starch, and sugars, using lactic acid fermentation bacteria, such as *Lactobacillus*, *Streptococcus*, *Pediococcus*, and *Sporolactobacillus*. PLA polymers are synthesized by direct polycondensation of lactic acid and ring-opening polymerization (ROP) of lactide, esters of lactic acid (Dubey et al. 2017; Masutani and Kimura 2014; Vert 2015). PLA is commercially produced by ring opening polymerization of lactide (Garrison et al. 2016).

By hydrolysis of ester bonds, PLA is broken down into smaller water-soluble fragments (monomers or oligomers) that can facilitate uptake into microorganisms. Subsequent microbial activity further breaks down the smaller fragments into CO_2 , H_2O , CH_4 , and other metabolic end products, while a portion of the carbon is converted into biomass (Garrison et al. 2016). Microorganisms mainly bacteria, such as *Amycolatopsis*, *Lentzea*, *Kibdelosporangium*, *Streptoalloteichus*, and *Saccharothrix*, and fungi *Tritirachium album* were reported in PLA biodegradation (Garrison et al. 2016).

Two common degradation pathways of PLA are (1) hydrolytic chain scission and (2) β -C-H hydrogen transfer of PLA (main chain scission). As shown in Fig. 16, the hydrolytic degradation of PLA produces hydroxyl- or carboxyl-terminated PLA end groups, while β -C-H hydrogen transfer of PLA produces carboxylic acid end groups and vinyl esters (Scaffaro et al. 2019).

Microbial Polymers

Various polysaccharide-based biopolymers, including xanthan from (*Xanthomonas campestris*), gellan (*Sphingomonas paucimobilis*), bacterial alginates (*Pseudomonas*

Fig. 16 Two common degradation pathways of PLA: (1) hydrolytic chain scission and (2) β -C-H hydrogen transfer of PLA

spp. and *Azotobacter vinelandii*), bacterial cellulose (*Acetobacter xylinum*), and hyaluronic acid (*Streptococcus equi*), are produced from various microbes (Banik et al. 2000). Other than these, microbes produce polyesters such as PHAs (PHB, PHBV) and lactic acid monomers for PLA (Ferreira et al. 2016).

Polyhydroxyalkanoates (PHAs)

Polyhydroxyalkanoates (PHAs) are microbial-based aliphatic polyesters synthesized as water-insoluble intracellular granules by various microbes, mainly by bacteria, such as *Bacillus* species, in response to environmental stress. PHAs, such as poly-3-hydroxybutyrate (P3HB), poly-4-hydroxybutyrate (P4HB), polyhydroxyvalerate (PHV), and poly(hydroxybutyrate-co-hydroxyvalerate) (PHBV), are produced by various microorganisms, such as *Bacillus megaterium*, *Pseudomonas aeruginosa*, *Pseudomonas putida* (previously known as *Pseudomonas oleovorans*), *P. stutzeri*, *Staphylococcus* spp., and *Cupriavidus necator*. PHAs have various types and are classified into three groups based on the length of the carbon chain: short-chain (3–5 carbon monomers), medium chain (6–14 carbon monomers), and long-chain PHAs (>14 carbon monomers) (McAdam et al. 2020; Mohapatra et al. 2017; Muneer et al. 2020; W. Meereboer et al. 2020). Long-chain PHAs are rare in nature. Fig. 17 shows the general structure of the repeating unit of PHA, where R denotes the functional group, n varies from 1 to 4, and × represents the number of repeating units in the polymer chain (Muneer et al. 2020). Monomer length and molecular weights of PHAs are determined by bacterial strain and growth medium conditions (Garrison et al. 2016).

Figure: General chemical structure of the repeating unit of PHAs. (a) PHB, (b) PHV, and (c) PHBV

PHB is the most common homopolymer of PHAs. PHB has a highly crystalline structure due to its linear structure. PHB has higher permeability barrier properties than synthetic polymers (PE and PP), is more rigid and less flexible than PP, and has higher biodegradability. Therefore, PHB has potential applications in food packaging (McAdam et al. 2020). PHBV is the co-polymer of PHV and PHB polymer. PHBV has better mechanical properties than PHB, including lower brittleness and stiffness and higher tensile strength and elongation at break (Frącz et al. 2021).

Fig. 17 General chemical structure of the repeating unit of PHA

PHAs such as PHB and its co-polymer PHBV are highly used in commercial applications due to their biocompatibility, nontoxicity, and negligible cytotoxicity and show biodegradability in all aerobic and anaerobic environments (Mohapatra et al. 2017; Meereboer et al. 2020). PHAs are water-insoluble thermoplastic polymers. PHA-based flexible food packaging is widely used for oily foods, such as marinated olives, cheese, and nuts, frozen foods, and organic foods (Grujić et al. 2017). Other applications include agriculture mulching films, 3D printing materials, tissue engineering, medical implants, drug delivery carriers, textile, nonwoven materials, and animal nutritional supplements, as well as new types of biofuels from PHA polymers (Mohapatra et al. 2017).

PHAs, microbial-derived polymers, biodegrade into CO_2 and water. PHAs are biodegradable by soil bacteria, such as *Bacillus*, *Xanthomonas*, *Stenotrophomonas*, *Pseudomonas*, *Acinetobacter*, *Variovorax*, *Schlegelella*, and *Azospirillum*, and molds, such as *Acremonium*, *Penicillium*, *Verticillium*, *Paecilomyces*, and *Zygosporium* (Mohapatra et al. 2017). These degrading microorganisms produce extracellular PHA depolymerase, which converts the polyesters into water-soluble oligomers and monomers that are used as a carbon source by the organisms (Anjum et al. 2019).

Composites and the Biodegradability

Biodegradable plastics generally have limitations, such as hydrophilicity, brittleness, poor mechanical and barrier properties, and higher degradation rate in their pure form; thus, chemical and physical modifications and various blends and composites are widely used to combat these limitations (Garrison et al. 2016; Jiang et al. 2020; Rosseto et al. 2019; Tarique et al. 2021; Meereboer et al. 2020). The effect of these treatments on biodegradability should be studied.

Biodegradable plastics can potentially lose their biodegradability when blending into polymer composites. Therefore, biodegradation testing is required to ensure that no chemical interactions hinder the overall biodegradation rate (Meereboer et al. 2020). Furthermore, degradation of biodegradable polymers takes place only under certain environmental conditions (temperature, humidity, light, oxygen availability, and microorganisms). Therefore, the impact of disposal of these biodegradable polymers on the environment should be studied (Bagheri et al. 2017). The

biodegradation of many natural polymers and composite polymers has been mentioned in many literatures.

A major fraction of whole potato flour is starch, about 80%, and the rest is protein. However, whole potato flour-based bioplastics have brittle behavior and poor mechanical properties. The study showed that incorporating proteins with potato starch greatly improves the mechanical properties. This may be due to the proteins in combination with starch forming a stable three-dimensional network through strong hydrogen bonds and intermolecular interactions (Omrani-Fard et al. 2020).

Natural polymers are not thermoplastic, with only a few exceptions (gluten). Structural polysaccharides, including cellulose, have strong inter- and intra-interactions, which prevent thermal processing in unmodified cellulose. However, thermoplasticity of natural biopolymers, such as cellulose, lignin, and chitin, can be induced by various chemical and physical modification techniques, including plasticization or polymer blending (Müller et al. 2019).

Chemical modification through acetylation of thermoplastic starch can impact biodegradability. A study revealed that thermoplastic acetylated starch materials showed lower biodegradability than thermoplastic non-acetylated starch (2 mm pieces, i.e., 100 mg) when buried at 58 °C for 90 days. Further, biodegradation of acetylated thermoplastic starch decreased with the degree of acetylation. The hydrophilicity of acetylated starch is decreased with the degree of acetylation process due to the substitution of hydroxyl groups, which in turn lowers the biodegradability (Nevoralová et al. 2019). Plasticization process also significantly affects the biodegradability of polymers (Nevoralová et al. 2019).

The combination of thermoplastic cassava starch and the polylactic acid composite film was shown to have 65% of biodegradability in 32 days under aerobic composting conditions at 58 °C \pm 2 °C. Based on the analysis of changes in the chemical structure, TPS/PLA blended polymers undergo three phases of biodegradation: fragmentation; then disintegration, mainly by the effect of abiotic hydrolysis; and mineralization by the compost microbiota (del Rosario Salazar-Sánchez et al. 2019).

Starch/polyhydroxyurethane hybrid film was recorded with the highest biodegradability with weight loss of about 88% when buried in soil for 120 days. Moreover, the presence of cellulose nanocrystals reduces the potential of biodegradability (about 44% after 60 days) of the nanohybrid film (starch/polyhydroxyurethanes/cellulose nanocrystals) (Ghasemlou et al. 2022).

Ray et al. synthesized biodegradable composite film by date palm leaf fibers reinforced with PVA/corn starch matrix and tested the biodegradability by burying the materials in farmland soil at 10 cm deep under ambient conditions (30 °C and 79–80% RH) for 6 weeks. Composite material containing 40 wt% date palm leaf fiber showed 32% of weight loss, which is lower than the value recorded for PVA/corn starch (95%). Further, it was observed that increasing the fiber content reduces the biodegradability of the composite film, which may be attributed to the presence of relatively low-biodegradable cellulose in higher levels in fiber (Ray et al. 2021). de Freitas et al. observed that the incorporation of kraft lignin as fillers in thermoplastic starch film reduces biodegradability (de Freitas et al. 2021). Starch

reinforced with lignocellulosic fibers (cellulose and lignin) improved the mechanical properties (Yang et al. 2019), negatively impacting its biodegradability.

Incorporation of antimicrobial agents, such as neem-oil or oregano essential oil, slightly affected the biodegradation and disintegration of starch/PVA film. However, the incorporation of silver nanoparticles significantly reduced the biodegradability to 58% at 58 ± 2 °C after 45 days of composting, much lower than the starch/PVA film (68%). The starch/PVA/silver film lasts longer in the environment, due to the greater antimicrobial potential of silver than oregano and neem-oil (Cano et al. 2016).

Cassava-based simple bioplastic showed higher biodegradability than that of corn starch in burial test in soil for 14 days. Factors including the nature of starch, humidity, temperature, and enrichment of microorganisms showed an effect on the biodegradability of polymer cassava and corn starch (Zoungranan et al. 2020).

Hasan et al. (2020) observed that the addition of chitosan in higher content in the brown rice starch-based film significantly improved the tensile strength and thermal stability as well as decreased the biodegradability.

The application of acetyl tributyl citrate (ATBC) plasticizers in the PHBV matrix improved the biodegradation rate in the vermicomposting, freshwater biotope, and thermophilic composting. Further, in PHBV/ATBC with CaCO_3 or L-CNC bio-composite film, 57–60% are disintegrated in thermophilic composting after 30 days (Brdlík et al. 2022).

The main function of the plasticizers is to enhance the elasticity and mechanical strength of the bio-based polymers (Maraveas 2020). Generally, bio-based polymers are brittle because of strong intermolecular forces, such as dipole and hydrogen bonds. Plasticizers, such as glycerol and other polyols, are used to improve the toughness and flexibility of many polymers. The hydroxyl groups in glycerol can form strong hydrogen bonds with the polymers by breaking intermolecular hydrogen bonds in the polymer resulting in an increase in the system's molecular mobility (Özeren et al. 2021; Tarique et al. 2021).

Arrowroot starch (AS) plasticized with glycerol (15% w/w) showed 77.5% of weight loss when buried in soil compost after 20 days. Moreover, when increasing the glycerol concentration 15–45% (w/w), the biodegradability of the AS film was reduced. The addition of glycerol improves brittleness and flexibility. In contrast, it reduces the water vapor barrier properties (Tarique et al. 2021).

Water act as a plasticizer in gluten-based biopolymers, but it evaporates from the material depending on humidity and temperature. Therefore, another plasticizer, such as glycerol, is required to improve the processibility (Alonso-González et al. 2021; Özeren et al. 2021).

Gluten-based film (plasticized with glycerol), produced by various processing methods, including cast (hot-molded and cold and hot mixing), degraded completely within 50 days (Domenek et al. 2004).

Complete bulk degradation of PLGA in seawater and freshwater after 270 days, whereas PHB was degraded by 8% after 365 days, and PCL and PLA did not show any significant degradability (Bagheri et al. 2017). Table 2 summarizes the few recent findings on the biodegradability of various biopolymers.

Table 2 Biodegradability of different polymers

Biodegradable polymer	Conditions	Biodegradability (%) and observations	References
Cassava starch and corn starch	Burial tests in soil for 14 days	Cassava-based simple bioplastic showed higher biodegradability than corn starch Temperature, humidity, and microorganism enrichment influence biodegradability	Zounggran et al. (2020)
Cassava starch/polylactic acid films	Aerobic biodegradation of film (1 × 1 cm) under controlled composting conditions, 58 °C ± 2 °C for a month	65% of biodegradability in 32 days	del Rosario Salazar-Sánchez et al. (2019)
Acetylated or non-acetylated thermoplastic starch	Under composting condition: Material (2 mm pieces, i.e., 100 mg) under compost at 58 °C for 90 days	Biodegradation decreased with the degree of acetylation/substitution	Nevoralová et al. (2019)
	Under outdoor condition: highly acetylated material for 14 and 22 days	18–37% and 23–39% of weight loss after 14 and 22 days, respectively	
Thermoplastic starch (TPS)/polybutylene adipate-co-terephthalate (PBAT)/compatibilizer (either maleic anhydride [MA] or PBATg-MA)	Under compost conditions based on the emission of CO ₂ monitoring at 58 °C, 50% moisture content, with 10 mL/min air (CO ₂ -free) flow rate to provide aerobic conditions	Biodegradability of PBAT/TPS (40–60%) without any compatibilizer was 82–87% after 90 days, 72–74% in the presence of PBATg-MA	Dammak et al. (2020)
Thermoplastic starch/kraft lignin	Using soil microorganisms in the liquid biological medium at 30 °C for 10 days	Complete biodegradation before 10 days	de Freitas et al. (2021)
Tapioca starch/glycerol/polyvinyl alcohol (PVA) liquid/glycerol/bamboo fibers	According to ASTM G160, at a controlled burial location for 15 days	After 15 days, untreated, alkali-treated, and permanganate-treated samples lost about 5.44%, 5.97%, and 6.15% of their initial weight, respectively	Yusof et al. (2019)
Wheat gluten (WG)/shrimp shell powder	Accelerated weathering process under controlled conditions (UV, temperature, and moisture) for 120 h	WG, WG/shrimp shell powder, WG/calcinated shrimp shell powder composites showed 14.06%, 13.02%, and 4.29% of weight loss after 120 h	Thammahiwes et al. (2018)

(continued)

Table 2 (continued)

Biodegradable polymer	Conditions	Biodegradability (%) and observations	References
PLA/chitosan, PLA/CNC, PLA/gum	Aerobic composting condition using the thermophilic microflora already present in the compost at 58 ± 5 °C	Microbial colony formation (higher in PLA/Chitosan), contact angle confirmed the increase in hydrophilicity, and decrease in transparency	Kalita et al. (2019)
PLGA, PHB, PCL, PLA	Bulk degradation in seawater and fresh water at 25 °C under fluorescence light (16 h light and 8 h dark) for 1 year	Complete bulk degradation of PLGA in seawater and freshwater after 270 days PHB showed about 8.5% degradation after 1 year, while no significant biodegradability was reported with PCL and PLA	Bagheri et al. (2017)
PCL	Complete degradation under controlled conditions at 50 °C after 91 days in compost	Complete biodegradation (100%) after 91 days	Al Hosni et al. (2019)
Starch/polyhydroxyurethanes (PU) Starch/PU/cellulose nanocrystals	Film materials (44 cm) buried in the soil at a depth of 4–6 cm, 20–28 °C, 70% moisture content, and about 40% RH for up to 180 days	Starch/PU: mass losses about 66.4% after 60 days and 88% after 120 days Starch/PU/cellulose nanocrystals: about 44% after 60 days	Ghasemlou et al. (2022)
Starch/PVA, Starch/PVA/antimicrobial agents (neem-oil or oregano essential oil)	Under controlled composting at 58 ± 2 °C for 45 days	Essential oil slightly affects the biodegradation and disintegration behavior of starch/PVA film Biodegradability ranged from 68% to 114% after 45 days of composting	Cano et al. (2016)
Date palm leaf fibers reinforced PVA (polyvinyl alcohol)/corn starch hybrid composites	Soil burial method: composite material ($20 \times 5 \times 1$ mm) buried in farmland soil at a depth of 10 cm, 30 °C, 79–80% RH for 6 weeks	32% (PVA/corn starch containing palm leaf fiber, 40% wt) and 95% (PVA/corn starch) of weight loss after 6 weeks The incorporation of date palm leaf fiber into PVA/starch composite reduced biodegradability	Ray et al. (2021)
Brown rice starch/chitosan plasticized by palm oil	Material (2.5×2.5 cm) buried in compost media at 10 cm depth for 20 days	Highest biodegradation rate in film contains 70% (w/w) of starch	Hasan et al. (2020)

(continued)

Table 2 (continued)

Biodegradable polymer	Conditions	Biodegradability (%) and observations	References
Gluten/glycerol (plasticized gluten) (cast, hot-molded, and cold and hot mixed gluten materials)	Mineralization of material in aerobic fermentation (liquid medium, Modified Sturm Test) Samples (0.5 g) buried in farmland soil 20 °C	85% mineralization after 36 days in aerobic fermentation (liquid medium, Modified Sturm Test) 100% weight loss after 50 days in farmland soil	Domenek et al. (2004)
PHBV/acetyl tributyl citrate (ATBC) with CaCO ₃ or lignin-coated cellulose nanocrystals (L-CNC)	Thermophilic composting in accordance with ISO 14855-1 standard (mineralization: 10 g [1 × 1 mm], 58 °C, in 150 g compost for 3 months; biodegradation: films 100 × 35 mm, 58 °C, 50% humidity, for 30 days), vermicomposting (films 100 × 35 mm, 21 °C, 81% MC, for 30 days), and freshwater biotope (films 100 × 35 mm, 27 °C, for 30 days)	Highest biodegradation rate in thermophilic composting (>90% after 90 days) Degree of disintegration thermophilic composting in PHBV/ATBC with CaCO ₃ or L-CNC (57–60% after 30 days) Application of ATBC increased the biodegradability in all medium	Brdlík et al. (2022)
Arrowroot starch (AS) films using glycerol at 15, 30, and 45% w/w	Soil burial degradation: 20 × 20 mm film was buried in the depth of 100 mm soil compost	In AS film, addition of glycerol reduced the tensile strength (16.48–1.95 MPa) and modulus (1258.9–36.08 MPa) and increased the elongation at break (2.49–57.33%) and water vapor permeability (to 10.83 g·s ⁻¹ m ⁻¹ Pa ⁻¹) Weight loss in AS and AS/glycerol (15% w/w) were 74.4% and 77.5%, respectively, after 20 days	Tarique et al. (2021)

Conclusion

Biodegradable polymers have been widely used as a substitute for petroleum-based polymers due to their cost-effectiveness, availability, nontoxicity, biocompatibility, biodegradability, and feasibility of producing films alone or in combination with other polymeric matrixes. Many polymers, polysaccharides, proteins, and other

microbial polyesters have been used in food, packaging, agriculture, biomedical, environmental remediation, and many other fields.

Natural polymers have a poor mechanical, thermal, barrier, and other functional properties. As a result of these constraints, natural polymers undergo various physical and chemical modifications, including blending with other polymers or incorporating with fillers, additives, and nanoparticles. These modification processes may have an influence on the overall biodegradability. Therefore, it is essential to assess the biodegradability of polymer material. Various studies on the biodegradability of different biopolymers suggest that biodegradability can be altered by the process method, combinations of polymer, structure, and environmental conditions. Since biopolymers are treated with additives, including NPs, plasticizers, and other chemicals, the migration behavior of these materials should be extensively studied.

Abstract

Because of their significant contribution in various products present in modern society, biopolymers are regarded as a diverse class of materials. The designing and marketing of renewable and suitable biopolymers have attained a serious development in recent decades. However, on the other side, their frequent utilization and waste pose a number of environmental risks including pollution, health, and depletion of nonrenewable natural resources. Although most of the

biopolymers offer some kind of waste management solution, there are limitations to their efficacy in reducing vulnerabilities associated with them. Proper waste management strategy is obviously a definite requirement to protect the environment from their harmful impacts. In this chapter, different strategies that have been successfully applied for the reuse, recycling, and disposal of biopolymer waste are discussed. Moreover, the pros and cons of methods to treat this waste are also discussed. The applicability of biopolymer waste treatment at domestic and industrial level has also been elaborated.

Keywords

Biopolymers · Waste management · Recycling · Reuse · Disposal

Introduction

Biopolymers are organic molecules that are found in natural sources. The word biopolymer is derived from two Greek terms “bio” and “polymer.” These words reflect the life and the natural environment. These are larger macromolecules composed of multiple repeating units (Ezeoha and Ezenwanne 2013). Biopolymers are made up of a wide variety of molecules, each of which has a unique chemical structure. Some of these include proteins, polysaccharides, polyamides, bioplastics, polyesters, etc. They are biodegradable and biocompatible, which makes them useful in a variety of uses like packaging materials, emulsions, edible films, drug transport materials, wound healing, and tissue scaffolds, medical implants, and dressings in the pharmaceutical industries (Baranwal et al. 2022). Besides, they are quite abundant in nature and have a wide variety of applications; yet, they have also developed into one of the most serious wastes produced by industrial and agricultural processes, which contributes to environmental contamination. (Bayón et al. 2018).

The term waste was examined and redefined as an emergent property of a substance. When a substance is not employed to the fullest extent, it is said to be a waste. Under this concept, any method can be utilized for the conversion of waste to get rid of this quality label, and it becomes abundantly clear that there is a need for a comprehensive approach to the management of resources and waste (Dijkema et al. 2000). The ever-increasing human population and the spread of urbanization have both contributed to the constantly increasing quantity of waste. Manufacturing processes, industrial activities, and municipal solid waste (MSW) lead to the formation of waste products (Kan 2009). MSW refers to waste that includes nondurable products, durable products, food scraps, packages, yard clippings, and various inorganic wastes that arise from industrial, commercial, and residential sources.

The majority of biopolymer waste originates from the food service and healthcare industries. Bottles, utensils, cups, plates, trays, straws, towels, toothpicks, etc. are examples of food service items, whereas medical tubing, gloves, blood pressure cuffs, face masks, bandages, adhesive tape, waste bags, sheets, syringes, enema tips and bags, intravenous liquid bags and tips, etc. are examples of healthcare products.

Waste from hospitals and other medical facilities poses a threat to public hygiene and must undergo special processing before being disposed of. Incineration is the preferred method for disposing the vast majority of hazardous wastes that are produced in the healthcare industry, and it is still regularly utilized. Additional sources of waste material include forestry, agricultural, automotive, and construction products that are manufactured from biopolymers. Residues from post-industrial processes are another key cause of waste biopolymers (Niaounakis 2013a). Recently, about 140 million tonnes per year of biopolymers are manufactured across the globe with the vast majority originating from resources derived from petroleum. They have broad applicability as packaging materials in the food, pharmaceutical, cosmetic, detergent, and chemical industries (Shah et al. 2008). Approximately 30% of this manufacturing is used for packaging purposes, with around 90% of that being used for food packaging. Their use is constantly growing, at a yearly rate of 12%. This means that industrial wastes bring a significant proportion of these chemicals into the environment. Plastics have acquired more public and media attention than any other type of solid waste because of their increased visibility in litter (Siracusa 2019).

The waste management has emerged as one of the most serious environmental challenges of the world. The increase in the rates of solid waste generation has been attributed to human activities, as well as modifications in lifestyle and consumption patterns. The method of recovering resources from waste is another part of waste management. The management of waste may involve the treatment of solid, liquid, gaseous, or radioactive materials, each of which requires a unique set of procedures and areas of expertise (Dijkema et al. 2000; Kan 2009). Sewage disposal, wastewater treatment, and biological and chemical processing comprise liquid waste management. The waste management strategies of developing versus developed nations, rural versus urban areas, and residential versus industrial areas may vary. Recycling generally refers to the extraction of resources from waste, as well as the recovery or reuse of the extracted material. There are a variety of ways to recycle waste material; the raw materials can be recovered and reprocessed, or its heat can be transformed into energy (Demirbas 2011). Figure 1 depicts the basic components of waste management: collection, transportation, recovery, recycling or disposal, and analysis of waste substances. A typical system of waste management consists of residue collection, transportation, treatment, processing, and finally disposal.

The residues of biopolymer residues can be gathered from producers and end users. It is preferable to collect waste biopolymers from industry because they produce them in vast quantities. Some organizations that specialized in recovering waste biopolymers from major gatherings such as sports and concerts may choose to collect from the end users directly. When these events take place, huge volumes of biopolymer waste are generated as a result of the use of bottles, cups, and fast-food items. A majority of these wastes are disposed of in one of two ways: either they are placed in trashcans and sent to landfills or, at best, they are taken to a waste treatment company (Niaounakis 2013a).

The goal to manage waste is creating a sanitary living conditions, minimizing the number of chemicals entering or leaving the community, and promoting the reuse of substances in the community (Demirbas 2011). The huge amounts of waste cannot

Fig. 1 Waste management process

be removed. Yet, the effect on the environment can be mitigated by finding more environmentally friendly uses of it. That's what it refers to as the waste hierarchy (Batayneh et al. 2007). There are three levels of the waste hierarchy, which categorize waste management solutions in terms of waste minimization: reduce, reuse, and recycle. Reducing, reusing, recycling, composting, incinerating, and dumping are the six disposal choices in descending order of environmental impact. The waste hierarchy serves as the basis of the majority of waste reduction approaches. The objective of the waste hierarchy is to extract the maximum benefit from products while generating the least quantity of waste (Siddique et al. 2008). The scope of this chapter is to present a brief overview of waste management of biopolymers including possible ways of its reuse, methods of physical and chemical recycling, and known techniques of their disposal.

Reuse of Biopolymers

Reuse is a typical approach that can be implemented to discarded or used polymer items. It is preferable to reuse biopolymers because of less energy consumption and use of cheaper resources. Defective preforms or molds, as well as worn articles, are reprocessed in their current state without the chemical composition of the

biopolymer being altered in any way. Biopolymers can be reused in the following ways (Niaounakis 2013b):

- The immediate recovery of scrap material during the molding process
- Mixing the polymer materials with other polymer materials, frequently in association with compatibilizers, to produce new materials
- Combining with a variety of chemicals, including reinforcing agents and antioxidants
- The alteration of the structure of the polymer so that it can regain its original qualities

In the process of recuperation, industrial wastes are ground up, combined with virgin material, and then immediately injected into the processing machines. This is one of the most common methods for recycling scrap materials from the manufacturing industry. The treatment through heat is needed for the process of agglomeration, but the biopolymers should not be changed thermally. If this happens, the biopolymers will degrade chemically, release gases that are mostly harmful, and make wastes unusable for the technological reuse that was intended for them (Vilaplana and Karlsson 2008). The primary technical challenges that need to be taken into account to produce a material with attributes that are comparable to those of the virgin one are (i) modifying the ratio of recycled materials in the blend and (ii) optimizing the processing technique (K.G., P.M.G.C. *n.d.*).

The treatment of biopolymers wastes results in products that, on average, have lower-quality features than the materials from which they were originally derived. This is because of differences in chemical structure that were brought about by earlier phases of degradation. The procedure of restabilization is known for its role in shielding recycled substances from the thermomechanical deterioration that occurs during reprocessing and in strengthening the long-term durability of the materials through reuse (Södergård and Näsman 1994). It cannot efficiently recover the damaged material, but it can stop further chemical changes that may be accelerated by the oxidative compounds that are found in its composition or by humidity. It has been observed that certain additives, such as catalyst deactivators, can stabilize PLAs in the melt. 1,4-Diaminoanthraquinone (McNeill and Leiper 1985a), benzoyl peroxide (Södergård and Näsman 1996), and 2,4,6-cycloheptatrien-1-one,2-hydroxy (McNeill and Leiper 1985b), natural and biodegradable acids, are the examples of such additives. In order to delay the biopolymer hydrolysis, additives like carbodiimide substances are often used (Hartmann 1999).

The most prevalent and known method for improving the qualities of single-stream biopolymers wastes is the blending of recycled polymers with virgin materials (Imre and Pukánszky 2013). Recycling technology has been created by Sharp, which allows for the repeated recovery of plastic from used consumer devices and the reuse of the material in the construction of new consumer devices. In 2009, Sharp (JP2009161655) published a method for reusing waste bio-based thermoplastic resins. The method involves melting or heating a mixture of the waste thermoplastic resin and at least one polymer chosen from the group consisting of vinyl-based

polymer, aliphatic polyester, and a styrene-based polymer. In 2011, DU PONT (WO2011146562) revealed a technique for the production of a fiber that contained 0.1–99.9 weight percent of recycled poly(trimethylene terephthalate) (PTT), with the range of 5–10 weight percent being preferred (Niaounakis 2013b; Teaca et al. 2018).

The composition of the recyclates can also be chemically modified, which is yet another method for efficiently upgrading the functionalities of recycled materials. During melt reprocessing, the use of various substances, like substances having reactive functional groups, radical generators, or chain extenders can be able to induce branched and cross-linked reactions or enhance the molecular mass of deteriorated biopolymer chains derived from wastes (Hu 2014). This type of treatment will result in the increase of weight of polymer chain, as will the improvement in their mechanical and rheological aspects. Upgrading of deteriorated bio-based aromatic polyesters achieved through the application of chemical modification has proved successful (Arbenz and Averous 2015).

The reusability of polymeric materials can be evaluated using multiple processing methods, and this can also be employed to examine the thermomechanical degradation that occurs during physical recycling. The study of alterations in structure and morphology brought on by successive processing steps provides valuable data that may be used to optimize the processing parameters during physical recycling to prevent further degradation of materials (Pillin et al. 2008). The selection of appropriate conditions for processing and the subsequent addition of stabilizing agents and many other chemicals is one example of this method. The macroscopic features and molecular structure of biopolymers are altered when they are subjected to several processing steps. A reduction in the weight of biopolymer chains is caused by chain scission. This in turn causes a reduction in viscosity, a rise in crystallinity, and a variation in the mechanical characteristics of the material. This leads to a gradual increase in the brittleness of the material that has been reprocessed (Hamad et al. 2011).

Recycling of Biopolymers

The market for biopolymers is expanding quickly as a result of the public's growing concern for ecological sustainability (Rajan et al. 2019). Researchers have shown a great deal of interest in this relatively new area to explore the usage of biopolymers as biofuels (Ma and Sahai 2013). Additionally, bio-based products can be progressively used in medical applications such as surgery and therapy, as well as drug delivery systems, and find its potential use in nanomedicines (Kabir et al. 2020). Despite the rapid expansion of biopolymers, their waste streams are still lower and dispersed. On the other side, stress is laid on the recycling of these biopolymers (Cornell 2007). The proper design for waste management of biopolymers is necessary both for the environment and for the circular economy by utilizing these wastes in an appropriate way. Different strategies are used to recycle waste biopolymer. Recycling biopolymers is essential for cutting down on the amount of renewable

resources needed to make the equivalent monomers to produce new polymers using them (Soroudi and Jakubowicz 2013).

Biopolymer recycling is a controversial subject. The merits and demerits of biopolymer recycling are the topics of the current discussion. The critics claimed that recycling does not take advantage of the biodegradability of biopolymers. In addition, biodegradable polymers represent a significant issue when they enter systems for traditional plastics recycling or decomposition of green waste (Cornell 2007). The main techniques for the recycling of biopolymers are:

- Physical or mechanical recycling
- Chemical recycling
- Enzymatic De-polymerization

Mechanical Recycling

In mechanical recycling, discarded polymers are put through mechanical processes like grinding (Åkesson et al. 2016), crushing, and extrusion (Resch-Fauster et al. 2017). Waste material is subjected to washing and drying prior to mechanical method. The polymers are kept intact during mechanical recycling, allowing for numerous uses of the polymers in the formation of the same products or for their applicability in different fields (Niaounakis 2019). These processes of mechanical methods are illustrated in Fig. 2.

Cellulose nanofibers (CNF) are progressively gaining attention because of its renewability as compared to synthetic polymers. CNF can be isolated from the waste

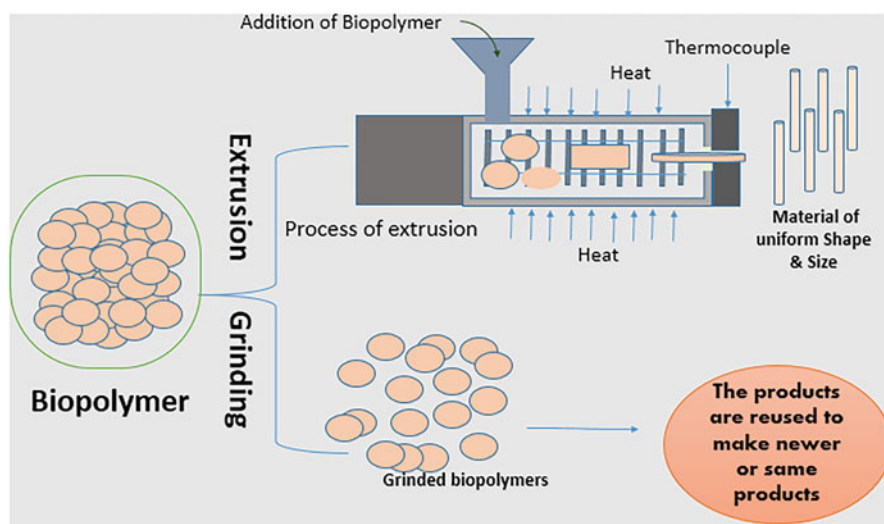

Fig. 2 Different mechanical techniques used for the recycling of biopolymers

material of industry which uses cellulose-containing materials as raw materials, e.g., paper industry. However, it will be possible to scale up from the laboratory to the commercial applications if its production from waste material is cost-effective to compete with cheap synthetic polymers. Josset Sébastien et al. used the process of grinding to study the direct fibrillation of cellulose-containing matrix. The basic purpose of this study is to find the cost-effectiveness of this process. Wheat straw and secondhand newspaper which are regarded as waste material are used as raw material. Bleached wood pulp was also used for comparison. The mechanical characteristics and specific surface areas of the CNF were studied and compared. The greatest values for the characteristics of the bleached wood pulp were already attained with little energy cost. The various characteristics of CNF isolated from waste materials might reach values close to their maximums with energy input as low as about 5 kWh/kg and high-pressure homogenization required 10 kWh/kg. (Josset et al. 2014).

Biopolymer waste is passed through a series of mechanical operations, such as crushing, grinding, and melting, as part of the mechanical recycling of biopolymers. In some cases, these procedures are along with drying or washing. Because the polymer materials are not damaged during the process of mechanical recycling, it is possible to reuse the polymers several times in the similar or comparable material. Mechanical recycling is a promising approach for recycling typical polymers; however, it cannot be effectively applied to the recycling of biopolymers. Aliphatic polyesters make up the vast majority of commercially available biodegradable biopolymers. These include biopolymers like polylactic acids (PLAs), polyhydroxyalkanoates (PHAs), and polyglycolide (PGA). PHAs are members of one of the families of commercially available polymers that exhibit the highest degree of temperature sensitivity, whereas PGA and PLA are both extremely prone to thermal decomposition, which results in discoloration and a loss of molecular weight and is caused by heating the material. Hygroscopicity, sticking at a higher temperature, and thermal destabilization are some of the other issues (Niaounakis 2019). The recycling potential of PGA and PHA is still practically nonexistent except for PLA. To avoid hydrolysis of the molecular chains in the plasticization phase of the PLA reprocessing, it is essential that the material being recycled be as dry as feasible. However, PLA being a hygroscopic material, drying it effectively might be challenging. Additionally, the existence of paper contaminants that contain a significant proportion of moisture renders the process of drying more complicated (Hiebel et al. 2017). Furthermore, the low temperature range (55–60 degrees Celsius) at which PLA seems to become sticky, combined with its relatively large time of crystallization, makes it difficult for drying or crystallizing using typical drying or crystallization systems. In a similar manner, plasticized starch is susceptible to the process of hydrolysis while in use, and it can't be reprocessed again for a similar purpose. The recrystallization, grinding, and drying of the biodegradable wastes are some of the suggested solutions to the difficulties listed above that are experienced in the physical recycling of chosen aliphatic polyesters (Niaounakis 2019).

Chemical Recycling

The term chemical recycling refers to the various chemical methods that break down biopolymers waste into monomers or oligomers or directly into some other valuable materials. The techniques for chemical recycling are varied and numerous, and depending on the type of polymer being recycled, each approach will have both benefits and drawbacks associated with it (Payne et al. 2019; Hopewell et al. 2009). In chemical recycling method, different reactions are carried out between reagents and biopolymers to obtain the subunits or monomers which are utilized to make new biopolymers to make different products (Lamberti et al. 2020a). In chemical method, dry heat is also used to break the bonds in material to depolymerize it (Niaounakis 2013c). The products of depolymerization are again polymerized into newer compounds. This method saves the material source, and it is beneficial for circular economy. Mostly solvolysis (Thiele et al. 2004) and depolymerization (Ponomarev 2018) methods are used in chemical recycling. These Chemical methods used for recycling are illustrated in Fig. 3.

Agaricus bisporus is an edible mushroom which is mostly used in the United States. A majority of the waste generated during mushroom cultivation and reap are stubbles and mushrooms with erratic shapes and sizes. The waste is 20% of the total yield. As a result, there is about 50,000 metric tons of garbage produced per year that cannot be used for viable purposes. The heaps of these wastes can be hazardous to the environment because of its decomposition and high volumes. However, the waste of this mushroom contains large amounts of chitinous biopolymers which find potential applications in bioinsecticide (Bhaskara Reddy et al. 1999), antimicrobial agent (Roller and Covill 1999), and it is also used to coat materials (Yu et al. 2020) and for water treatment methods. Wu, Tao, et al. extracted the chitinous material from the waste of these mushrooms and also determined glucosamine.

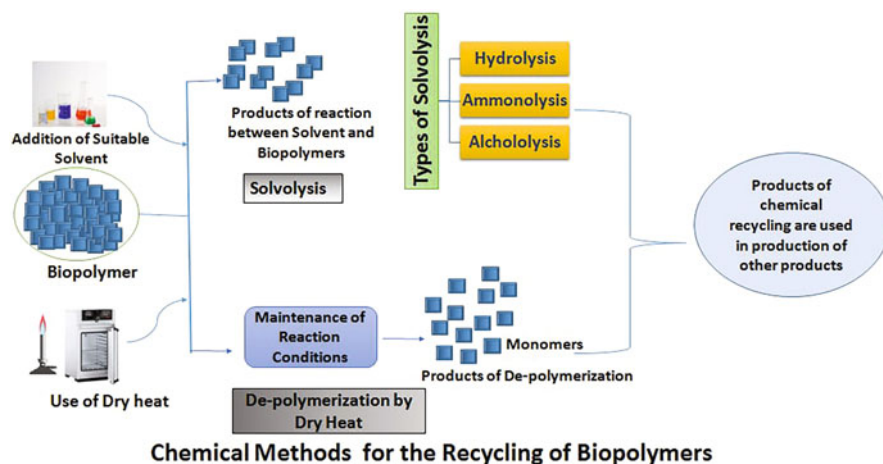

Fig. 3 Strategies used in chemical recycling of biopolymers

The acid and alkali treatment method was used to extract chitin from waste, and it was hydrolyzed to determine glucosamine. During postharvest storing, the chitin material in mushroom stalks increased to 19.02% dry weight (DW) which can be effectively removed. Given the type and volume of waste generated by mushroom cultivators each year, the suggested method might produce around 1000 metric tons of fungal chitin yearly. These materials obtained from waste can be effectively used as biopesticide, antimicrobial agent, and feed additive to regulate the growth of plants. This study was the initial step to change mushroom waste into a useful product (Wu et al. 2004).

The recycling of biopolymers through chemical methods is related to the restoration of usable chemical constituent such as any monomer or oligomer from the waste material. Recycling biopolymers is mostly done to preserve the material resources, reuse the recovered monomers, or make new polymers. The main chemical recycling techniques are (Niaounakis 2013d, 2019):

- Depolymerization by dry heat
- Hydrolysis
- Alcoholysis

Depolymerization by Dry Heat

It is a process that involves the conversion of polymers like PLA to their cyclic dimers or lactide form by subjecting them to temperatures higher than their transition temperatures in catalyst's presence. The depolymerization of PLA into its cyclic dimer via heating and reduced pressure is an old method that has been the subject of extensive research (Nishida et al. 2003; Fan et al. 2004). The method of depolymerization of PLA of high molecular weight by dry heat was reported by UHDE INVENTA FISCHER (EP2559725 A1) in 2013. The method has a limited polymeric production and is quite slow because of relatively low end-group composition; therefore, the reaction rate must be enhanced by increasing the temperature and catalytic concentration. According to a 1994 report by DU PONT (US5342969), thermal decomposition of PLA happens at an elevated temp, various side reactions take place, and it is hard to achieve a highly pure product. Furthermore, the racemization of the lactide happens when PLA is depolymerized by dry heat above its T_m , regardless of the PLA's molecular weight (Niaounakis 2019). Utilizing specialized catalysts at temperatures higher than T_m allows one to overcome the issues that were discussed earlier. The depolymerization catalysts are responsible for temperature reduction throughout the depolymerization process. The rate of thermal disintegration of PLA is accelerated by the use of the depolymerization catalyst, and the molecular weight of PLA immediately begins to decrease. One example of a catalyst is magnesium oxide that can be used to depolymerize PLA, whereas strontium oxide, calcium oxide, and barium oxide are some examples of additional alkaline earth metal oxides that may potentially be applied. Sn(II) 2-ethylhexanoate can also be utilized as a polymerization catalyst, and aluminum hydroxide can be employed as a flame retarder (Niaounakis 2019).

Hydrolysis

Hydrolysis is a chemical technique that has showed a great deal of potential for recycling biopolymers through depolymerization into its monomer subunits. Neutral hydrolysis, acidic hydrolysis, and alkaline hydrolysis are the three main kinds of hydrolysis which have been investigated in depth. In neutral hydrolysis, water or steam is used, heated to high temperatures (between 200 and 399 degrees Celsius), and subjected to high pressures (between 1 and 4 MPa). When the reaction takes place at temperatures that are quite close to the melting point of polymers and high-pressure mechanisms are applied, then high depolymerization rates can be achieved (Sinha et al. 2010). In acid hydrolysis, in addition to other mineral acids such phosphoric or nitric acid, concentrated sulfuric acid is the primary acid used. During the process of alkaline hydrolysis, an aqueous alkaline solution of sodium hydroxide or potassium hydroxide that has a concentration ranging from 4% to 20% by weight is used (Grigore 2017).

The hydrolysis of biopolymers relates primarily to the depolymerization of aliphatic polyesters in an aqueous medium at high temperatures and pressure in acid catalyst's presence. Lactic acid (LA) is produced through the hydrolysis of polylactic acid (Niaounakis 2019). Within two hours at temperatures between 160 and 180 degrees Celsius, PLAs undergo hydrolysis to produce LA at a conversion rate of 95 percent. Third-order kinetics is followed by the hydrolytic deterioration of PLA because the hydrolysis rate is dependent on the amount of water, biopolymer linkages, and acid-hydrolyzed byproducts (Piemonte and Gironi 2013). It is essential to remember that PLA hydrolysis is an autocatalytic process. This indicates that carboxyl groups that are formed on every hydrolytic cleavage will catalyze the reaction further. If the medium used for hydrolysis is basic, then the process of ester cleavage is arbitrary; however, in acidic medium, the process is chained unzipping. Rate constant, diffusion coefficient of chain fragments, percentage of absorbed water, solubility of byproducts, temperature, crystallinity, and pH of the PLA are the factors that affect hydrolytic degradation (Schliecker et al. 2003). The recovery of LA is an excellent illustration of the potential provided by chemical recycling method. It has been predicted that LA production by corn fermentation requires approximately 55 MJ energy per kg of lactic acid produced, whereas the production of LA through PLA hydrolysis requires a significantly lower amount of energy, approximately 14 MJ of energy per kg of LA produced (Piemonte et al. 2013).

Alcoholysis

Alcoholysis is a chemical process in which alcohol acts as the nucleophile. In the process of chemically recycling polyesters, a transesterification reaction takes place in which the alcoholic group breaks the ester linkages. Polymer is then depolymerized into its monomeric units or into materials with additional value (Lamberti et al. 2020b). For instance, valuable products can be produced from PLA by depolymerizing it through the process of alcoholysis. During a transesterification reaction, a wide range of alcohol groups are employed to target the

ester linkages of PLA, which then results in the production of lactate esters. In addition to this, a transesterification catalyst is needed to achieve adequate depolymerization under moderate reaction parameters (Román-Ramírez et al. 2018). Depolymerizing PLA waste with methanol, ethanol, propanol, or other solvents will result in the production of methyl lactate, ethyl lactate, and propyl lactate, each of which is a useful chemical in the manufacturing industry (Bowmer et al. 1998).

DU PONT (US5264614 A) reported a procedure for recycling aliphatic hydroxyl carboxylic acid-derived polyester wastes in 1993. The method involves heating of the waste in the presence of lower alkyl alcohols, i.e., CLEC6 alcohol or in H_2O , under high pressure in order to make the polyester soluble; the heating is carried out in such a way as to prevent deterioration of polyesters and by recovering polymers after the solution has been cooled (Niaounakis 2013d). In 2009, TEIJIN FIBERS LTD (P2009029757) reported a technique for the depolymerization of PLA. This approach involves the use of a catalyst that is simple to handle. Alcoholysis of PLA (such as Lacty[®] 9010, manufactured by Shimadzu) with methanol at temperatures ranging from 60 to 100 degrees Celsius in the vicinity of catalyst of zinc-containing compounds that is made of $ZnCO_3$ or zinc carboxylates is the depolymerization process. It was possible to obtain a sufficient amount of methyl lactate. PLA is derived from resources used in agriculture and fishing as well as containers used for food packaging and materials used in civil engineering and building (Niaounakis 2015).

Enzymatic Depolymerization

A majority of the chemical and thermal recycling processes described above require a significant amount of energy input, produce a low quantity of monomers in a short time, and eliminate additives and catalysts that were employed in the alcoholysis, hydrolysis, and depolymerization steps (Tsuji et al. 2003). The enzymatic depolymerization of biopolymers is an emerging and potentially useful recycling technology. The primary objective of this method is to reuse the products formed as a result of enzymatic degradation. This is what differentiates it from the disposal. The ability to polymerize and depolymerize a substance in an enzyme-catalyzed reaction is one of the benefits of using an enzyme, particularly hydrolases. The action of a hydrolase enzyme is used to cleave biodegradable biopolymers that include enzymatically hydrolyzable components such as esters. This step is necessary before biodegradable biopolymers may be further processed. To develop the enzymatic recycling of biodegradable biopolymers, like PHB, poly(butyl acrylate) (PBA), PLA, polycaprolactone (PCL), and poly(butylene adipate co-succinate) (PBAS), the enzymatic depolymerization and re-polymerization processes were executed. In a solution of organic solvents that also contained a minute quantity of water, lipase was used to degrade them, which resulted in the production of cyclic oligomer. This oligomer was easily polymerized again in great amount by the same catalyst, which resulted in the production of polyester with a molecular weight that was either equivalent to or

higher than that of the original polymer (Kobayashi et al. 2000; Takamoto et al. 2001; Takahashi et al. 2004; Matsumura 2002).

Keio University in Japan is responsible for the vast majority of the work that has been done thus far in the field of enzymatic recycling of biopolymers. A technique for manufacturing trimethylene carbonate (TMC) was disclosed in 2002 by UNIV KEIO (P2002017384). This approach involves selectively transforming a poly(trimethyl carbonate) (PTMC) into a polymerizable polymer in the presence of hydrolase. The depolymerizing hydrolase was successfully retrieved and put to further use without suffering any apparent loss of activity. The lipase that is developed from *Candida antarctica* (Novozym® 435) is the most commonly used. After adding the lipase to the chloroform, it was filtered to separate the components. Through the use of an evaporator, the solvent was extracted from the filtrate and concentrated. The silica gel column chromatography method was used to obtain 75 percent of the expected yield of trimethylene carbonate. Re-polymerization of PTMC that has been converted into monomer can occur in a selective manner. The recycling of PTMC by using an enzyme was reported by Matsumura et al. Using lipase from *Candida antarctica* in acetonitrile at a temperature of 70 degrees Celsius, the enzymatic transformation of PTMC with M_n of around 3000 to approximately 48,000 yielded the comparable cyclic monomer (TMC) yielding up to 80 percent (Matsumura et al. 2001).

A hydrolase was used in a depolymerizing process that was published in 2002 by UNIV KEIO (JP2002017385) to synthesize dicalpolactone. This method involved the selective transformation of PCL to monomer that can be polymerized again. By applying this process of depolymerization, the dicalpolactone can be produced in large quantities, and it is then possible to re-polymerize the dicalpolactone in the presence of a hydrolase, like lipase that is derived from *Candida antarctica*. Because enzyme activity is rarely diminished, the hydrolase that was used for depolymerization can be recovered and reused on multiple occasions (Ebata et al. 2000). To enhance intramolecular cyclization, the depolymerization of PCL by using enzymes into dicalpolactone demands high volumes of organic solvent like toluene solution (0.2%) (Kondo et al. 2002).

Disposal of Waste Biopolymers

Disposal of waste biopolymer is the last option for the end of the life products. Various techniques are used to dispose of the waste biopolymers which are illustrated in Fig. 4. Synthetic biopolymers cause more hazards to the environment as compared to bio-based material. The disposal mechanisms used for these wastes are not so efficient and eco-friendly. These waste materials cause pollutions and are hazardous to human being. Moreover, some biopolymer wastes are biodegradable, while others are not. Ecological conditions are deteriorated by disposing wastes in an inappropriate way (Kuppens et al. 2010). Therefore, different strategies are employed to dispose waste materials into the environment.

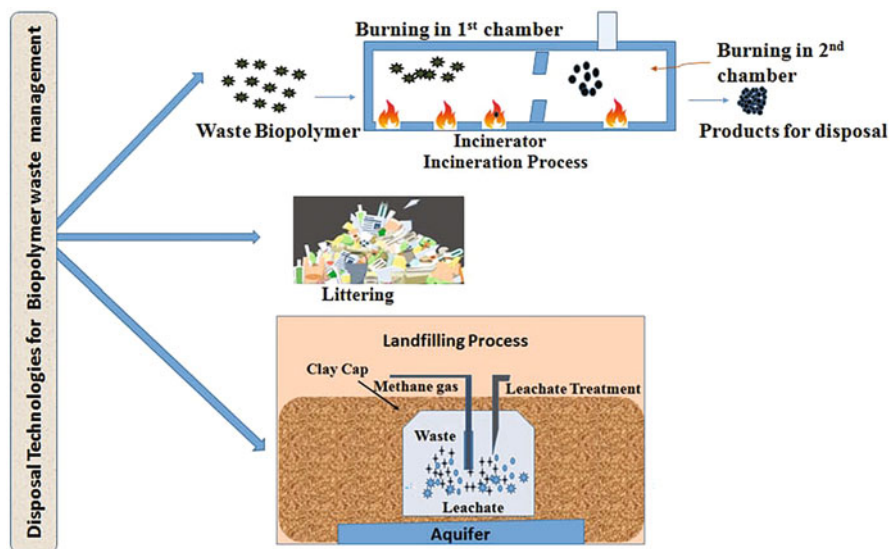

Fig. 4 Different strategies used for the disposal of biopolymers

Over the past ten years, the use of biodegradable natural polymers has increased in the United States, and it is anticipated that this trend will continue in the years to come. Few researchers have looked at how consumers actually use and discard biopolymers, despite the fact that some have been conducted to evaluate their environmental impacts. Meeks, Diana, et al. accessed and studied the data where biopolymers are used and their disposal. Audits of nearby grocery stores and semi-structured interviews with compostable biopolymer users in four separate food service types (restaurants, catering businesses, limited food premises, and outdoor recreation concessionary) were done to determine where compostable biopolymers are still being used. According to research, commercial food settings are where customers are most likely to come into contact with compostable biopolymers. Composability of biodegradable biopolymers was not the only consideration when deciding whether to buy them; other considerations included their presumed sustainability (Meeks et al. 2015). Accessibility to the infrastructure for composting and the general growth of the compost industry were the two most significant factors for all companies when making decisions about how to dispose of compostable biopolymers (Yates and Barlow 2013). The decision to compost biomaterials may even have the effect of diverting food waste from landfills, minimizing the environmental effects of both food scraps and the dumping of natural polymers (Levis and Barlaz 2011). Environmental impact studies will only be able to produce significant results that can guide best practices for municipal garbage management if they are conducted with a full knowledge about the real-world use. Sometimes the disposed waste material is valorized to form useful products. The development of foodstuff packaging materials using biopolymer derived from food processing wastes is seen to be a sustainable option to improve resource efficacy, and moreover, it lowers the

environmental issues caused by the disposal of packaging waste. Proteins exhibit considerable potential because of their richness in nature and inexpensive availability. Gelatin obtained from different sources, including fish, bovine, and pig, can be used to make active packaging. Gelatins find its use as bioactive component carriers for foodstuff packing in addition to medicinal uses. The shelf-life of food can be extended and food losses decreased by adding natural antioxidants and antibacterial agents in the formulations that create films (Etxabide et al. 2017).

The main global concern is the adverse effects of waste disposal on the environment because contamination and harmful compounds present in waste can migrate into soil and water bodies and through seepage can contaminate and pollute the groundwater as well. As polymers are complex structure made by the reaction of many repeating units called monomers, their degradation is not easy. A large amount of synthetic and natural rubbers is used in day-to-day life for various purposes (Shah et al. 2013). Their disposal on land causes harmful impact to the environment. Additionally, because there are fewer landfills available for the safe disposal of rubber debris, challenges with water and land pollution are being created by improper disposal of waste. One of the primary causes of climate change is the tremendous amount of energy released in the form of heat and smoke produced when rubber scrap is burned (Stevenson et al. 2008). Recovering or reclamation of rubber is a more advantageous technique of disposing waste rubber products because it not only conserves our finite supply of fossil feedstock but also preserves environmental quality (Adhikari et al. 2000). To save the environment, disposal regulation standards must be set and followed by the local government, industries, and domestic people. Proper treatment of waste is necessary before disposing them on open places (Ustra and Elis 2018).

Landfill

Biopolymer waste is disposed in landfills. It generates gases, and their uncontrolled gas release enhances the biological activity in organic matrix present in waste. If proper method is used, the gases released during landfill can be collected and used to convert energy to incinerate the waste material. Methane is usually released during landfill, but its amount is higher in the early stages, and later on a decline in its amount is observed. With the decline in methane content, the incineration process becomes difficult and expensive. Inert material is more preferred in landfill because they don't participate in the creation or emission of carbon dioxide or methane in an uncontrolled manner. Biopolymer landfills are generally considered as the least preferable alternative for dumping because they produce no benefits while simultaneously increasing emissions of greenhouse gases (Endres and Siebert-Raths 2011). Kendall, Alissa et al. studies the life cycle assessment (LCA) to investigate a possible path for generating PHB from the cellulosic portion of organic waste from material recovery facilities that otherwise would have been dumped in a landfill. This limitation applies not just to landfill activities, but also to any long-term processes related to product disposal. Increased variation in CO₂ emission estimations for PHB results from taking into account fluctuations in landfill gas

output, with values ranging from 1.7 to 6.3 kg carbon dioxide equivalent/kg PHB. The analysis of the evolving fate of carbon in MRF residuals revealed a prevailing weakness in LCA procedure: landfill simulation tools were not so accurate, and there was no agreement or a set of guidelines for choosing an analytical time horizon for taking into account landfill gas production and associated discharges (Kendall 2012).

Incineration

Incineration is thought to be the second-most popular end-of-life option after landfilling, with 800 metric tons of waste having been burned since polymers first entered the market (<https://assets.kpmg/content/dam/kpmg/uk/pdf/2019/06/to-ban-or-not-to-ban-v6.pdf>). Generally speaking, incineration (also known as burning) describes a reaction of waste at high temperatures and in the presence oxygen. It is a catalytic, exothermic reaction, and the heat radiation and free radicals it produces are what keep it moving forward. The irreversible chemical breakdown known as pyrolysis, on the other hand, is caused by an enhancement in temperature in the absence of oxygen and without the use of any oxidation processes. Municipal solid waste incineration is a technique for handling leftover that decreases the volume and quantity of solid waste that requires to be landfilled while utilizing the material's energy content. In Europe, it is a common technology (Oppelt 1987; Lam et al. 2010; Sabbas et al. 2003). In the Netherlands, accumulated polymers which cannot be recovered or reused are burned because landfilling is not allowed (Somers et al. 2021).

The researchers choose burning as a way to dispose, particularly for natural polymers, not only because of its high recycling efficiency but also because the thermodynamic efficiency yields the most return with the least effort and money. Since biopolymer includes a lot of bio-based components, incineration produces more CO₂-neutral energy. Additional energy recovery is appropriate irrespective of the input materials' foundation, renewability, or recyclability of all forms of bioplastics and their composites (Endres and Siebert-Raths 2011). Owing to the renewable calorific value, PLA biopolymers have always been the best alternative with a reduced carbon footprint when it comes to the end-of-life method which is most frequently utilized in Europe (incineration). After usage, the carbon footprint for PLA bio-composite items with low humidity may even be negative. With more energy needed for incineration due to a high moisture content, there are more CO₂ emissions. Biodegradable bioplastics have a smaller carbon footprint and can divert organic material for these purposes (PLA and PLA 2020).

Littering

Littering means throwing away of products carelessly. This ambient disposal is mostly observed in parks and other places. The usage of appropriate biodegradable polymers would ensure the products' eventual dissolution and degradation; in this

way, littering is done without taking into consideration the degradability and environmental impacts. If biopolymers were employed, the throw-away mentality would expand, and consumers would cease to distinguish between plastic garbage that degrades and waste that doesn't degrade without considering the degradability and environmental impacts (Endres and Siebert-Raths 2011).

Future Prospective

Researchers investigate anticipated future developments in the production and recycling of polymers and their potential effects on the accomplishment of recyclability objectives. The characteristics and behavior of the compound should be examined in order to determine the alternatives and constraints for the improvement of the recyclability of biopolymer products in the future. To manage bio-based waste effectively in the future, it is important to understand how these products are currently managed. Waste made of biopolymers must not be dumped in landfills, even if they are biodegradable. There are fundamental requirements and issues when handling bio-based polymers. To ensure the quality required when employing recycled materials obtained from biopolymer waste, the major industries must harmonize quality requirements at the level of the circular economy. The extensive use of recycled biopolymer manufacturing is thus supported by these standards, which may also contribute to a rise in the quantity of novel bio-based materials whose recycling will be possible by a number of cascade usage phases. The assessment approach thus emphasizes the identification of pertinent polymer advances and ranges for standardization (Hildebrandt et al. 2017). Disposal of the waste material should be the last option because when a material deteriorates, their products can be harmful for the environment. The management of individual waste streams following waste segregation is a key necessity, as a mixture of all home garbage and industrial waste is invalid for processing to recover materials. The used products that a consumer wants to discard must be tagged appropriately in order to make the waste management easy. This will make it possible to identify recycling routes, which will eventually boost the throughput of secondary raw resources. The selection of suitable method for the waste management will create multipurpose avenue for improved reuse, recycle, and disposal roadmap to manage solid waste in a cost-effective way.

Conclusion

Modern waste management must deal with a brand-new kind of garbage called biopolymers. There are numerous strategies to convert biopolymer waste treatment through recycling, salvaging, and reuse to decrease waste and boost revenue. An increasing drive toward a sustainable future includes hazardous waste sustainable or "green" management techniques that endeavor to preserve nature, reduce overall resource use, and improve energy efficiency. It has been demonstrated that

biomaterial sector can gain substantially from the implementation of waste management strategies that focus on appropriate dumping of waste and their reuse and recycling. To manage bio-based waste effectively in the future, it is important to understand how these products are currently managed. Industrial biodegradable polymers like PLA presently have minimal, dispersed waste streams, and their existing usage rates do not justify the establishment of an independent PLA recycling stream. As their large-scale commercial application takes off, the handling of biopolymers in the waste stream will become a critical concern.

Abstract

Petroleum-based polymers are linked to a variety of health and environmental issues throughout their life cycle, such as pollution, greenhouse gas emissions, persistence in marine and terrestrial habitats, etc. On the other hand, biopolymers are a fast-expanding class of polymeric materials that are frequently offered as substitutes for traditional plastics made from petroleum. However, there is a need to assess the true health and environmental impact of using biopolymers because they have also been connected to significant health and environmental problems like greenhouse gas emissions and adverse land use change. Though numerous evaluations include biopolymers, very few fully and concurrently analyze the advantages and disadvantages of using biopolymers for the environment. The

current chapter deals with the safety aspects of biopolymers in human health and the environment.

Keywords

Polymers · Biopolymers · Health impact · Environmental impact

Introduction

Polymers are macromolecules obtained through the association of monomers linked together with chemical bonds (Elias 1997). The word polymer originates from Greek and means many (poly) parts (meres). A polymer molecule size usually varies between 10,000 and 1,000,000 g/mol (St. Pierre 1972; Elias 1997). Polymers have immense applications in our day-to-day life, and even a new branch raised as polymer chemistry and people from different fields such as biomedicine and pharmacy, textile technologists, mechanical engineers, biochemists, and biophysicists contribute significant information that make polymer as an unavoidable thing in different fields including medicine (Pillai and Panchagnula 2001).

Polymers can be classified into two based on their origin: synthetic polymers and biopolymers (Fig. 1). Synthetic polymers are man-made, and biopolymers are polymeric macromolecules found in living organisms.

Synthetic polymers are structurally similar to biopolymers but are chemically synthesized for special uses. The physical forces included in the formation of synthetic polymers are similar to that of biopolymers such as dipole-dipole interactions, hydrogen bonds, and London forces (Ouellette 2015). Hydrogen bonding between amides and polyamides is responsible for the strength of synthetic polymers. Different polymerization methods like addition, copolymerization, and condensation are used, and products showed different characteristics based on their polymerization methods (Ouellette 2015). The synthetic polymer industry showed

Fig. 1 Classification of polymers

Table 1 Comparison between biopolymers and synthetic polymers (Shrivastava 2018)

Biopolymers	Synthetic polymers
Origin from nature	Man-made synthesis
Similar repeating units	Identical repeating units
Formation by biological processes	Formation by chemical process
Contains carbon, hydrogen, and nitrogen	Contains mostly carbon
Biodegradable	Only few are biodegradable
Sensitive to heat, chemicals, etc	Resistant to heat, chemicals, etc
Environmental friendly	Produce environmental issues

exponential growth because of its advantages over biopolymers. Table 1 illustrates the comparison between biopolymers and synthetic polymers (Shrivastava 2018).

Basic raw ingredients, termed monomers, are used to create synthetic polymers, which are collectively referred to as plastics (polycondensation, polymerization, and polyaddition) under specific circumstances. Plastics can take on a variety of shapes, including pipes, thin sheets, bottles, and bags, among others. They also resist corrosion and other chemical variables, are easy to handle, and work as thermal and electrical insulators; therefore, they have spread and are utilized in practically all spheres of human endeavor. Despite its undeniable usefulness in daily living, synthetic polymers turn into garbage after being utilized. 25 million tonnes of plastic are thought to be added to the environment each year, which can stay the same for a time period of between 100 and, due to its relatively slow disintegration, 500 years consisting its breaking up into smaller pieces. These particles cause issues with water, air, and pollution of the soil that directly affect the health and the environment. Moreover, the highest portion of plastics is made using fossil fuels, which places an undue burden on nonrenewable resources.

From Table 1, we could easily identify that synthetic polymers cause environmental problems, which prompted people to consider an alternative solution to synthetic polymers that has a lower environmental impact. Thus, people are again concentrated on biopolymers and think about the procedures that can be adopted to modify and make natural polymers with the advantages of synthetic polymers. Due to the aforementioned, the so-called biopolymers have been created, which have thermoplastic and physicochemical qualities comparable to petroleum-based polymers with the exception that they are biodegradable. The use of these resources raises a number of issues and problems, though, as the use of renewable raw materials does not necessarily indicate sustainability. We have to first understand the reason of emergence of biopolymer as an option. For this we have to understand the advantages and disadvantages of biopolymers and synthetic polymers, and that are listed in Table 2 (Muhamad II et al. 2014; Satturwar et al. 2003; Kulkarni Vishakha et al. 2012; Gavasane and Pawar 2014; Muxika et al. 2017; Muslim et al. 2013; Ahsan et al. 2018; Jesus et al. 2018; Maghsoudi et al. 2020; Jani et al. 2009).

The emerging trend of identifying and modifying biopolymers increases as it is believed that biopolymers are devoid of health and environmental effect of synthetic

Table 2 Advantages and disadvantages of biopolymers and synthetic polymers

Polymer	Advantages	Disadvantages
Natural polymers	Water-soluble Abundance Less toxic Biocompatible Biodegradable Less side effects Exerts less toxicity along with drugs Chemical modification possible Low cost Low angiogenesis Low immunogenesis Mucoadhesiveness	Chemical molecules are vary based on climate, geographical conditions, availability of nutrients, and thus chemical constituents different from batch to batch Microbial contamination is high Adulteration needed Heavy metal contamination Time consumption for extraction and purification Low mechanical strength Sensitive to heat and chemicals Recycling and reuse not possible
Synthetic polymers	Mechanical stability Durability Inertness Tunable Beneficial tailoring properties Reproducibility Bioabsorbable Environmental stability Biocompatible	Intrinsic biocompatibility and bioactivity are absent Toxic Oncogenesis Inflammation and immune response High production cost Water-insoluble

polymers. This chapter tries to understand the classification of biopolymers, their applications, and the impacts of biopolymers on health and the environment.

Biopolymer

Biopolymers are organic substances found in living organisms, and the term originates from Greek words bio and polymer (Ezeoha 2013). Biopolymers are biocompatible macromolecules that have immense applications in our day-to-day life. Biomolecules include nucleic acids, lipids, carbohydrates, proteins, etc. Polymers such as plastics are synthetic polymers but have more lifelong benefits compared to biopolymers.

Biopolymers can be classified based on different parameters, and one of the most important features for classification is based on their monomer, their origin, and source (Fig. 2). Based on their monomeric units, biopolymers come under three groups: polynucleotides, polypeptides, and polysaccharides (Pakawadee 2012). Based on origin, biopolymers can be classified into polyesters, proteins, polysaccharides, lipids, surfactants, polyphenols, and specialty polymers from natural fats and oils (Kaplan et al. 1994). Based on source, polymers can be classified into two and named as natural biopolymers and synthetic biopolymers (Baranwal et al. 2022).

Fig. 2 Classification of polymers based on origin, source, and its individual unit

Based on the source of polymers, biopolymers are classified into natural biopolymers. Natural polymers are obtained from living organisms and are good replacements for synthetic petroleum-based plastics. They are very much accepted by the people because of their abundance, renewability, cost-effectiveness, biocompatibility, and biodegradability. Starch, cellulose, chitosan, gelatin, carrageenan, and alginates are good examples of natural biopolymers. They are isolated from bacteria, fungi, plants, and animals.

Even though the abovementioned features of natural biopolymers are attractive, there are certain disadvantages that make us think about other nature-friendly materials. The disadvantages include low tensile strength and barrier properties (Baranwal et al. 2022). Since the origin is biological, some also exert immunogenicity and angiogenic properties (Shankar and Rhim 2018; Dmour and Taha 2018). And a multistep purification process is also required after their isolation from the source. Thus, modification of natural polymers is a thought that came to exist, and people tried to modify natural biopolymers to overcome the side effects associated with them. And this leads to the development of a new category called synthetic biopolymers. Polylactic acid, polycaprolactone, and polyvinyl alcohol are examples of some synthetic polymers (Kaplan et al. 1994).

Synthetic biopolymers can be defined as polymers that are produced from synthetically produced monomers or ones that are natural polymers modified with chemical processes (Jenkins et al. 1996). Biodegradability is the added advantage of synthetic biopolymers over synthetic polymers produced from nonrenewable sources like petroleum. Thus, synthetic biopolymers got much attention over both synthetic and natural biopolymers. Synthetic biopolymers are even better than natural biopolymers because of their higher stability and durability for their transportation and use. The most important advantage is that they are sterilizable and heat and chemical resistant, and so they can be used in the medical field.

Applications of Biopolymers

Natural and synthetic biopolymers have significant roles in our day-to-day life. Each and every field of our life is now connected to biopolymers, and some fields are listed below (Fig. 3).

Automotive industry: Biopolymers are nowadays used in automotive industry. Plastics are vital to the automotive industry because they are a readily available and manageable material, yet consumers are increasingly seeing pictures of mounds of trash and enormous floating islands of plastic. The issues with ordinary plastic might be partially resolved by the use of bioplastics. Polylactic acid, a polyester developed from cellulose, is proven as a replacement for synthetic polymers (Barillari and Chini 2020). By fermenting sugar, a raw material that is widely accessible in large quantities practically in any place, lactic acid for biopolymers is produced. Corn (USA), starch (Asia), and sugarcane all play important roles depending on the region. A great degree of efficiency can also be achieved in the conversion of sugar to the ultimate product: only about 1.6 kg of fermentable sugar is needed as a raw material to produce 1 kg of PLA (Lovett et al. 2017). This indicates that PLA are biopolymers that can be created using a technology that is very energy- and resource-efficient. PLA are with low softening skill, chemical resistance, aging resistance, and workability. These features prevent them from being a good alternative in automotive industry (Koltzenburg et al. 2014; Maier and Schiller 2016; Notta-Cuvier et al. 2014). Modification of conventional PLA with different new chemical treatment options makes it as a suitable material for automotive industry.

Textile industry: Textile can be defined as the network of intangible fibers (Law 2004). Natural, semisynthetic, and petroleum-based synthetic fibers are used for the production of textile fabrics (Karthik and Rathinamoorthy 2017). Problems

Fig. 3 Application of biopolymers

associated with conventional and synthetic fibers lead to the use of biopolymers. Biopolymers are used in textile industry as binding agents; levelling agents, providing uniform coloring to the cloth material; viscosity modifier; thickening agent; and textile finishing and for coloring.

Adhesive industry: Adhesive itself has huge applications in other industries like medical field. Renewable materials are now used as a source of adhesive synthesis (Gesthuizen and Robert 2018). Vegetable oils are one of such biopolymers with increased adhesive property because of its hydrophobicity. Renewable building blocks such as sebacic acid, itaconic acid, succinic acid, and even glycerol and fatty acids from vegetable oils are used as either biopolymers or building molecules (Heinrich 2019). Resin is another biopolymer which is used in pressure-sensitive adhesives and wooden floorboard adhesives (Quack and Yaacoub 1998).

3D printing industry: The rapid development of products with complex architectures is made possible by the groundbreaking additive manufacturing process known as three-dimensional (3D) printing. This review discusses the current state-of-the-art biopolymers (“protein- and carbohydrate-based materials”) used in pharmaceutical, bioengineering, and food printing, as well as the primary biomacromolecular structure reinforcement techniques used in the creation of 3D structures. There are also some viewpoints and key restrictions on the use of biomaterials in sophisticated 3D printing processes (Shahbazi and Jäger 2020). Biopolymers are the most often used materials for 3D printing applications due to the enhanced mechanical strength of the printed architectures and improved ink flow behavior. By utilizing the ability to change ink viscosity, bio-based polymers could enhance the resolution of deposited layers and printing accuracy and subsequently generate well-defined geometries. Protein-based biomaterials like gelatin, collagen, zein, soy, casein, and wheat flour are used in blend with other substances like starch, potato granules, etc. Chitosan, starch, pectin, and cyclodextrin are some of the polysaccharide-based biopolymers used for 3D printing (Shahbazi and Jäger 2020).

Packaging material industry: Flexible packaging typically uses biodegradable bioplastics, whereas rigid packaging typically uses bioplastics that are not biodegradable. The market for biodegradable, semi-durable, and durable bioplastics utilized in consumer and industrial applications is the main emphasis of the future of bioplastics (European bioplasticsb 2017). In place of traditional polymers, biodegradable polymers can be utilized for modified atmospheric storage (MAP) of fruits and vegetables. Starch-based polymers have wide acceptance as a packaging material for food, and some such polymers are polylactic acid, polyhydroxyalkanoates, etc. (Weber et al. 2002).

Biopolymers and health industry: As we mentioned above, biopolymers are used in different fields of health like pharmaceutical field and medicinal field. New technology always aims for maintaining health and life expectancy of humans. Synthetic and semisynthetic polymers are replaced by biopolymers, and they are now used in almost every field of medicine and treatment options. Drug delivery systems and surgery related processes like cell proliferation, isolation, covering, occlusion, adhesion, tissue guiding, etc. all hugely depend on biopolymers (Neuendorf et al. 2008; Chen et al. 2018; Tsai et al. 2018; Park et al. 2017). New

processes and techniques have been introduced to make biopolymers as the most suitable material for biomedical applications (Yahya et al. 2021). The applications of biopolymers in the medical field are soft tissues replacement, artificial hearts, bone cement, pacemaker, breast implants, extracorporeal oxygenators, contact lenses, sutures, adhesives, coating of pharmaceutical medications, blood substitutes, encapsulations, joint replacement, dentistry, drug delivery, cardiac assist devices, targeting sites of tumors and inflammations, tissue engineering, etc. (Pattanashetti et al. 2017; Reddy et al. 2015; Wróblewska-Krepsztul et al. 2019; Gagliardi et al. 2021). Biopolymers that are used in different fields and their application in the medical field are listed in Table 3.

Health and Environmental Impacts of Biopolymers

The impacts of biopolymers on human health and the environment depend on the type of feedstock used for biopolymer production. The feedstocks are divided into three generations: first, second, and third (Ahorsu et al. 2018).

First generation: carbohydrate-rich feedstocks include corn, wheat, sugarcane, sugar beet, potato, plant oil, and rice and are used as human and animal food.

Second generation: feedstocks include nonfood crops like cellulose or byproducts of the first-generation feedstocks like corn stover or sugarcane bagasse.

Third generation: biomass derived from industrial or municipal water, algal biomass, and food industry byproducts.

The first-generation feedstocks do not produce much health effects at lower concentrations since they are consumed as food products. But they have a high impact on the environment; for the production of feedstocks, huge agriculture land is required which affects the ecological balance (Tenenbaum 2008). Like the first-generation feedstocks, the second-generation feedstocks do not produce much conflict on health unless it is a residue of the first-generation feedstocks. A high cost is required for the processing of the second-generation feedstocks (Rosenboom et al. 2022). Both generations use fertilizers, herbicides, and pesticides which in turn causes serious health issues in humans and animals. The third-generation feedstocks do not need fertilizers and pesticides. The third-generation feedstock does not need fertilizers and pesticides but industrial and municipal wastes, phytoplankton and algae contaminated with toxic substances like heavy metals affect health of living organisms. The process of removing such toxic substances is nearly impossible, and the cost and time of production are more (Atiwesh et al. 2021).

Overall, life cycle evaluations have shown that the initial generations of bio-based plastics have lesser substantial negative impact on human health and the environment than their petrochemical competitors (Brizga et al. 2020). Not all categories, nevertheless, fall within this category. When compared to petrochemical materials, the feedstock growing phase has a higher need for water and arable land (Haider et al. 2019; Bishop et al. 2021; Atiwesh et al. 2021). There are linked environmental effects when land use changes from a natural environment to biomass agriculture. Because native plants and animals are displaced or have less space to establish a

Table 3 Biopolymers and its applications in health

Biopolymers	Applications	Reference
Collagen	Suture, hemostatic agent, bone graft substitute, drug delivery	Burke et al. 1981 ; Royce et al. 1995 ; Merodio et al. 2002
Natural poly(amino acids)	Drug delivery vehicle, tissue engineering scaffolds, thermosensitive polymers	Akio et al. 2008
Elastin	Injectable drug delivery system	Chilkoti et al. 2006
Fibrin	Treatment of chronic wounds	Wang et al. 2001 ; Grassl and Tranquillo 2006 ; Terasaka et al. 2006
Hyaluronic acid	Wound dressing, synovial fluid substitute, bone graft for bone fracture	Prestwich et al. 1998 ; Mori et al. 2004
Chondroitin sulfate	Antiinflammatory properties, wound dressing, production of hydrogels for biomedical applications	Iovu et al. 2008 ;
Chitin and chitosan	Wound healing accelerator, chitosan conjugates for cancer treatment, scaffolding material, antibacterial and hemostatic properties	Onishi et al. 2001 ; Illum et al. 2001 ; Jayakumar et al. 2007 ; Hein et al. 2001 ; Dodane and Vilivalam 1998
Alginic acid	Wound dressing, drug delivery, protein delivery system, wound healing	Salgado et al. 2002
Xanthan	Controlled drug delivery	Shingel and Marchessault 2006
Gum arabic	Suspending and emulsifying agent, reduces blood cholesterol, blood pressure	Seema and Arun 2015
Starch	Controlled drug delivery, tablet disintegration	Matveev et al. 2001 ; Lu et al. 2009
Cellulose	Controlled pharmaceutical delivery systems, hydrogel production	Swabrick and Boyan 1991
Pectin	Suspending and thickening agent, reduce blood cholesterol, treat gastrointestinal diseases, tissue engineering applications	Munarin et al. 2011 ; Linshu et al. 2004
Carrageenan	In drug solution for increasing the permeability of drugs	Pacheco-Quito et al. 2020
Poly(α -esters)		Burg 2014
Polyglycolide	Sutures, as bone internal fixation devices	Singhvi et al. 2019 ; Gorrasi and Pantani 2018
Poly lactides	Drug delivery, scaffolding material for tissue regeneration, suture development	Fu et al. 2000
Poly(lactide-co-glycolide)	Multifilament suture	Makadia and Siegel 2011 ;

(continued)

Table 3 (continued)

Biopolymers	Applications	Reference
Polycaprolactone	Contraceptive device, monofilament suture	Thomas 2011 ; Malikmammadov et al. 2018
Polydioxanone	Treating small bone and osteochondral fragments	Martins et al. 2020 ; Chen et al. 2006
Poly (3-hydroxyalkanoates)	Drug delivery vehicle, surgical implant	Hu et al. 2003 ;
Poly(ester amide)	Site-specific delivery of small hydrophobic drugs and peptides	Dias et al. 2006 Hu et al. 2003 ; Khanna and Srivastava 2005 ; Jeon et al. 2007 Francis et al. 2010
Poly(orthoesters)	Drug delivery especially for ocular applications	Mansour et al. 2010
Polyanhydrides	Localized drug delivery vehicle in chemotherapy for brain cancer and osteomyelitis	Basu and Domb 2018 ; Gunatillake and Adhikari 2003
Polypropylene fumarate	Bone tissue engineering applications	Armmrtno et al. 2010 ; Heller and Gurny 1999
Poly(alkyl cyanoacrylates)	Tissue adhesive for skin application	Andrianov and Payne 1998
Polyphosphazenes	Scaffold for tissues engineering	Langer 1997
Polyphosphoester	Drug delivery applications, scaffold for tissue engineering	Naser et al. 2021

home, biodiversity declines as natural areas are converted to agriculture (Haider et al. [2019](#); Atiweish et al. [2021](#); Nanda et al. [2022](#)). The usage of pesticides and fertilizers throughout the growth stage of the feedstock is frequently observed as the primary source of concern for human health and the environment. Pesticide exposure can occur orally, topically, or through soil, water, or air contamination. Harmful algal blooms, which produce toxins and other toxic substances in water, are associated to pesticide exposure (Nanda et al. [2022](#)).

Respiratory issues, neurological impacts, stomach or liver disorders, and skin irritation are some of the negative health effects of exposure. Additionally, 99 percent of utilized pesticides and 95 percent of applied micronutrients for agrochemicals bounce off the plant and are wasted (Duarte et al. [2016](#)). Due to the creation and application of fertilizers, the eutrophication and acidification consequences of the first-generation feedstocks are often harsher than those of their fossil fuel counterparts. Eutrophication can result from fertilizer nutrients entering the bodies of water, and biopolymers' acidification action is aided by emissions from fertilizers into the soil (Nanda et al. [2022](#)). In particular, even when accounting for the CO₂ emission at the end of the product's life and the net CO₂ effect from plant growth, the use of nitrogen fertilizers increases the global warming impact (Nanda et al. [2022](#)).

The food vs. fuel dispute is significant since the first-generation feedstocks are also utilized as food, which results in biopolymer synthesis being in direct conflict with food production (Duarte et al. [2016](#)). An adverse economic effect might be

higher food costs, which would increase food insecurity, resulting from increased demand for corn and sugar for the development of bioplastics. One of the most important effects of the food vs. fuel debate on public health is identified as being food security (Duarte et al. 2016). Currently, there is little competition between industrial production and food and feed production for arable land. Less than 0.02% of the world's agricultural land is now dedicated to the production of bioplastic feedstock (Duarte et al. 2016). The agricultural sector is anticipated to remain at a low 0.06% in 2025 despite the forecasted increased growth in the bioplastic market (Duarte et al. 2016). For background, around 91% of the agricultural acreage is used for grazing, food, and feed (Duarte et al. 2016). Even though there is no competition between the productions of food, feed, and biopolymer feedstock, there are still rising food demands and ongoing strains on the food supply. The resources available for industrial production will be affected.

Health Impacts of Biopolymers

The health impacts of biopolymers are still under study, and a long duration is necessary to understand the toxic effects of biopolymers. The three primary reasons why biopolymers are harmful are well explained in the literature: The first is that they cause an excessive amount of granulomas, an inflammatory response, in the body due to the immune system's recognition of the biopolymer as a foreign substance item, and encapsulating it causes a defensive response it. Second, they can move away from where they were applied, resulting in issues on other distant places. The third reason is because they frequently fail to meet the minimal standards for health controls, which raises the danger. Local reactions include fibrosis and lesions, and modifications in skin texture are key additional effects of biopolymers. When this occurs, it can occasionally result in death from an embolism when chemicals are directly injected into the blood vessel (Samir et al. 2005a; Peng et al. 2011).

Certain studies reported the deleterious effect of biopolymers on health. Nanocellulose is a biodegradable biopolymer derived from bacteria and algae and has been used for their pharmaceutical and cosmetic effects (Terech et al. 1999; Siqueira et al. 2009; Lima and Borsali 2004; Grunert and Winter 2002; Samir et al. 2005b; Adamis 1997; Cullen 2002). Several studies reported the pulmonary toxicity of nanocellulose (Kovacs 2010; Tatrai 1995; Warheit et al. 1998, Warheit et al. 1998, Roman et al. 2009; Yanamala et al. 2014). In human endothelial cells, it is nontoxic at a concentration of 0–50 µg/mL, and above that it exerts physiological changes (Eroglu et al. 2017). Other studies also supported the abovementioned findings, and they proved that nanocellulose induces fibrous bronchiolitis, pulmonary granulomas, inflammation, alveolitis, etc. (Radu et al. 2019).

Calcium hydroxyapatite causes infection, arterial embolization, swelling, nodule, blindness, necrosis, and blanching as clinical complications (Taghizadehghalehjoughi Taghizadehghalehjoughi et al. 2018; Voss et al. 2020; Velard et al. 2015; Bharadwaz and Jayasuriya 2020). In in vitro studies, exposure of calcium

hydroxyapatite increases inflammatory markers like TNF- α , IL-8, IL-10, and IL-1 in monocyte culture (Morhenn et al. 2002).

Collagen showed discoloration, skin necrosis, granuloma formation, blindness, and foreign body reactions as clinical manifestations (Velard et al. 2015; Farina et al. 2018). In *in vitro* studies, phagocytosis of collagen by immune cells released TNF- α (Saththianathan et al. 2017).

Hyaluronic acid clinically showed swelling, pain, arterial embolization, bleeding, blanching, Tyndall effect, infection, and nodule formation (Taghizadehghalehjoughi et al. 2018; Voss et al. 2020; Velard et al. 2015; Bharadwaz and Jayasuriya 2020; Tesar et al. 2006). Hyaluronic acid helps bacterial growth in biofilm and contaminated tissue engineering material (Jeong et al. 2021). In murine cell culture, it acts as innate immune agonist (Jeong et al. 2021; Centeno and Young 2006; Saththianathan et al. 2017).

Poly-L-lactic acid causes infection, swelling, blindness, bleeding, granuloma, nodules, etc. (Taghizadehghalehjoughi et al. 2018; Voss et al. 2020; Velard et al. 2015; Cabral et al. 2020). *In vitro* studies showed that cells treated with poly-L-lactic acid cause a reduction in cell proliferation and viability (Shoenfeld and Agmon-Levin 2011; Ameratunga et al. 2017).

Autoimmune/inflammatory syndrome induced by adjuvants (ASIA) is another health condition induced by adjuvants that are used along with biopolymers (Colafrancesco et al. 2014). Silicosis, postvaccination phenomena, macrographic myofasciitis syndrome, Gulf War syndrome, sick building syndrome, Sjogren's syndrome, and autoimmune thyroiditis have been reported as part of ASIA (Wadat et al. 2016; Vera-Lastra et al. 2013; Hawkes et al. 2015). These conditions lead to clinical characteristics such as chronic pain, fibromyalgia, chronic fatigue syndrome, cognitive dysfunction, myalgia, fever, arthralgia, and autoantibody positivity (Pachón et al. 2021; Tchounwou et al. 2012; Jamshaid et al. 2017).

Biopolymers are preferable to synthetic polymers in terms of their safety, but they also possess health issues, such as bioaccumulation, carcinogenetic properties, air pollution, and respiratory illness. Technologies have to be developed further to remove the health impacts of biopolymers.

Environmental Impacts of Biopolymers

Invention of biopolymers helps to avoid many environmental issues including the removal of heavy metals and dye, cleaning of oil spillage, carbon dioxide adsorption, and wastewater treatment, etc.

Removal of heavy metals: Heavy metals are needed for various industrial processes for energy production (Anastopoulos et al. 2017). Thus, large quantities of industrial waste containing heavy metals are generated. And these wastes are sometimes not even processed further and dumped into the environment which leads to the contamination of water, air, soil, and biosphere. They are toxic and nonbiodegradable, and one of the most serious issues associated with heavy metals is their persistence and bioaccumulation. They enter the food chain and reach the

human body through contaminated plants and animals. Heavy metal contamination is a serial health issue that causes birth defects, skin irritations, liver toxicity, stomach cramps, nerve system damage, and autoimmune diseases. Industrial wastes are subjected for heavy metal removing using processes like coagulation, biological treatments, chemical precipitation, membrane filtration, adsorption, etc. Adsorption is the most effective method, and biopolymers are nowadays used as a cheap and energy-efficient method, and cellulose, chitosan, and chitin are used as heavy metal adsorbents (Zhang et al. 2016; d'Halluin et al. 2017; Chequer et al. 2013). Biopolymers in combination with other compounds are proven to be effective in removing heavy metals. For example, cellulose with ethylenediaminetetraacetic acid removes heavy metals from water and is effective in removing lead, cadmium, nickel, zinc, etc. (Yagub et al. 2014).

Removal of dye: Dye is an important component in textile, paper, leather, printing, and paint industry, and about 10–20% of totally produced dye is discharged directly into the water sources (Zhou et al. 2011; Li et al. 2013; Zhu et al. 2007). Among the dyes, mostly colored and acid dyes are very dangerous because it cannot be easily removed from the water bodies especially using conventional methods. Organic dye discharge into water bodies has caused immediate and ongoing issues for human health and ecosystems. For instance, the release of those organic dyes might result in eutrophication, non-esthetic pollution, imbalance in the aquatic biological systems, chronic toxicity, carcinogenicity, and neurotoxicity toward humans and animals, among other negative effects. Chemical precipitation and adsorption (Patel and Vashi 2012; Teh et al. 2016), coagulation and flocculation (Chan et al. 2009; Işık and Sponza 2006), aerobic and anaerobic treatment (Alaoui et al. 2015; Ciardelli et al. 2001), electrochemical oxidation and reduction (Zhang et al. 2011), membrane separation (Dariani et al. 2016), H_2O_2 /ultraviolet (UV), photocatalysis (Rosario-Ortiz et al. 2010; Huang et al. 2014; Raghu and Basha 2007), ultrafiltration (Zhang et al. 2011), ion exchange (Zhuang et al. 2010), sonochemical degradation (Lim et al. 2006), Fenton and heterogeneous Fenton-like catalysis (Hsueh et al. 2005; Matheswaran and Raju 2010; Serpil 2019), and electrolysis (Liu et al. 2015) are some of the commonly used technologies for removing organic dyes from wastewater (Ruan et al. 2018).

Biopolymers are used for removing dyes because of their sorbent properties. Aerogels are used to remove cationic dye malachite green from water sources, and cellulose-based bioadsorbent was used to remove anionic dye (acid blue) and cationic dye (methylene blue) along with acrylic acid and acrylamide (Doshi et al. 2018). 2,3-Dialdehyde cellulose-chitosan showed 100% of Congo red dye removal (Tu et al. 2018). More technologies are being developed to identify the best adsorbent for different categories of dyes (Ruan et al. 2018).

Oil spilling and solvent spilling cleanup: Oil or solvent spilling is the discharge of oil or solvent accidentally or intentionally to the environment and which causes intense water pollution (Ruan et al. 2018). The production of oils and solvents results in huge costs and increased usage demanding for its transport into different parts of the world. One of the most important things in oil spillage other than money loss is its impact on water bodies. To protect the aquatic environment and subsequent

contamination to human body, the spillage should be removed as soon as possible. Different approaches are used like bioremediation, physical diffusion, mechanical recovery, and in situ burning (Xu et al. 2018; Cheng et al. 2017). Different studies proved the effectiveness of biopolymers to adsorb oil/solvent filling, and one such study showed that magnetic hydrophobic polyvinyl alcohol-cellulose nanofiber aerogels absorb oil effectively (Le Quéré et al. 2012). Cotton/cellulose aerogels also remove oil and organic solvents (Cassie and Baxter 1944).

Carbon dioxide adsorption: Synthetic polymers and huge carbon monoxide and carbon dioxide emission lead to global warming and climate change (Wang et al. 2011). By 2030, the carbon dioxide levels will be in the range of 600–1550 ppm (Leung et al. 2014). CO₂ is a greenhouse gas that has inherent ability to increase temperature which leads to the rising of sea levels, changing rainfall patterns, and weather changes including flood, freezing winters, and severe heat waves and droughts (Ruan et al. 2018). Carbon dioxide capture, storage, and utilization technique is widely used to control CO₂ emissions (Dassanayake et al. 2016; Sehaqui et al. 2015). Different materials are used for this purpose, and biopolymer also showed good results for the absorption of CO₂. Activated carbon monoliths from cellulose-based gel have CO₂ absorption properties at low temperature (Rahman and Hasan 2019). Nanofibrillated cellulose-polyethylene foams are reported to have direct absorption of CO₂ (Kehinde et al. 2020).

Effect of Biopolymers on Our Environment

The development of new solutions to ease our human life mostly ends up with issues in the environment. That is why sustainable development has its huge acceptance. Invention of artificial or synthetic polymers is thought to be a major advantage for us which overcomes the disadvantages of natural polymers which include the variability associated with the source, complex structures, tedious and costly extraction process, etc. Synthetic polymers that are mostly developed from nonrenewable petroleum sources have good strength, resistivity, and flexibility, and its most favorable feature is its chemical and biological inertness. Chemical and biological inertness is responsible for its long-lasting usage and is one of the most favorable reasons for its wide acceptance. Even though it was considered as the most beneficial advantage of synthetic polymers, within a short period of time, the blessings turn into a curse; because of their inertness to chemical and biological reactions, the synthetic polymers became a problem as a waste material and cause detrimental effects on the environment. Every year, the demand for synthetic polymers is also increasing. This leads to thinking about modified biopolymers that are compatible with synthetic nonbiodegradable polymers except for its biological degradation. The advantages of synthetic biodegradable polymers can be understood by knowing the detrimental effects of nonbiodegradable polymers on the environment. Synthetic nondegradable polymers are artificial polymers like plastics that are developed from fossil fuels and synthetic biopolymers that are modified from natural polymers or produced from chemically synthesized synthetic monomers (Blettler et al. 2018).

The nondegradable polymers from nonrenewable resources have deleterious effects on the environment. The accumulation of nondegradable polymers contaminates water, land, and air which further affects the lives of organisms and the ecosystem (Kaza et al. 2018).

The aquatic system is polluted with the accumulation of polymers like plastics in water resources (Charles et al. 2008). Humans either directly introduce synthetic, nondegradable polymers into water sources or indirectly through the soil. When plastics are released into the ocean as sediments, a concentration that is far more hazardous than that found in sea water is created automatically. Heavy metals and organic chemicals created by hazardous pollution brought on by this plastic debris being dumped in the water are priority pollutant metals. By ingesting this contaminated seafood, humans can become exposed to this pollution through their tissue and skin as well as through aquatic life. Because they spend most of their time near the ocean on land or on the water surface, drinking sea water, or eating these infected seafood, ocean birds are also at risk (Charles et al. 2008).

According to the US National Institutes of Health, 44 percent of seabird species are known to have consumed synthetic polymers that were mistaken for food (Saleh and Gupta 2016). Millions of seabirds per year perish as a result of this ingestion. This is one of the most frequent environmental issues connected to the pollution of synthetic polymers. Given that shorebirds are crucial for maintaining fish and crustacean population numbers, the widespread loss of shorebirds poses a serious environmental issue.

Persistent organic pollutants, such as pesticides, DDT, and toxaphene, are well-known poisons that linger in the environment for many years. In a 2007 investigation, scientists from the University of the Pacific took samples of synthetic polymers from coastal locations in the northern Pacific Ocean and discovered hazardous chemicals in each sample. These artificial polymers pose a threat to the sustainability of human food-producing ocean fisheries by continuously secreting toxic compounds into fish and other species.

Synthetic polymers can cause environmental issues throughout the production process in addition to their obvious ocean contamination. According to the Environmental Working Group, the DuPont chemical plant has been leaking contaminants used to make Teflon into nearby watersheds for many years. The US Environmental Protection Agency claims that this toxin builds up in fish gills and can go far up the food chain (Armand 1994).

Synthetic polymers are a huge problem on land since they are frequently disposed of in landfills, where they will linger for generations while gradually leaching toxins into the soil. This is in addition to their persistence in seas and the water contamination they cause during production. Less than 1% of the synthetic polymer plastic bags that are used each year in the United States, according to the Clean Air Council group, are recycled. In addition to slowly releasing toxic compounds into the soil, the longevity and nonbiodegradability of these synthetic polymers mean that, as their use expands, landfills will continue to be required on a regular basis.

The initial step in the production of conventional petroleum-based synthetic polymers is the distillation of crude oil in an oil refinery. The heavy crude oil is

divided and fractionated into segments or collections of lighter parts. Polymeric hydrocarbon chains with various sizes and structures make up each section. The essential ingredient required to manufacture plastic-making monomers like ethylene, propylene, and styrene is naphtha, one of these fractions. With the aid of particular catalysts, these monomers undergo polyaddition and/or polycondensation to create plastics (Buis 2019; Barker et al. 2007). But this process generates pollutants and greenhouse gases like carbon dioxide (CO₂), which worsens environmental pollution and accelerates global warming (Weiss et al. 2012).

Biopolymers are produced from nature itself, and people believed that since its origin is not toxic. But thorough study is required to understand the effect of biopolymers on the environment. The appeal of bioplastics as alternatives to petroleum-based polymers depends in part on their capacity to achieve both economic and environmental objectives. The following reasons make bioplastics and other bio-based products of great societal, environmental, and commercial interest:

- Their use of renewable resources, which reduces the dependence of plastics on fossil fuels, which are becoming more expensive
- Their potential to provide better recovery and recycling options than petroplastics and other materials, including frequently high biodegradability or compostability
- Their potential to increase industrial competitiveness through novel, eco-efficient bio-based goods and uses
- The potential for bio-based products to create more jobs than biofuels do

Biopolymers and greenhouse gas (GHG) production: GHG production and its effects on climate change are significant aspects of the plastic manufacturing process. It will be extremely difficult for all economic sectors to meet the forecasts for stabilizing atmospheric GHG concentrations at 450 ppm CO₂ by 2050 (Ojeda et al. 2009), which call for emission reductions of 80% from the 1990 levels. Many nations have set goals for such drastic cuts in GHG emissions (Yagub et al. 2014), and many have made developing a national strategy for a bio-based economy a top priority. Based on 44 LCA studies covering roughly 60 different bio-based materials and 350 different life cycle scenarios, a comparison of the cradle-to-grave GHG emissions linked to conventional and bio-based chemicals suggests that the GHG emission savings connected with bio-based products (including bio-based plastics like polytrimethylene terephthalate, polylactic acid, and PHA) are superior to those for their conventional counterparts (Sudhakar et al. 2008). Statements about the advantageous effects of bioplastics for GHG emissions are dubious because of the wide error margins attached to these predictions.

Ocean accumulation of biopolymers: When considering that 75–80 million tonnes of packaging plastics are used globally each year and that 25 million tonnes of plastics are added to the environment each year, much of which ends up in the oceans (Teuten et al. 2007; Jim et al. 2013), it becomes clear that there is a problem with plastic pollution caused by nonbiodegradable materials. The pace of biodegradation is extraordinarily slow once an object is in the ocean. Additionally, there are almost no data on the rate at which plastics mineralize in the marine environment.

While there are often relatively low levels of pollution in ocean waters, hazardous and persistent bioaccumulating pollutants can concentrate when they bind to drifting plastic garbage. The buildup of polychlorinated biphenyls (PCBs), chlorinated insecticides, and polycyclic aromatic hydrocarbons (PAHs), which are proven carcinogens and are thought to be endocrine disruptive substances, on such polymers is of special concern (Naser et al. 2021). Tauten et al. proved that the tendency for dangerous, poisonous contaminants to accumulate on plastics in the marine environment is demonstrated in the laboratory by this (Agrawal et al. 2010).

Fully biodegradable bioplastics do not provide the same issues as traditional plastics that are not biodegradable. However, it has only just come to light that “microplastics,” which can be produced when bioplastics partially degrade, are accumulating in the environment, particularly in coastal habitats (Haider et al. 2019). Microplastics have been proven to be swallowed by a variety of creatures and have enormous surface-to-volume ratios, which may facilitate the exchange of contaminants. If this results in the bioaccumulation of the contaminant load (absorbed and plastic additives), and consequently if microplastics constitute an additional and major vector for transferring pollutants and dangerous compounds, then this is one of the biggest unknowns.

Water pollution: Growing and processing bio-based feedstocks used to make plastics use a lot of water. Industrial agriculture-derived feedstocks have the potential to contaminate water supplies since they used a large amount of chemical fertilizers and pesticides. These may reach to our body through the consumption of polluted water and lead to bioaccumulation of toxic substances (Rosenboom et al. 2022). Current biopolymers put pressure on the available water resources in both of their realities. Several water bodies are contaminated with plastics, which are not intended to degrade in water (Rossi et al. 2015).

Biodegradation of biopolymers: If given the right, controlled environment, biopolymers can biodegrade and recover energy (Naser et al. 2021). Usually, composting is an aerobic process (with oxygen). Compostable biopolymers don’t always improve compost quality or allow for energy recovery (Wang et al. 2021). Not all biopolymers are compostable or biodegradable and will instead be recycled, dumped in the ground, or burned. Composting may provide a few benefits over incineration with heat recovery in municipal solid waste incinerators, according to many research (Wang et al. 2021). Composting can produce a small number of useful byproducts and energy (Wang et al. 2021). CO₂ emissions from municipal incineration and composting are comparable. Although bio-based plastics won’t emit hazardous gases if they don’t degrade, landfilling is the least advised method (Hahladakis et al. 2018). Inconsistent temperatures, a lack of moisture, oxygen, and other factors prevent biopolymers from degrading in a landfill environment (Hahladakis et al. 2018). Polymers that are compostable and biodegradable are made to break down when they are exposed to specific environmental factors. A biopolymer, such as PLA, won’t decompose in a landfill (Hahladakis et al. 2018). This puts more strain on landfills and necessitates extra space for trash. This goes against one of the motivations for biopolymer innovation, which is to decrease garbage generated physically and reliance on landfills. Additives and biodegradable

materials are another issue. Biodegradable plastics that are released into the environment produce microplastics. At any point during their lifespan, bioplastic products have the potential to release additives and microplastics. Conclusions about the costs to the environment and public health associated with the destiny and migration of bio-based microplastics require further study. The potential of biopolymers to recycle help to prevent the carbon cycle and support a circular economy. To reduce the amount of raw materials required and waste should be a top goal to produce valuable byproducts from bio-based resources.

Energy source for biopolymer production: Even though biopolymers originated from natural materials, the processing and purification of biopolymers use non-renewable resource as energy source (Hahladakis et al. [2018](#)).

Conclusion

The health and environmental impact of biopolymers is less when compared to conventional polymers. But it does not mean that they are sustainable in production and completely safe for our environment. There are several factors that determine the synthesis, toxicity, degradation, and features of biopolymers. So each polymer should be studied separately for identifying their impact on the environment. Environmental impact of biopolymers are not only associated with its purified form but the production of raw material and its required resources, processing and purification techniques etc also cause harmful impact on environment. It would prevent the pressure on resources caused by the production of the first-generation feedstocks, which includes the usage of land, water, hazardous chemicals during cultivation, fertilizer input, and emission impacts. The third-generation feedstocks' latent CO₂ emissions into the atmosphere are at their lowest since their carbon is integrated into the polymers. Overall, it would have a lessening effect on aspects of the environment relating to climate change, local ecological harm, and human health. The obvious drawbacks of this generation include its advanced technology needs and energy-intensive requirements. To minimize the negative effects on the environment and human health, responsible integration of sustainable agriculture is required while pursuing the first- and second-generation feedstocks. Despite the fact that bioplastics only occupy a small amount of land globally, it is crucial to utilize that area effectively. The sustainability and efficacy of the feedstock should be taken into consideration when choosing the biomass type for a biopolymer. The first generation of biomass currently has the highest yields and requires the least amount of growing space. Due to their extremely high land efficacy, growers should concentrate on high-yielding crops to reduce the negative effects of intensive agriculture on the environment and human health. Particularly, sugar crops have the most developed infrastructure, the biggest GHG reductions, and the lowest GHG abatement costs followed by starch crops. Because pesticides and fertilizers have such wide-ranging effects on the environment and public health, reducing and regulating their use need to be a top focus. By developing better tools, creating goods with better chemicals, and altering the ways chemicals are utilized, pollution of the soil, water, and air can

be prevented. Each strategy must be developed because of uneven access to any available remedies. By considering these things, we can develop good biopolymers with less harmful effects on humans and the environment.

Abstract

Biopolymers have recently received tremendous deliberation in numerous daily-life applications. Besides food industry and other industrial applications, biopolymers are mainly employed in biomedical fields for tissue culture and drug delivery. However, these biopolymers offer lower end-use characteristics. As a result, considerable research is currently underway to increase its mechanical properties, crystallization kinetics, thermal resistance, and barrier qualities. Many studies have been carried out in order to improve the qualities of biopolymer to cope with the challenges that reduce their functionalities and applicability. This

chapter introduces an overview of various applications of these biopolymers and concludes with a discussion on potential challenges that the group of biomolecules faces in terms of commercial viability.

Keywords

Biopolymers · Biomedical field · Drug delivery · Food industry

Introduction

Biopolymers are derived from natural sources. (Das et al. 2021) Because of their abundance, biocompatibility, and unique properties (Van de Velde and Kiekens 2002) such as nontoxicity (Yadav et al. 2015), biopolymers are fascinating materials. Many of these biopolymers and derivatives have found commercial applications in a variety of industries, including food (Adeyeye et al. 2019) and pharmaceuticals (Jacob et al. 2018). Some of their applications are labelled in Fig. 1. In recent years, the commercial viability of these adaptable material yet durable scaffolds has increased. Biopolymers are being explored for use in a growing number of ways, using different reinforcements to improve their characteristics and practical uses. However, like other materials and methods, use of biopolymers also has pros and cons. The main focus of this chapter is to elaborate issues and challenges using these biomolecules for various applications.

Although biopolymers have numerous advantages, their production has a variety of drawbacks, from beginning their extraction to get their final product. First, because biopolymers are entirely natural, their ultimate qualities are heavily influenced by the raw material. Due to the origin, climate conditions, area, collecting, and handling, this might vary greatly. As a result, global biopolymer

Fig. 1 Applications of biopolymers in various fields of life

manufacturing cannot constantly maintain the same level of sustainability. To date, no universally approved processes for the collection and synthesis of biopolymer material from vegetable sources have been identified. This is critical for both the end product's safety and its quality and functionality. Second, because biopolymer production is still in its beginnings, their production is relatively expensive (Mtibe et al. 2021). Biopolymer manufacturing and extraction from natural and synthetic sources demand specialized tools and instruments that are sometimes not ordinarily available. The expansion of such technology and protocols takes time, money, and qualified staff. Due to the ease and accessibility of biopolymer processing technologies, some existing instruments have been modified to use for this purpose, lowering the expenses in manufacturing of these biopolymers (Ortelli et al. 2019). Their challenges in biomedical and food industry and other drawbacks related to their use are discussed in this review.

Biomedical Fields

Natural biopolymers are advantageous in biomedical applications (Yadav et al. 2015), since they don't produce cytotoxic degradation by-products, and are frequently treated using eco-friendly aqueous-based approaches (Stoppel et al. 2015). Despite the major recent improvements in the pharmaceutical field, several issues and significant tasks such as fine control of biomaterial decomposition rate and spinoffs are restrictive aspects in the translation of tissue engineered products to clinical setups (Kaur and Singh 2020). Although constant research developments in methodology and material blends demonstrate substantial gains in their features that are equivalent to traditional materials now utilized, biopolymers' poorer performance in comparison with traditional materials may decrease their usage (Baloch and Labidi 2021). The usage of biopolymers in gynecology, drug delivery, and wound healing is promising, yet several problems need to be solved.

Challenges of Biopolymer Applications in Gynecology

Even though biopolymers have numerous applications in obstetrics and gynecology (Bibire et al. 2022), they still need to be developed to meet the desired characteristics for their proper use in this field. A few drawbacks have been noted while employing some biopolymers, which vary depending on the type of application and the category of biopolymer used. Many biopolymers decompose quickly and have poor mechanical characteristics which may be undesirable in some gynecological applications (Ostovan et al. 2018). Some researchers advocated employing biopolymer hybrids to solve this problem, and they were able to greatly improve the mechanical characteristics while delaying degradability. Another concern mentioned in the literature is a high hydrophilic capacity, which may not be advantageous in a humid environment like the vaginal canal or in vivo uses (Pattanashetti et al. 2017). Different biopolymer characteristics can be greatly improved to match the requirements of any preferred

application. Even yet, the cost of production may not be efficient or dependable enough for commercialization. It is vital to conduct more upgrades and economic analyses, as well as the development of new materials (Gzyra-Jagiela et al. 2016; Bibire et al. 2022), to solve the cost-effective issue which contribute to scientific knowledge and, as a result, contribute to forthcoming generations and certify sustainability. The key challenges in developing novel biopolymer-based mucoadhesives are examining their long-lasting effect, checking the interactions between the biopolymer and tissues, and bio-dispersion of the formulation content upon vaginal administration (Jummaat et al. 2021).

Challenges of Biopolymer Applications in Drug Delivery

Drug delivery systems are very essential to obtain better therapeutic effects of a medicine at a specific area of disease which may cause less toxicological effect (Jacob et al. 2018). A large number of biopolymers are used in drug delivery (Duttagupta et al. 2015; Saikia et al. 2015). The usage of a drug delivery system permits tailoring of both the rate of drug delivery and the area of drug distribution. It has the potential to overcome systemic drug toxicity, allowing for more efficient disease treatment or tissue remodeling (Abd Rahim et al. 2013; Grøndahl et al. 2020). Several constraints are still preventing the extensive usage of biopolymers. First, most investigations have been carried out *in vitro*; subsequently, additional *in vivo* and clinical trials are prerequisite to determine the well-being advantages of polymers and their biocompatibility in diverse biomedical applications, particularly when utilized as drug delivery encapsulating materials. More research is desired to assess the suitable composite, either unaided or in mixture, to attain the intended payload in an extremely controlled and site-specific way at remedially appropriate amounts when utilized to treat various disorders (Zabihollahi et al. 2020). The improvement of end-use mechanical characteristics, kinetics and release, and heat resistance is a second major constraint. Some products, for example, have a limited mechanical strength, fast deterioration, and a high hydrophilic capacity, making them unsuitable for use in humid or unfavorable environment. Third, in this fast-developing field, difficulties linked to budgets, commercial considerations, and the gap between policy and employment of new methodologies on a worldwide basis must be addressed. The biomaterials have their own biological activities. These materials in conjunction with nanocarriers have synergistic activities. Nanoparticles functionalized by biopolymers have antibacterial activities and are used for drug delivery. However, their toxicological aspect is a major issue. It will be very important to have their detailed study for their effective use in drug delivery (Rai et al. 2015). The biocompatibility of biopolymers for the purpose of drug delivery is important. However, with the lack of rigorous clinical trials, this assertion must be viewed with caution. Just because they come from natural sources and have the same building blocks as the living body does not indicate that they will be able to respond appropriately in a given environment. Effective *in vivo* and clinical testing or well-organized biological models mimicking the application of released medications are required to check compatibility

with living tissue or a living system for toxicity, harmfulness, or physiological reactivity without producing immune rejection (Gopi et al. 2018). Many promising medication candidates fail due to insufficient drug transport to the site of action. Poor medication stability, which can occur at any point of the manufacturing process, as well as during storage and administration, frequently leads to intolerable adverse effects and/or loss of efficacy (Williams et al. 2013).

Silk is a biopolymer which is approved by the Food and Drug Administration. Because of their biocompatibility and biodegradability, it is used in pharmaceuticals as wound dressing (Farokhi et al. 2018). Silk is also widely used for drug delivery (Yucel et al. 2014). Systematic research must be conducted to explore the limitations of silk as a drug delivery system in order for this field to evolve and silk-based products to make a safe progress from bench to bedside. Safe and repeated use of silk for drug delivery still requires more research. Biocompatibility data sets from silk films are insufficient to prove the safety of silk products. In hemato compatibility experiments, we have found that silk has a low thrombogenic reaction and limited hemolytic activity, but its inflammatory response is higher than the clinical reference material polytetrafluoroethylene (PTFE). Silk shows slow thrombogenic response, and its hemolytic action is very low as compared to polytetrafluoroethylene (PTFE) which is a well-known clinical material (Seib et al. 2012). This raises questions about creating unmodified silk for systemic uses until more research is done. Because silk was only recently offered for systemic administration, there are little data to back up the safe transfer of these silk-based drugs to clinics. Examining nanomedicines could be a useful guide for designing and carrying out research that is necessary for this path (Budman et al. 2004). Electrospinning is widely regarded as the most effective nanofiber production technology for biomedical applications. Silk fibroin is used in biomedical field because of simplicity of purification and sterilization. Moreover, it is biodegradable and biocompatible and has lower immunogenicity and higher capabilities to load and stabilize the drugs. These properties, together with the advantages of electrospinning, open up the possibility of developing acceptable silk nanofibers for drug administration. To improve the natural activity of the electrospun silk fibroin nanofibers, several functional moieties can be added. Various methodologies for the production of silk nanofibers have been formulated; however, electrospinning is the most popular because it is a simple and cost-effective method and its processing from different polymeric sources is quite easy (Farokhi et al. 2020). Additionally, nanofibers can be mass-produced on a huge scale for industrial applications (Braghirolli et al. 2014). The production of electrospun silk fibroin and its use in drug delivery are shown in Fig. 2.

Controlled delivery methods are critical in regenerative medicine and chronic illness treatment. These are required to evade drug burst release, which lessens systemic toxicity and unavoidable side effects. This improves therapeutic effects in the targeted area as well. Various polymers can be employed to form diverse delivery carriers. Electrospun silk fibroin mats, for example, are material of choice in drug delivery applications (Wenk et al. 2011). Fabricated silk nanofibers with adaptable diameter and thickness can be made using electrospinning to control drug release kinetics in a specific therapeutic window (Weldon et al. 2012). Despite their

Fig. 2 Electrospun silk fibroin application in drug delivery

advantages as drug delivery platforms, electrospun nanofibers do have significant disadvantages. Although electrospun silk fibers find many applications in drug delivery systems, still it requires further studies to cope with all the problems associated with this technique. One of the key issues is the abrupt discharge of the loaded drug, which could be caused by drug buildup near the nanofibers' surface.

This happened most likely because the drug was mixed in the polymeric solution before the electrospinning process. Another crucial consideration is maintaining the drug's bioactivity during the electrospinning process. Using ultrasonication or high voltage during electrospinning may alter the biomolecule's structure and functionality (Yang et al. 2008). Emulsion and coaxial electrospinning have piqued interest among electrospinning methods because of their capacity to shield medicinal ingredients and reduce the problems of early burst release. Furthermore, drug-polymer contact occurs only during the nanocarrier production phase, significantly reducing undesired reactions between polymeric solutions and loaded biomolecules (Balaji et al. 2015). The properties of silk fibroin sometimes reduce the capability of drug to bind. It has PI 4.2 because of anionic side chains in its strong hydrophilic structure. As pH exceeds than 4.2, their interaction with charged drugs especially positively charged medicines increases. Anyhow, some suitable moieties like SF can be added to modify the product so that it can also interact with anionic drugs (Sagnella et al. 2016). Many studies have confirmed the electrospun silk fibroin mat drug delivery potential in vitro. In vivo trials should be more focused to check the potential of these drug delivery systems. Still, understanding of drug interaction and systematic mechanism of release of drug are not fully known. Another main constraint to use these biopolymers in biomedical field is limited methods of sterilization. Sterilization of these material is difficult because most of the biopolymers are thermally sensitive and their physiochemical properties are effected by heat (Vasconcellos et al. 2012). These treatments can denature proteins and can destruct the loaded drugs (Rnjak-Kovacina et al. 2015). It is very important to use alternative sterilization techniques to maintain the characteristics of biopolymers (Yaman 2001). Batch-to-batch variations in biopolymers also affect their characteristics (J and McClements 2016). Mainly, FDA-approved synthetic polymers are generally used in drug delivery systems (Ghosh 2004). More research is required to use

FDA-approved natural biopolymers in drug delivery. These materials are still under study to use them effectively for drug delivery (Kogan et al. 2007; Singh 2011; Kamaly et al. 2016).

Challenges in the Use of Biopolymers in Wound Dressing

The fundamental role of normal undamaged skin is to permit microorganisms to persist on the surface while preventing their penetration under unbroken skin, which could result in underlying tissue infection or other problems. When the skin barrier is disrupted, infection is significantly more likely since most wounds create an ideal environment for both aerobic and anaerobic bacteria (Bowler et al. 2001). Because of its intricacy, this phenomenon is prone to a variety of anomalies. Several biocatalytic pathways become active during repair and aid tissue healing, in addition to cellular and biochemical components (Sezer and Cevher 2011). Different types of natural and synthetic dressing material are used for healing of wounds. Mostly alginate is considered as an ideal material for wound dressing. It has unique properties like its capability to absorb exudates, and it does not become adhesive to wounds. It can absorb exudate 15–20 times more than its own weight (Smith et al. 2016). It works on the mechanism of ion exchange between dressing and wound (Jones 1999). This mechanism of absorbing the exudate of wound by alginate dressing was studied by Qin who elaborated how Na^+ and Ca^{+2} ions are exchanged during absorbance of exudate (Qin 2004). The mechanism is shown in Fig. 3. Biopolymer-based materials are regarded as smart material. They provide a diverse and tunable framework for designing the proper extracellular matrix to assist tissue

Fig. 3 Mechanism of absorbance of wound exudate by alginate dressing. (Reprinted from (Smith et al. 2016) with the permission of Elsevier)

regeneration while preventing unfavorable events from occurring. Fabrication of bioactive materials based on natural polymers, either protein-derived or polysaccharide-based, has been widely used to address wound-healing-related issues in recent decades (Suarato et al. 2018). However, the use of these biopolymers in pharmaceutical and wound healing has become a challenge to fulfill the requirements of environment-friendly methodologies to meet our future demands.

Environmental sustainability has become an urgent issue to address in a struggle to balance both the industrial production and the earth's ability to produce resources. The main challenges in this regard are proper management to neutralize wastes and to mitigate polluting processes. The healthcare industry's material and energy usage, which ranges from complicated material synthesis processes to medicine packaging to heaps of medical wastes, may contribute significantly to overall effluence, with unintended detrimental consequences for human health (Jameton and Pierce 2001). Several studies have raised concern that alginate material left in the wound can trigger an inflammatory response. However, their biodegradable nature stems from the assumption that biocatalyst present in the body can degrade the trapped fibers of alginate in wound. Berry et al. challenged these claims when he and his colleagues studied the use of Kaltostat for operating cavity wound. Kaltostat is mixture of Na and Ca alginate. They showed the inflammatory reaction in the form of massive cell foreign body reaction (Berry et al. 1996). Scientists have manifested that if these matrices remain in wound, they can cause inflammatory reaction. Therefore, professionals should be cautious when removing alginate dressing, like any other dressing, and make sure it is done with extreme care (Thomas 1992). Furthermore, the development of genomics and proteomics studies has enhanced the demand for more individualized medicines that are developed based on the understanding of the unique biology of the patient. The various beneficial features of biopolymers are expected to be used in creating and delivering these cures in the future, and this has the potential to transform wound remedial treatments (Smith et al. 2016).

Food Industry

Biopolymers are extensively used in food items (Stoica et al. 2020). Biopolymers are used in food as well as in food packaging (Khan et al. 2007). Various biodegradable polymers like carbohydrate, starch, and lipids are frequently used to make food material. Yeast and other products obtained from bacteria, fungi, and algae are used in food products. The techniques used for the production of these materials are cost-effective and easy and require few steps and do not pollute the environment (Grujic et al. 2017). The edible biopolymers can cause no or very minute hazards as they are biodegradable and meet the standards of edible products (Baranwal et al. 2022). However, the material used in the oxygen barrier food packaging sometimes faces some challenges and issues (Gheorghita Puscaselu et al. 2021). Mostly, biopolymers are used as an emulsifying agent to stabilize the food emulsions and to improve their physical and chemical properties. However, it is a big task to choose the most suitable emulsifier because they differ considerably in their capability to stabilize

food emulsions and their ability to perform (McClements 2009). In order to prevent any bad impacts that may occur with these innovative materials, it is obvious that the scenario requires a hazard analysis and vulnerability assessment to be conducted.

Challenges in the Use of Biopolymers for Food Packaging

A majority of the materials used to pack food are nonbiodegradable and cause environmental hazards. For a decade, the utilization of biopolymers as a smart agent for the packaging of food products has drawn a lot of attention from biochemists, and it has become an emerging field to use these bio-products for the safety of food. These polymers are effectively used to pack food and to monitor the quality of food. The entrapment of micronutrient in biopolymers and antioxidant packing of food have made the food safety easy. Moreover, the use of smart and intelligent packing mechanism has the potential to enhance the shelf life of edible items (Stefani et al. 2016). Different types of polymers are utilized to produce environment-friendly food packing. However, the use of these materials in food packing has to face various feasibility issues which include their high budget for product, and this expensive process also does not give a better performance in comparison with their counterparts – synthetic polymer products – employed for food packaging. Therefore, the use of this method at industrial level still finds its limitation. Scientists are trying to introduce a method for their cost-effective production and use in packaging. Biopolymer-associated nanocarrier can provide the smart characteristics to food packing. These nanocomposites can add antibacterial, oxygen scavenger ability and biocatalyst immobilization. It can also indicate the decomposition-related factors. However, safety concerns are also associated with the use of these nanocomposites in packaging, as the size of nanocomposite is very small and they can easily get into the cell by penetration. The qualities and safety of biopolymer material used in bulk for the formation of nanocomposite is typically understood, but the nanocarriers associated with them frequently display unique properties as compared to biopolymers which can also cause health hazards. The scientific research on the migration of these materials from food packing directly into food and indirectly to the human body is scarce. But there is a plausible possibility that they can get into the food. Therefore, more studies are needed to get the precise information about their migration to avoid health hazards after their prolonged exposure (De Azeredo 2009). The use of cellulose- and starch-based products does not cause any issues to health, and these biopolymers are eco-friendly (El-Saied et al. 2004; Medina-Jaramillo et al. 2017). However, the biopolymers like polyhydroxyalkanoates (PHAs) and polylactic acid obtained from different microbes cause problems when used in food packaging. The strains of microbes which are used to extract these materials could be possibly precarious (Conn et al. 1995). In contrast to the additives employed in the fabrication of traditional plastics, biopolymer materials typically use different types of additives. The potential passage rate of biopolymers' constituents depends on their physical and chemical characteristics and the environment in which they are produced. The qualities of clean biopolymers

(those without additives) are typically less than those of traditional ones. The use of starch-based nanocomposites in food packing does not cause any environmental and health issue (Avella et al. 2005). Oxo-biodegradable materials are the most prevalent cause of migration of chemicals from food packing into the food (Grujić et al. 2017). Although, the nano-biocomposite showed cytotoxicity effects however, it is not possible to attain recognized uniform testing conditions because of production of incredible diversity of material even prepared in a same batch. These investigations are not able to take into account the final decision about their toxic capability (Jorda-Beneyto et al. 2014).

Challenges in the Use of Biopolymers for Industrial and Environmental Applications

The key factors influencing the prevalent approval of natural products and biopolymers as green matrix are the quick depletion of petroleum resources and the growing attentiveness to environmental issues associated with the usage of traditional plastics. Because of their sustainability and eco-friendly nature, these products have garnered a significant interest from scientists and industrialists. They can be used for various applications in textile, food, automotive, and bioenergy production (Sanyang et al. 2016). Sugar palm is a multiuse plant, and it is highly enriched with natural products and biopolymers which can be extracted and used for various industrial applications (Huzaifah et al. 2017). Sugar palm fibers (SPF) largely contain cellulose which is recognized by its extraordinary mechanical properties. The starch obtained from sugar palm plant can be used for plasticization, or it can be blended with other biopolymers to reinforce its characteristics to find their potential applications at industrial level. Significant work has been done on sugar palm-based composites thus far, but no published research on sugar palm-based nanocomposites has been done. Investing in sugar palm nanocomposites can help the industry's image and offer up new markets, including those for electronic and pharmacological packaging. In order to solve various issues impeding future industrial applications of sugar palm fibers, biopolymers, and their composites, an innovating and virgin research is required for this brand-new area of study and invention (Sanyang et al. 2016). Moreover, further studies are required to use these biopolymers at a large scale, because their manufacturing at a large scale and the difference in the batch-to-batch products might cause hindrances in their proper use (Imre and Pukánszky 2013; Sanyang et al. 2018). Ford was the earliest automaker to use biopolymer-containing plastics in paints, varnishes, and parts made of molded plastic (Drzal et al. 2001; Brosius 2006). Additionally, Ford used natural fibers in a variety of the car's components (Phillips 2008). The biopolymers are mostly used for 3D printing and find promising application in various industrial fields. The additive manufacturing (AM) of biopolymers consists of a series of steps that change the computer-aided design (CAD) into composite or other designs in a layered fashion (Wong and Hernandez 2012; Gibson et al. 2021). 3D printing is more advantageous as compared to conventional methods. However, the waste products of this processing

cause a threat to the environment. Heaps of garbage and plastics end up in seas and open places, which is also hazardous for human beings as well as other animals. The use of biopolymers and biodegradable materials in this process is more beneficial because of their eco-friendly properties. The required material qualities also differ greatly depending on the intended use. For instance, a material must have a holistic characteristic that includes printability, biocompatibility, degradability, and mechanical qualities in order to be used in the biomedical industry. Contrarily, textile items need to be sufficiently flexible, resilient, and tensile in order to accommodate the wearer's comfort and movement. Additionally, edible, easily printable, and resistant to shape distortion during post-processing are all desirable qualities for 3D-printed foodstuffs (Liu et al. 2019, Li et al. 2021). For example, a novel cellulose approach was used for the modification and functionalization of textiles. Extensive studies on the adsorption of the cellulose derivatives to cellulose and durability testing were integrated with the prototyping of 3D-printable cellulosic textile applications utilizing a design-driven technology. The QCM-D peeling and washing tests proved that acetoxypentyl cellulose (APC) was not very firmly bonded to cellulosic materials because of its more branched molecular structure. The printed structures had strong adsorption and great linkage qualities as a result of the rectilinear structure of cellulose acetate (CA), which allowed the material to arrange in a line with the cellulose molecules in the substrate. Both materials may be used in fabric 3D printing. The process of 3D printing is illustrated in Fig. 4.

Although many well-designed and graphical textile demonstration prototypes were effective in showcasing their potential for a wide range of application possibilities, the use of 3D-printed cellulosic components on cellulose fabrics opens up new possibilities for the development of customizable all-cellulose textiles without labor-intensive processing. Additionally, the creation of new materials and services could be done in an environmentally sustainable way by utilizing recyclable and renewable resources (Tenhunen et al. 2018). The main concern in the use of biopolymers in 3D processing is strength and inflexibility of these products. Their mechanical characteristics are not comparable to the conventionally used products. Therefore, there is a restriction in the applicability of biopolymers in 3D printing to an extent. Moreover, biopolymers are not thermostable. They decompose in high temperature, while in 3D printing process, materials having a high thermostability

Fig. 4 The use of cellulose and its derivative for 3D printing in textiles. (Reprinted from (Tenhunen et al. 2018) with the permissions of Elsevier)

can broaden their applications. More research and advances in 3D printing technology are required. An efficacious development and marketing of these material can also be made possible by advancements in engineering technology and 3D printing techniques (Pradhan et al. 2021).

Future Prospective

Exploring alternate methods for the manufacturing of bioplastics and recyclable polymers has become possible as a result of emergent environmental apprehensions regarding traditional plastic materials. By overcoming the difficulties, the possibility of employing biopolymers can become a reality. They should be adapted and modified for commercial applications. The creation of custom biopolymer structures is necessary because pure polymers cannot provide the desired characteristics to final the product for their applicability at industrial level. Moreover, various post-processing methods should be changed, and more advancement is required to improve the performance in order to keep the actual shape of the product. In addition to chemically modified biopolymers, the physically blended biopolymers can provide another method of producing products with advantageous processability, printability, mechanism, and bioactivities properties. More research is required to fill the knowledge gap to overcome the challenges and issues in biopolymer applications so that new ways can be paved for new technology and advancement in the previous ones to achieve an effective production and applicability of these products.

Conclusion

Biopolymers are extensively utilized in food, industrial, and various other fields of life. Due to their distinctive qualities, including low density, easy manufacturing, and chemical stability, polymers are appealing for a variety of applications. The biopolymers used in conjunction with other materials like nanoparticles to form nanocomposite for use in food packaging can cause a major concern to food safety because of the migration of these nanomaterials into the food. It is necessary to determine the maximum nanoparticle concentrations that can be present in food. The biggest problem researchers are facing in recent times appears to be establishing such regulatory restrictions, as well as their limited thermostability and mechanical characteristics. Research is still required to understand the mechanism by which biopolymers can be used for proper food safety and in environmental, industrial, drug delivery, and pharmaceutical fields, as well as their influences on the human body and the ecosystem. Beyond these challenges, these biopolymers provide a chance to increase the range of applicability of raw materials, which is not possible with the utilization of synthetic polymers. Because of the many benefits that biopolymers offer, this objective can be achieved. Biopolymers can be used as alternatives to avoid the disposal of huge amounts of garbage that nonbiodegradable packaging materials produce. There are various obstacles to the industrial synthesis

of biopolymers that have not been investigated yet to determine their viability from an economic and environmental standpoint. For their applicability and functionality to evolve more quickly and effectively, a comprehensive examination and a detailed study and trial of these biopolymers are necessary to overcome the challenges and issues associated with them.

- Bio-plastics, 727, 1196
 - biodegradation, 408
 - ceasing, 408
 - non-biodegradable degradation, 409, 410
 - plastic materials, 406
 - polymer blends, 410, 412, 413
 - purpose-built nature, 406
 - ripple effect, 406
 - safe degradation, 407
 - waste consumption, 407
- Biopolymers, 8, 136, 176, 526, 552, 657, 786, 943, 976, 1086, 1174–1176, 1178, 1184, 1185, 1187, 1188, 1191, 1192, 1336–1340, 1342
 - acetylation, 391
 - in adhesive industry, 1475
 - adsorption of macromolecules, 387
 - advantages, 30, 1472
 - agricultural and agro-industrial applications, 53
 - agriculture/fishery, 159
 - alginates, 146
 - amination, 391
 - applications, 48, 49, 51, 52, 226, 231–234
 - automobile parts, 1142
 - coatings, 1142
 - construction materials, 1142
 - furniture, 1142
 - packaging, 1142
 - printing, 1142
 - utensils, 1142
 - in automotive industry, 1474
 - bacterial, 18–21
 - bacterial nanocellulose coating, 386–387
 - based on polysaccharides, proteins and lipids, 1110
 - biobase-degradable, 228
 - bio-based monomers, PLA, 36
 - bio-based products, 28
 - biodegradable, 31, 492
 - biodegradable materials, 29
 - biodegradable plastic, 29
 - biological compounds, 628

Biopolymers (*cont.*)

- biomass, 34, 35
 - biomedical applications, 158–159, 234, 639
 - bionanocomposites, 227, 228
 - bio sources, 224
 - carbohydrate based, 9–12
 - cellulose, 145
 - cellulose chemical compounds, 31
 - challenges and future research, 21
 - characteristics, 580
 - characteristics and practical uses, 630
 - chemical modification, 387–391
 - chitosan modification, 392
 - classification, 8, 31, 32, 177–178, 369, 580, 630–632, 1137, 1472
 - composites, 493
 - cosmetic applications, 159
 - curdlan, 147
 - definition, 28, 224, 226, 580
 - development, 630
 - dextran, 145
 - disadvantages of, 1472
 - 3D printing applications, 1475
 - drug delivery, 640–642
 - effect on environment, 1482–1486
 - electrical components, 270
 - electrical properties, 225
 - electronic fabrication techniques, 229
 - electronics devices, 225
 - as engineering materials, 632–645
 - environmental impact of, 1480–1482
 - epoxidation, 391
 - essential oils, 50
 - esterification, 388–389
 - etherification, 388
 - fabrication techniques, 225
 - flexible electrically conducting sheets, 226
 - fuels and chemicals, 28
 - functional groups, 225
 - functions, 151–158
 - Gellan, 147
 - glucans, 146
 - glycogen, 146
 - health and environmental impacts of, 1476–1479
 - health impacts of, 1479–1480
 - and health industry, 1475–1478
 - in hemostatic gauge and dressings, 852–856
 - heteropolysaccharide based, 13–16
 - humus derived biopolymers, 18–19
 - hyaluronic acid (hyaluronate), 146
 - industrial applications, 158
 - from marine sources, 148–154
 - material's thermal behavior, 270
 - materials, 629
 - mercerization, 387
 - molecular engineering strategies, 225
 - monomers, 32
 - nanocellulose surfaces, 226
 - nanotechnology, 159
 - natural biopolymers, 324
 - non-biodegradable, 31
 - optical components, 240
 - optical properties, 238, 239
 - packaging material industry, 1475
 - PHA, 37, 38
 - pharmacological and biological applications, 628
 - physical and chemical properties, 143–144
 - physical modifications, 384–387
 - plant materials and microbes, 28
 - plasma treatment, 384–386
 - polyamides, 147
 - polyesters, 147
 - polymer grafting, 390
 - polyphosphates, 147
 - printing techniques, 225
 - produced microorganism, 45
 - production/source, 34
 - production process, 30
 - protein-based, 16–17
 - pullulan, 145
 - radiation, 387
 - renewable, 492
 - renewable materials, 225
 - renewable raw materials, 40
 - renewable resources, 29, 40
 - second-generation biopolymers, 629
 - silylation, 389
 - sulphonation, 391
 - surface modification types, 369
 - synthetic biopolymers, 324
 - vs. synthetic polymers, 1471
 - technological features, 629
 - TEMPO-oxidation, 390
 - in textile industry, 1474
 - third-generation biopolymer, 629
 - for treating vertebral parts, 866
 - triazine modification, 393
 - types of shapes, 40, 41
 - xanthan, 145
- Biopolymer applications
- biomedical fields, 1499–1504
 - challenges in drug delivery, 1500–1503
 - challenges in food industry, 1504
 - challenges in gynecology, 1499–1500
 - in fields of life, 1498

- future research, 1508
- for industrial and environmental applications, 1506–1508
- in organ culture, 843–845
- in wound dressing, 1503–1504
- Biopolymer-based antimicrobial packaging, 633–634
- Biopolymer based biosensors, 858
- Biopolymer based blend nanocomposites
 - applications, 572
 - physicochemical properties, 572
 - synthesis of, 553
- Biopolymer based composites, 493, 514
- Biopolymer based gels
 - amphiphiles, 479, 480
 - chemical cross linking, 473
 - collagen based polymer, 471
 - fibrin, 472
 - gelatin, 472
 - host guest macromers (HGMS), 476, 477
 - hyaluronic acid, 472
 - mechanism of gelation, 473
 - nanofillers, 478, 479
 - natural polymer-agarose gel, 470, 471
 - physical cross linking, 474
 - pros and cons of, 484
 - stability of, 475
 - volume phase transition, 474, 475
- Biopolymer based implants, 863, 864
 - and sensors, 858
- Biopolymer-based nanocomposites
 - biosensing applications, 538–540
 - bulk phase, 524
 - cellulose, 527
 - cellulose and cellulose derivatives, 533
 - chitosan, 534, 535
 - food packaging, 525
 - minor phase, 524
 - nanofillers, 527, 528
 - natural polymers, 526
 - optical properties, 529
 - packaging, 531, 532
 - photocatalytic applications of, 542
 - properties of, 530
 - silk fibroin, 535, 536
 - synthetic methodologies of, 530
 - tissue engineering, 536–538
- Biopolymer-based nanocomposites, wastewater dyes, 659–668
 - organic contaminant removal, 659–679
 - pesticides, 668–674
 - pharmaceutical drugs, 674–677
 - phenols, 677–679
- Biopolymer-based soil treatment (BBST), 611
 - addition, 613, 614
 - challenges, 621
 - contaminant barriers and clay liners, 618–621
 - erosion resistance of, 616–619
 - geotechnical and geoenvironmental engineering applications, 611
 - strength improvement, 614–616
- Biopolymer coatings, 1232
 - on dental metallic implant, 1244
- Biopolymer composites
 - adsorbents for remediation of fluorosis, 504
 - alginate-chitosan microsphere, 510
 - applications, 518
 - automobile industries, 509
 - bi-enzyme amperometric sensor, 514
 - binders, 517
 - bioactivity, 508
 - biodegradation, 503
 - biological pathways, 518
 - biomedical application, 508
 - commercialization of, 502

 - multifunctionality, 518
 - optical property and stability, 502
 - preparation, 493, 495–499
 - properties, 499
 - stent, 509
 - sustainable scaling-up synthesis and commercialization, 517
 - systematic analysis of the variables, 518
 - textiles, 501
 - thermal analytical techniques, 500
 - thermal property, 500
 - thermal stability and conductivity, 500
 - tissue development, 508
 - tribology, 501
 - for wound dressing, 508
- Biopolymer films, 1231
 - and coatings preparation methods, 1232
 - and composite coatings, 1231
- Biopolymer mulches, 1253

- Biopolymer nanofibers (BPNFs), 1283–1285
 as biosensors and analytical systems, 1290–1291
 in drug delivery, 1288
 filtration, 1291–1292
 in tissue engineering application, 1285–1287
 in wound healing treatment, 1288–1290
 Biopolymer nano-membranes, 1292–1293
 drug delivery, 1296–1297
 molecules' selective separation, 1293
 tissue engineering, 1295
 wastewater treatment, 1295–1297
 wound dressing, 1293–1295
 Biopolymers application in biomedical sciences
 attributes, 835
 fabrication technique, 837, 839
 scaffolds and matrices, bio-engineering, 835, 837
 Bioprocess technology, 89
 Bioreactor-assisted approach, 73, 74
 Bioreactor-assisted strategies, 75
 Bioreactor-assisted technology, 60
 Bio-renewable natural compounds, 1306
 Bio-scaffold printing via three-dimensional method, 737
 Biosensing and sensing, 512, 513
 Biosensing applications, 538–540
 Biosensors, 1016, 1285, 1290, 1291
 disruption in neurotransmitter signals, 860
 intracranial pressure, 860
 Biosynthesis of BC of Bacteria, 107
 Biotechnological technologies, 28
 Bio-thiol sensor, 1019
 Bismuth ferrite (BFO), 931
 Blending, 552
 Blend nanocomposites with of 3 phr
 FGNP, 566
 BliLacc catalysts, 954
 Blocklets, 1308
 Bloom index, 755
 BNC-IKVAV, 996
 BNC-PMETAC, 1001
 BNC synthesizing bacteria, 74
 BNNT inorganic composites, 210
 BNNT-ZnO QD nanocomposites, 210, 211
 BNT-BTx ceramics, 215
 Bone grafts, 843
 Bone marrow-derived stem cells (BMSC), 986
 Bovine serum albumin (BSA), 533, 591, 820, 1382, 1391
 hydrogels, 1165
 nanodispersion, 1391, 1392
 Branched chain polymers, 143
 Breast implants, 868
 Broken bones, 1168
 Bulk erosion, 1415
 Bunsen burner test, 501
 Butachlor, 669
C
 Calcium hydroxylapatite, 1479
 Calcium phosphate nanoparticles (CaP-NPs), 1385
 Calcium phosphates (Ca/P), 1167
 Calcium titanate samples, 212
 Camellia seed cake (CSC), 825
Campylobacter jejuni, 157
Candida albicans, 1000
Candida antarctica, 1459
 Capsular exopolysaccharides, 138
 Carbodiimide chemistry, 996
 Carbohydrate, 638
 based biopolymers, 9–12
 polymer, 911
 Carbohydrate-derived fulvic acid, 171
 Carbon aerogel (CA), 926
 Carbon allotropes for High performance natural rubber, 801–803
 Carbon-based fillers, 793, 803
 Carbon-based materials, 1061
 Carbon nanofibers (CNFs), 587
 Carbon nanofillers, 801
 Carbon nanotubes (CNTs), 587, 802, 946
 Carbon nitrogen ratio (C/N ratio), 150, 151
 Carbonyls, 922
 Carboxylated rod-like cellulose, 915
 Carboxymethylation, 102
 Carboxymethyl cellulose (CMC), 246, 534, 558, 635, 639, 641, 931, 951, 1138
 Carboxymethyl chitin microspheres (CMCH-Ms), 691
 Carboxymethyl chitin (CMC) nanoparticles, 691, 695
 Carboxymethyl substitution, 1313
 Cardiac tissue engineering, 826
 Cardiac valves, 863
 Carrageenan, 236, 374–375, 1091
 based IPN, 447
 Casein, 1251
 Caseinates, 1093
 Casting method, 339
 Catalysis, 910
 Catalysts, 933
 Catalytic applications, 917–920
 metals and photocatalysts, 929
 nanocelluloses, 933
 Catalytic oxidation, 103

- Catalytic reduction, 922
- Catalytic transformation, 920–929
- chemical derivatization, 963
 - coupling reactions, 925–926, 955, 956
