Preface

Biopolymers constitute some of the most diverse groups of organic molecules, which recently become an area of great research interest for their applications toward many dimensions of human life. Topics covered in this book include biopolymers from renewable sources, marine prokaryotes, soy protein and humus oils, biopolymer recycling, chemical modifications, and specific properties. Applications in key areas such as material, biomedical, sensing, packaging, biotechnology, and tissue engineering are discussed in detail. This handbook will be a very valuable reference material for graduate and postgraduate students, academic researchers, professionals, research scholars, scientists, and for anyone who has a flavor for doing biomaterial research. It provides universal perspectives for an emerging field where classical polymer science blends with molecular biology with highlights on recent advances.

Contents

Volume 1

Part I Introduction	1
1 Biopolymers	3
Bejoy Thomas and Krishnakumar Melethil	
Part II Biopolymers: Synthesis/Extraction	25
2 Biopolymers from Renewable Sources	27
Devu P. Kumar, Amrutha S. Nair, Preetha Balakrishnan, and Sreerag Gopi	
3 Recent Approaches Toward Bacterial Nanocellulose (BNC) Synthesis	57
Chhavi Sharma and Puneet Pathak	
4 Bacterial Nanocellulose from Agro-industrial Wastes	95
Heru Suryanto, Uun Yanuhar, B. Brailson Mansingh, and J. S. Binoj	
5 Biopolymers from Marine Prokaryotes	135
P. Nisha, M. Thangavel, Anju Mohan, C. Jyothilekshmi, T. A. Raslana, and K. A. Razeena	
6 Biomolecules from Humus Oil	167
Samuel Ogbeide Ebhodaghe	
7 Soy Protein Biopolymer	175
B. S. Subi and S. Shabanamol	
Part III Biopolymers: Properties	201
8 Piezoelectric Properties of Biopolymers	203
R. Divya, Swathi Yempally, and Deepalekshmi Ponnamma	

9	Optical Properties of Biopolymers	223
	Meenu Eldhose, Cincy George, Sona John, Alex Joseph, and Liz George	
10	Mechanical Properties of Biopolymers	253
	Samuel Ogbeide Ebhodaghe and Henry Ndibe	
11	Thermal Properties of Biopolymers	269
	Amrutha S. R., Rejimon P. K., Suja N. R., and Alson Mart	
12	Gas Barrier Properties of Biopolymers	297
	Neena George and B. Venugopal	
13	Structural, Morphological, and Textural Properties of Biopolymers	323
	Geethy P. Gopalan and Saithalavi Anas	
Part IV	Biopolymers: Modifications	365
14	Tuning the Hydrophilic/Hydrophobic Behavior of Biopolymers ...	367
	Reeba Mary Cherian, Hanieh Kargarzadeh, Noor Afizah Rosli, Cintil Jose, and Sabu Thomas	
Part V	Biopolymer-Based Blends, IPNs, Gels, and Composites ...	403
15	Biopolymer-Based Blends	405
	Sanjiv Sonkaria, Ji-hyun Cho, Hyeon Su Jo, and Hyun-Joong Kim	
16	Biopolymer-Based Interpenetrating Polymer Networks	435
	T. R. Anju and J. Sindhu Rachel	
17	Biopolymer-Based Gels	469
	Antony V. Samrot, Shree Krithika Sivasuriyan, Sneha Xavier, Nagarajan Shobana, Deenadhayalan Rajalakshmi, Mahendran Sathiyasree, and Sanjay Preeth Ram Singh	
18	Biopolymer-Based Composites	491
	D. H. Nagaraju, Srinivasa Budagumpi, and Zhoveta Yhobu	
19	Biopolymer-Based Nanocomposites	523
	Anju Paul and Sreekala S. Sharma	
20	Biopolymer-Based Blend Nanocomposites	551
	P. K. Sandhya, M. S. Sreekala, and Sabu Thomas	
21	Nanofibers and Nanomembranes of Biopolymers	579
	Vinod V. T. Padil	

Volume 2

Part VI Applications of Biopolymers	607
22 Biopolymer Based Soil Treatment for Geotechnical Engineering Applications	609
Evangelin R. Sujatha and Brendan C. O’Kelly	
23 Biopolymers as Engineering Materials	627
P. S. Shasiya, K. Simi Pushpan, and Ajalesh B. Nair	
24 Biopolymer-Based Nanocomposites for the Treatment of Organic Pollutants from the Synthetic Wastewater	655
Ruksana Sirach and Pragnesh Dave	
25 Biomedical Applications of Chitin	685
Hema S., Greeshma U. Chandran, Jyothi P. R., and Sreedha Sambhudevan	
26 Sustainable Biodegradation and Extraction of Keratin with Its Applications	713
Shinar Athwal, Swati Sharma, Shreya Gupta, Ashok Kumar Nadda, Arun Gupta, and Mohamed Saad Bala Husain	
27 Material Applications of Gelatin	749
C. S. Julie Chandra, Sreesha Sasi, and T. K. Bindu Sharmila	
28 Natural Rubber and Gutta-Percha Rubber	783
Hema S., Malavika Sajith, Rashid Sulthan A., Sreelekshmi C., and Sreedha Sambhudevan	
29 Albumin	819
Samuel Ogbeide Ebhodaghe	
30 Tunable Biopolymers	833
Ameek Krishnakumar, Urja Shedaliya, Kavya Shah, and T. R. Anju	
31 Nanocellulose from Cladophora	877
P. V. Sandhya, M. Nishaf Naseeha Farsana, and K. S. Femina	
32 Cellulose Nanocrystals (CNCs) Supported Inorganic Nanomaterials for Catalytic Applications	907
M. H. Rubiya, Krishnakumar Melethil, Albin James, Sharon Varghese, and Bejoy Thomas	
33 Bacterial Nanocellulose (BNCs) Supported Inorganic Nanomaterials for Catalytic Applications	941
Krishnakumar Melethil, Sharon Varghese, Albin James, M. H. Rubiya, and Bejoy Thomas	

34	Biocompatibility of Nanocellulose	975
	Jorge Padrão, Liliana Melro, Marta Fernandes, Rui D. V. Fernandes, Ana Isabel Ribeiro, Xinyu Song, Liangmin Yu, and Andrea Zille	
35	Sensing and Biosensing Applications of Nanocellulose	1007
	Meenu Eldhose, Roshny Roy, Cincy George, and Alex Joseph	
36	Packaging Applications of Biodegradable Nanocellulose Composites	1033
	Sanjiv Sonkaria, Kwang-Hyun Ryu, Varsha Khare, and Hyun-Joong Kim	
37	Nanocellulose-Based (Bio)composites for Optoelectronic Applications	1059
	Roshny Roy, Meenu Eldhose, Cincy George, and Alex Joseph	
38	Biopolymers for Edible Films and Coatings in Food Applications	1085
	Maria Râpă and Elisabeta Elena Popa	
39	Peptide-Based Biopolymers in Biomedicine and Biotechnology ...	1117
	Rini Thresia Varghese, Cintil Jose Chirayil, and Sabu Thomas	
40	Cross-Linking Biopolymers for Biomedical Applications	1135
	Anu Mary Joseph and Benny George	
41	Natural Fiber-Reinforced Biopolymers as Construction Materials	1173
	Deepa Narayanan, M. T. Giffin, P. S. Neetha, Cintil Jose, and Sabu Thomas	
42	Polylactic Acid (PLA)	1195
	Anju Paul, K. Sreedevi, Sreekala S. Sharma, and V. N. Anjana	
43	Biopolymer Films and Composite Coatings	1229
	Mariana Altenhofen da Silva and Andrea Cristiane Krause Bierhalz	
44	Gas Barrier Properties and Applications of Nanocellulose-Based Materials	1263
	Nisha Nandakumar and Ajalesh B. Nair	
45	Applications of Biopolymer-Based Nanofibers and Nanomembranes	1281
	Arooj Ramzan, Azeem Intisar, Nazish Mumtaz, Nazim Hussain, and Muhammad Bilal	
46	Amylose–Amylopectin Ratio	1305
	Sharon Varghese, Monika Awana, Debarati Mondal, M. H. Rubiya, Krishnakumar Melethil, Archana Singh, Veda Krishnan, and Bejoy Thomas	

47	Biopolymers: Building Blocks for the Synthesis of Advanced Materials	1335
	Ritika Tripathi, Akshit Malhotra, Ashwini Chauhan, and Suchitra Rajput Chauhan	
48	Nature-Inspired Biomimetic Polymeric Materials and Their Applications	1349
	Sherin Antony, T. R. Anju, and Bejoy Thomas	
49	Cosmetic Applications of Albumin	1379
	R. Rajakumari, Sabu Thomas, and Nandakumar Kalarikkal	
Part VII	Future Scope of Biopolymers	1401
50	Biodegradation of Biopolymers: Reflections Towards Possible Biomagnification	1403
	Punnamoorthy Thiviya, Ashoka Gamage, Asanga Manamperi, Sudhagar Mani, and Terrence Madhujith	
51	Biopolymer Waste Management	1447
	Azeem Intisar, Arooj Ramzan, Mateen Hedar, Nazim Hussain, and Muhammad Bilal	
52	Safety Issues, Environmental Impacts, and Health Effects of Biopolymers	1469
	Ragitha V. M. and Lekshmi K. Edison	
53	Challenges and Issues in Biopolymer Applications	1497
	Mateen Hedar, Azeem Intisar, Tajamal Hussain, Nazim Hussain, and Muhammad Bilal

About the Editors

Sabu Thomas Ph.D., FRSC (UK), D.Sc. (UL, France), D.Sc. (UBS, France)

Vice Chancellor, Mahatma Gandhi University, Priyadarshini Hills, Kottayam, Kerala, India

Professor, School of Chemical Sciences & Director, School of Energy Materilas

Founder Director, International and Inter University Centre for Nanoscience and Nanotechnology, Mahatma Gandhi University, Kottayam, Kerala, India

Professor Sabu Thomas is currently Vice Chancellor of Mahatma Gandhi University. He is also Full Professor of Polymer Science and Engineering at the School of Chemical Sciences of Mahatma Gandhi University, Kottayam, Kerala, India, and the Founder Director and Professor of the International and Interuniversity Centre for Nanoscience and Nanotechnology. Prof. Thomas is an outstanding leader with sustained international acclaim for his work in Nanoscience, Polymer Science and Engineering, Polymer Nanocomposites, Elastomers, Polymer Blends, Interpenetrating Polymer Networks, Polymer Membranes, Green Composites and Nanocomposites, Nanomedicine, and Green Nanotechnology. Prof. Thomas's groundbreaking inventions in polymer nanocomposites, polymer blends, green bionanotechnological, and nano-biomedical sciences have made transformative differences in the development of new materials for automotive, space, housing, and biomedical fields. In collaboration with India's premier tyre company, Apollo Tyres, Professor Thomas's group invented new high-performance barrier rubber nanocomposite membranes for inner tubes and inner liners for tyres. Professor Thomas has received a

number of national and international awards which include: Fellowship of the Royal Society of Chemistry, London FRSC, Distinguished Professorship from Josef Stefan Institute, Slovenia, MRSI medal, Nano Tech Medal, CRSI medal, Distinguished Faculty Award, Dr. APJ Abdul Kalam Award for Scientific Excellence – 2016, Mahatma Gandhi University – Award for Outstanding Contribution – Nov. 2016, Lifetime Achievement Award of the Malaysian Polymer Group, Indian Nano Biologists award 2017, and Sukumar Maiti Award for the best polymer researcher in the country. He is on the list of most productive researchers in India and holds a position of No. 5. Because of his outstanding contributions to the field of Nanoscience and Polymer Science and Engineering, Prof. Thomas has been conferred HonorisCausa (D.Sc.) Doctorate by the University of South Brittany, Lorient, France and the University of Lorraine, Nancy, France. Very recently, Prof. Thomas has been awarded Senior Fulbright Fellowship to visit 20 universities in the United States and most productive faculty award in the domain Materials Sciences. Very recently he was also awarded with National Education Leadership Award – 2017 for Excellence in Education. Prof. Thomas also won 6th contest of “mega-grants” in the grant competition of the Government of the Russian Federation (Ministry of Education and Science of the Russian Federation) designed to support research projects implemented under the supervision of the world’s leading scientists. He has been honored with Faculty Research Award of India’s brightest minds in the field of academic research in May 2018. Professor Thomas was awarded with Trila – Academician of the Year in June 2018 acknowledging his contribution to tyre industry. In 2019 Professor Thomas has been selected as a member of Prestigious European Academy of Sciences. Last year he was honored with C.N.R. Rao Award Prize Lecture in Advanced Materials by Materials Research Society of India (MRSI). In 2019, Professor Thomas has been selected as a Member of Prestigious European Academy of Sciences. He was also selected as the Fellow of International Academy of Physical Sciences and was honored with Life Time Achievement award by the Indian Association of Solid State Chemists and Allied Scientists (ISCAS). This year he was selected for the DST Nanomission award and very recently in May

25, 2020, he was selected for the honorary title of “Honoured Professor of Siberian Federal University.” Professor Thomas has published over 1000 peer-reviewed research papers, reviews, and book chapters. He has co-edited and written 137 books published by Royal Society, Wiley, Woodhead, Elsevier, CRC Press, Springer, Nova, etc. He is the inventor of 15 patents. Prof. Thomas has guided nearly 107 Ph.D. scholars in India and abroad. The H index of Prof. Thomas is 101 and has more than 50356 citations. Prof. Thomas has delivered over 350 plenary/inaugural and invited lectures in national/international meetings in over 30 countries.

A. R. Ajitha is Senior Researcher at International and Interuniversity Centre for Nanoscience and Nanotechnology (IIUCNN), Mahatma Gandhi University. She completed her doctoral research in the area of Polymer Science, incorporating nanomaterials in thermoplastics. Her research area includes preparation of nanocomposites, their characterization, and modification of nanofillers. She received 2 patents and published 11 research articles in international journals of high impact factor. She edited one book titled *Compatibilization of Polymer Blends* (Elsevier publication). She has also authored more than 14 book chapters in international books and presented papers at many international conferences and seminars. She is an expert in the field of engineering application of nanomaterials.

Cintil Jose Chirayil is Assistant Professor at the Department of Chemistry, Newman College, Kerala, India. She received her Ph.D. in Polymer Science from Mahatma Gandhi University, India, and completed a post-doctoral fellowship at the Centre for Advanced Materials, Qatar University, Doha. She has 12 years of research experience in the field of nanoscience and nanocellulose with 20 publications in international peer-reviewed journals and 15 book chapters and 1 edited book with Elsevier International publishing company. In addition to the Young Scientist Award, 2011 (Leed's University London and NIT Calicut), she was the recipient of Foreign scholarships from the

University of Potsdam, Germany; University of Mara, Malaysia; and Institute of Chemistry, Austria, for in-depth research in the field of nanoscience. She is an approved research guide of Mahatma Gandhi University, Kottayam, in the subject area Chemical Sciences.

Bejoy Thomas studied Chemistry at the University of Bangalore (India) and received his Ph.D. in Physical Chemistry from Cochin University of Science and Technology (India). As a DFG (German Chemical Society) Postdoctoral Fellow at the Institute of Chemical Technology, University of Stuttgart, he moved to Germany after working for a few years in NMR spectroscopy at the NMR Research Centre at the Indian Institute of Science (India) under CSR-SRF. Before returning to India to join Newman College in Thodupuzha, Kerala, as Assistant Professor of Chemistry in 2011, Dr. Bejoy first moved to Paris, France, as a CNRS Postdoctoral Associate at the Laboratoire de Chimie de la Matière de Condensée de Paris (LCMCP), UPMC-P6-Paris. His research focuses on the self-assembly of biosurfactant molecules, such as long-chain fatty acids and their esters, small proteins, polysaccharides, etc. for the development of new materials, the creation of organized mesoporous materials, surface science, catalysis, and hierarchical zeolites, as well as in situ NMR spectroscopy of working catalysts. The extraction, properties, and use of nanocellulosic materials from biomass resources have recently been the subject of active research, particularly with regard to catalytic applications. Nearly 50 research articles by Dr. Bejoy have been published in high impact journals, including one in *Chemical Reviews* that has received the highest citations in recent years from authors in India.

Abstract

Biopolymers, as opposed to petroleum, the conventional source of polymers, are those that are created by or obtained from living creatures, such as plants and bacteria. Given their applications to numerous facets of human existence, biopolymers, one of the most diverse groups of organic compounds, have recently attracted a lot of study interest. Although only partially, these molecules and the materials created with them have replaced the chemical polymers and materials sourced from petroleum. For instance, nanocellulose, which is regarded as the material of the twenty-first century, has applications in a variety of fields (or facets) of human life, including advanced biomedical, packaging, gas-sensing, and electronic ones. Today, biopolymers are among the study fields that have been most thoroughly explored due to the increasing interest in this sector from academic and industrial researchers.

Introduction

The field of polymer science, often known as polymer chemistry, is extremely prevalent and important in the modern world. To distinguish it from other human eras that were dominated by a variety of different materials, it has even been suggested to refer to the current period as the “polymer age” (the Stone, the Bronze, and the Iron Ages, classical era, etc.). The advent and widespread adoption of polymer technology have gradually affected current world perspectives and discourses, much like earlier revolutionary technical developments like the advancement of the computer and more modern humanoids powered by artificial intelligence (Brydson 1999; Campbell 2002). Despite the astounding advancements in polymer science that have been made over the years, including those in simple household applications, computers, AI, and MI, there are still many fascinating challenges that need to be solved. These challenges are worthwhile to solve due to their effects on our daily lives and, more specifically, the environment. Traditional examples of problems include issues with environmental contamination and a lack of efficient disposal methods, micro- to nanoscale plastics and their intended design for long life spans, polymers for energy depository and delivery, polymers for the human body, green polymer chemistry and technology, etc. (Limaye et al. 2011; Cella et al. 2022).

When plastic (especially the nonreusable form) is discharged into the environment after use, several of the polymers’ strikingly favourable characteristics, such as their chemical, physical, and biological inertness and durability or life span under environmental conditions, offer problems. Common plastics like polyethylene (PE), polypropylene (PP), polystyrene (PS), polyvinyl chloride (PVC), thermoplastic polyurethanes (TPU), polypropylene (PP), polytetrafluoroethylene (Teflon), and polyethylene terephthalate (PET) are exceedingly tenacious in the environment, slowly disintegrating into tiny particles over decades by optical, physical, and biological degradation processes. A stage of the degradation process that cannot be avoided is the fragmentation of the substance into smaller and smaller particles. In 2020, Min et al., developed a data-driven method for illuminating plastic debris degradation trends by tying physical characteristics and molecular structures to biotic and abiotic degradation behavior in saltwater. The findings show a hierarchy of predictors to measure surface erosion as well as combinations of characteristics, such glass transition temperature and hydrophobicity, to divide ocean plastics into fast, medium, and slow degradation groups.

As a result, both developing and developed nations now face a threat from the requirement for effective waste disposal due to the growing use of polymeric materials and plastics made from fossil fuels. There are serious environmental

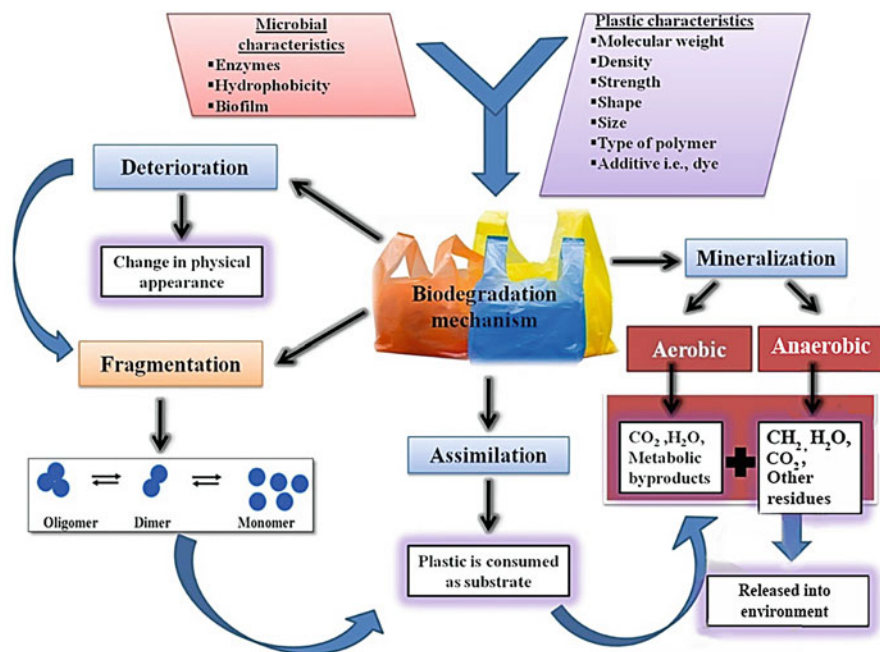

Fig. 1 Schematic representation of the consolidated mechanism of microbial degradation of plastics under environmental conditions such as soil-bound microorganisms into degradation products including CO_2 , CH_4 , etc., some potent greenhouse gases

concerns as a result of the over usage of plastic and the inappropriate methods of disposal used in many nations. The systems and procedures used for this process of disposing of plastic through various chemical and physical processes are very expensive and produce organic pollutants, such as micro- or nanoplastic degradation products, which worsen the environment (Lambert et al. (2014); Azapagic et al. (2003)). Using the biodegradation of common plastics like polyethylene terephthalate (PET), polyethylene (PE), and polystyrene (PS) under various environmental conditions as an example, recent studies have demonstrated that using enzymes and various microbes for assimilation and disintegration, respectively, is a viable bioremediation pathway (Fig. 1).

The field of polymer science, often known as polymer chemistry, is extremely prevalent and important in the modern world. To distinguish it from other human eras that were dominated by a variety of different materials, it has even been suggested to refer to the current period as the “polymer age” (the Stone, the Bronze, and the Iron Ages). Without polymers, modern lifestyle is rarely imaginable. Just like with other major technological advancements, such as the creation of the computer and more contemporary humanoids based on artificial intelligence, the advent and widespread establishments of polymer technology have dramatically altered the present world’s perceptions and discourses over time (Brydson 1999;

Campbell 2002). Despite the astonishing achievements of polymer science witnessed over the years, from simple household applications to computers to AI to MI, many exciting challenges remain to be addressed; these are well worth to tackle because of their impact on our everyday life and, more accurately, the ecology. Classical examples of challenges include environmental pollution issues and a lack of effective disposal mechanism, micro- to nanoplastics and designed designation of long life times, polymers for energy storage and delivery, polymers for the human health, green polymer chemistry, etc. (Cella et al. 2022; Singh et al. 2020).

Unfortunately, many of the plastics' strikingly positive qualities – such as their durability, longevity, and chemical, physical, and biological inertness – present problems when plastic, especially the nonreusable kind, is discharged into the environment after use. The degradation of typical plastics like polypropylene (PP), polyethylene (PE), polystyrene (PS), polyvinyl chloride (PVC), thermoplastic polyurethanes (TPU), polypropylene (PP), polytetrafluoroethylene (Teflon), and polyethylene terephthalate (PET) by optical, physical, and biological processes causes a very slow fragmentation of the material into minute particles, which is thought to take millennia. A stage of the degradation process that cannot be avoided is the fragmentation of the substance into smaller and smaller particles.

Therefore, the requirement for effective waste disposal has become a threat to both developing and developed countries due to the growing usage of polymeric materials and plastics made from fossil fuels worldwide. In many nations across the world, excessive plastic consumption and a poor method of disposing it have raised serious environmental issues. Disposal system and methods adopted for this process of plastic through various chemical and physical processes are very expensive which also produce organic pollutants including micro- or nanoplastic degradation products, resulting in environmental deterioration (Azapagic et al. 2003; Lambert et al. 2014). For instance, recent studies on the biodegradation of common plastics like polyethylene terephthalate (PET), polyethylene (PE), and polystyrene (PS) in various environmental settings have shown that using enzymes and different microbes for assimilation and disintegration, respectively, is a practical bioremediation pathway (Fig. 1).

Biodegradable Polymers

The creation and manufacture of so-called biodegradable plastics, which could have shorter residence duration under environmental conditions, have received a lot of attention during the past couple of decades. One type of polymers that is frequently pushed under the banner of “biodegradable” plastics is “oxo-degradable” plastics. In actuality, these are common plastics (including PE, PS, PP, and PET) that contain prodegradants or additives that may speed up the oxidation process. Oxo-degradable plastics offer a significant problem because, when exposed to sunshine and oxygen,

they quickly fragment into massive amounts of microplastics. While it helps large plastic materials degrade more quickly than conventional plastics in 2010 (O'Brine and Thompson 2010), the produced microplastic is identical to any other type of microplastic from conventional plastics and takes a long time to fully biodegrade, continuing to pose a threat to the environment (Tosin et al. 2012).

Internationally accepted standard procedures that enable biodegradability to be assessed over a range of typical environmental matrices are available to aid in the creation of biodegradable plastics (including marine, soils, wastewater treatment plants, etc.). The biodegradability of plastics (biodegradable) under ideal industrial and municipal composting circumstances can also be evaluated using standard requirements and test techniques (e.g., ASTM D6400, EN 13432, ASTM D5338, ASTM D5929). Plastics that fully mineralize over a reasonable period of time in industrial composting facilities' high temperatures and controlled conditions can be regarded as biodegradable or compostable. The process might be profitable because these components of the compost are also valued commercially (Fig. 2). Additionally, because the degradation occurs inside of a closed and controlled system, the fragmentation occurs quickly in an industrial composter and poses little risk for microplastics to be exposed to the environment (Chamas et al. 2020). As of right now, there are only a very limited number of products made of compostable polymers, such as bags, take-out containers, coffee pods, food packaging, cups, plates, and service ware, as well as items made of biodegradable polymers like polyglycolic acid (PGA), polycaprolactone (PCL), poly(vinyl alcohol) (PVA, PVOH), polylactic acid (PLA), and polybutylene succinate (PBS). The proportion of biodegradable and compostable plastics that are composted as opposed to ending up in common waste streams, however, does not appear to be well-documented globally (Andersen 2007). In fact, the volume of composted material must be much less than the vast amount of (bio)degradable polymers generated globally (ca. 367 million metric tonnes in 2020).

Fig. 2 An on-the-field image of a composting facility in the United States for compostable products including food packaging materials and biodegradable polymers including polyglycolic acid (PGA), etc.

Biopolymers

Biopolymers, as opposed to synthetic polymers formed from petroleum and biodegradable polymers, can be produced using materials that are perpetually renewable, sustainable, and carbon-neutral. Because the majority of these components are derived from agricultural crops, their utilization might develop a sustainable sector. Biopolymers are organic materials made by living things' cells. These molecules are made up of monomeric components that join or together through covalent bonds to form bigger molecules. Depending on the type of monomeric molecule that contributes to the entire structure of the polymer, three *categories can be found, namely*, polynucleotides, polypeptides, and polysaccharides, which are further divided based on the monomers employed and the final biopolymer structure. DNA and RNA are 2 examples of polynucleotides, which are lengthy polymers made up of 13 or more nucleotide monomers. Proteins and polypeptides are polymers of amino acids, with collagen, actin, and fibrin serving as some prominent examples. Examples of polysaccharides, which are linear or branched polymeric carbohydrates, include starch, cellulose, heparin, and alginate, among others. Other types of biopolymers include natural rubber (isoprene polymers); chitin, which is the second most prevalent natural polysaccharide after cellulose and is a linear polymer made up of (1,4)-N-acetylglucosamine units; suberin and lignin, which are complex polyphenolic polymers; cutin and cutan, which are complex polymers of long-chain fatty acids; and melanin, which produces hair, eye, and skin pigmentation (Niaounakis 2015; Baranwal et al. 2022). Figure 3 illustrates a broad taxonomy of biopolymers.

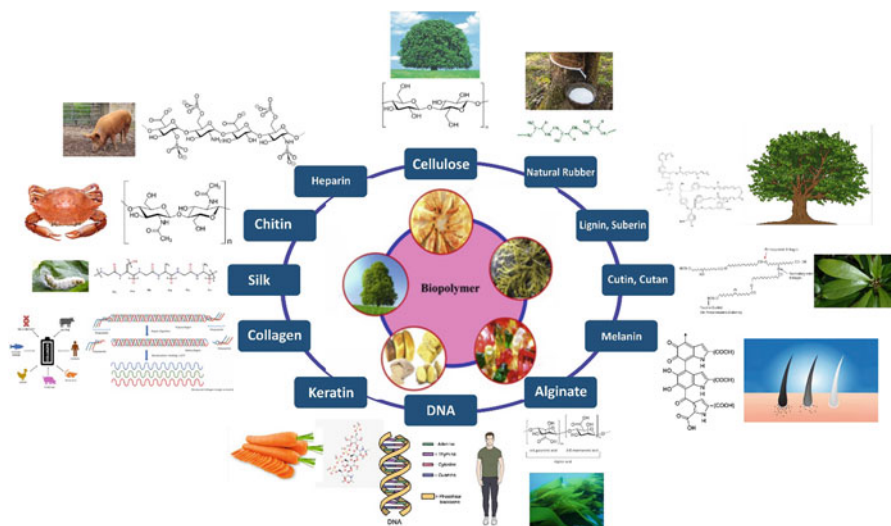

Fig. 3 Schematic representation of the general broad classification of biopolymers based on the types and the potential sources

Such naturally derived molecules/materials from strongly hierarchical organization are appealing candidates for high-performance and functional advanced materials because of their renewable nature, nontoxicity, biocompatibility, biodegradability, flexibility, greater availability, cost-effectiveness, and eco-friendliness as compared to non-biodegradable petroleum-based polymers (Niaounakis 2015). Similar bio-enabled nanocomposites constructed of biopolymers also have these intrinsic properties, but the synergistic combination of biological and synthetic components made feasible by strong interfacial contacts can greatly enhance structural performance and enable new activities. Therefore, compared to synthetic polymers, these natural materials have multiple advantages, specifically in the social, economic, and environmental domains. Many biopolymers have been compared with petroleum-based (bio)polymers using life cycle assessment (LCA; life cycle assessment is a cradle-to-grave or cradle-to-cradle analysis technique to assess environmental impacts associated with all the stages of a product's life, which is from raw material extraction through materials processing, manufacture, distribution, and use). The results are in line with expectations and demonstrate that biopolymers have specific, well-defined environmental benefits (Yates and Barlow 2013). Additionally, compared to biopolymers, petroleum-based polymeric goods have a far greater negative influence on the sustainability of the environment. Advanced uses of biopolymers in (bio)medicine, biomedical engineering, food coatings, food packaging, tissue engineering, manufacturing, military, and environmental applications imply that they are better for the environment than synthetic polymers (Baranwal et al. 2022).

Carbohydrate-Based Biopolymers (Marine and Terrestrial)

Biopolymers, particularly those based on carbohydrates and proteins, had already seen extensive use in the food and pharmaceutical industries much prior to the emergence of the petroleum industry. Biomacromolecules called polysaccharide biopolymers, which can thicken, cross-link, adsorb, and perform other diverse functions, are obtained from renewable resources. These molecules are made up of O-glycosidic links that connect monomeric units of sugars or their simple derivatives (such as glucose and its derivatives found in cellulose and chitin, respectively) to build bigger structures. The characteristics and possible applications of this class of biopolymers are determined by the characteristics of the monomers, the types of connections, and any potential chemical alterations of the surface (Verma et al. 2020). Some of the crucial members of this class are cellulose, starch, epoxy-polysaccharides, and marine chitin.

Marine prokaryotes, including bacteria and archaea, present a wide range of opportunities for the creation of new biopolymers. Numerous innovative material characteristics and business prospects are provided by these biopolymers. Hyaluronic acid (a well-known heteropolysaccharide or heteroglycan), chitin and chitosan, peptides, collagen, enzymes, polysaccharides from algae, and secondary metabolites like mycosporines are among the marine macromolecules. The

distinctive qualities of marine products, such as exopolysaccharides and melanins, which improve the ability of the organisms producing them to survive, can be utilized for a variety of products, from emulsifiers to adhesives. Polyhydroxyalkanoates are the molecules that prokaryotes use to store carbon, but their technical use is altogether different because it might be used as a base for biodegradable plastics. Epoxypolysaccharides from microorganisms (EPS) are a class of significant goods that are gaining interest from a wide range of industrial sectors. Although several known marine bacteria create exopolysaccharides, the ongoing hunt for microorganisms that produce polysaccharides shows promise. According to the screening of a variety of mesophilic heterotrophic bacteria obtained from various places, hydrothermal deep-sea vents might be a source of new EPS. Some bacteria have been demonstrated to biosynthesize novel EPS in a lab setting while coming from such a harsh environment. Deep-sea *Alteromonas infernus*, deep-sea *Alteromonas macleodii* strain, *Alteromonas* strains obtained from French Polynesia marine environments, etc. all generate epoxypolysaccharide. Marine EPS-producing bacteria have also been isolated from a number of extreme niches, including the frigid marine habitats typical of Arctic and Antarctic sea ice, which are characterized by low temperature and low nutrient content. Finally, it may be said that marine biopolymers represent a large and underutilized biological resource (Grandics 1981; Kaur and Singh 2020).

The manufacture of chitosan often requires an alkali or enzymatic treatment to deacetylate chitin, which is the second most frequent structural polysaccharide found in nature after cellulose. It is the most prevalent renewable polymer in the oceans and provides vital carbon and nitrogen for marine life. The cycling of nutrients in the oceans involves the process of chitin breakdown, and chitinolytic bacteria are crucial players in this cycle. Chitin's natural form is that of organized crystalline microfibrils, which serve as structural elements, primarily in the exoskeleton of arthropods (Fig. 4). Since shrimp and crabs and other crustaceans produce chitin, chitin is separated from their exoskeletons. It has been identified that the β -form of chitin, which is found in squid and has been shown to be more susceptible to deacetylation. Alternative sources of chitin/chitosan can also include some species of bacteria, fungi, algae, and insects. With annual production exceeding 1011 tonnes, chitin is regarded as the primary biomass resource. Chitin can be used as a biosurfactant because it has both hydrophilic and lipophilic components, making it an amphiphilic molecule. It can self-assemble into nanometric-sized fibers. Chiral nematic self-assembly of chitin nanofibers has been reported, and it uses the so-called natural route, which forgoes chemical etching in favour of calcium ions (Ravi Kumar 2000; Narkevicius et al. 2019).

Cellulose is a highly sustainable raw material for a variety of chemical applications due to its abundance as a renewable natural resource and its intriguing structure, characteristics, and activities. Due to its inherent qualities, renewability, ease of functionalization, and diversity brought on by natural abundance, nanocellulose (NC) has emerged as one of the most promising green materials of the modern era. Choosing lignocellulosic biomass, an agricultural waste, as the cellulose source makes it more appropriate. Producing cellulose and NC from biomass

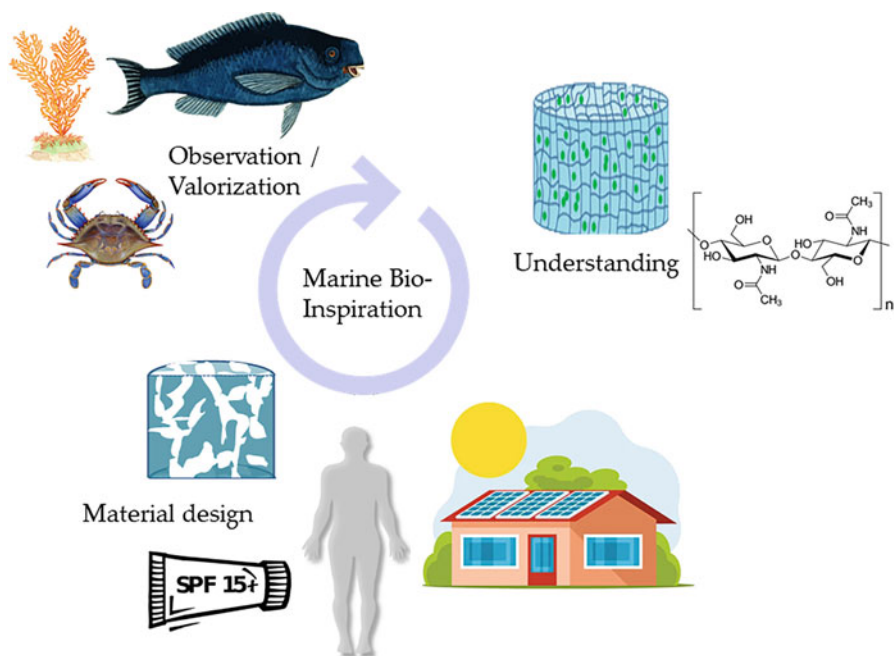

Fig. 4 Schematic representation of the marine bioinspiration, which potentially produce marine biopolymers, including chitin

feedstocks, microbial cultures, and plant materials like cotton, softwood, bark, and leaves can be done in a variety of chemical, chemo-mechanical, biochemical, and combination processes. Due to many of cellulose's well-known desirable properties, such as low density, nontoxicity, biodegradability, flexibility, affordability, environmental friendliness, the availability of multiple reactive sites for introducing novel functionalities, thermal stability, mechanical properties, reinforcing abilities, and tunable self-assembly in aqueous media, NC have attracted considerable interest. It is possible to divide the resulting nanocellulose into cellulose nanocrystals (CNCs), cellulose nanofibers (CNFs), and bacterial nanocellulose (BNC). The source and extraction technique used during the production stages affect the physical qualities of nanocellulose. Strong mineral acids are used to hydrolyze cellulose to produce cellulose nanocrystals; cellulose nanofibers are separated mechanically or chemically; and bacterial cellulose is produced biochemically. A crucial step in implementing sustainability into the extraction process is substituting the destructive sulfuric acid used during acid hydrolysis, and alternative technologies utilized at this point have been thoroughly investigated. Its numerous applications are made possible by characteristics including its high surface area and aspect ratio, rheological behaviour, capacity to absorb water, crystallinity, customizable surface chemistry, and, most importantly, its lack of cytotoxicity and genotoxicity. One of the main benefits of nanocellulose is its highly functionalized surface. Functional groups'

(primarily the $-CH_2$ group) decoration by various methods like esterification, etherification, amidation, urethanization (hydrophobic decorations), phosphorylation, sulfonation, TEMPO-oxidation, and carboxymethylation (hydrophilic surface modifications) have frequently been done over nanocellulose for various cutting-edge applications, such as biomedical. Tissue engineering, antimicrobial coating, wound dressings, medication delivery, and other innovative uses of NC-based materials in the field of medicine are just a few (Thomas et al. 2018).

Nanocellulose can be derived from a variety of sources, including plants, microbes, algae, and aquatic animals (tunicates). A comparison of the four different types of nanocellulose types is shown in Fig. 5. When compared to other extraction methods, *Cladophora* nanocellulose has distinct characteristics like high crystallinity ($>95\%$), large fiber aspect ratio, large surface area, and good mechanical and rheological properties (Zhou et al. 2019). It is very important to use dried, redispersible cellulose nanomaterials for many specific applications, and in this sense *Cladophora* nanocellulose is known to have a higher level of redispersibility. Green algae called *Cladophora* sp. have the ability to be synthesized and extracted as

Fig. 5 TEM images demonstrating the morphological features of four different types of nanocelluloses: (a) cellulose nanocrystals (CNC), (b) cellulose nanofibers, (c) bacterial nanocellulose, and (d) *Cladophora* nanocellulose

nanometer-sized crystalline cellulose (Sucaldito and Camacho 2017). *Cladophora* cellulose (CC) is simple to extract and offers exceptional solution processability, low moisture adsorption capacity, adjustable mesoporosity, high surface area, high chemical stability, low moisture absorption, robust and flexible mechanical capabilities, and diverse surface modifiability. These distinctive physical and chemical characteristics of CC can be used to create new features and improve the performance of nanocellulose-based materials, providing advantages over other sources in application areas like energy, environmental science (such as water and air purification, pollutant adsorption), and the life sciences (virus isolation, protein recovery, hemodialysis, DNA extraction, bioactive substrates, etc.). Over the past ten years, these characteristics have garnered a lot of study attention, particularly in the fields of energy storage (sustainable paper-based energy storage devices), environmental science, and life science. For instance, using CC-based separators during device manufacturing can improve the safety, stability, and capacity of lithium-ion batteries (Suciyati et al. 2022).

Heteropolysaccharide-Based Biopolymers (Animal and Plant)

Heteroglycans are heteropolysaccharides that typically contain two or more distinct monosaccharide units; however, some of the more uncommon examples may have three or more. A majority of naturally occurring heteroglycans, however, only have two distinct monosaccharide units and are intimately linked to lipid or protein. The tremendous complexity of the nature of these kinds of polysaccharides has produced the ideal environment for thorough structural research. Such research are, however, very challenging. The main heteropolysaccharides are the blood group substances (blood group antigens, which can be either proteins (Rh, Kell) or glycoproteins and glycolipids (ABO)), the connective-tissue polysaccharides (also known as glycosamino-glycans), and the connective-tissue heteropolysaccharides (contain acidic groups (uronic acids or sulfate groups)) and can bind water. Glycoproteins (combinations of carbohydrates and proteins) like gamma globulin; glycolipids (combinations of carbohydrates and lipids), especially those found in the central nervous system of animals; and a variety of plant gums (Fig. 6) can all play a part in other physiological processes, such as the accumulation of calcium prior to bone formation (Glasser 2008).

The most significant types of heteropolysaccharides can be found in the connective tissues of all mammals. These huge molecules that are included in this class of heteropolysaccharides range in size, shape, and how they interact with other components of the body. Individual connective-tissue polysaccharides have structural roles, and these roles are tied to particular animal functions. For example, hyaluronic acid, the main component of joint fluid in animals, serves as a lubricant and a shock absorber. These molecules can easily bind both water and inorganic metal ions because they have acidic groups (such as uronic acids or sulfate groups). They may also be involved in other physiological processes, such as the build-up of calcium prior to bone formation. Heparin, a heterogenic mixture of sulfonated

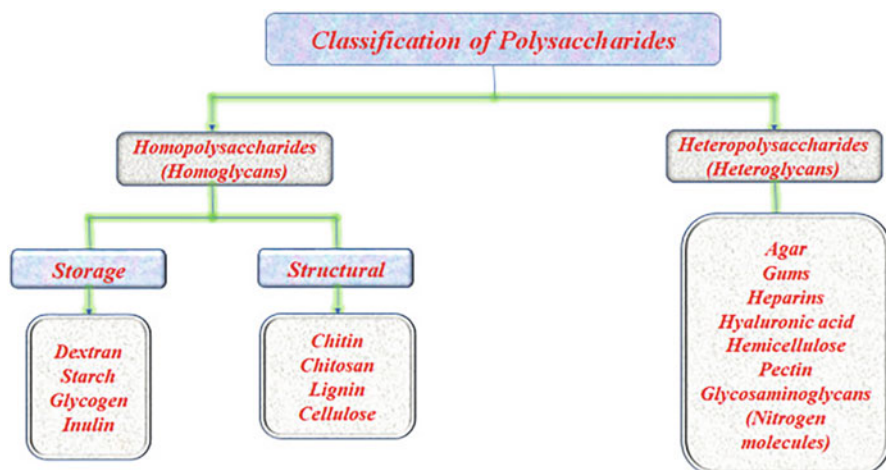

Fig. 6 An illustration showing the classification of polysaccharides into homo- and heteropolysaccharides with corresponding examples for each class

polysaccharides made from repeating units of D-glucosamine, D-glucuronic acid, and L-iduronic acid, is used to prevent or treat a variety of blood vessel, heart, and lung conditions. Ion-binding capacity also seems to be connected to heparin's anticoagulant activity. Additionally, extensive surgical procedures including open-heart surgery, bypass surgery, and kidney dialysis and blood transfusions all involve the use of heparin to stop blood clotting (Gan et al. 2017).

Agar is made up of dry, sulfuric acid esters that are water-soluble and is extracted from several *Gelidium* species (red algae). Agar's gel strength is derived from two different types of heterogeneous polysaccharides: (1) agarose constitutes up about 70% of the mixture and is a linear polymer made up of repeating units of agarobiose, a disaccharide made up of D-galactose and 3,6-anhydro-L-galactopyranose (it forms the supporting structure in the cell walls of certain species of algae), and (2) agaropectin, a sulfonated polysaccharide in which galactose and uronic acid units are not entirely esterified with sulfuric acid. Agar swells when treated with cold water, dissolves in boiling water, and forms gel on cooling. Some of the most widespread uses include making bacterial culture media, acting as an emulsifier, treating constipation, acting as a bulk laxative, and thickening ice cream, among others. It is also used in the preparation of vaginal capsules and suppositories, which is a cone-shaped capsule-like structure with the medicine in it, to be introduced into the rectum, urethra, or vagina (Williams and Phillips 2000; Cui 2001).

Galacturonic acid and arabinose make up pectin, which has a very complicated molecular weight. It is created during the ripening of citrus fruits and is typically isolated from the pulp of fruits like lemons and oranges, whose structures noticeably shift during ripening. Its ability to conjugate toxins and absorb them makes it a protective substance with some of the most important applications in the treatment of intestinal illnesses like diarrhea and dysentery. It is employed in pharmacies as a gel

and emulsion stabilizer as well as the creation of jams and jellies (Izydorczyk et al. 2005). Naturally occurring polysaccharides, such as those found in natural gums, have the ability to significantly improve a solution's viscosity even at low concentrations. As thickening agents, gelling agents, emulsifying agents, and stabilizers, these are employed in the food sector. As adhesives and binding agents, they are widely utilized in various sectors. These compounds are created in higher plants either spontaneously or as a result of mechanical harm as a kind of post-injury protection (pathological). Gum tragacanth and gum arabic are two of the most prevalent examples (G. tragacanth). The characteristic of gums to swell in water and transform into viscous, sticky, or adhesive solutions is a common one. These are neutral salts of complicated polysaccharide acids that have residual uronic and sugar acids. Pentose (D-xylose, L-arabinose), methylpentose (e.g., L-rhamnose), hexose (D-mannose, D-galactose), and uronic acid residues are some frequent ingredients, such as D-glucuronic or galacturonic acid (Cui 2001).

The majority of research on mushrooms has focused on their heteropolysaccharides, which are a class of more complicated polymers in addition to their D-glucans. It's possible to view mushroom heteropolysaccharides as a fascinating source of compounds with both industrial and medical uses. The types of polysaccharides that are obtained from various sources of mushroom-forming fungus, such as Basidiomycetes, Ascomycetes, hybrid mushrooms, etc., exhibit a tremendous diversity. The many polymers discovered in these mushrooms are structurally analyzed to determine the heteropolysaccharides. These polymers can be divided into heterogalactans, heteroglucans, and heteromannans depending on the primary chain they contain (Ruthes et al. 2016).

The backbone of polymers typically consists of (1–6)-linked D-galactopyranosyl residues, some of which have side chains made of L-fucopyranosyl, D-mannopyranosyl, D-galactopyranosyl, or 3-O- α -D-mannopyranosyl- α -L-fucopyranosyl residues. When D-Manp as end units are absent, the various sorts of substitutions give heterogalactans, such as fucogalactans, different names. The main chain of heterogalactans can also be partially O-methylated, displaying 3-O-Me-D-Galp units. Natural sugars may be etherified by various groups, but methyl ethers are the most frequently used. The most common polysaccharides found in mushrooms are D-glucans, specifically in a particular configuration. But other scientists hypothesized the existence of heteroglucans, which had branches made up of several monosaccharides and a core chain made of D-glucopyranose residues. The structures described thus far typically consist of -D-Glcp residues that are (16)-, (14)-, and/or (13)-linked, with terminal non-reducing residues of β -d-Glcp; α -D-Galp; α -L-Fucp; and α -D-Glcp replacing them at O-3 or O-6. In polymers derived from various sources, disaccharides or tiny branches of monosaccharide assemblies were also seen. *Lepista sordida* produced α -D-glucan, substituted at O-2 by α -D-Galp residues substituted at the O-2 position, which was described as having the most complicated structure of all the mushroom heteroglucans hitherto reported (Shirakawa et al. 1998; Luo et al. 2012). Common polysaccharides like mannans and heteromannans are found primarily in Ascomycetes. They make up a portion of the fungus' cell wall structure and can be joined to proteins to create the cell wall matrix (Netea

et al. 2008). Galactomannans, glucogalactomannans, and xylomannans are three examples of the heteromannans that have been isolated from mushrooms. Extreme complexity was revealed by structural analyses on a variety of heteromannans that were isolated from diverse mushrooms. There aren't many studies on heteromannans, and their complicated characteristics made purifying them difficult.

Peptide- or Protein-Based Biopolymers

For various reasons, a wide variety of proteins are derived from sources that are either animal or plant. Protein-based biopolymers are used to create scaffolds for regenerative tissue engineering applications because of their inherent bioactivity, biocompatibility, and biodegradability. These biopolymers are made into tissue engineering structures, carriers for the delivery of medicinal molecules, emulsifiers, and food packaging materials. Some of the most significant examples of this kind of biopolymer are collagen, albumin, keratin, insulin, hemoglobin, PFF, and others (Nagarajan et al. 2019). Proteins like collagen, gelatin, keratin, sericin, and fibroin are utilized to create a variety of formulations, including films, Pickering emulsions, hydrogels, nanogels, and nanofibers. These formulations were taken into consideration for the regeneration of both hard and soft tissues, including nerve, bone, and cartilage tissues. The extracted proteins are generally very brittle, have poor toughness and elasticity, and have a poor inclination to form films. Thus, by adding reinforcement in the form of synthetic polymers and inorganic nanoparticles, the physical properties of the biopolymer scaffolds must be enhanced. Proteinaceous biopolymers provide a number of benefits, but their uses are restricted by factors including antigenicity and immunogenicity. By carefully enhancing the extraction process to get rid of the antigenic residues, these drawbacks can be eliminated or at least reduced (Reddy et al. 2021).

There are 28 members of the collagen family, and each one has at least one triple-helical domain. Based on how they are dispersed throughout the animal, type I, type II, and type III of collagen can be identified. Along with type I, type II and type III are also typically observed. The skin, tendons, organs, the bone (the main organic component of the bone), and the vasculature are all home to type I and type II, respectively (major collagenous component of cartilage). One property of this protein, which is identified by its unique chemical composition, is the specific amino acid composition of collagen. Collagen, regardless of its origin or form, includes 19 amino acids, including hydroxyproline, which is absent from other proteins. Proline and glycine are present in significant concentrations, and cysteine is absent, which are characteristics of its unusual amino acid composition. Fig. 7 depicts the collagen's hierarchical arrangement. The extracellular matrix is where collagen is deposited, and there, the majority of it forms supramolecular assemblies. Collagen is the protein found in most animal tissues and is found both in soft and hard connective tissues. Natural collagen may be created in a lab setting into highly structured, three-dimensional scaffolds that have great tensile strength and are innately biocompatible, biodegradable, and nontoxic when applied externally. Collagen is the

Fig. 7 A schematic illustration of the hierarchical organization of collagen from fibers to amino acid sequence (a). Open and three-dimensional structure of collagen highlighting the unique amino acids hydroxyproline, proline, and glycine (b) and part of a typical amino acid sequence of a collagen chain (c).

chosen material for tissue engineering and wound healing applications because of these characteristics (Mitra et al. 2011; Chattopadhyay and Raines 2014).

In the presence of diluted acids, collagen found in animal skin and bones is thermally denaturalized to create gelatin, a biopolymer. Glycine, proline, and 4-hydroxyproline residues are abundant in gelatin. Gelatin's history dates back many centuries, but it wasn't until the first patent for its manufacture in England in 1754 that its significance was understood. Since then, it has been the preferred material used by all scientists for creating hydrogels at all scales, including nanoscale for drug delivery. Gelatin is now regarded as a food additive by the WHO and is deemed to be entirely safe. Chemically, gelatin is a pure, natural protein that contains 18 different amino acids, including glycine, which makes up 27% of the protein; proline, 16%; valine, 14%; and hydroxyproline, 14%, among others. Gelatin is used as a gelling agent in food, medicine, vitamin capsules, cosmetics, paper, and photographic films, among other notable applications. Probiotics, a mixture of living bacteria and/or yeast that reside in the host body, are also encapsulated in gelatin, either alone or in conjunction with other substances. The use of collagen in food also extends to the pharmaceutical, meat, dairy, dessert, and cosmetic industries as well as beverages and juices (Haug and Draget 2009; Ramos et al. 2016).

Humus-Derived Biopolymers

The “black side” of life, referred to as humus, is created through the interaction between soil organic matter (SOM) and soil organisms. A majority of the benefits humus offers the soil ecosystem are associated with its large surface area for nutrient exchange, capacity for holding onto water, and strong affinity for mineral particles. Humus plays a significant role in the ecosystem by moving organic matter throughout the soil profile and mixing closely with mineral particles. The biological origin of humus and the series of physicochemical processes by which living matter is transformed and recycled within the soil ecosystem to produce a range of chemical compounds, ranging from amino acids (phenylalanine, tyrosine, tryptophan, aspartic acid, arginine, and histidine, to name a few) to large molecules typically categorized as biopolymers, are revealed by thorough examination of humus profiles by microscopic and other spect.? The carbonaceous, polymeric by-products known as humins, which include humic acid, fulvic acid, humin, etc., are generated virtually invariably (Fig. 8). The unregulated cross-polymerization processes of the precursor molecules, such as hydroxymethylfurfural (HMF), levulinic acid (LA), and other reaction intermediates, culminate in the formation of these humins in SOM (Greenland 1971; Aiken et al. 1985).

Bacterial Biopolymers

Nearly all areas of the world are home to bacteria, which are essential to its ecosystems. Some organisms can survive in harsh environments with high pressure and temperatures. In fact, it is thought that there are more bacterial cells in the human body than there are human cells. These tiny, one-celled critters are tiny. Bacteria are efficient cell factories capable of converting carbon and nitrogen sources, and they are capable of producing a wide range of intracellular and extracellular biopolymers, including polysaccharides, polyamides, polyesters, polyphosphates, extracellular DNA, and proteinaceous components. Numerous classes of biopolymers, including polyesters (hydroxy fatty acids linked by ester bonds), polyamides (consisting of amino acids connected by peptide bonds —NH-CO-), polysaccharides (consisting of sugars and/or sugar acids connected by glycosidic (C-O-C) linkages), and polyphosphates (polyPs; composed of inorganic phosphates connected by anhydride bonds), can be produced. Charged or uncharged, non-repeating or repetitive, branched or unbranched, and homopolysaccharides or heteropolysaccharides are all possible characteristics of polysaccharides. Numerous bacteria produce polysaccharides, which they can either exude as free exopolysaccharides or as capsular polysaccharides that are adhered to the cell surface or store inside the cells (like glycogen) (e.g., alginate and cellulose). These biopolymers, which also exhibit remarkable material properties, are home to the most significant virulence factors. Another family of biopolymers produced by bacteria is intracellular cyanophycin, a copolymer of L-aspartic acid and L-arginine that can act as a matrix or capsule for biofilms. It is related to polyamides and poly(amino acid) chains of the same family

Fig. 8 Scheme showing the humus pool (a), the main chemical constituents such as soil protein (nitrogen pool) and active carbon (carbon pool) microbial activity (respiration) (b), and the certain biopolymers extracted from humus including fulvic acid (c), humin (d), and humic acid (e)

(Fig. 9a). Bioplastics made from bacteria include poly((R)-3-hydroxybutyrate) and other polyhydroxyalkanoates (PHAs). They are hydrophobic spherical inclusions made of linear polyesters that are produced and used as carbon and energy storage (Fig. 9b). Polyphosphates (polyPs) are highly negatively charged polymers of condensed phosphates that are abundant in “high-energy” anhydride linkages. They can include three to several hundred inorganic phosphates. It performs the role of an energy-storing polymer (Fig. 9c). The lifestyle, persistence, viability, growth, stress tolerance, and virulence of bacteria are all impacted by the regulation of cell signalling by polyPs. Other biopolymers, such as extracellular DNA and proteinaceous components, are also produced by bacteria. They are taken into consideration for the creation of bio-based materials in addition to being significant in bacterial parthenogenesis.

A growing amount of attention has been paid to bacterial nanocellulose (BNC) during the past few decades due to its exceptional physical and chemical

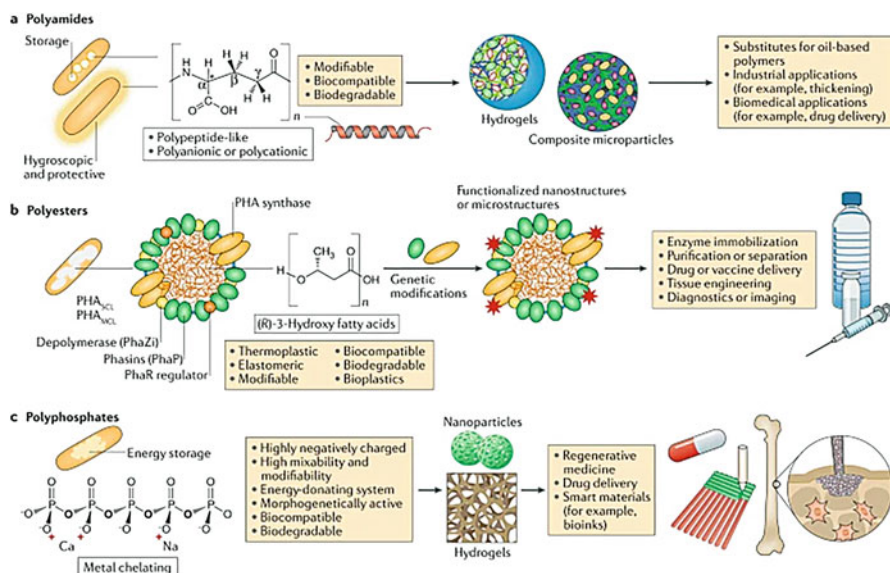

Fig. 9 Bacterial polymer granules of polyamides, polyesters, and polyphosphates have been taken into consideration as alternatives to synthetic polymers made through chemical synthesis that can be used in formulations for industrial, medicinal, pharmaceutical, and cosmetic applications. **(a)** Specific synthetases produce polyamides, which are made of amino acids and synthesized outside of the ribosome. **(b)** Polyhydroxyalkanoates (PHAs), including polyhydroxybutyrate, are hydrophobic spherical inclusions that are produced from (R)-3-hydroxybutyric acid. PHA nanobeads can serve as efficient platforms for tissue engineering, protein purification, medication or vaccine delivery, bioseparation, enzyme immobilization, diagnostics, and imaging. **(c)** Orthophosphates, which range in number from three to hundreds of phosphates, make up polyphosphates. These orthophosphates are joined by phosphoanhydride (P-O-P) bonds. They can be transformed into hydrogels or nanoparticles for a variety of uses and aid in energy storage

characteristics. BNC, often referred to as microbial cellulose, is a fascinating pioneering biomaterial with a distinctive structure and set of features. It has advantages over conventional synthetic fibers, including superior biocompatibility, high mechanical strength, and tailorable surface chemistry, availability everywhere in the globe, biodegradability, and nontoxicity. In comparison with cellulose derived from plants, it also has advantages such as high purity (free of lignin, hemicellulose, and pectin), high crystallinity, high elasticity, high conformability, low density, high specific surface area, high degree of polymerization, excellent permeability, high porosity, and water content. BNC is a highly pure form of cellulose that is created by bacteria from dextrose and other cheap carbon sources with precise metabolic reactions. The bacteria then exude cellulose fibrils that self-assemble in the culture medium (Bäckdahl et al. 2006; Reiniati et al. 2017). It is devoid of additional polymers like lignin, hemicelluloses, and pectin, typical constituents in plant cellulose composites, as well as functional groups like carbonyl and carboxyl added in plant celluloses during the meticulous isolation and purifying procedures (Klemm

et al. 2005). BNCs are made from pure cellulose and have stable network architectures, with average diameters of 20–100 nm and micrometer lengths. To generate bacterial nanocellulose, gram-negative bacteria including *Rhizobium*, *Xanthococcus*, *Gluconacetobacter xylinus*, *Pseudomonas*, *Medusomyces gisevii*, *Azotobacter*, *Aerobacter*, and *Alcaligenes* were combined. This is a new biomaterial that has enormous promise as a biological implant, a material for healing wounds and burns, and scaffolds for tissue regeneration, among other uses.

Challenges and Future Prospects

Therefore, further biopolymer-based research needs to be done in order to close the gaps that now exist by transferring production from a laboratory size to an industrial or commercial scale, achieving the viability and sustainability of completed materials, and putting them on the market as a desirable product. Developing functional materials from molecules and biopolymer research face a number of significant hurdles in the future, which include (1) understanding the crystallization and nucleation mechanisms of pure biopolymers to identify the best bio-additives to enhance crystallization kinetics, (2) streamlining the entire process and creating new (sustainable) techniques for the production of new materials, (3) implementing life cycle assessment related to environmental aspects of biopolymer-based materials, (4) reducing the energy and time consumption of the biopolymer-based materials, (5) energy auditing of the various preparations, (6) how biomimetics can be achieved with various biopolymers and biopolymer-based functional materials, and (7) developing bio-nanocomposites made of nanocrystals or nanofibers derived from renewable resources or agricultural wastes. Despite these multiple significant challenges, we believe that biopolymers and biopolymer-based products will surely enhance people's quality of life in the future through the development of a variety of new functional materials. As a result, to address the present issues and upcoming challenges in creating materials from biopolymers for the human, future research on biopolymer-based materials must take into account various aspects such as numerical models, artificial intelligence (AI), and machine learning (ML)-based algorithms.

Conclusions

Nonetheless, before use on a widespread scale, the development process must integrate the overview of durability, scalability, and real-world efficacy of the materials. Many of these substances are promoted as “green,” “sustainable,” or “eco-friendly” substitutes for conventional petro-based goods. These credentials must, however, pass rigorous testing that examines every stage of the lifetime of each of the products under consideration, from diverse bacterial biopolymers to biomaterials derived from humus, including treatment, discharge, and environmental disposal. Extensive use of biopolymers brings additional challenges to scientists.

Biopolymers exhibit lower end-use properties, crystallization kinetics, and processability than conventional petro-based polymers. Consequently, the major current research effort is to improve mechanical properties, crystallization kinetics, and thermal resistance and barrier properties of biopolymers, which can potentially bring in desired properties for cutting-edge applications.

Abstract

Plastic trash has long been recognized as a significant environmental issue throughout the world. Due to their resistance to microbial attack and difficulty in degrading, traditional polymeric substances build up in the environment and are a significant cause of pollution. Due to the problems brought on by synthetic waste, new polymeric materials that are biodegradable and environmentally benign must replace the current ones. Due to their numerous uses in packaging, agriculture, and biomedicine, biodegradable polymers based on renewable resources have received a lot of attention lately. This study seeks to provide an overview of classification, properties, and application areas.

Keywords

Biopolymers · PLA · PHA · pHBA · Renewable resources · Biodegradable

Introduction

The biodegradability, biocompatibility, lack of toxicity, ease of manipulation, and pervasive nature of biopolymers derived from natural sources like plants, microorganisms, and animals have aroused interest in medical applications. Renewable resources are the main sources of biopolymers. The recent growth of nanoscience has revealed a strong preference for the creation of secure and useful nanobiomaterials. It is becoming more and more important to create novel bio-based products and other cutting-edge technologies that can end the global reliance on fossil fuels. To put it simply, bio-based materials are manufactured items made from renewable agricultural and forestry feed stocks. For material applications, a large range of naturally occurring polymers generated from renewable resources is accessible. Some of them, like cellulose and starch, are being used in products, but many others are still unused.

Fossil carbon sources have limited supply, accessibility, and explorability. Over the previous few decades, there has been almost constant growth in oil prices, which peaked in the summer of 2005. Alternative resources and processes will soon replace fossil ones due to the scarcity and high cost of these resources. Because they could assist us in resolving these issues, biotechnological technologies for the production of energy and chemicals have drawn a lot of interest. Approximately 94% of the fossil fuels used today are used to produce energy; the chemical industry uses far less of these resources to produce bulk and fine chemicals.

Biopolymers from plant materials and microbes, which can be developed endlessly, would establish a sustainable industry since they are renewable, carbon neutral, and always sustainable. The effective use of biopolymers and promising new routes with lower carbon footprints resulting from green materials augur well for the design and development of ever-more advanced green materials in the future.

Getting fuels and chemicals from renewable sources is gaining popularity. The problem is that petroleum, the rival resource, is not expensive. Additionally, 50 years

of investment in petroleum processing have made it possible to efficiently transform petroleum into an incredible variety of products. As a result, in low-value applications, items obtained from renewable resources have had little success competing with those derived from petroleum (e.g., fuels and simple chemicals). Even for intermediate-value goods, renewables have had trouble competing with petrochemicals (e.g., specialty chemicals and polymers). For instance, it is possible to create water-soluble polyacrylamides that have a variety of functional characteristics that can be tuned for certain purposes. If cellulose is heavily chemically altered, some of these qualities can also be obtained with this natural polymer.

For a variety of biomedical, agricultural, and ecological goals, it is desirable to have a biodegradable plastic that will disintegrate in the physiological environment or by microbial action in the soil. A lot of work has gone into improving the biodegradability of plastics, with the major focus on the development of new biodegradable polymers, modifications to natural and synthetic polymers, and composites made of biodegradable polymers. Attention has been paid to biopolymers as beginning materials in the hunt for biodegradable polymers based on renewable resources. One of the main biopolymers in crops is plant protein. It is a biopolymer that is renewable and biodegradable. The use of plant proteins as a material is not very common. Casein, zein, and other types of plant proteins have been used to make fibers and polymers.

An organic polymer that is generated by living creatures is referred to as a "biopolymer." Recent developments in our understanding of important biosynthetic processes and the options to control or modify these pathways through genetic changes have led to the investigation of new possible applications for polymers generated from renewable resources. Biopolymers are composed of numerous polysaccharides, proteins, lipids, polyphenols, and specialized polymers made by bacteria, fungus, plants, and humans. For instance, environmental compatibility would be enhanced because using it wouldn't result in any additional environmental duties in. The use of renewable resources encourages the production of more nonrenewable petrochemicals. The improvement of biopolymers using polymers derived from renewable and sustainable resources is a modern and promising way to minimize greenhouse gasoline and hazardous emissions, as properly as strength consumption and the use of nonrenewable resources.

Synthetic polymer-based materials are not biodegradable and are frequently thrown carelessly. Environmental problems have resulted from the massive development of conventional plastics created from synthetic polymers derived from petroleum that cannot break down in a composting or landfill environment. A creative and practical solution to reduce toxic and greenhouse gas emissions, energy demand, and the use of nonrenewable resources is the development of biopolymers employing polymers generated from sustainable and renewable resources.

There are many benefits to using naturally occurring polymers in materials. The use of biodegradable materials for packaging, agriculture, medicine, and other applications has gained popularity recently. As an alternative to the synthetic polymeric materials now used, a variety of biopolymer mixes should be used. These include starch, chitosan, alginate, gelatin, PLA, PHAs, and other common and useful biopolymers.

One significant advantage of biopolymers is their complete success at biodegradation at accelerated rates, decomposing in a controlled amount of time under the enzymatic action of microorganisms into simple molecules. Under certain environmental conditions, polymeric materials made from renewable resources may be biodegradable or compostable. They are labeled based on the production process or the source:

- Polymers like proteins and polysaccharides that can be quickly removed from biomass.
- Standard chemical synthesis is used to create polymers, beginning with sustainable bio-based monomers like polylactic acid (PLA).
- Microorganism- or genetically modified-derived polymers such bacterial cellulose and polyhydroxyalkanoates.

Consumer expectations and technological advancement are increasing the demands on the world's resources, which is creating serious problems with material availability and environmental sustainability. Biofiber composites have seen a remarkable metamorphosis during the past few decades. As novel compositions and technologies have been extensively explored, created, and then used, these materials have gotten steadily more sufficient. Biocomposites have gained major importance as a result of the oil crisis and have developed into engineering materials with a very diverse set of features. However, like all materials, they are continually subject to market competition on a worldwide scale, which calls for ongoing study. The days of simply combining plastics with natural waste fillers and describing the major characteristics of the resulting mixture are over.

Nano-catalysts based on biopolymers can be made more stable and effective by immobilizing them on reactive groups with unique properties. The abundance of size, structure, and molecular chains in low-cost biopolymers such polysaccharides makes them desirable candidates for stabilization and immobilization as well as the reduction of NPs. Biodegradable materials are increasingly being used in packaging, agriculture, medicine, and other fields in recent years. Recently, a wide range of applications for biopolymers have been identified, from bioplastic additives and mixes to consumer goods, research products, and personal hygiene items – all of which offer the benefit of environmentally friendly decomposition. The functionality of biopolymers in a variety of applications is influenced by the choice of the biopolymer, its intended use (emulsion and foam surface recreation or viscosity forming bulk shape or gelation), the process of structure development, and its interaction with any additional formulated matter.

For a variety of biomedical, agricultural, and ecological goals, it is desirable to have a biodegradable plastic that will disintegrate in the physiological environment or by microbial action in the soil. A lot of work has gone into improving the biodegradability of plastics, with the major focus on the development of new biodegradable polymers, modifications to natural and synthetic polymers, and composites made of biodegradable polymers. Attention has been paid to biopolymers as beginning materials in the hunt for biodegradable polymers based on renewable

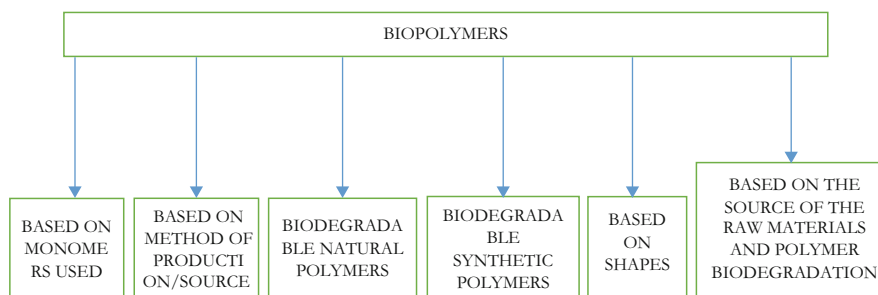

resources. One of the main biopolymers in crops is plant protein. It is a biopolymer that is renewable and biodegradable.

In addition to their usage in construction materials and for specialized purposes, biopolymers are widely used as packaging materials. For this reason, cellulose chemical compounds made from plant biomass have been employed for many years. For use as packaging materials, a number of biopolymers made using biotechnological techniques have been created. It might be advantageous for the environment if biodegradable polymers made from renewable resources are available. The biotechnological production of non-biodegradable biopolymers for applications that require them hasn't gotten much attention yet, despite the enormous demand for persistent materials. Without the availability of synthetic durable polymers like polyethylene, polystyrene, or polyvinyl chloride, it would be impossible to build modern homes, cars, or other significant advancements.

Classification of Biopolymers

In the modern day, using compounds that disintegrate easily in the environment plays a significant role. Biopolymers are one of these materials; they are made utilizing living creatures. The monomeric components of biopolymers include nucleotides, amino acids, and sugars. Among the chemicals that make up biopolymers include cellulose, starch, chitin, proteins, peptides, DNA, and RNA. Biopolymers and their derivatives exhibit the qualities of an excellent and are becoming increasingly important for many activities. A variety of biopolymer mixtures could replace some of the synthetic polymeric materials currently in use. Starch, chitosan, alginate, gelatin, PLA, PHAs, and other commonly used and prospective biopolymers are also listed. The primary resource for developing renewable and biodegradable polymer materials to replace petrochemicals is herbal polymers generated from agricultural products. New potential applications for the utilization of renewable polymers are being researched thanks to improvements in our understanding of major biosynthetic processes and our capacity to control or customize those pathways through genetic changes. Of their herbal surroundings, evidently going on polymers serve an extensive variety of duties. Membranes, intracellular communication, cellular surface reput, mobile wall construction, capsular layers or protective barriers around cells, emulsifiers, adhesives, and water, nutrition, and steel sequestration for cells are all places where polysaccharides are hidden. Proteins serve as building blocks, catalysts, cell characteristic regulators, adhesives, and reputation-building elements. Biopolymers have created an excellent competition with their fossil gasoline-based totally equivalents in phrases of useful characteristics and manufacturing charges. While the cost of producing biopolymers could be very low, continuous efforts are made to enhance their purposeful residences.

Biopolymers are divided into classes: biodegradable and non-biodegradable. Some other classification is based on their source of starting place: herbal resources (plant life, animals, and microorganisms) or fossil fuels. While measured in terms of usability, non-degradable biobased biopolymers outperform biobased degradable

Table 1 Biopolymers and their classifications

biopolymers in several functional domains. Biopolymers are classed as elastomers, thermosets, or thermoplastics based totally on their potential to respond to warmness situations. In evaluation to biobased thermoplastics, biobased thermosets have lately sparked more interest in generating components, even as elastomers have inspired many scientists and scholars to produce revolutionary substances with their personal set of appropriate capabilities. Finally, biopolymers are classified into three groups based on their composition: blends, laminates, and composites. Classification of biopolymers are divided in Table 1.

Recently, microbially produced biopolymers including polyhydroxy alkonates (PHAs) polymers have gotten quite a few hobby. Using renewable materials is turning into extra essential, and the world's essential industries and producers are seeking out ways to update diminishing petrochemical-based totally feedstock with composites crafted from herbal fibers and biopolymers.

Based on Monomers Used

Based totally on monomers used, biopolymers can be categorized into three: polysaccharides (from sugar), proteins (from amino acids), and nucleic acid (from nucleotides). Most biopolymers' monomers are composed of repeating molecules of either nucleic acids or nucleotides, amino acids, proteins, or saccharides generated from sugars.

Polysaccharides from Sugars

Amylose/Amylopectin is a kind of starch. Relying on the plant species, the ratios of amylose and amylopectin range (normally about 25–30% amylose in corn starch). Starch is crucial as a biopolymer resource because of its low cost, availability as an agricultural surplus uncooked fabric (approximately one billion bushels/12 months carryover in the), and thermal processability using standard plastics processing equipment. Because of the hydrophilic nature of starch, water management is crucial both during and after processing.

Even though the starch percentage in early starch blends was often around 10% and non-biodegradable additions like polyethylene served as the main component, starch blends were created to capitalize on the biodegradable properties of starch. Some of those mixtures contain a car-oxidant that interacts with steel salts in diverse environments or soils, producing peroxide radicals that catalyze the breakdown (depolymerization) of the mixture's polymers, including polyethylene.

The starch is handled with a silane coupling agent to make it compatible with polyethylene, and an unsaturated ester, such as soya or maize oil, can be used as the car-oxidant. Temperature triggers based on a composting habitual have been considered with the aid of different era.

Cellulose. Vegetation and microorganisms produce cellulose, that's a linear polymer made of p-1,4-related n-glucose (e.g., *Acetobacter xylinum*). Cellulose is the most abundant naturally occurring polymer in the biosphere. The cellulase enzyme complex catalyzes the formation of cellobiose and glucose during regular cell biochemical cycles, which causes mineralization. Due to the excessive hydrogen bonding, cellulose cannot be thermally handled and need to go through thermal disintegration earlier than melting; however, it may be solvent solid. The lyotropic mesophase is discovered in cellulose and numerous cellulose derivatives.

In addition to being used in paper and paper products, membranes and films, fabric, food, and medicine, cellulose also serves other purposes. The speaker diaphragms in headphones are made from cellulose derived from bacteria because it has a better crystallinity and smaller diameter fibrils than cellulose derived from plants. Cellophane is one of the most prevalent types of cellulose used in packaging. Due to its transparency and oil barrier features, it is utilized as laminated wrappers for more than a few food. To enhance moisture barrier features, cellophane is typically covered with nitrocellulose or poly (vinyl chloride), despite the fact that those coatings are not biodegradable.

Cellulose is water insoluble in its local circumstance, making it difficult to convert into films or coatings. Derivatization reactions boom water solubility through forming carboxymethyl cellulose, methyl cellulose, hydroxy propyl cellulose, and other systems. Mineralization rates are slowed by crosslinking. With increasing levels of substitution, both steric difficulty and a lower hydrophilicity is liable for the lower degradation rates. Nitrocellulose (containing di- or trinitro substitutions consistent with monomer), in addition to cellulose tripropionate and cellulose tributurate, is all proof against microbial assault.

Pectins. Pectins are structural polysaccharides that may be isolated from plant cells and consist primarily of α -1,4-n-galacturonic acid with varying degrees of methyl esterification (middle lamella). Pectin is a viscous substance that dissolves in water. Citrus peels and apple pomace are the maximum common business resources of pectin. In the presence of calcium ions, low methoxyl pectin forms a gel in the presence of calcium ions and is used as a coating and additive in the food zone.

Proteins from Amino Acids

Soy, Zein, Wheat Gluten, Casein, and Serum Albumin are a number of the proteins discovered in soy. Soy, zein (an alcohol-soluble protein extract from corn gluten),

and wheat gluten are all components of vegetables. A protein blend called casein is produced from the milk of mammals. Blood plasma or milk from mammals are the sources of serum albumin. Among other things, casein is used to make glue, fortify flour, and create microbiological media. The genes encoding those proteins have been cloned and produced, and serum albumin is hired as a therapeutic protein for blood diseases.

Collagen/Gelatin. Collagen is the most ample protein inside the animal country and an enormous structural thing in animal tissue. Mammalian skin, bone, and connective tissues all contain collagen. Collagen has an essential shape that has the glycine-X-Y trimer repeat, where X and Y are usually proline or hydroxyproline. The movement of some of protease enzymes can depolymerize collagen, similar to every other protein. Water or solvent processes generate collagen films, which are sometimes crosslinked. Those fibers are broadly speaking employed in clinical programs and as a casing fabric in meals. Collagen has been used in pharmaceuticals for tissue and nerve repair, wound dressings, medication delivery, ophthalmology, vascular grafts, and sutures of many types, including sheet, tube, sponge, and powder.

Gelatin. It is an animal by-product made by partially hydrolyzing collagen and then extracting it with hot water. Gelatin is biodegradable and without difficulty crosslinked. Chemical processes consisting of glutaraldehyde, carbodiimide, acyl azide, isocyanates, and different chemistries may be used to crosslink substances. In widespread, gelatin has a molecular weight variety of 15,000 to 250,000. The majority of natural solvents are insoluble in gelatin, but water, acetic acid, and polyhydric alcohols are soluble. With the addition of plasticizers, gelatin can also be used in textiles in the food, pharmaceutical, and photography sectors. Biodegradability of gelatin and poly(ethyl acrylate) graft copolymers in movie shape has been discovered.

Silks. Many animals, including insects and spiders, create silks, which are large-molecular-weight proteins. Many silks contain a secondary structure known as a “sheet,” which is maintained via hydrophobic interactions between sheets and interchain hydrogen bonds. Many silks include high levels of short-chain amino acids including glycine, alanine, and serine, which can range from 65% to 85%.

Method of Production and Source

Underneath certain environmental conditions, polymeric materials made from renewable assets can be biodegradable or compostable. They are classified primarily based on the method of production or the source of formation.

Polymers Directly Extracted from Biomass such as Polysaccharides and Proteins

Because of its abundance, low fee, and renewability, starch is a probably promising biodegradable material. Furthermore, starch’s utility in the plastics industry can assist to lessen reliance on synthetic polymers. Amylose and amylopectin are

typically the two types of polymers that make up the heterogeneous fabric known as starch. It has been demonstrated that it is a heterogeneous material even if the shape of it has not yet been fully investigated. Even though starch is a commonplace aspect in biodegradable plastics, natural starch-primarily based films have poor mechanical traits. The most crucial polysaccharide is starch, which is abundant in nature and comparatively reasonably priced. Herbal starch is to be had in granular shape and has been used as a filler in polymers, but it may additionally be thermoplasticized and handled with conventional plastic processing techniques along with extrusion, foaming, and film blowing. The hydrophilic function of starch is its predominant disadvantage, proscribing its software in excessive-moisture situations. Starch can be used to create PLA composites, and it can also be mixed with other biodegradable polymers and derivatives to create fully degradable biomaterials, such as polyvinyl alcohol, poly-hydroxybutyric acid, polycaprolactone, and chitosan. Chitosan has become one of the most well-liked biopolymers for the creation of drug delivery systems for a range of packaging due to its promising properties, which include high biocompatibility, remarkable biodegradability, low toxicity, plentiful availability, and low cost of coffee manufacture. Chitosan is a biopolymer made via the de-acetylation of chitin, the second one maximum universal biopolymer after cellulose in nature.

Chitin can be found inside the exoskeletons of bugs, crabs, shrimp, lobsters, and sure fungal cellular walls. It is economically feasible to supply chitosan from crustacean shells, which can be discarded by using the seafood enterprise. Due to its film forming competencies, chitosan has been recommended as an appropriate meals packaging cloth, specifically for fit for human consumption movies and coatings. However, one of the most enormous hazards of chitosan-based composites is their low mechanical strength. By causing inter- or intramolecular crosslinking in the polymer matrix, chitosan is frequently combined with other polymers or crosslinked to improve their usable qualities.

Cellulose is a crucial and charming biopolymer, as well as almost infinite and sustainable herbal polymeric raw cloth with applications in both industry and ordinary existence. Within the cell partitions of superior flowers are microfibrils with a helical organization on multiple levels, crystalline domains (domains with ordering high cellulose chains), and amorphous (section fields distorted, twisted, and deformed).

A few of cellulose's intriguing properties are its mechanical toughness, hydrophilicity, biocompatibility, biodegradability, relative thermostability, excessive sorption capacity, and modifiable visual appearance. Cellulose is broadly utilized in a diffusion of programs. Based on cellulose, they offer numerous benefits (specially their wise responses to environmental stimuli) and may be used in a variety of situations. Every 12 months, around 51,011 metric tonnes of cellulose are produced. Lamentably, just 2% of the full is recovered industrially. Cellulose's first rate qualities permit it for use in an extensive variety of fields.

Collagen is extensively hired as a biomaterial in a huge variety of biomedical applications. The most prevalent proteins found in the extracellular matrix of vertebrates are collagens. The most abundant type of collagen found in animal

hides and skins is type I collagen, which is also the most crucial structural component of tendon, bone, and connective tissue. Collagen is seen as fibrils, which are responsible for the structural support and mechanical function of connective tissues. Because of their natural structure, biodegradability, and biocompatibility, collagens have a wide range of applications as biomaterials in tissue engineering, wound healing, drug transporters, and cosmetics. For instance, fibril-forming collagens serve as a scaffold for cell attachment and migration while also supplying mechanical properties.

A key task in fabric studies is the creation of suitable modification strategies to enhance the properties of natural polymers. One example is the creation of natural polymers based on wheat gluten or wheat protein. One of the most affordable plant proteins is wheat protein, often known as wheat gluten, which is derived from the second-largest cereal crop (after maize). Super viscoelastic, tensile, and gasoline barrier properties describe the properties of wheat proteins or gluten. Wheat gluten, a derivative of the starch industry with an excessive protein content (>75 wt%), may be considered best for a variety of applications due to its suitable thermoplastic properties, processability, and high-quality biodegradability.

Polymers Produced by Classical Chemical Synthesis Starting from Renewable Bio-based Monomers such as Polylactic Acid (PLA)

Because of its renewability, biodegradability, biocompatibility, properly thermo-mechanical traits, and occasional fee, polylactide (PLA) is the quality polymeric replacement for various petropolymers inside the context of ecologically friendly procedures and products. To begin with, the general public of its applications were in the biomedical area and quick-time period usage which includes packaging, because to PLA's biodegradable qualities. Due to the depletion of petroleum resources, PLA is increasingly being considered as a valuable bio-sourced polymer substitute in long-term applications such as automotive and electronics. PLA is a more environmentally friendly material with more residences for usage inside the human body (nontoxicity). There are numerous ways to create lactic acid polymers, which results in products with a wide range of chemical and mechanical properties.

Due to their excellent biocompatibility and mechanical properties, PLA and related copolymers are being used more frequently in tissue engineering to restore function to injured tissues. It's a biodegradable polymer with an extensive range of applications that may be changed into unique resin grades for processing into a spread of merchandise. Lactic acid-primarily based polymers (PLA) are one of the maximum promising classes of renewable polymers. PLA has various advantages over petroleum-based polymers which might be usually utilized in packaging: (i) transparency, which is commonly defined as visible light transmission in the 540–560 nm range and is somewhat higher than that of poly (ethylene terephthalate) (pet) and poly (styrene) (playstation); (ii) degradation in biological settings like compost or soil; (iii) biocompatibility: because PLA has been shown to be biocompatible and decompose into non-toxic components, the Food and Drug Administration has approved its use for implantation inside the human body (FDA); (iv) processability: mild processing is the primary way of transforming PLA. Due

to its glass transition temperature (T_g), which is close to 55 °C, PLA is brittle and hard at ambient temperature. PLA is a glassy polymer with a negligible break elongation (commonly less than 10%). In an effort to increase their ductility, a significant number of experiments have been done to modify the properties of PLA-based materials by plasticization and combining with various polymers.

Polymers Produced by Microorganism or Genetically Modified Bacteria such as Polyhydroxyalkonates, Bacterial Cellulose

Polyesters at the moment are widely hired as fibers and films in a variety of applications, and plastic waste control has nowadays emerged as a primary environmental problem. Many microorganisms produce polyhydroxyalkanoate (PHA), an environmentally friendly polymeric substance that can be become movies and fibers from renewable carbon sources. PHA is likewise a terrific material for making resorbable scientific gadgets such sutures, meshes, implants, and tissue engineering scaffolds, consistent with the findings. Under nutrient unbalanced situations such as nitrogen, phosphorous, or oxygen predicament, a huge variety of bacteria can amass those polymers as a carbon and power storage fabric. Greater than three hundred species of Gram-high-quality and Gram-negative microorganism, as well as an extensive spectrum of archaea, use them as a carbon/electricity storage. PHAs may be made from renewable primary materials and are destroyed evidently by microorganisms in the surroundings, permitting carbon dioxide and natural compound recycling and offering a climate exchange buffer. PHAs can be made from renewable basic materials and are destroyed certainly via microorganisms inside the surroundings, permitting carbon dioxide and organic compound recycling and providing a climate trade buffer. Extra-cellular PHA depolymerase launched via microorganisms in various herbal habitats is chargeable for biodegradation of PHA material. In the meanwhile, new research efforts are being made to generate PHAs in transgenic flora. Polyhydroxybutyrate (PHB) and poly (hydroxybutyratecohydroxyvalerate) (PHBV) are the maximum famous polymers of the polyhydroxyalkanoate family. Polyhydroxybutyrate (PHB) is a polyester from the PHA circle of relatives this is saved intra-cellular by means of an extensive range of microorganisms as an organic carbon and chemical power source.

PHB is a biodegradable thermoplastic polyester which is much like many traditional petroleum-primarily based polymers already in use. It also offers some extra blessings, together with being biocompatible and being capable of be created from a renewable raw material in a sustainable method from a monetary and environmental perspective.

Bacterial cellulose (BC) is a fascinating and renewable herbal nanomaterial with suitable functions which include exceptional mechanical features, porosity, water absorbency, moldability, biodegradability, and excessive biological affinity. Intensive research and exploration on BC nanomaterials has generally centered on their biosynthetic procedure if you want to attain low-cost education and application in clinical, meals, advanced acoustic diaphragms, and other fields over the last few many years. Bacterial cellulose has the equal molecular method as plant cellulose; however, it carries three-dimensional porous network architectures which can be specific and complex.

Bacterial cellulose has several advantages over plant cellulose, which include (i) loss of lignin and hemicellulose, making it an exceedingly pure source of cellulose; (ii) polymerization with a high degree of crystallinity (60–70%), ensuing in excessive young's modulus at room and accelerated temperatures; (iii) extremely excessive waterholding potential, as much as 100 times its selfweight; (iv) splendid biodegradability and organic affinity.

Numerous change procedures were investigated to see if extra features may be delivered to BC. In recent years, there was a boom in international hobby in phrases of extensive scientific inquiry and expanded efforts to place BC materials to practical use. The yearly guide activity on BC is growing (also referred to as microbial cellulose or bacterial nanocellulose). In latest years, research has targeted on the investigation and alertness of BC in purposeful materials, and a growing variety of papers have been published in this challenge. Functional BC-based nanomaterials are particularly appealing because they permit the production of substances with better or novel competencies via combining numerous factors and leveraging synergistic effects like as electrical, optical, magnetic, catalytic, and other capabilities.

Biodegradable Natural Polymers

Biodegradability, as well as the ability to support the regeneration of new tissue without causing irritation should be recommended. Polymers as biological entities, are classified into 3 types (i) polysaccharides, (ii) proteins, and (iii) polyesters. Natural polymers can be generated through fermentation of microorganisms or in vitro manufacture by enzymatic techniques, both of which are based on biotechnology advances.

Sugar-Based Biopolymers

Blowing, vacuum forming injection, and extrusion are all methods for making sugar-based biopolymers. Lactic acid polymers (Polyactides) are made from lactose (milk sugar) derived from maize, potatoes, wheat, and sugar beet. Polyactides, which are made through vacuum forming, blowing, and injection molding, are water resistant.

Starch-Based Polymers

Starch-based biopolymers are a natural polymer that can be generated from plants such as wheat, tapioca, potatoes, and maize. This substance is stored as carbohydrates in plant tissues. It is made up of glucose and is made by melting starch. Animal tissues do not contain this polymer. Dextran is a category of low-molecular-weight carbohydrates generated by starch hydrolysis and enzymatically synthesized by immobilized *Enterococcus faecalis* Esawy dextranucrase onto biopolymer carrier.

Cellulose-Based Polymers

Cigarettes, CDs, and sweets are all packed with cellulose-based biopolymers. This polymer is made up of glucose and can be found in natural resources such as cotton, wood, wheat, and maize cellular walls.

Biodegradable Synthetic Polymers

Petroleum is used to make biopolymers based on synthetic chemicals, such as aliphatic aromatic copolyesters, which are biodegradable polymers. Despite the fact that they are made of synthetic materials, they are entirely compostable and biodegradable.

Polyglycolide Acid (PGA)

It's a crystalline polymer with a crystallinity of 45–55%. It also has a high tensile modulus but is poorly soluble in organic solvents (Fatland et al. 2005). Poly (glycolic acid) and poly (lactic acid) are the most extensively utilized synthetic biodegradable polymers at the moment. Because of its superior fiber forming capabilities, polyglycolide was initially studied for use in making resorbable sutures. The citric acid cycle breaks down polyglycolides into glycine or converts them to carbon dioxide and water.

Poly lactide Acid (PLA)

It's a crystalline polymer (37% crystallinity), just like polyglycolide. It has a glass transition temperature of 60–65 degrees Celsius and a melting temperature of 175 °C. In comparison to polyglycolide, poly (L-lactide) degrades slowly. L-lactide (LPLA) homopolymer is a semicrystalline polymer with high tensile strength, minimal elongation, and a high modulus, making it appropriate for orthopedic fixation and sutures with diverse applications such as load-bearing.

Polycaprolactone

A semicrystalline polymer with high polycaprolactone solubility and a low melting point (59–64 °C) can encourage biomaterial development. Due to the short half-life of bioactive compounds, effective transportation of bioactive agents such as drugs, enzymes, and other bioactive agents is required. Starch-poly-epsilon-caprolacton microparticles were then used in a variety of applications, including medication delivery and tissue engineering. In addition, these microparticles were generated using an emulsion solvent extraction/evaporation process.

Polyurethane

The polycondensation reaction of diisocyanates with alcohols and/or amines is used to make polyurethanes. Bio-stable polyurethanes and poly (ether urethanes) are intensively explored for the future view in medical implanting, mostly for cardiovascular disorders such as pacemakers and vascular grafts. Polyurethane is biocompatible and used in a wide range of medical devices due to its flexibility and mechanical strength. Polyurethane can connect to membranes and does not easily elicit immunological reactions, hence it is biocompatible. The Knauth team, who work on prosthetic skin for premature neonates, has also produced a semipermeable membrane.

Poly (ortho esters)

Poly (ortho esters) is a biodegradable polymer that has gained popularity in recent years. Because of its hydrophobic qualities, poly (ortho esters) erode slowly in water

conditions. Poly (ortho esters) are distinguished not only by their surface erosion mechanism but also by their rate of degradation, pH sensitivity, and flexibility in glass transition temperatures, which can be manipulated by altering chain diol levels.

Based on Source of the Raw Materials and Polymer Biodegradation

The definition of a “biopolymer” (or “bio plastic”) is based on two basic criteria: (1) the raw material source and (2) polymer biodegradation.

Biopolymers Made from Renewable Raw Materials (bio-based), and Being Biodegradable

These polymers can be made chemically from biological starting elements or created by biological systems (microorganisms, animals, and plants) (e.g., corn, sugar, starch). Biodegradable bio-based biopolymers include (1) synthetic polymers made from renewable resources, such as poly (lactic acid) (PLA); (2) biopolymers made by microorganisms, such as PHAs; and (3) naturally occurring biopolymers, such as starch or proteins. Natural polymers are defined as those that are biosynthesized through various pathways in the biosphere. Starch and PHAs are the most often utilized bio-based biodegradable polymers.

Biopolymers Made from Renewable Raw Materials (bio-based), and Not Being Biodegradable

These biopolymers are nonbiodegradable and can be made from biomass or renewable resources. (1) Renewable resource synthetic polymers, such as specific polyamides from castor oil (polyamide 11), specific polyesters based on bio propanediol, bio polyethylene (bio-LDPE, bio-HDPE), bio polypropylene (bio-PP), or bio poly (vinyl chloride) (bio-PVC) based on bioethanol (e.g., from sugarcane), etc.; (2) naturally occurring biopolymers, such as natural rubber or amber.

Based on Shape

Biopolymers have been classified by the shape into many types. These type include disks, beads, thin films (membrane), and nanoparticles.

Disk

In the literature, gel discs are frequently employed. Researchers commonly generate a single film of gel using the casting process, such as a Petri plate, and then cut it into discs with cork borers. Previously, a novel equipment called parallel plates are devised that allows them to make several uniform in one step with high accuracy.

Beads

Gel beads are commonly used in industry because they have the largest surface area and may be made using a variety of procedures, including the interphase technique,

ionic gelation methods, dripping method, and the Innotech encapsulator. The Innotech Encapsulator has a high bead production rate (50–3000 beads per second, depending on bead size and encapsulation product mixture viscosity), making it ideal for industrial scale production.

Thin Films (Membranes)

Polymeric membranes are made by dissolving polymer materials in their solvent, then casting, washing, and drying them. Sakurai's study team examines the domain structure and concludes that polymeric materials alter the intracellular concentration of calcium ions, a second messenger in the transmission of biological signals or an enzyme cofactor in the coagulation system. It was also reported in the study that surface grafting of polyoxyethylene chains can significantly improve the membrane from nonthrombogenicity of a PEUU.

Nanoparticles

Nanoparticles are solid particles with a diameter of less than one micron that can be utilized to nanoencapsulate bioactive substances. Depending on the method of preparation, nanoparticles, nanospheres, or nanocapsules can be obtained. Biodegradable polymeric nanoparticles can be made from proteins (such as gelatin and milk proteins), polysaccharides (such as chitosan, sodium alginate, and starch), and synthetic polymers (such as chitosan, sodium alginate, and starch). Various ways for creating nanoparticles from natural materials have recently been used.

Production of Renewable Polymers from Crop Plants

Plants produce a variety of biopolymers which have several functions such as protection of structural integrity, carbon storage, and protection toward pathogens. Several of these natural polymers are used by human beings as food and materials, and more and more as a strength carrier. Plant biopolymers are used as substances in wide applications, such as plastics and elastomers, due to the depletion in resources and climatic changes. Biopolymers have the ability to compete with petrochemical plastics used in consumer goods (e.g., polyethylene and polypropylene) can be a good targets for low-value high-volume biopolymers produced in target proteins are known as fibrous proteins, that are non-ribosomally produced poly-amino acids such as cyanophycin, and plant proteins acquired as co-products of starch, vegetable oil or biofuels (van Beilen and Poirier 2008).

Proteins

In past few years proteins derived from starch or oil crops have been converted to different materials. Through cross-linking with glutaraldehyde, formaldehyde, or other chemicals, plastics can be produced from zein, soy protein, and wheat gluten.

Fibrous proteins include repeated short unit of amino acids and considered as difficult to block co-polymers with special strength to weight, elastic, or adhesive properties. Elastin, wheat glutenin, mussel adhesive proteins, collagen, silk, keratin, and resilin are the examples for fibrous proteins. By changing the linker elements between the repeat sequences, a tremendous combinatorial range was obtained (van Beilen and Poirier 2008).

Non-ribosomally produced polyamino acids: Cyanophycin is a nitrogen storage polymer synthesized with the aid of large range of cyanobacteria. It is synthesized through the enzyme cyanophycin synthetase without the involvement of ribosomes, and deposited as granules. It consists of polyaspartate spine with arginine aspect chains that are connected by using their β -amino group with the α -carboxy group of each aspartate. Although cyanophycin is not a polymer with appropriate properties, it is oftenly used as source of polyaspartate, can change the chemically synthesized fabric and used as a gorgeous adsorbant or antiscalant different poly-amino acids, such as polylysine and polyglutamate, currently they are used in many attainable non-food applications ranging from hydrogels, biochip coatings and drug carriers to cryoprotectants. The genes encoding their synthesis machinery have been cloned and are available for expression in plants (van Beilen and Poirier 2008).

Natural Rubber

Natural rubber is the most important organic material used in non-food applications. it is a polymer composed of isoprene units linked collectively in a 1,4- cis configuration. Natural rubber is formed by using the rubber tree consisting of polyisoprene.

Because of its structure, molecular weight and poorly described components such as proteins, lipids, carbohydrates and minerals natural rubber has unique properties. These residences consist of resilience, elasticity, and abrasion and have a great impact on resistance, efficient heat dispersion and malleability at cold temperatures (van Beilen and Poirier 2008). Synthetic rubbers, such as styrene–butadiene or acrylonitrile–butadiene co-polymers, are commercially produced that are comparable to the herbal rubber. The exceptional residences of natural rubber are irreplaceable for many applications, such as heavy-duty tires for trucks, buses, and airplanes, also latex merchandise for clinical applications. While some distinctive vegetation can produce different varieties of polyisoprenes, but none of them have cloth homes or value similar to Hevea rubber.

Degradation of natural rubber by way of the usage of fungus has been reported. Rubber is used substantially all through the array of materials science functions and in medical fields. Rubber polymers containing polyisoprene (natural rubber and artificial polyisoprene) had been biodegraded by using fungi such as *Penicillium* and the Actinomycete *Nocardia* sp. Recently, a rubber degrading enzyme used to be isolated from the extracellular subculture medium of *Xanthomonas* sp. and crude fractions had been successful of depolymerizing herbal rubber (van Beilen and Poirier 2008) (Fig. 1).

Fig. 1 Schematic pathway for rubber biosynthesis from isopentenyl diphosphate (IPP). A straight side branch of the common isoprenoid route is used to create natural rubber, with the crucial step 3-hydroxy-methyl-glutaryl-CoA coming from acetyl-CoA via the main mevalonic acid pathway. IPP isomerase changes IPP into dimethylallyl diphosphate (DMAPP). Trans-prenyltransferases then combine IPP with DMAPP in a series of steps to create geranyl diphosphate (GPP) and farnesyl diphosphate (FPP). A rubber transferase, also known as cis-prenyltransferase or rubber polymerase, catalyzes the cis-1,4-polymerization using the non-allylic IPP as substrate

Polyhydroxyalkanoates

Numerous bacteria make polyhydroxyalkanoates (PHAs), which are biological polyesters that operate as granule-forming, osmotically inert carbon and energy storage molecules. The majority of naturally occurring PHAs are made up of 3-hydroxy fatty acids with chains ranging from 4 to 16 carbons, which are polymerized by an enzyme PHA synthase employing intermediates called R-3-hydroxyacyl-CoA. PHAs are thought to be particularly well suited for consumer goods including bottles, films, and textiles because of their impermeability to water and air. Due to the amorphous, soft, and sticky nature of PHAs, which are composed of high molecular weight monomers, also known as medium chain length PHA; mclPHA), polymers must find extensive uses.

Plant cytosols include beta-ketothiolase, the first enzyme in the PHB process. The redirection of acetyl-CoA and acetoacetyl-CoA away from the endogenous flavonoid and isoprenoid pathways is one of the harmful impacts of PHB synthesis in the cytosol. Small alterations in these pathways, which are involved in the manufacturing of a variety of plant hormones and sterols, may have significant impacts on plant development (Poirier et al. 1992). The primary enzyme responsible for creating acetyl-CoA in the cytosol is similar to the phenotypes seen in transgenic plants that produce PHB in their cytoplasm. The plastids are an ideal setting for PHB because they have a strong metabolic flux of acetyl-CoA for fatty acid synthesis and can collect a sizable amount of starch.

The optimum polymer for PHA could not be PHB, which only contains C4 monomers. A more flexible material is produced by adding 3-hydroxyvalerate or longer 3-hydroxy fatty acids, which lower crystallinity. Using a threonine deaminase, propionyl-CoA was introduced to create P(HB-co-HV) co-polymers. This enzyme produces 2-ketobutyrate, which the endogenous pyruvate dehydrogenase complex can convert to propionyl-CoA. P(HB-co-HV) accumulation was caused by the three PHB biosynthetic proteins' coexpression in the plastid (van Beilen and Poirier 2008) (Fig. 2).

A bacterial enzyme called chorismate pyruvate lyase may convert chorismate, which is present in the plastid, to pHBA (CPL). By some unidentified process, pHBA moves from the nucleus to the cytoplasm, at this time it is glycosylated by endogenous uridine diphosphate glycosyl transferases (UDP-GT) and then deposited in the vacuoles. The alternate process involves the conversion of 4-coumaryl-CoA to 4-hydroxybenzaldehyde via a 4-hydroxy-cinnamoyl-CoA hydratase/lyase (HCHL) intermediate. A plant enzyme that has not been discovered oxidizes the bulk of the 4-hydroxybenzaldehyde to pHBA (Fig. 3).

Fig. 2 Pathway for the synthesis of PHA Pathway for the synthesis of 4-hydroxybenzoate (pHBA)

Fig. 3 Pathway for the synthesis of 4-hydroxybenzoate (pHBA)

Chemical Synthesis Produced Polymer (PLA)

The most common example of a biopolymer made from a renewable resource is PLA, a plastic made from maize and starch esters. Recent advances in fiber development and composite engineering provide opportunities for novel resources creations. From recent advanced technology in fiber development and in composite engineering that provide opportunity for novel creations from resources.

It is possible to create PLA by fermenting simple sugars from plant such corns, potato, and sugarcane. Production of PLA is mostly accomplished by enzymatic hydrolysis, fermentation, and catalytic depolymerization (Munoz-Bonilla et al. 2019). In addition to other industrial areas including the agriculture and food packaging industries, the biomedical industry also makes extensive use of PLA.

Produced by Microorganisms

Recombinant DNA or rDNA techniques help to create the chains of polymer, which is almost continuous in length, structure, and orientation.

Polyhydroxyalkanoates

Managing plastic waste has become a serious issue for the environment on a worldwide scale, yet polyester is currently employed in many kinds of applications such as fibers and films. An ecologically friendly polymeric substance, polyhydroxyalkanoate (PHA), may be used to create films and fibers produced by many microbes from renewable carbon resources. PHA may be used to make resorbable medical devices such as meshes, implants, sutures, and scaffolds for tissue engineering. Numerous bacteria can collect these polymers as a carbon source when there is an excess of carbon and nutritional imbalances such as nitrogen, phosphorus, or oxygen constraint and energy storage material. More than 300 species of Gram-positive and Gram-negative bacteria as well as a wide range of archaea can be composed of more than 100 types of different monomers which can act as a carbon or energy storing place (Popa et al. 2014).

PHAs can be made from renewable raw materials and degradation enable for the ecosystem's carbon dioxide and organic compound recycling in the ecosystem by microorganisms, which can act as a climate change buffer. An extracellular PHA depolymerase enzyme secreted by microorganisms causes biodegradation of PHA material. New studies are now being conducted to create PHAs using transgenic plants. The most well-known polymers in the family of polyhydroxyalkanoates are polyhydroxybutyrate (PHB) and poly(hydroxybutyrate-co-hydroxyvalerate) (PHBV). PHAs may be isolated and extruded into hard and flexible plastic films with good moisture and oxygen barrier qualities since they naturally accumulate in microbial populations as their source of carbon and energy. PHAs are able to effectively replace the conventional polymers like polyethylene terephthalate (PET). Most studied among PHAs, polyhydroxy butyrate (PHB) homopolymer and copolyester of β -hydroxy valerate (PHB-co-HV) are used (Popa et al. 2014).

Li and Wilkins (2020) suggest that traditional petroleum plastics be replaced by PHA in the production of a variety of items such as drug delivery system, films, and medical devices. Agro-industrial by-products such as sugarcane, rice straw, peel of orange, and cassava wastewater are the most commonly used low-cost fermentation media for the production of PHA polymer. *Bacillus subtilis*, *Cupriavidus necator*, *Haloferax halophila*, *P. aeruginosa*, and *P. putida* are a few bacterial strains that may manufacture various PHAs from a range of feedstocks (Popa et al. 2014).

A wide range of bacteria accumulate polyhydroxybutyrate (PHB), a polyester from the PHA family, as an internal source of organic carbon and chemical energy. By varying the valerate content, the properties of the PHBV co-polymer can be easily changed. PHB (biodegradable thermoplastic polyester) is considered as analogous to many conventional petroleum-derived plastics. PHB is also biocompatible and may be produced using a sustainable method from both an economic and ecological perspective.

Bacterial Cellulose

Bacterial cellulose (BC) is a naturally occurring nanomaterial that can be renewable and has exceptional mechanical, porosity, water absorption, moldability, and

biological affinity. Still there are vast research and exploration on bacterial cellulose because of the availability. Advanced acoustic diaphragms, the food industry, the medical area, and other fields require low-cost preparation and application, nano-materials mainly focused on their biosynthetic process (Weili et al. 2014; Zhang and Luo 2011). Except with unique three-dimensional porous network structures, the molecular structure of bacterial cellulose and plant cellulose is identical. Compared to plant cellulose, cellulose produced from bacteria is known to have unique properties such as its absence of lignin and hemicellulose, and it is a very pure source of cellulose. Additionally, it possesses a high Young's modulus at both ambient and high temperatures, high degrees of polymerization and crystalline nature (60–70%), a very high water-holding capacity of up to 100 times its own mass, great biodegradability, and a strong biological affinity (Philippini et al. 2020). At the industrial phase, the microbial biopolymers are produced mainly by bacteria and fungi. Several factors can influence the production of biopolymer; apart from the microorganism of choice, optimizing physical factors including pH, temperature, aeration, and fermentation time is necessary to achieve high output yields. It can be found in several forms, including (i) inside the cell, where it serves as a storage area for carbohydrates; (ii) on the cell wall, where it provides structural support; and (iii) as an exopolysaccharide, found in capsules, slime, or biofilm.

The manufacture of bacterial biopolymers such dextran, curdlan, gellan, and xanthan is the principal usage of the agro-industrial biomass. The majority of industrial biopolymer synthesis is accomplished by fermentation of glucose or other simple carbohydrates. The makeup of the media, particularly the sources of carbon and nitrogen, as well as the minerals, additions, and vitamins, must be carefully taken into account in order to achieve maximum production (Philippini et al. 2020).

Xanthan

Xanthan gum (a complex copolymer) is the first commercially viable bacterial polysaccharide generated by bacterial fermentation and is utilized in both food and non-food industries. The bacteria *Xanthomonas campestris* created “repeat units” in the xanthan polymer that have five distinct sugar groups. Gelling agents are used in applications such as cheese spreads, ice creams, puddings, and other desserts whereas industrial applications include pharmaceuticals (being evaluated for sustained drug release), paper manufacturing (used as a modifier), mineral ore processing (used as a biocide), agriculture (acts as plant growth stimulator), and so on (Rao et al. 2014).

Pullulan

Pullulan compounds are formed outside of the cell membrane by numerous species of yeast, mostly by *Aureobasidium pullulans*. They are water-soluble linear

polysaccharide made up of monomers, contain three linked glucose sugars. It has no flavor or smell and is nontoxic. Pullulan compounds exhibit a wide variety of elasticity and solubility qualities, have good heat resistance, and are biodegradable in biologically active conditions. As a result, they can be used as food additives in low-calorie meals and beverages to provide texture and volume in place of starch or other fillers. Since it doesn't degrade in presence of ingested digestive enzymes. Pullulan functions as a plasma expander in the medical field without causing any negative effects. It is entirely eliminated after metabolic conversion. Pullulan also is used in medicinal adhesives and medication carriers. It can be used to solid fertilizers as a binding agent (Rao et al. 2014). Additionally, the potash clays, uranium clays, and ferric hydroxide that are precipitated from slurries used in the beneficiation of mineral ores can be precipitated using this biopolymer.

Glucans

Glucans are homopolymers of glucose, a typical simple sugar found in yeast cell walls. *Saccharomyces cerevisiae* is frequently used as a source of this glucan. About 12–14% of total dry cell mass, glucan is the most prevalent polymer in yeast. Hot alkali treatment makes it simple to separate glucan from yeast cells and eliminate all other cellular components, enabling the recovery of the insoluble glucan substance. Due to its immunomodulatory effects, research has been done on the use of glucan in plants as a powerful antiviral and anti-infective agent. Several studies have shown that glucans can slow the development of tumors. Another characteristic that increases test animals' survival after radiation dosages that would otherwise be fatal is radioprotective. A backbone of glucose residues connected by α -(1,3)-glycosidic bonds makes up glucans, while attached side-chain glucose residues are connected by α -(1,6) connections. Half of the fungal cell wall are made up of the glucan which appear to have therapeutic promise for a number of disorders (Rao et al. 2014).

Applications of Biopolymers

Food Applications

The two main food degradation processes that affect food quality, safety, and shelf life are oxidation and microbial spoilage. Due to their antioxidant and antibacterial properties, biopolymers have a significant impact on food preservation. The possibility of using antibacterial and antioxidant biopolymers as food preservatives leads to an increase in the preference for natural antimicrobial and antioxidative molecules over synthetic ones. This benefits the customer by raising knowledge of the harmful effects of artificial preservatives on health.

Biomedical Application

Biopolymers can be progressively breakdown assimilate and or remove by the body. They are particularly amazing for biomedical technologies including tissue engineering, bone regeneration, dental applications, and controlled drug administration due to the fact that they are made of a variety of harmless components and are thought to be innately biocompatible. Medical device applications employ biopolymers to interface with biological systems. They are also being tested as a matrix for tissue engineering and they can coexist with host reactions in a given use (Park et al. 2008).

Polysaccharides can be used to immobilize enzymes needed for diagnostics or chemically modifying pharmaceutical goods, as well as to encapsulate medications for their progressive distribution (Chaabouni et al. 2013). Exopolysaccharides are used in a variety of industrial processes. One such use is the purification of drugs and enzymes for diagnostic purposes using dextran and its derivatives on a laboratory and industrial scale, which has a direct or indirect connection to medicine. All of these uses make advantage of the functional traits like the ability to form gels and can be employed as vaccinations instead of complete microbial cells or cultures. Thus, undesirable consequences like proteins or lipopolysaccharides are avoided. A number of bacterial EPSs are crucial. As opposed to that due to their intrinsic biological activity as well as their capacity to build polymeric matrices, a number of bacterial EPSs play a significant role in the development of novel medicines. Xanthan, sulfated dextran, and sulfated curdlan for example are antiviral and anticancer drugs. FucoPol is a substance with the potential to be used in anticancer, anti-inflammatory, and immune enhancer medications due to its unique properties, including its high fucose concentration, FucoPol is a substance that has the potential to be employed in anticancer, anti-inflammatory, and immune-enhancer medications. It is rare and challenging to get fucose, which has high demand on the global market. It has been observed that fucose-containing formulations and oligosaccharides have qualities that enhance their usage in medicines (such as anti-inflammatory or anti-carcinogenic substances). EPS can be used as a source which constitute value-added applications (Chaabouni et al. 2013).

Antioxidant and Antimicrobial Applications of Biopolymers

Biopolymers play a vital function in food maintenance due to their antioxidant and antimicrobial properties and rising demand for natural antimicrobial and antioxidative compounds over artificial compounds (Irkin and Esmer 2015). Compounds such as imperative oils, polysaccharides (chitin and chitosan), proteins, and peptides (nisin) are extensively studied and used as antimicrobials, as direct components, or an additive delivered into the food packaging materials. They promise antimicrobial work against various types of food borne pathogens and spoilage microbes. **Natural antimicrobial polymers:** Antimicrobial activity may be added to polymeric materials for a variety of purposes. These include chemically

grafting antimicrobials onto materials, coating antimicrobials on to the polymer surfaces, and integrating antimicrobial compounds directly into polymers. Alginate, chitosan, gelatin, and other bioactive polymers can be employed in the packaging of food goods. Natural biopolymers are superior to manufactured polymers in that they are edible, biodegradable, and renewable (Khan et al. 2014; Rhim and Ng 2007; Shemesh et al. 2015). Some applications about antimicrobial polymers are as follows:

1. Polymeric packaging materials – on polymeric packaging materials, especially for low-density polyethylene (LDPE) films, since LDPE is commonly used as an inner layer in packaging combinations.
2. Biopolymers – Biopolymers may be made from renewable resources such cellulose, alginates, starch, zein from maize, whey protein, aliphatic and aromatic copolymers, and zein from milk. They offer defense against vapor, fumes, and moisture. In addition to these benefits, they degrade more quickly in the environment. Numerous antimicrobial substances, including bacteriocins and plant extracts, were combined to form diverse biopolymers.

Essential oils: The growth of dangerous organisms including *Salmonella* spp., *E. coli*, and *Candida* spp. can be inhibited by essential oils. Oils derived from clove, thyme, and oregano are recognized for their antimicrobial activities, and most active extracts have been oregano and thyme (Iturriaga et al. 2012). Also fennel, coriander, ginger, garlic, pepper, and other spices were suggested (Liu et al. 2017). *Cinnamomum zeylanicum* essential oil is used to examine six *Pseudomonas* species, such as *P. agglomerans*, *P. lundensis*, *P. proteolytica*, and the MIC ranged MIC50 of 3.125 and MIC90 12.50 $\mu\text{L/mL}$.

Modes of actions of essential oils as antimicrobials:

- The cytoplasmic membrane damage
- Coagulation of cytoplasm
- Cell wall damage
- Reduction in intracellular ATP pool

The key step in treating wastewater and sludge recycling is sludge dewatering. Better sludge dewaterability enables reuse and disposal at a lower cost, such as the production of polyhydroxyalkanoates or other bioplastics, the production of building bricks, and the use of sludge as a raw material for the growth of industrial microorganisms (Bhavaniramy et al. 2019).

Environmental Applications

During the wastewater treatment process exopolysaccharides play an important role in sludge dewatering. The key step in treating wastewater and sludge recycling is sludge dewatering. Better sludge dewaterability enables reuse and disposal at a lower

cost, such as the production of polyhydroxyalkanoates or other bioplastics, the production of building bricks, and the use of sludge as a raw material for the growth of industrial microorganisms. Sludge is negatively charged and therefore cationic artificial polymers are used to neutralize the sludge charge, which assists to settle down the sludge. All of this procedures can pollute the surroundings and are costly and consequently security precautions should be observed throughout handling. By using biofloculants/biocoagulants produced by bacterial strains derived from activated sludge help to overcome these problems.

The bioactive compounds microbes during their development mostly consist of carbohydrates, proteins, lipids, DNA, and RNA. Microorganisms are also capable of thriving in a variety of conditions. Microbial EPS reacts with the sludge particles to contribute significantly to the biological flocculation process. The microbial EPS might be non-ionic or include both cationic and anionic charges. The concentration and properties of EPS have a significant impact on its capacity to settle sludge. There is often an ideal EPS concentration for sludge settling. Sludge properties, EPS biochemical features, operational factors in a wastewater treatment plant, and kind of dominant microbial community in that treatment plant all have an impact on the concentration of EPS generated by sludge (Tyagi et al. 2002; Yezza et al. 2004).

Packaging

Polymers in packaging are affected by using their chemical structure, molecular weights, and crystallinity, and foods have more strict packaging requirements than solid commodities; however, all these physical characteristics required in packaging depend equally on the items to be packaged and the settings in which the applications will be kept, and products that will be frozen for an extended period of time require special packaging. The focus of recent research has been on developing polymeric matrices with the best homes (such as clarity, barrier and mechanical characteristics, or biocompatibility) for a number of applications, including coatings and packaging for consumable foods. In bulk packaging, bioplastics provide a variety of additional advantages over traditional plastics, including the same process that is utilized for conventional materials may be used to make bulk packages out of biologically produced polymers. These results show that they are just as significant as traditional plastics in terms of physical, thermal, mechanical, and barrier qualities (Yasuhiro and Yoshimitsu 2010). It plays a crucial part in preserving food quality, shielding the packaged product from the elements, and enhancing the qualities of the food during storage. However, often used packaging made of synthetic, non-biodegradable polymers seriously pollutes the environment. Bioplastics (such PHBV and PHB) can break down in compost, soil, streams, lakes, seas, aerobic and anaerobic sewage sludge, and other aspects of nature. Compost made in section from bioplastics improves soil natural content, water and nutrient retention, and suppresses plant diseases while lowering chemical inputs. Furthermore, it has been

demonstrated that starch-based bioplastics disintegrate 10–20 times faster than conventional plastics.

Burning conventional plastics releases toxic vapors that can be harmful to the environment and human health. If any bio-based films are burned, just a little amount of hazardous chemicals or gases are discharged into the atmosphere. In phrases of safety, the degradation research observed that greater than 90% of samples degraded in 10 months, based on weight loss and CO₂ production measurements.

Utility of a different bio-composite in process of making the laundry baggage for medical institution and different institutions, where the bag dissolves at some point of the washing and biodegrades after disposal into sewage. Solubility of water-soluble biocomposites is dependent on the quantity, molecular weight, and crystallinity. In anaerobic sewage sludge, for example, PHBV mineralizes to CO₂, water, and a little amount of methane over the course of 30 days (Chaabouni et al. 2013).

When comparing samples of bioplastic compost made by combining the test material with organic waste to samples of reference compost made simply with organic waste, it was discovered that when tested on plants, it did not emit compounds hazardous to the plants or the environment. Bio-based polymers contain more diversified stereochemistry and side chain architecture than traditional plastics generated from petroleum, giving research scientists additional options for customizing the qualities of the final packaging material. With these added benefits and nearly identical qualities to PVC, Nylon, PP, bioplastics can be used in the huge packaging to replace petroleum-based plastics that pollute the environment due to their non-degradability and toxic gas emissions.

Edible Coating with Silver Nanoparticles: On a variety of meals, including fruit and vegetables, meat, and cheese, the practical application of edible coating with integrated silver nanoparticles has previously been tried. Numerous research have examined the application of coating materials on fresh, little processed fruit and vegetables as a means of reducing spoiling and lengthening the shelf life during post-storage. All of these investigations demonstrate that silver nanoparticles, which were used as active agents and inserted into the polymer matrix, demonstrated wide antibacterial action, primarily against microorganisms that are liable for lowering the microbiological quality of food items. The advantages of adopting active packaging like as films and coatings relate to the slow and progressive release of antibacterial drugs onto the food surface from the polymer matrix, where the bulk of contaminating by spoilage or pathogenic bacteria occurs for most goods. The quantity of preservatives often injected directly into the main body of food might likewise be minimized or significantly reduced thanks to this use.

Food packaging systems with natural antimicrobial agents: Directly inserting incorporation of antimicrobial chemicals into packaging films, their coating on packaging films, and the use of polymers in packaging materials can all result in an antimicrobial packaging system. Antimicrobial packaging increases the shelf life, security, and quality of many foods due to its exceptional ability to prevent growth of microorganisms in non-sterile foods and reduce the danger of post-contamination of sterilized goods.

Classification	Antimicrobial agents and biopolymers
Polysaccharides and derivatives	Starch, chitosan, pullulan, natural gums
Proteins, enzymes, bacteriocins	Corn-zein, wheat-gluten, peanut, milk, collagen/gelatin Nisin, soy-protein isolate, whey-protein isolates
Chelating agents	EDTA

*Essential Oils significant antibacterial activity have been observed for extracts of cinnamon, oregano, and thyme against a variety of pathogens, including *Listeria monocytogenes*, *E. coli*, *B. thermosphacta*, and *P. fluorescens*. EOs considerably travel through the lipids of bacterial cell membranes, disturb the architecture of the cell walls, and make them less permeable because of their hydrophobic nature. For instance, trans-cinnamaldehyde, one of main EO components, has the ability to inhibit the development of *S. typhimurium* and *E. coli* by lowering intracellular ATP levels. The periplasm and deeper parts of the cell are also accessible.

Agricultural and Agro-Industrial Applications

Nowadays, controlled release of insecticides and nutrients, soil fertilization, seed coatings, and crop protection all include the usage of polymers like plastics, coatings, elastomers, fibers, and water-soluble polymers. Biodegradability plant pots, erosion control netting, are just a number of the agricultural uses for bioplastics. Bioplastics are also being investigated as crop mulching materials in fields and as agricultural plant containers. Composting has a one of a kind property that can significantly improve the state of the soil. Along with degradable plant pots, stakes, erosion control netting, and mulch film, they also serve a variety of other purposes. Except in political geographies where nondegradable plastic items are prohibited, receiving a top class for low-value merchandise such as disposable ware or horticulture functions will be pretty exceptional (McCormick and Lichatowich 1979).

Because of their non-Newtonian behavior and high viscosity in aquatic conditions, EPSs produced by bacteria are frequently used in high-value applications. These applications include thickening, stabilizing, binding, and structure building. They should be able to retain their abilities when incorporated into components with significant pH and ionic strength fluctuations, as well as under the influence of additional food ingredients, when utilized in food products. One of the materials found in agricultural wastes most frequently is biopolymers. Recovery of biopolymers found in trash is typically viewed as a backup option for agro-industrial activities. A lot of the time, agricultural and in order to produce energy, fermented chemicals, composts, and/or biofuels, industrial wastes are burnt. Although each hexose monosaccharide, which is only composed of C, O, and H in a biopolymer main chain, has a primary bond energy of C, O, and H, the energy losses of converting a biopolymer into fuels are quite substantial. Caseins, collagen and gelatin, chitin and chitosan, as well as alginates, bacterial cellulose, poly-hydroxyalkanoates, β -glucans, and xanthan can be obtained from animal feces.

Conclusion

A brand-new class of materials that is still in development, biopolymers are used to make things like food, clothes, medical supplies, packaging, food additives, engineering plastics, water treatment, and other necessities of everyday life. Biodegradable biopolymers can be made from natural-origin monomers as well as those that are derived from animals, plants, microorganisms, and chemicals. Even while biopolymers are found throughout nature, only a few numbers of plants and animals are heavily utilized for their commercial manufacture.

Non-biodegradable plastics are being used more and more in both terrestrial and aquatic ecosystems, which has a negative impact on the environment. Because of their biodegradability and environmentally friendly production processes, biopolymers are valuable replacements for non-sustainable goods. They also have a broad range of uses, including in the food industry, agriculture and agro-industry, packaging, biomedicine, and other fields. The creation of biodegradable polymers to replace their equivalents made of fossil fuels that are not biodegradable has been the focus of recent investigations for the creation of bulk biopolymers. These replacements for polyolefins include polyhydroxyalkanoates and polylactic acid. To fulfill the demands of customers for more ecologically friendly packaging for more natural products, bio-based films, or biopolymers, it's critical to improve the quality of numerous items. This strategy will continue to be crucial in the food business. Additionally, biomass may be used in a two-step procedure to create biobased polymers, where chemical modification of natural polymers can be used to create sustainable polymers from renewable resources.

Due to the accessibility of genetic engineering techniques and metabolic pathway engineering methods, which open up a constantly expanding design space for the creation of biopolymers with desirable material characteristics, bacteria continue to be suitable polymer production organisms. Additionally, if the relevant biopolymer is a key component of virulence, additional understanding of the molecular processes behind biopolymer production might be exploited to create customized biosynthetic enzyme inhibitors. There is, however, relatively little utilization of bacteria to make biopolymers, namely polysaccharides. In the entire hydrocolloid market, polysaccharides derived from plant, algal, and animal sources continue to dominate. This is mostly due to increasing pricing for bacterial polysaccharides, which are a result of the high cost of frequently utilized carbon sources and related downstream expenses.

Abstract

Bacterial nanocellulose (BNC) is a natural material of immense industrial applications and has relevance in multipurpose areas. BNC has ascended as a natural polymer of substantial status in various technoindustrial applications owing to its implausible biological and physicochemical features. It has potential in the bio-medical, food, paper, textile, and cosmetics industries. The feasible utilization of BNC in multidimensional areas is widely reliant on its production. However, the production cost, paucity of scale-up techniques, and the high prices of BNC-based products are the crucial facets that are the roadblocks to the commercialization of BNC. Therefore, the additional impetus is mandatory for making this green material a competing product while simultaneously being cost-effective. Despite the extensive research work in the field of BNC production, the aim of cost-effective large-scale BNC production is still far from reality. Thus, constant efforts are obligatory for viably obtaining BNC by cutting down the synthesis price, yield enhancement strategies, and overall functionalization to improve the physical, mechanical, and biological characteristics. In this chapter, we attempted to summarize recent reports on the BNC production technologies and the advancement in BNC synthesis strategies, such as static intermittent fed-batch technology, cell-free extract technology, and bioreactor-assisted BNC production. It also reflects various approaches toward significant BNC synthesis by addressing the challenges in high-quality BNC production. The scale-up strategies, like the use of novel substrates and strain improvement, have been conferred in detail.

Introduction

Bacterial nanocellulose (BNC) has ascended as a biomaterial that has grasped the attention of researchers at both the industrial and academic levels in the last decade. It has emerged as a biopolymer of imperative grade owing to its incredible biological and physicochemical features like high tensile strength, crystallinity, biocompatibility, thermal stability, and hydrophilicity. BNC materials have received the status of generally recognized as safe (GRAS) and thus suitable for wide-ranging purposes. BNC has gained the designation of “biocellulose” credited to its dynamic properties and potential. The exclusive properties of BNC made it suitable for various techno-industrial applications. Its most prodigious application exists in the biomedical area. It also has conspicuous potential in the biomedical field, pharmaceutical industry, food industry electroconductive composites, wastewater treatment, packaging industry, pulp, and paper industry, textiles, and even the construction field (Jozala et al. 2016). Despite the mounting status of BNC in versatile technoindustrial

applications, the production process still encounters several challenges which include long propagation time, low yield with limited cellulose layer thickness, and high cost of production. All these factors generate considerable barriers to large-scale BNC production and subsequently its utilization for varied applications (Sharma and Bhardwaj 2019a).

The increasing appliance of BNC and BNC-derived products in several branches of industry gave rise to intensive studies on the improvement of its synthesis efficacy while endeavoring toward lowering the costs of synthesis of BNC. The studies directed to comprehend the fruitful large-scale synthesis of BNC need much investigation.

The leading necessity of time is to focus on new research avenues for prolific industrial-scale BNC synthesis. In the twenty-first century, the main research focus is on the optimization of BNC production parameters using conventional media along with static and agitated strategies (Dubey et al. 2018). The substantial production methods, different aspects, and parameters for high-quality BNC synthesis are still the main focus of the research besides its applications (Campano et al. 2016). A lot of efforts have been taken by different research groups to augment BNC yield by altering the media composition, production protocols, and parameters or strain improvement at the genetic level. The medium accounts for around one-fourth of the overall production cost. Recent research has focused on the use of alternative media with inexpensive nitrogen and carbon sources such as effluents from the paper industry, agro-industrial wastes, textile waste, etc. Diverse substrates like industrial wastewater often have large amounts of sugars such as fermented black tea broth (Sharma and Bhardwaj 2019a), candied jujube-processing industry wastewater (Li et al. 2015), hot water extract of wood (Kiziltas et al. 2015), and agro-industrial wastes like molasses (Tyagi and Suresh 2016), therefore pineapple waste and coconut water (Vazquez et al. 2013; Jagannath et al. 2008) instead of conventional sugar sources are gaining importance. An alternative approach for upsurging BNC synthesis is by adjusting the synthesis parameters, which involved investigating a diversity of bioreactors to search for the appropriate synthesis environments for the particular bacterial strain, both in a static or agitated mode. An assortment of methods, ranging from batch to fed-batch bioreactors-assisted techniques, as well as several specific devices, are available for the synthesis of BNC (Watanabe et al. 1998; Bae et al. 2004). Numerous comparative research works had been done to investigate a better method of BNC synthesis by utilizing static and agitated production modes (Czaja and Romanovicz 2004; Zywicka et al. 2015). The physico-chemical, mechanical characteristics and supramolecular structure of BNC are strictly driven by its cultivation strategy, therefore the BNC production method depends on its usage. Another option to attain considerable yield is the selection of a high-efficiency bacterial strain. Meanwhile, new BNC-producing strains are been emanated (Castro et al. 2012).

Therefore, the cost-effective BNC synthesis with new substrates along with upgrading the synthesis by amended bioprocess strategies is mandatory to achieve entirely commercialized BNC for various applications in the industry, particularly for bio-based purposes. Currently, altered strategies including cell-free system, static intermittent fed-batch technique, and advanced reactor-assisted bioprocesses like

advanced rotary disc bioreactor systems, etc. have extensively attained significance as these technologies can enhance BNC synthesis.

The realization of abundant industrial-scale BNC synthesis is a prerequisite for exploring its comprehensive potential in different technological applications. Thus, this chapter provides information about the existing status of BNC, describing synthesis technologies and various types of substrates applied until now. It emphasizes the approaches for intensifying BNC yield and methods to scale up the BNC productivity toward commercialization by overcoming the roadblocks. Therefore, this chapter will certainly unravel the diverse hitches allied with prolific large-scale BNC production. The current scenario in BNC production and typically used static intermittent fed-batch technology, cell-free extract technology, bioreactor-assisted technology, and future perspectives of the BNC production strategies are presented and reviewed.

Importance of Bacterial Nanocellulose over Other Nanocellulose Types

The three classes of nanocellulose are: (1) cellulose nanocrystals (CNC)/cellulose nano-whiskers; (2) cellulose nanofibrils (CNF); and (3) bacterial nanocellulose (BNC), i.e., often called microbial cellulose (Gama et al. 2016). CNC and CNF are mainly extracted from various sources such as woody material, cotton fibers, flax and hemp fibers, potato tuber, wheat straw, sugarcane bagasse, algae, etc. (Gama et al. 2016).

If plants are abundant sources of cellulose, what is the need for bacterial cellulose? This question is quite germane when we talk about the importance of bacterial nanocellulose. The answer exists in the fact that most of the plant-based cellulose comes from the harvesting of a wide range of natural forests. Harvesting of tropical equatorial forests is the major cause of the destruction of the ecosystem and its associated species, land erosion, and pollution. Contrary to CNC and CNF, BNC is naturally synthesized mainly by the bacteria *Acetobacter xylinum* in pure cellulosic form and does not involve various processing steps to eliminate unsolicited impurities or contaminants like lignin, hemicellulose, and pectin (Fig. 1). However, extraction of CNC and CNF is generally accompanied by de-structuring strategies using chemical treatments such as acid-based hydrolysis, kraft pulping, bleaching, etc., which make their extraction process prolonged and laborious. Such chemical extraction makes CNC and CNF a lot unsuitable for biomedical use and also presents an environmental concern.

Thus, there is a logical requirement to quest for alternative sources of cellulose. Bacterial nanocellulose has some discrete features unlike the cellulose obtained from other sources. Firstly, BNC is generated as a never-dried film; secondly, unlike plant-based cellulose, the absence of lignin and hemicellulose components in BNC avoids the use of hazardous chemical treatment required during its synthesis; and thirdly, BNC has great mechanical strength and tailorable physical, chemical, and biological properties.

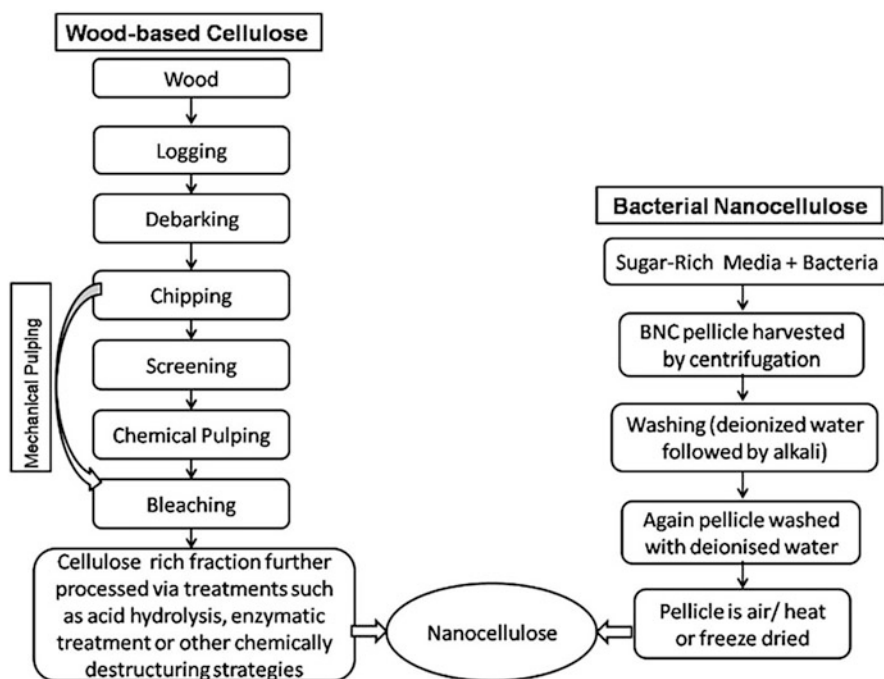

Fig. 1 Comparison of wood-based nanocellulose and bacterial nanocellulose synthesis process

Furthermore, the versatile application of BNC (Fig. 2) itself dictates the splendid worth of BNC. Applications of BNC in the biomedical field include scaffold fabrication; fabrication technologies for innovative structures and medical devices; tissue engineering functional tissues; regenerative medicine for in vivo replacement of functional tissues and organs; nanoparticulate systems for delivery of therapeutic agents and vaccines; and biocompatibility and toxicology studies. Other applications are the production of edible, eco-friendly packaging films and coating for the food industry; production of superior quality paper; development of nanocellulose-implanted air and water purifying systems; development of green cosmetics; fabrication of eco-friendly, surface-modified smart fabrics from microbial cellulose; nanocellulose-based sustainable dyeing strategy, etc.

Bacterial Nanocellulose (BNC): Biosynthesis Pathway and Its Properties

A. J. Brown in 1886 revealed the development of viscous gel-like growth casing the upper surface during the fermentation of vinegar (Brown 1886). The responsible organism for this gelatinous mass was identified as *Gluconacetobacter xylinus* (*G. xylinus*) and the resultant mass was identified as bacterial nanocellulose. In

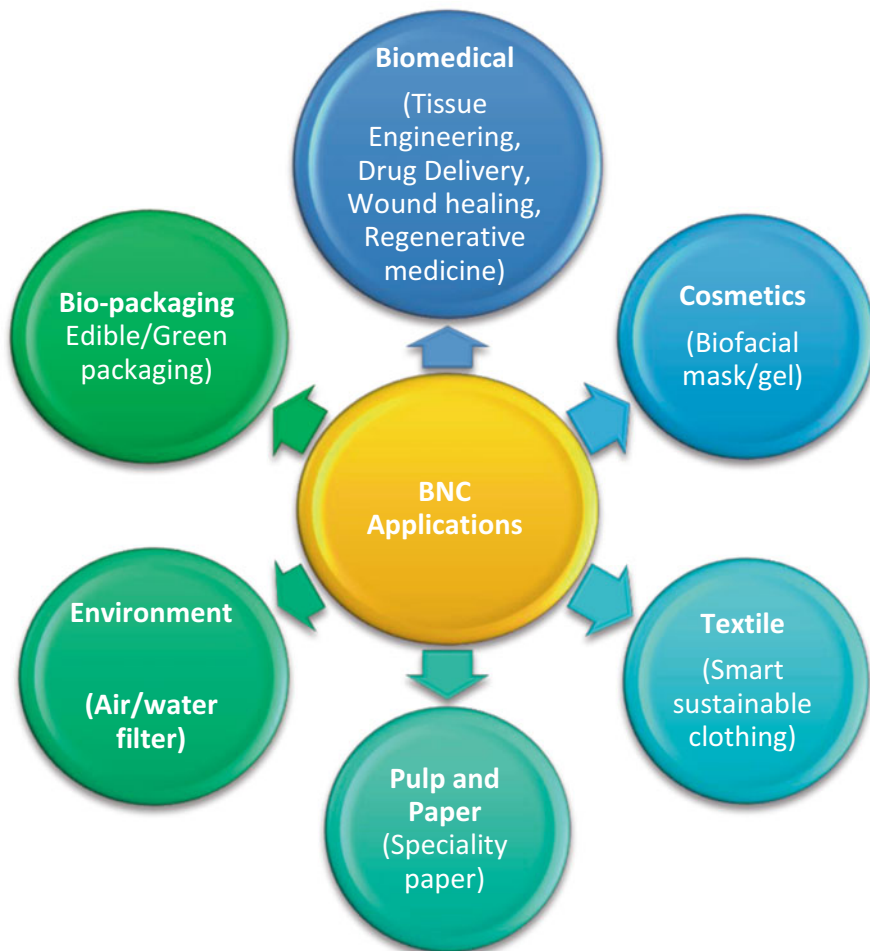

Fig. 2 Multidimensional uses of bacterial nanocellulose

1954, Hestrin and Schramm started evaluating the elementary metabolic processes of *G. xylinus* and developed a typical medium for its culturing to obtain an optimized BNC production at a laboratory scale. They have used carbon source as D-glucose and yeast extract as nitrogen and vitamin sources. These two discoveries are the leading fundamentals for designing all the available BNC production methods. Bacterial genera that are identified as nanocellulose synthesizers include *Acetobacter*, *Bacillus*, *Achromobacter*, *Sarcina*, *Agrobacterium*, *Escherichia*, *Rhizobium*, *Azotobacter*, *Enterobacter*, *Aerobacter*, *Klebsiella*, and *Salmonella*. BNC is produced by all these bacterial strains as a guarding structure against harsh chemical

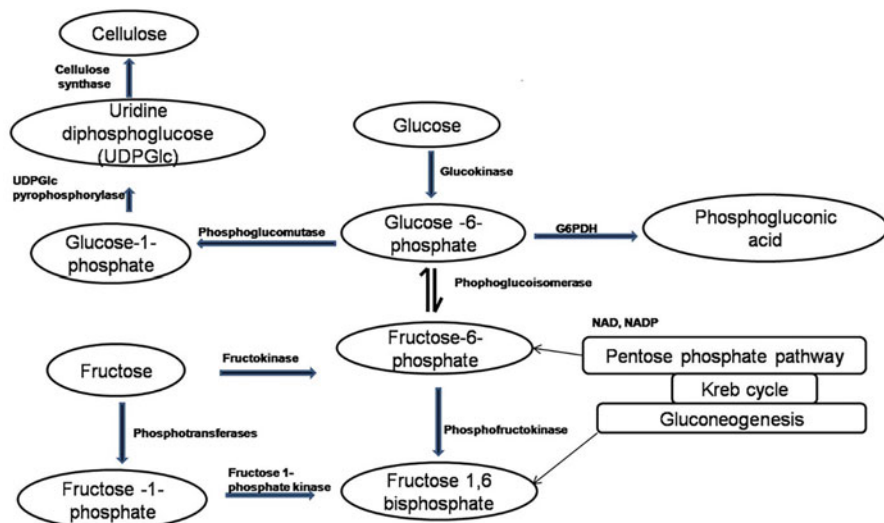

Fig. 3 Biochemical route of BNC synthesis by *A. xylinum*. *NAD* nicotinamide adenine dinucleotide, *NADP* nicotinamide adenine dinucleotide phosphate, *G6PDH* glucose 6-phosphate dehydrogenase

milieus and ultraviolet radiation. Nevertheless, *Gluconacetobacter xylinus*, a gram-negative bacterium, is the utmost predominant BNC synthesizer. It was earlier recognized as *Acetobacter xylinum* (Mikkelsen et al. 2009). Bacterial cellulose synthesis occurs through a bottom-up approach that generally involves four stages: (a) monosaccharides stimulation via the development of sugar nucleotides; (2) assemblage of repeating units of sugars by polymerization; (3) within-time accumulation of acyl units (if existing); and (4) exudation of BNC from the cytoplasm of the cell to the exterior via plasma membrane (Fig. 3) (Siro and Plackett 2010; Benziman et al. 1980). X-ray diffraction studies reveal the similarity between the chemical structure of cellulose derived from *Gluconacetobacter xylinus* and plants. Its molecular formula is $(C_6H_{10}O_5)_n$ with repetitive subunits of $\beta(1,4)$ D-glucose. At the plasma membrane level, the enzyme cellulose synthase is responsible for synthesizing BNC. Roughly 200,000 glucose molecules can be polymerized each second by *G. xylinus* into β -1,4-glucan chains, thus discharging a thread-like packet of warped microfibrils into the nearby milieu (Ring 1982). These ribbons relate to the cellular division progression and persist elongated sideways with the cell envelope (Ring 1982). In a static culture of *A. xylinum*, these ribbon-like fibrils gather to produce a mat-like surface at the interface of air medium which is called a pellicle. The bacterium grows by consuming a range of substrates and excretes nanocellulose. Hence *A. xylinum* is used as a classic bacterium for BNC synthesis because this can produce nanocellulose as an extracellular deposit and is free of impurities. Moreover, the nanocellulose formed is metabolically inert in comparison to plant-based cellulose (Reiniati et al. 2017).

BNC is a biomaterial of outstanding worth in vital research as well as industrial applications. This is because of its intrinsic nanostructure and multidimensional properties like appropriate mechanical strength, hydrophilicity, etc. (Table 1). Figure 4 shows the nanostructure morphology of BNC fiber via field emission

Table 1 BNC properties: conferring about its substantial applications. (Adapted from Sharma and Bhardwaj 2019a)

S no:	Properties	Applications
1.	Resistance to fiber lift and absorbance	Paper-like wound dressings
2.	Strength in the wet state: the capability to resist acute temperature	Adhesive labeling on clinical specimens like blood
3.	Inert nature	Packaging of surgical instruments and medicines
4.	Endure tremendously high temperature	Easy disinfection by gamma radiations or steam required for packaging of sterile equipment
5.	Biocompatibility: no cytotoxicity	Fabrication of nanocellulose-incorporated implants, wound dressings, cellulose-based diapers, and facial masks
6.	Biodegradability	Scaffold fabrication
7.	Mechanical strength	Load-bearing polymer for various applications, such as dental and bone tissue engineering implants
8.	Application-based tailorable nature	Enrichment in obstruction property, tensile strength, oil permeability, air permeability, and antimicrobial properties can be attained by BNC functionalization for varied usage

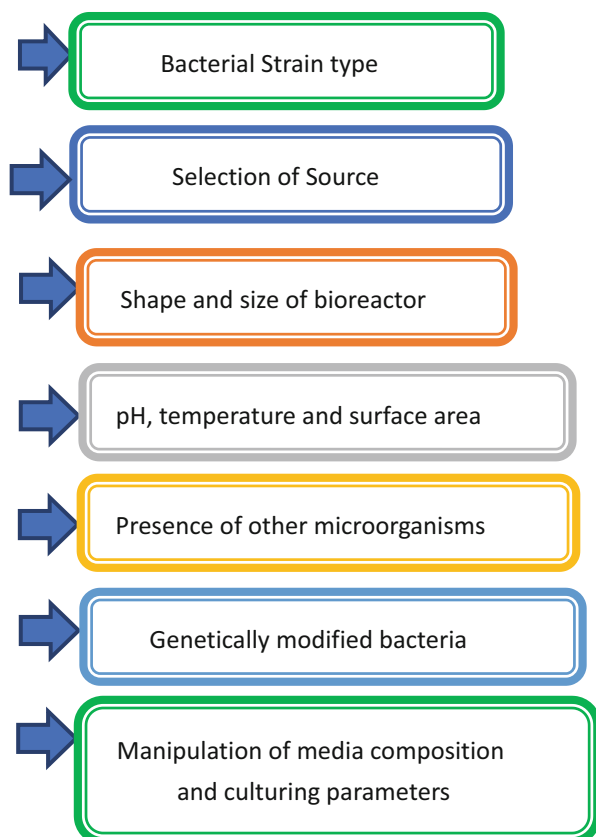

Fig. 4 Morphology of BNC by FE-SEM. (Adapted from Sharma et al. 2021b)

scanning electron microscopy (FESEM). Depending upon the synthesis mode and cultural parameters, BNC morphology can differ.

Factors Influencing BNC Production

Independent of the synthesis technique or the strain used, the process of BNC production could likewise be depicted by a great number of additional factors, together with the constituents of the media, its pH value, oxygen tension, and temperature (Chao et al. 2000; Jonas and Farah 1998; Krystynowicz et al. 2002). Several additives, such as organic or inorganic substances, water-soluble polymers (Yoshinaga et al. 1997), and nanoparticles of metal oxide and metal (Serafica et al. 2002) also affect BNC productivity. Figure 5 depicts some of the factors affecting BNC synthesis. In all cases, the optimization of the synthesis conditions shows an explicit part during the scale-up from investigational (grams/day) to trial (kilograms/

Fig. 5 Factors affecting bacterial cellulose formation

day) or manufacturing scale (tons/day). Furthermore, other parameters and tactics that must be considered and adapted include decontamination of the apparatus, sturdiness, and firmness against corrosion of the reactor vessel components, uniformly dispersed supply of medium and air, defense against impurities, and biological conditions. Though an assortment of methods for BNC synthesis in numerous styles has been anticipated in the last 20 years, in the manufacturing process, BNC is virtually solely synthesized statically in shallow containers utilizing negligibly automated methods. Consequently, the comprehensive commercialization of BNC has been struck by the dearth of competent systems and voluminous synthesizing price of high-quality BNC (Gama et al. 2016).

BNC Production Technologies: Current Status

BNC generation can occur through several techniques ranging from the conventional static synthesis like batch and fed-batch to constant synthesis techniques such as bioreactors and some specialized devices-based synthesis. The choice of production technology is highly influenced by the end use of BNC. Furthermore, the mechanical, physical properties and supramolecular structure of BNC are quite dependent on the method of BNC production (Gama et al. 2016).

To outstretched the array of commercial BNC applications, access to numerous forms of BNC with tailorable supramolecular structure and various material properties became a requisite. Thus, for the potential scaling-up of future commercial production processes, diverse forms of synthesis mode (Table 2) moderately mingled with in situ variations by supports or additives have been documented. By varying the method of synthesis and culture conditions, BNC can be obtained in numerous types and sizes, e.g., flat BNC foils or fleeces, spheres, thin pellicles, fibrous aggregates, tubes, or as BNC pulp. Until now, flat BNC materials have attained industrial importance owing to their self-effacing, nontechnical static cultivation in diverse vessels. Static cultivation has remained an industrially feasible method owing to the colossal utilization of BNC fleeces and foils in the biomedical industry (e.g., tissue engineering and regenerative medicine, wound dressing, drug delivery patches, etc.) (Czaja and Romanowicz 2004) and technical appliance as membranes or material for filtering (Sokolnicki et al. 2006). BNC is typically synthesized as flat sheets/films by conventional static synthesis on diverse permeable sheaths (Putra et al. 2008) or solid phases like silicone rubber (Onodera et al. 2002), agar (Brown et al. 1992), etc. The subsequent foils/fleeces classically possess a three-dimensional (3D) network of uniformly surfaced homogeneous nanofibers. The characteristics of the resultant BNC can be tailored by numerous altering parameters. In 1989, Williams and Cannon investigated the variation in thickness of flat BNC by synthesizing it using diverse *Gluconacetobacter* strains. The thickness of the BNC film can also be controlled by changing the culture medium volume, time of cultivation, and type of container used (Borzani and De Souza 1995; Levy et al. 2004). Besides BNC production under static conditions, synthesis under stirring and shaking (Watanabe

and Yamanaka 1995) and some altered measures (Table 2) employing these methods (Chao et al. 2001; Wu et al. 2001) are vital for exemplary BNC production.

Static Method

Since the advent of exhaustive research on BNC in the mid-1990s, static synthesis has attained the status of a classic BNC synthesis method. This type of synthesis is still observed as the ideal manufacturing technique to produce BNC in flat form with outstanding and reproducible structures and properties for market applications. The dessert “nata de coco,” is soundly recognized as a primary existing BNC-based edible foodstuff in the food industry of Asia. It is generally statically produced in the form of sheets. In one of the studies, BNC synthesis was enhanced by occasionally providing culture media from underneath the synthesized BNC pellicles (Toda et al. 1994).

Benefits and Limitations of Static Synthesis Method

As BNC was formed at the air-liquid interface, therefore, static synthesis requires a large production zone for producing a reasonable amount of BNC. Alike the agitated method in deep tank fermenters, the static method is not at all automated and hence needs additional labor-intensive work and higher worker expenses. Besides this drawback, in the static mode, the change in the nutrients amounts during fermentation restrained the required synthesis time and increase the demand for regular costly holding periods.

Agitated Method

BNC production of various types such as irregular masses, fibrous suspension, pellets, or spheres can be attained by agitation (Krystynowicz et al. 2002). The synthesis of defined sizes BNC with tailorable surface characteristics can be obtained by using certain cultivation parameters. Studies showed large-scale industrial production of BNC by agitation method (Czaja and Romanovicz 2004). Many studies present a view that static cultivation affords only a constrained amount of BNC yields escorted by synchronized use of large surfaces and space demands. Unlike in static synthesis, the production limit of BNC can be surpassed by utilizing agitated synthesis in fermenters leading to feasible BNC production. This is because shear stress during agitation could lead to disruption of bacterial cells, resulting in low productivity. This often causes spontaneous mutation of bacteria from active cellulose producers to non-cellulose-producing strains. The agitated methods hold their peculiar inimitable potential for future industrial usage. The consequential BNC spheres, filaments, or pulps are suitable for wide end use, for example, as an additive for papermaking and fiber reinforcement of synthetic or biopolymers, etc.

Benefits and Limits of Agitated Cultivation Forms

When the agitation technique is used in stirred aerated fermenters or submerged cultures in a shaken flask, the synthesis duration can be ten times decreased in contrast to static fermentation (Gama et al. 2016). Nevertheless, the concept of augmenting the BNC productivity by increasing the air drift rates was a failure as it led to a reduction in the BNC productivity. Limited *Gluconacetobacter* strains, such as ATCC 53582, are suitable for agitated cultivation. This is because shear stress during agitation could lead to disruption of bacterial cells, resulting in low productivity (Hestrin and Schramm 1954; Krystynowicz et al. 2002). This often causes spontaneous mutation of bacteria from active cellulose producers to non-cellulose-producing strains. A study by Park et al. (2003) reported the alteration from cellulose-synthesizing to cellulose-nonsynthesizing *Gluconacetobacter hansenii* PJK strain due to shear forces and subsequent cessation of BNC production.

Recent Advancements in BNC Production Technologies

Presently, the research direction focuses on enhancing BNC productivity, either by altering the medium composition, production methodology, and conditions, or strain improvement of BNC producers. Over 30% of the BNC production cost depends on the type of medium used. Thus, one of the directions of research is to focus on experiments with inexpensive nitrogen and carbon sources like food leftovers, wastes from the agriculture and textile industry, paper industry effluents, etc.

Optimization of the production parameters by investigating various types of bioreactor-assisted approaches along with different strains and culture medium is another research strategy to get access to the appropriate synthesis conditions for particular bacteria under static or agitated mode. The selection of a high-yielding

strain for BNC production is a crucial step in the mass production of BNC. Some of the BNC synthesis techniques that differ from the conventional static and agitated methods are briefed below.

Semicontinuous Generation of Flat BNC

One of the effectual methods is the semicontinuous synthesis of BNC devised by Kralisch et al. (2010). In this method, BNC was synthesized as foils and fleeces in plan form. He utilized a horizontal lift reactor (HoLiR) idea for generating unremitting sheets of BNC with tailorable thickness and desired dimension. The planar BNC material so formed has a 3D network morphology. This valuable union of constant dispensation and virtually static cultivation resulted in the uniform synthesis of the anticipated size BNC. It was raised and carried out of the reactor constantly utilizing a separator device placed at the reverse end of the reactor. The extraction step was performed without disturbing the medium surface to defend the BNC sheet under synthesis.

An evenly surfaced plane BNC sheet having a thickness of 0.5–1.5 mm/day was obtained after the prepolymer surface was entirely sealed. The nutrient-deprived culture medium was directed out and the initial fed-batch synthesis is swapped to slowly progressing synthesis and constant harvesting between 7 and 10 days. A novel BNC was formed at the unoccupied surface of the synthesis medium. During its growth, the BNC fleece was continually transported through the bioreactor. The fleeces sizes can be adjusted by altering the speed of transport. The BNC was harvested through numerous belt conveyors. Once the BNC production has been started, the bioprocess could be kept continuous over some months, uninterrupted, and with no manual interference. Here, the steady-state condition was attained by continuous feeding of culture medium and air into the system. JeNaCell[®] is the BNC produced under HoLiR as a homogeneous, uninterrupted network assembly. It was reported to have 82–86% crystallinity when *G. xylinus* ATCC 11142 and *G. xylinus* DSM 14666 strains were used, respectively. This novel approach has significantly reduced not only the price of BNC synthesis, but also the time for starting, stoppage, and cleansing of the reactor in comparison to conventional static cultivation.

Static Intermittent Fed-Batch Technology

The cessation of bacterial growth and BNC production occurs in static production when the pellicle achieves a certain thickness. This occurs due to a cut down in the oxygen supply to the underside portion of the pellicle (which is in contact with the media) as the pellicle grows. This hampers the nutrient supply to the top portion, i.e., in the pellicle zone exposed to air (Dubey et al. 2018). This problem could be surmounted by supplying the media each time directly over the newly synthesized pellicle intermittently as shown in Fig. 6.

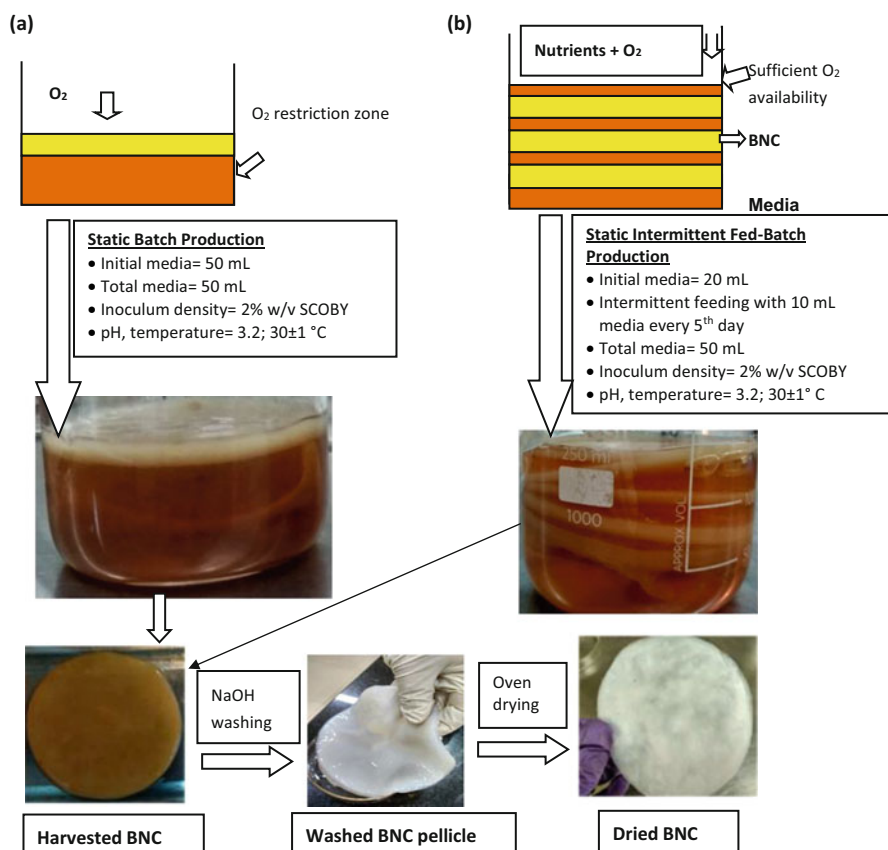

Fig. 6 Schematic showing BNC production using (a) conservative static method where media supplied only once resulted in oxygen reduction as BNC pellicle developed, thus blocking further BNC synthesis; (b) static intermittent fed-batch process with the addition of fresh media periodically, straightly over synthesized pellicle certified adequate oxygen and nutrients accessibility thus enhancing the BNC synthesis. (Modified and adapted from Sharma et al. 2021a)

Dubey et al. (2018) made use of static intermittent fed-batch technology for upgrading the BNC synthesis using a strain designated as *Komagataeibacter europaeus* SGP37. Here they made use of waste sweet lime pulp as a low-priced substrate. In conventional static synthesis, when the pellicle grows to a definite thickness, the nutrient and oxygen supply get reduced and slowly cut off leading to lesser BNC production. To defeat this constraint, fresh media was poured straightly over the formerly synthesized BNC pellicle periodically to uphold the high demand for oxygen and nutrient. Upon employing a static intermittent fed-batch process, the yield of BNC upsurged to 38 g/L from the initial yield of 26.2 g/L BNC as obtained through fed-batch cultivation (Dubey et al. 2018).

One of our recent studies (Sharma et al. 2021a) offers an industrially noteworthy strategy for the development of low-cost and eco-friendly BNC films using static intermittent fed-batch technology along with low-cost medium, i.e., fermented black tea broth. The outcome showed a creditable BNC formation of 29.2 g/L and 63.2% of substrate got converted to BNC which was nearly twofold higher than attained using the conventional static process (32%).

Cell-Free Extract Technology

Currently, a cell-free extract method (Fig. 7) has been discovered for the identification of the numerous intricate metabolic pathways leading to boosted production of BNC (Ullah et al. 2015). A cell-free system utilizes a series of enzyme-based biochemical processes to attain the transformation of the substrate to BNC. Here, the enzymatic, thermal, or mechanical treatments are performed to obtain a cell-free extract (Ullah et al. 2015). However, rupturing the *A. xylinum* culture mechanically by applying bead beating is one of the efficient, low-cost, and convenient methods for procurement of the cell-free extract.

Cell-free extract technology deviates from the conventional BNC synthesis techniques in the end phase (Islam et al. 2017). Here, the release of the chains of β -1,4 glucan to an exterior milieu skips the requirement of a distinct carrier scheme. The cell-free extract itself forms an exposed system where BNC can be collected directly onto the surface of media due to the disruption of the cell wall or membrane barrier. Thus, this process eradicates the requirement of enzyme-based bacterial transport machinery for the extraction of cellulose chain to the surrounding (unlike

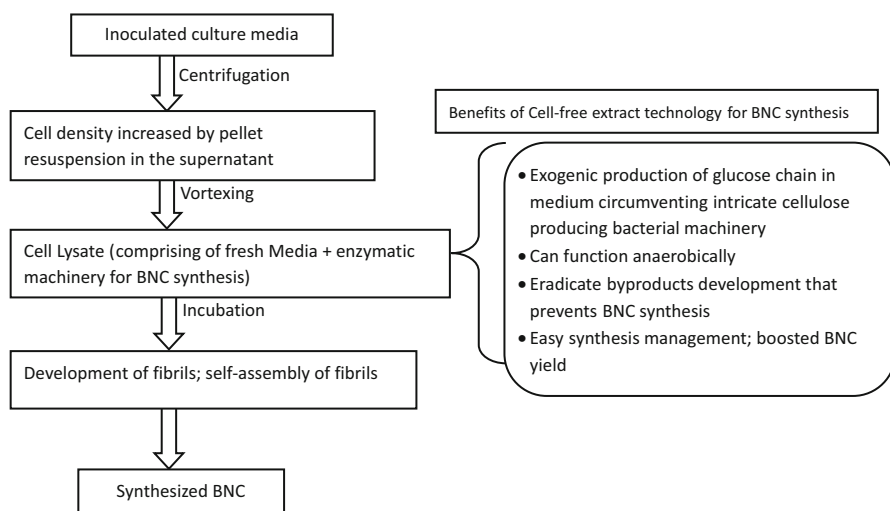

Fig. 7 Cell-free extract technique and its benefits over conventional BNC synthesis technique. (Adapted and modified from Sharma and Bhardwaj 2019a)

obligatory in conventional systems). In this way, this technique also aids in avoiding energy consumption in the form of adenosine triphosphate (ATP). Thus, large-scale BNC production can be achieved using this novel cost-effective metabolic engineering strategy. Therefore, the cell-free extract technique could emerge as an ideal impending method for BNC production. It was reported that the yield of BNC in the cell-free system was 57.68% in contrast to 39.62% in the traditional static system (Ullah et al. 2015).

Bioreactor-Assisted Approach

A bulk quantity of research on BNC synthesis was done using either the static or agitated synthesis approach. The BNC synthesis using alternate methods that might provide creditable BNC production has been investigated in a limited amount. There is scarce research on BNC production using alternative approaches (Sharma and Bhardwaj 2019a). Due to this research void, the effectual production of BNC has been hindered. The use of a bioreactor-based approach for BNC synthesis can offer a commendable BNC yield at an industrial scale; however, this necessitates additional study. The use of a bioreactor certifies rational regulation of nutritional and physiological parameters, thus assisting the appropriate growth of BNC producers. At present, scientists are focussing on increasing BNC productivity by exploring diverse categories of bioreactors (Chao et al. 2000; Krystynowicz et al. 2002; Campano et al. 2016). A prerequisite is to accomplish appropriate control of parameters during BNC synthesis. Consequently, a bioreactor that lowers the culture period and conserves the cultural authenticity is extremely desired for effective BNC synthesis. The bioreactors employed earlier for BNC synthesis have a simple design. Therefore, additionally complicated and unusual bioreactors are essential requirements for BNC synthesis. The augmentation in the BNC synthesis can be accomplished by fixing the production parameters like temperature, pH, and oxygen pressure to an optimum level throughout the fermentation process. Thus, *probing into customized bioreactors for BNC synthesis is still an open matter to upsurge BNC productivity for the envisioned practice.*

The current research emphasis is to enhance BNC throughput by utilizing diverse forms of bioreactors (Krystynowicz et al. 2002; Campano et al. 2016). Weyerhaeuser was the first company to investigate the production of bacterial nanocellulose called “cellulon” produced by stirred fermenters (Gama et al. 2016). Subsequently, numerous types of culture devices have been envisaged and investigated for BNC synthesis using agitated mode. These include stirred tanks, shake flasks, and modified airlift or gas-lift bioreactors. Sphere-shaped particles or fiber-like structures are usually formed within such devices. Figure 8 reveals few reactors employed for BNC synthesis so far.

Airlift or stirred tank reactors when used for BNC synthesis resulted in decreased yield due to the attachment of culture broth to the interior and upper side of the reactor (Krystynowicz et al. 2002).

Fig. 8 BNC produced in advanced rotary disc bioreactor: BNC deposited on both sides of discs

A reactor designed in the form of a cylindrical vessel escorted with a silicone membrane of distinct thickness was anticipated for BNC synthesis. Here the BNC pellicles were synthesized on the oxygen permeable sheath at the surface of the liquid. Its design resembles a cylindrical vessel and contains a silicone membrane of definite thickness at the bottom. The rate of nanocellulose production on silicone membrane firmly depends on the degree of roughness. A fivefold increase in synthesis rate was observed with the glossy surface as compared to the embossed surface (Yoshino et al. 1996). A twofold surge in BNC productivity was observed in a silicone membrane-based reactor by *A. pasteurianus* AP-1SK strain.

Other recognized examples are the linear conveyor film bioreactors and nonstatic rotating discs used by Bungay and Serafica (2000) for BNC synthesis. The BNC was synthesized in a tubular shape by Klemm et al. (2001).

The next reactor type was the aerosol bioreactor presented by Hornung et al. (2007). The aerosol generator used two removable and sterilizable chambers and operates by the production of a spray of the nutrient broth by ultrasound.

Another one is the rotating disk bioreactor (RDBR) which was designed so that the surface of the discs remained partially exposed to the nutrient broth and partly to the air. Consequently, during BNC synthesis, bacterial cells wedged to the disc's surface. They obtained nutrients from the medium and were subsequently remained in contact with the air. It was documented that the previous investigation using a self-constructed rotating disk system provided a nonhomogeneous mass of low-quality and mechanically weak BNC segments. Besides, the growth of cellulose in the substrate vessel has caused interference in the rotation of the discs. Here, the BNC was attached consistently to the mesh present on the discs. The tremendously promising environment for the BNC synthesis under a rotating disk bioreactor was studied by Krystynowicz et al. (2002), by shifting parameters like the number of discs, medium volume, and rotational speed. It was reported that the maximum BNC synthesis has occurred with a surface area to culture volume (S/V) ratio of 0.71 cm^{-1} at 4 rpm (Krystynowicz et al. 2002). BNC-synthesizing bacteria obtained an appropriate oxygen distribution and do not experience severe shear stress under rotary disc bioreactor-assisted synthesis. Kim et al. used a rotary disc bioreactor equipped with

eight discs for BNC synthesis using *Gluconacetobacter sp.* to produce 5.52 g/L BNC (Kim et al. 2007). However, it has a very primitive design and cultural parameters could not be controlled throughout the synthesis process.

BNC synthesis can be augmented by the addition of plastic composite supports (PCS) to the bioreactor (Cheng et al. 2010). The PCS-assisted bioreactor (10 L) produced 28.3 g BNC dry weight in 4 days of fermentation (Zahan et al. 2016).

Another type of reactor for BNC synthesis was designed with a spin filter. It has the following parts: a fermenter vessel, a six-bladed turbine impeller, and a spin filter containing a cylinder enclosed with a mesh of stainless steel and an agitator (Jung et al. 2007). It was reported to produce 2.9 times higher BNC yield than attained in a static fermenter in 140 h using *G. hansenii* PJK strain. Another reactor design includes a spherical-type bubble column bioreactor that abetted for obtaining huge BNC productivity, i.e., 1.9–2.27 g/L/day (Campano et al. 2016). It offered appropriate aeration and oxygen level and curtailed the shearing stress caused by agitation.

Our recent study investigated the advanced rotary disc bioreactor (RDBR) for BNC synthesis employing the strain *Gluconacetobacter xylinus* NCIM 2526 (Fig. 8) (Sharma et al. 2022). RDBR-assisted synthesis of BNC provided the wet weight of BNC equivalent to 189 ± 14 g/L, which corresponded to 6.6 ± 0.3 g/L dry BNC yield in 10 days. It was also investigated that under static mode only 56 ± 12 g/L wet weight of BNC, corresponding to 2.4 ± 0.4 g/L dry weight, was produced. RDBR has produced approximately 2.75-fold greater BNC as compared to static synthesis utilizing the equal volume of the media. The BNC got deposited on both sides of the discs during fermentation due to increased surface area provided by mesh present on the discs. It was found that the conversion yield of sugar to BNC was $12.2 \pm 0.8\%$, i.e., double the value obtained using static BNC synthesis ($6.2 \pm 1.4\%$) with effectual sugar consumption of $90.0 \pm 3.3\%$ (Sharma et al. 2022). It was the earliest description of the BNC synthesis in the advanced RDBR, using *Gluconacetobacter xylinus* NCIM 2526 strain. The pH and temperature were regulated throughout the synthesis process. This study might offer a productive technical approach for the resourceful synthesis of BNC.

Whereas improved BNC yield was obtained employing these reactor designs, there remains a dearth of planned experiments using different bioreactors. Bioreactor-based studies accompanied with appropriate conditions and economical substrates must be further researched to attain an exciting yield of BNC following the escalating industrial interest. Forthcoming research must emphasize BNC synthesis using bioreactor-assisted strategies in combination with different low-cost media and other bacterial strains and mixed cultures. Figure 9 presents some of the reactor designs used to date for BNC production.

Scale-Up Strategies for BNC Productivity Enhancement by Surmounting Snags

Augmenting BNC Synthesis by Substrate-Based Strategies

The increasing industrial appliance for BNC and its derivatives in varied technological fields present a driving force for carrying out exhaustive studies for enhancing the synthesis strategies and reducing the synthesis cost. The right media for the synthesis of BNC is vital for economical synthesis and yield enhancement. The frequently used carbon sources include fructose, glucose, sucrose, mannitol, glycerol, etc. (Mohammadkazemi et al. 2015; Bungay and Serafica 2000; Hornung et al. 2007; Zahan et al. 2014). A typical Hestrin-Schramm media (HS media) used for the synthesis of BNC is overpriced (Lin et al. 2013) and entails supplementary kinds of stuff like yeast extract, glucose, peptone, and ethanol. So, one of the key hurdles clutching attention in BNC synthesis technology is to predict an appropriate cheap carbon source. Attempts have been made to procure cheap BNC by using an array of carbon sources, and additional kinds of stuff (Cheng et al. 2017; Dourado et al. 2016). An extensive range of substrates, supplements, and methods of BNC synthesis used till now, aiming to expand BNC synthesis, are stated in Table 3.

The BNC synthesis using alternate substrates like sweet lime pulp (Dubey et al. 2018), sugarcane molasses (Tyagi and Suresh 2016), fruit juices and rotten vegetables, sugarcane straw hydrolysates, paper mill sludge, etc. have been achieved so far (Jozala et al. 2016).

Molina-Ramírez and his team made use of a new bacterial strain, i.e., *Komagataeibacter medellinensis*, which was resistant to acid, for BNC synthesis utilizing low-cost substrates like food supply chain wastes and agricultural by-products unsuitable for human eating (rotten bananas, rotten mangoes, and cheese whey (Molina-Ramírez et al. 2018)). Various additives were included in the

media for upsurging BNC production such as alcohols (Mikkelsen et al. 2009), organic acids and vitamins, agar (Reiniati et al. 2017), carboxymethyl cellulose corn steep liquor (Reiniati et al. 2017), etc.

BNC synthesis was reported by other substrates like residues from the wine industry (Cerrutti et al. 2016). Ethanol is reported to be a very efficient additional carbon source. It was observed that there is an increment of 2.31 g/L from 1.30 g/L in BNC yield by *G. hansenii* when the culture medium was supplemented with ethanol. In another study, a fourfold increase in BNC productivity was observed by *Acetobacter* sp. A9 strain when ethanol was added to the medium (Son et al. 2001). Another supplement is reported to augment the BNC yield by 0.4% in *K. xylinus* BPR2001 (Bae et al. 2004). It was observed that agar addition offers increased viscosity to the medium which has influenced BNC yield (Kim et al. 2012).

Replacement of water with thin stillage (a rice wine distillery wastewater) boosted the BNC yield by 2.5 times (Wu and Liu 2012). When the constituents of sugarcane molasses such as sucrose, glucose, fructose, nitrogenous compounds, agar, nonnitrogenous acids, and vitamins were added to the HS medium, the BNC yield got upsurged with *Acetobacter xylinum* ATCC 10245 strain (Premjet et al. 2007).

A study showed that a healthy drink of Chinese origin, i.e., kombucha (fermented black tea) sweetened with glucose under static conditions, resulted in the synthesis of BNC film adhering to the air-liquid interface of the culture medium. A symbiotic culture of bacteria and yeasts (SCOBY) is known to start the fermentation of tea (Fig. 10) (Sharma and Bhardwaj 2019b). Owing to the typical occurrence of vital nutrients and growth supplements like polyphenols, ethanol, vitamins, etc., fermented black tea can serve as a low-priced medium in comparison to conventionally available media (Jayabalan et al. 2014). *Gluconacetobacter xylinus* ZHCJ618 was known to be isolated from kombucha and indorsed for marketable usage owing to its virtuous stability in culture media and reasonable synthesis of BNC, i.e., 7.56 ± 0.57 g/L and 8.31 ± 0.79 g/L under static and shaking conditions, individually (Zhang et al. 2018). Different parameters of BNC synthesis using fermented tea have been evaluated and it was observed that 90 g/L sugar concentration added to the black tea provided the maximum productivity of 66.99% in 8 days (Goh et al. 2012). In a study, the glucose-supplemented fermented black tea broth was employed as a cost-effective medium for BNC synthesis, providing 13.3 g/L BNC yield (Sharma and Bhardwaj 2019b). Fermented black tea along with glucose serves as a complete media without the necessity of supplements which are normally added to the conventional media. Furthermore, the study revealed that brewed tea (waste remained after tea making) can also offer a virtuous yield of 12.8 g/L BNC. Such a low-cost medium, if used sideways with altered strategies, can bring innovations in the area of acquiring low-priced BNC. Additionally, this research work showed that the assorted culture of microorganisms might be valuable in enhancing BNC production in comparison to an individual conventional strain (Sharma and Bhardwaj 2019b). Thus, one of the cheapest media for the synthesis of BNC might be the fermented tea broth (Kombucha).

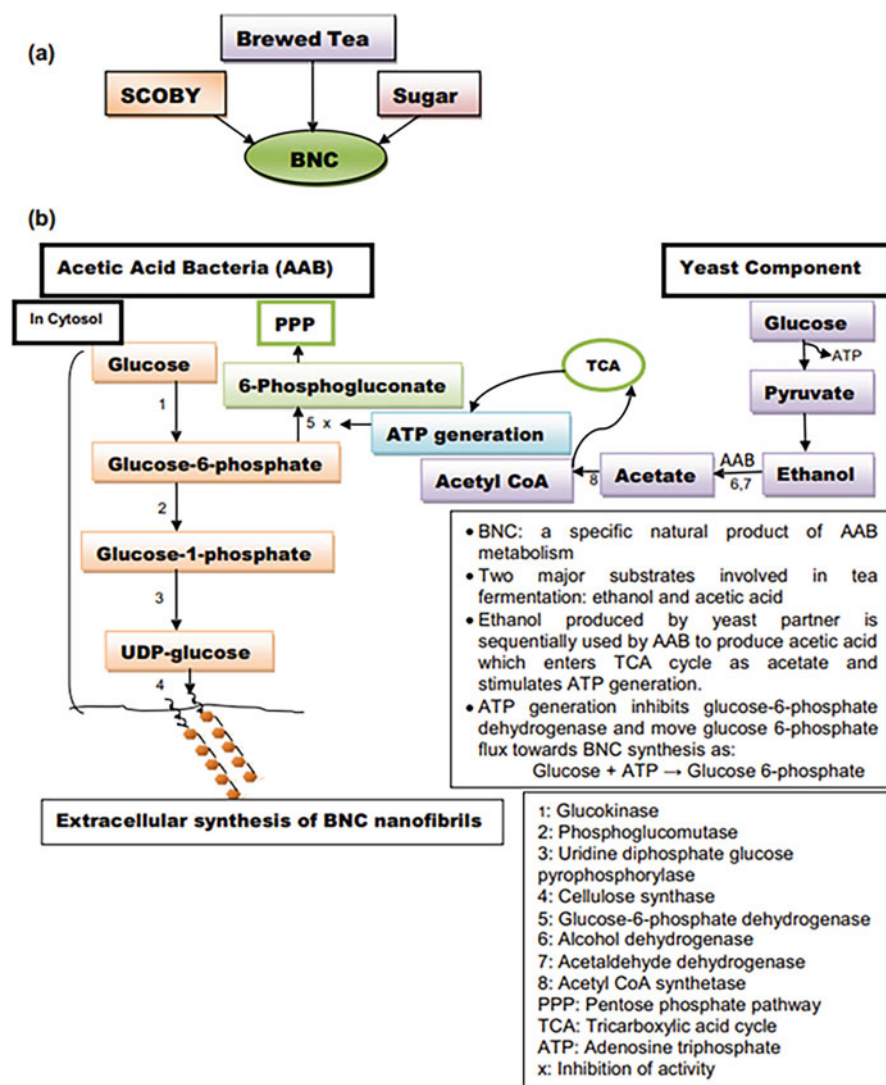

Fig. 10 (a) Three essential components for BNC production in FBTB; (b) understanding dynamic interplay of SCOBY in FBTB directing BNC production. (Adapted from Sharma and Bhardwaj 2019b)

Coconut water is the next vital substrate for BNC synthesis. Nata de coco, the first accessible edible BNC product, resulted from the fermentation of coconut water via acetic acid bacteria (Jagannath et al. 2008). This work permitted the resourceful consumption of coconut water, a hitherto wasted by-product of the coconut industry as a means of procurement of value-added products for other industries. Onggo et al. 2015 used coconut water to form BNC (Nata de coco). Additionally, they were

reported to impart magnetic properties to the BNC for various use (Onggo et al. 2015). Coconut water comprises worthy nutrients for *Acetobacter xylinum* such as proteins, soluble sugars, few oils, salts, and vitamins and it mainly comprises sugar as a topmost portion of soluble solids. Coconut skim is the remnants of the virgin coconut oil synthesis process and is customarily discarded of causing environmental pollution. Coconut skims having countless dietary values in form of protein, vitamins, and minerals could be employed as a medium for BNC synthesis. It was the first report on the fruitful consumption of coconut skim as a constituent of media for BNC synthesis (Andasuryani et al. 2017).

In-depth research with substituted economical carbon sources is obligatory in the pursuit of searching for appropriate substrates for superior BNC synthesis. Accordingly, the usage of substituted affordable media accompanied by altered synthesis processes as well as innovative BNC synthesizing strains (other than the typically used strains) must be the emphasis of imminent research to acquire worthy BNC synthesis for its widespread usage.

Strain Improvement for Large-Scale BNC Production

Extensive research has been done to augment BNC production at an industrial scale as well as to curtail the BNC synthesis charges, such as by employing low-cost media and finding substitute carbon sources and supplements. However, one of the aspects which remained much untapped is the BNC biosynthesis mechanism itself to enhance productivity and yield and to tailor the basic structure of BNC to meet the necessities of definite applications (Manan et al. 2022). The molecular studies showed the contribution of specific operons (bcsABCD) in the BNC biosynthesis, extracellular transport, and in vitro supramolecular assembly of cellulose fibrils. It has been revealed that BNC is synthesized by definite operons leading to cellulose synthesis. This involves two homologous functional elements, the BNC synthesis operon (bcsABCD, type I) and acetobacter cellulose synthesis (acsABCD) operon, which translate crucial proteins for BNC production by *A. xylinum* ATCC 1306-3 and *A. xylinum* ATCC 53582 (*K. xylinum*), individually. The bacterial genome alteration can be accomplished by genetic recombination or gene mutation through an outside chemical or physical stimulus called mutagen. The effective reports on genetic alteration of some bacterial strains are intended for increased yield and productivity, as well as altering the BNC structure. Numerous genes also augment the biosynthesis of BNC producers. For example, sucrose synthase, which is encoded by the sucrose synthase (SS) gene that catalyzes the reversible translation of sucrose, fructose, and UDP-Glc in plants, is also known to boost BNC production. In research, genetic alteration of the *K. xylinus* BPR2001 strain with a disrupted SS gene from the Mung bean led to BNC biosynthesis augmentation up to threefold as compared with its wild-type counterpart. Battad-Bernardo and coworkers developed a recombinant *K. xylinus* ITz3 strain by incorporating the transposons into the chromosomal DNA, which formed a high concentration of β -glucosidase. The resultant mutant strain utilized lactose from whey as a carbon source and produced

28-fold more BNC than the wild strain (Battad-Bernardo et al. 2004). In a recent study, a genome-scale metabolic model (GSMM) of *K. xylinus* DSM2355 was formed using genome annotation data and metabolome study of the strain. This involved the overexpression of two genes, namely *pgi* (glucose6-phosphate isomerase) and *gnd* (phosphogluconate dehydrogenase) from *E. coli* or *Corynebacterium glutamicum*. The improved strain resulted in the synthesis of 3.15 g/L of BNC, which was about two times higher than the unmodified strain (1.46 g/L) (Jang et al. 2019).

BNC production was enhanced by around 40 and 230% in static and agitated cultures of the *Gluconacetobacter xylinus* strain, individually, by homologous replacement of the membrane-bound glucose dehydrogenase (GDH) gene with a deficient one (Kuo et al. 2016). The GDH system was known to be accountable for the wasteful conversion of medium glucose units to gluconic acid at the beginning of the incubation period. Jang and his coworkers reported that they attained the finest enhancement in the BNC yield by introducing the *pgi* overexpression gene heterologously to the strain *Komagataeibacter xylinus* 2325, which recorded about 3.15 g/L of BNC production and a 115.8% higher yield than the wild-type strain (1.46 g/L) (Jang et al. 2019).

Gamma ray has occupied the widespread attention of researchers due to its implications in genetic alteration for either augmented product yield or enhanced properties. Though it was selected as a pervasive disinfecting agent, the treatment of live cells by low dosages of gamma irradiation was described to attain exciting mutations. Besides, using gamma ray irradiation is economical and plausible in most research areas (Al-Hagar and Abol-Fotouh 2022).

BNC-Allied Challenges and Future Perspectives

Can bacterial nanocellulose substitute the traditional cellulose sources? It is enormously confrontational to discourse this query up to now. This question will remain unrequited till the scale-up strategies of BNC for marketable practice and fermentation bioprocesses to obtain reasonable BNC become furthermore innovative. The goal of prudently viable BNC synthesis has not been yet attained efficaciously despite plentiful studies executed on BNC synthesis. Figure 11 reflects the snags allied to efficacious BNC synthesis and its utility. The BNC-associated obstacles can be categorized into four key headings, i.e., synthesis-based, substrate-based, strain-based, and clinical advancement and marketing of BNC-based therapeutics.

Synthesis-Based Challenges

Most of the studies for BNC synthesis had been executed using either the agitated or static method. To date, a restricted quantity of bioreactor-assisted research has been performed. Thus, bioreactor-assisted BNC synthesis is required to be executed to certify appropriate regulation of culture conditions for the cutting-edge BNC

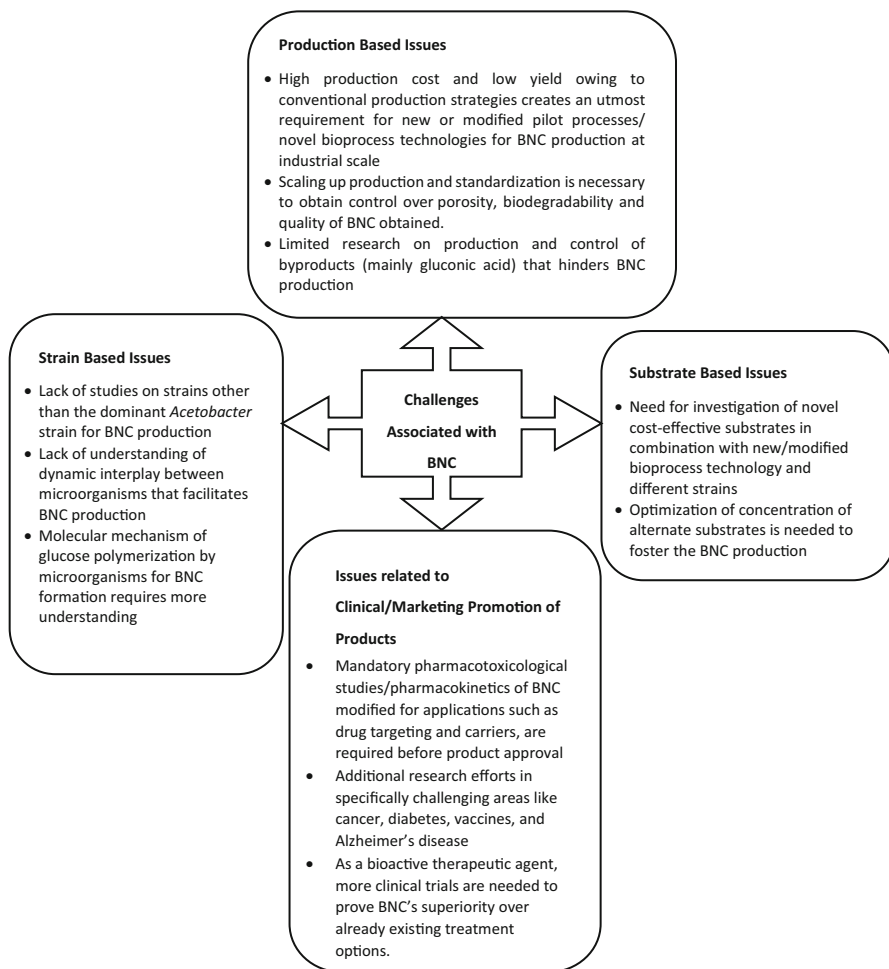

Fig. 11 BNC: challenges to be surmounted. (Modified and adapted from Sharma and Bhardwaj 2019a)

synthesis. At present, a very basic type of bioreactors has been employed for BNC synthesis. A potential BNC synthesis demands a more complex and advanced designed bioreactor. In an advanced bioreactor, the maintenance of pH and temperature of a bioreactor throughout the fermentation process could be attained using a pH probe and water jacket. This might bring an increment in BNC yield. The upgraded synthesis mode like cell-free extract system and static intermittent fed-batch strategy should be implicated with different agro/industrial wastes and strains to discover novel and germane union of technique, substrate, and strain for substantial BNC synthesis.

Substrate-Based Challenges

Approximately, one-fourth of the entire synthesis cost depends on the culture media, i.e., the substrate used for BNC synthesis. Thus, the pursuit of finding novel lucrative substrates which can contribute toward superior BNC yields in less duration is quite an arduous job for the reasonable BNC synthesis. Agro/industrial wastes have recently emerged as one of the profitable substrate groups being low cost. Studies utilizing these substrates must also be executed under precise conditions in advanced bioreactors to certify worthy BNC productivity. Furthermore, the application of agro/industrial wastes is likewise appreciable as it eradicates the wastes by transforming them into value-added products like BNC.

Strain-Based Challenges

To date, *Acetobacter* is the prevalent genus and a wide number of BNC synthesis research have been accomplished using *Acetobacter*. The application of mixed-culture strains of *Acetobacter* or other bacteria and yeasts along with low-cost agro/industrial-based media might enhance BNC synthesis. Attempts have been made in the last 20 years for isolating efficient BNC synthesizing strains. The pursuit of novel microbial strains either individually or in symbiotic associations that can synthesize BNC must be the emphasis of impending studies. So far, there are limited published data on the fruitful conversion and reprogramming of BNC-synthesizing bacterial strains. There is inadequate accessibility of plasmids (expression systems) of genes in biosynthetic pathways and regulatory networks for optimized BNC synthesis. Moreover, many available microorganisms such as *K. hansenii* ATCC 53582 are reported to have a low transformation rate. Therefore, this aspect must be comprehensively needed to be investigated for improving the BNC synthesis (Manan et al. 2022).

While there are prominent pathways for the synthesis of uridine diphosphoglucose (UDPGlc – a cellulose precursor), the molecular mechanism of polymerization of glucose into unbranched long chains necessitates further study. Therefore, studies to explore glucose polymerization at the genetic level might open a path to boost BNC synthesis in reduced time. Strain improvement and metabolic engineering might be the other approaches for enhancing the BNC synthesis. The assembly of toxic metabolic by-products often occurs during the industrial-scale BNC synthesis. The formation of gluconic acids as a by-product during the BNC fermentation had been experienced as one of the factors that negatively affect BNC synthesis (Pa'e 2009). Moreover, a noticeable trend is the conversion of cellulose-synthesizing strains to noncellulose synthesizers under oxygen-rich conditions inside the fermenters. The strains with decreased tendency to form gluconic acid during fermentation could be designed by strain improvement employing selection and mutagenesis. No definite data has been reported till date revealing the quantity of the gluconic acid formed during a fermentation process leading to BNC synthesis. Thus, studies to evaluate the amount of gluconic acid formed by different strains

during BNC synthesis might offer a more clear pathway for enhancing productivity. This could be attained by selecting the strains and carbon sources that produced a low amount of gluconic acid. The doubling time of *G. xylinus* is more as compared to *E. coli* and *B. subtilis*. Bacterial strains can be genetically modified to lessen the doubling time. Identification and isolation of strains that can readily be modified by genetic engineering to produce high-quality BNC with low-cost substrates must be investigated (Gama et al. 2016). The low-nitrogen-demanding strain of *Komagataeibacter rhaeticus* (*K. rhaeticus* iGEM), which is highly resistant to toxic chemicals, has been recently identified (Florea et al. 2016). As this strain can grow well under nitrogen stress, this property allowed its cultivation under cheaper, low-nitrogen-containing media. This has resulted in diminishing the synthesis cost. The team also succeeded in maintaining an external control over BNC production by *K. rhaeticus* iGEM, through the development of a modular genetic response that enables balanced reprogramming of the bacterial cell (Florea et al. 2016). Genomic sequencing of this strain was performed to reveal genetic circuits accountable for the functionalization and determining heterologous genetic expression within the BNC matrix (Florea et al. 2016). This cutting-edge discovery has set the basics for exploring genetic engineering for the synthesis of cellulose-based nanomaterials with versatile applications as biomaterials in basic sciences, nano-biocomposites designing, etc. The inclusive genetic information about diverse BNC-producing species followed by their metabolic modeling can provide the quality optimization of the BNC synthesis process. The scarcity of available genetic data creates an interruption of the utilization of this strategy for BNC synthesis. Thus, searching for the genomic sequence of the BNC synthesizers is of utmost necessity to evaluate the resemblances and variances at the gene level (Gama et al. 2016). Genome sequencing is beneficial in producing recombinant strains that might have the potential to produce a worthy amount of BNC with tailorable properties for diversified usage.

If the direct management of gene coding for the catalysts aiding BNC synthesis, regulatory protein machinery, and other genes directly or indirectly involved in the BNC synthesis could be attained, then this could create a remarkably promising step toward obtaining an industrially valuable bacterial strain. Nevertheless, BNC synthesized using genetically modified bacterial strains might have regulatory issues, mainly in the food and medical industries. Moreover, owing to the complicated regulatory mechanism involving each gene expressing its proteins with definite functions, changes at the molecular level may not certainly lead to a positive effect on the productivity of the synthesized BNC.

Besides this, more research must be executed by using microorganisms other than the dominant ones as these despite being present in a subsidiary amount might offer a required boost-up strength for starting the fermentation processes leading to BNC formation (Gama et al. 2016; Keshk and El-Kott 2017).

Clinical Advancement and Marketing-Related Challenges

BNC-based products and their marketing face a variety of obstacles at the clinical study level. Perhaps the greatest complex matter is to interpret the outcomes of in vitro analysis and animal-based studies into clinical applications on humans and make them marketable. Many BNC-based therapeutics are available; however, only a few have been approved for patient usage. The chief explanation for only a handful of the approved product lies in the snags at the manufacturing level and synthesis price. Moreover, the sterility problems and patent apprehension also restrict the products from being used for patient well-being.

Conclusions

BNC is an industrially significant biomaterial having wide usage in diverse high-tech applications. Thus, persistent efforts have been made for the viable acquisition of BNC by cutting down the synthesis price, yield enhancement, and comprehensively enlightening its performance by modifying the biological, physical, and mechanical properties. Currently, the three crucial strategies commonly applied for enhancing the BNC synthesis are: (i) reconnoitering the pioneering or altered synthesis tactics with both static and agitated modes like static intermittent fed-batch strategy, manipulative cell-free extract system, and employment of innovative bioreactors like advanced rotary disc bioreactor; (ii) substitution of conventional culture media with a low-cost agricultural/industrial wastes to bring down the synthesis cost; and (iii) genetic alteration of microorganisms used for BNC synthesis. Besides this, studies must be conducted using other possible strains in addition to the dominant BNC synthesizers.

There is no efficient and automated mass production process for industrial-scale BNC synthesis, whereas numerous BNC-based products are commercially available that predict the status of BNC in the development of bio-based products. Thus, BNC is presently not economically competitive in comparison to other more recognized polymers in most applications. Nevertheless, the designing of new technical processes and their optimization are ongoing to obtain diverse achievable forms of BNC. For the synthesis of flat BNC in the fleeces and foils forms, novel reactor types have been developed to overcome the most important drawbacks of the static method. The (semi) continuous HoLiR method has been recently shifted to synthesis at a pilot scale. The rotary disc bioreactor-assisted synthesis has been successfully carried out to enhance the BNC production. All these signs of progress have reinforced the anticipation for future large-scale synthesis processes, which is instantly desirable to bring the auspicious BNC-based products from the laboratory to the market. Moreover, the advanced bioreactor designs and techniques like static intermittent fed-batch and cell-free extract, if investigated with different culture media, might build a road to substantial and economical BNC production. To summarize, it can be concluded that the reasonable utilization of BNC depends on its yield. Thus, if BNC can be effectually manufactured in a plentiful amount at a low

cost, it can be used in the production of various biomedical devices and other consumer products. If a further alteration in bioprocess technology such as bioreactor design, process parameters, and employment of cheap or wastes substrates as media components could be attained, it would undoubtedly assist in acquiring a high-quality nanocellulose. *Thus, the factors, that need further investigation for commendable BNC synthesis, are the appropriate combination of the production strategies, substrates, and strains.*

Abstract

The transition from an oil-based economy to a nature-based economy necessitates the innovative exploitation and transformation of high-value natural resources. Cellulose is mostly found in higher plants, but it is also created by marine organisms, particularly Tunicates, types of algae, and bacteria, by enzymatic and chemical processes, with a nanocellulose or nanofiber or nanocrystalline cellulose structure. For environmental sustainability, it would be preferable to use natural fibers as a renewable source as the worldwide waste problem caused by biomass is becoming an increasing environmental concern. Numerous agro-industrial wastes have been investigated for the synthesis of Bacterial cellulose (BC). Bacterial cellulose fiber is a natural fiber that is easy to cultivate and offers nano-sized fiber. BC pellicle can be created using two types of fermentation: dynamic and static fermentation using Hestrin and Schramm medium with carbon sources derived from agro-industrial waste. Bacterial Nanocellulose (BNC) is extracted through the fibrillation of BC pellicle in a high-pressure homogenizer, which reduces and homogenises the particle size. It is applicable as composite membranes or hydrogels. The X-ray diffraction, fourier transform infrared, scanning electron microscope, and strength analysis can be used for characterization. Bacterial strain and fermentation procedures determine the BC's properties. Small-scale and contemporary enterprises have utilised BNC for biomedical, energy harvesting and storage, electrical, environmental, and food applications. This chapter presents a review of agro-industrial waste, cellulose feedstock, bacterially produced cellulose fiber, its morphological, chemical, physical, and mechanical characteristics, as well as its potential applications.

Introduction

Cellulose is the earth's most abundant substance with low density and excellent mechanical characteristics. An estimated 10^{10} to 10^{11} tonnes are extracted annually from plants or garbage on a global scale (Figueiredo et al. 2014). Cellulose is mostly found in higher plants but is also created by marine organisms, such as Tunicates, algae, and bacteria, by enzymatic and chemical processes (Musa et al. 2016). Multiple industries are predicted to account for the majority of cellulose consumption in the current period. With a tensile strength of 16.9 MPa and a cellulose modulus of 2 GPa (Gallegos et al. 2016), cellulose is extensively utilized as a material for rayon fiberboard paper in the manufacturing business. Plant cellulose is a combination of carbohydrates, including hemicellulose and lignin, which weaken the cellulose fibers. As a bulking agent and fat substitute in low-calorie foods, many kinds of cellulose, such as texture modifiers, emulsifiers, and extenders, can be utilized. In food items, it is derived as a pulp from fibrous materials such as cotton or wood. It is a reinforcement for composite materials, biomedical implants, hydrophobic polymer matrices, and medicinal applications. Numerous researchers employ cellulose in the form of nanofibrils or nanocrystalline cellulose as a polymer composite filler. This nanocrystalline cellulose is recovered from plant fibers by crushing them and then subjecting them to an acid hydrolysis procedure to destroy the amorphous fraction and obtain crystalline cellulose. However, this procedure is costly due to its high energy requirements. Therefore, a method for manufacturing nanocellulose from bacteria was devised to facilitate the replacement of plant cellulose nanofibrils (Esa et al. 2014) and contribute to the environmental sustainability of plants.

Numerous research has discovered applications for lignocellulosic biomass that can be utilized as a starting point for the manufacture of other substances, such as biofuels and biopolymers. The primary sources of lignocellulosic waste are now classified as agricultural, forest, and industrial resources. As the main component of lignocellulosic waste, cellulose is a natural polymer consisting of glucose duplication units with unbranched chemical chains. Alternative therapies utilize the waste from argan-based cakes, olive tree pruning, cotton buds or apple pomace and grapefruit, as well as nanocrystals and cellulose nanofibers. Many sectors, including food packaging, biomedicine, mechanical reinforcement, and membrane filters, have used nanocellulose-based materials into their products. Nanocellulose has recently been the focus of a great deal of study about goods and applications, including nanocomposite, foams, fibers, barrier layers, films, viscosity fixes, gels and aerogels, energy consumption, and filters. Depending on the processing conditions, nanocellulose can be extracted from Lignocellulosic biomass by dissolving cellulose fibers into cellulose nanocrystals and cellulose nanofiber. The most common techniques for detecting cellulose nanocrystals and cellulose nanofibers, respectively, are acid hydrolysis and mechanical treatment; however, these processes have some shortfall related to environmental and economic factors, such as the high amount of water required for neutralization.

Enzymatic hydrolysis is a viable natural and ecological alternative to nanocellulose manufacturing due to the benefit of enzymatic treatment, while the enzyme cost can be low. Several authors have investigated the utilization of enzymes in conjunction with mechanical treatment to promote the formation of cellulose bonds and lower the energy demands of nanocellulose separation procedures. Nanocellulose is a general term that is often used for various nano-sized cellulose particles. Depending on the structure, nanocellulose is the result of distributing cellulosic fibers to a wide range and length. There are three forms of nanocellulose: cellulose nanofibers, which are typically obtained through enzymatic and/or mechanical dispersion processes; crystalline cellulose-shaped nanocrystals, which are typically obtained through hydrolysis containing concentrated mineral acids; and bacterial nanocellulose, which is almost exclusively found in the bacterial family known as *Gluconoacetobacter xylinus*. The fundamental disadvantage of producing cellulose nanostructures is the significant energy consumption at high repetition rates, notwithstanding the essential breakdown cycles of biomass structures. Efforts to lower this energy use and achieve a more effective dispersion have been bolstered.

Microorganisms, such as bacteria, are capable of generating bacterial cellulose (BC) pellicle in the form of nata by polymerizing glucose molecules into α -1,4-glucan chains within the BC core (Iguchi et al. 2000). *Acetobacter xylinum* is the prevalent BC that ferments coconut water to make nata de coco. Under static fermentation conditions, these bacteria produce pellicles with exceptional features, including high crystallinity, high purity, exceptional mechanical capabilities, and the ability to build uniform membranes. These nano-sized sheets are biocompatible and feature a delicate structure. In addition, BC has good mechanical qualities (high tensile strength) and biodegradability. It has several applications as a biomaterial in the cosmetics and pharmaceuticals industries, as well as the paper, textile, and food industries, and can be utilized in various polymer science research.

The transition from an oil-based economy to a nature-based economy necessitates the innovative exploitation and transformation of high-value natural resources. The potential for converting natural waste into valuable natural materials is substantial. Agricultural biomass wastes consist primarily of burned or discarded fruit peels, roots, leaves, crop stalks, and seed shells. In practice, biomass wastes are a viable source of important feedstock materials. Globally, agriculture/forest industries create around 4.6 gigatonnes of wood biomass and almost 923 gigatonnes of trash (Tripathi et al. 2019). These wastes have the potential to harm the ground and surface waters and cause eutrophication. When contaminants are introduced into the soil, the microflora in the biomass is stimulated to generate and emit greenhouse gases, resulting in a worsening of global warming. Due to the varying chemical compositions of plant cellulose fibers, nanocellulose extraction is a complex and time-consuming procedure that increases processing costs. Moreover, the extraction of plant cellulose might contribute to global warming. Therefore, alternate cellulose sources, such as bacterial fermentation, are necessary.

Agro-Industry Waste

In the past 50 years, agricultural production has more than quadrupled due to the development of area for agriculture, the contribution of technology that influences productivity, and the accelerated growth of the world's population. Globally, agriculture produces as much as 23,7 million tonnes of food every day. Increased agricultural production exerts increasing strain on the environment, hence posing a danger to the sustainability of the ecosystem, depleting land, water, and air resources, and negatively impacting population health (Duque-Acevedo et al. 2020). Waste is defined as all non-optimally utilized materials, including manufacturing and consumption byproducts. Biodegradable waste contains a variety of chemicals, but they can be categorized into three primary constituents: hemicellulose, cellulose, and lignin. In contrast, garbage is typically the product of human activity that cannot be avoided and is therefore inexpensive. This comprises agricultural, industrial, municipal, and crop residues. It consists of plant materials, industrial, agricultural, and municipal wastes as well as residues. These include industrial and urban wastes, agricultural and plant products, and residues (Esa et al. 2014). Inefficient food processing results in the loss of food through spillage, spoilage, the discard of substandard edible ingredients, and the disposal of edible food components. Food waste has a considerable economic, environmental, and public health impact (Sundarraj and Ranganathan 2018).

The three categories of agro-based industries are non-food agro-industrial, animal and plant-based wastes. Except for the textile and leather tanning sectors, non-food-based agro-industries produce primarily biodegradable, non-toxic waste. The majority of garbage is left unutilized or untreated, posing a threat to the environment and human and animal health. The components of plant-based waste are process residues and field residues. Processed residue is the waste formed by the processing and refining of raw materials. Common crop-based agricultural wastes include products from fermentation-based industries, the sugar sector, grain flour mills, food and fruit processing. A substantial amount of organic residue from the poultry, meat, and fish processing industry contains proteins that are susceptible to releasing offensive odors and disturbing the public. Field residues are the waste items (stems, pods, stems, and leaves) left in the field after harvesting the crops. This waste is commonly utilized as bedding and animal feed for cattle, as well as for horticulture purposes (Singh et al. 2021). Agriculture, as the largest biological sector that produces the most biomass, represents a significant opportunity as an important input for the bioeconomy, not only due to their utilization and exploitation can reduce the use of fossil fuels and greenhouse gas emissions, but also because they contribute to the development of new jobs and green markets, and promote the conversion of lignocellulosic waste into value-added products such as food, bioenergy, bioproducts, and feed. The majority of agro-industrial waste consists of hemicellulose, cellulose, and lignin and is in the form of wet biomass. They can be exploited as a permanent source for the manufacture of compounds with added value (Singh et al. 2021).

Industrial products or food scraps produced by food processing, furniture design, printing and paper production, printing and packaging, such as sweet lime waste,

bagasse, and recycling paper, are a significant form of recycled material biomass used for nanocellulose extraction. In reality, the food processing industry alone will generate more than 142 million tonnes of cane trash year in Brazil, leaving a vast quantity of cellulosic waste with potential application in high value-added production. Due to feedstock's chemical and structural heterogeneity, it varies and is highly reliant on the type of fossil. With its high cellulose content and loose structure, sugarcane bagasse is amenable to acid hydrolysis for nanocellulose extraction. Prior to chemical extraction and acid hydrolysis methods, pulping and cleaning will be required in the case of nanocellulose extraction in the recycled paper or solid waste and waste pack industries.

The procedure of smoke explosion and acid hydrolysis is proposed to remove nanocellulose from the furniture industry for residual processing. Nanocellulose with a width between 18 and 40 nm was treated to surface rotation and ice suspension to produce the hydrophobic aerogel for oil absorption. Using the NaOH / Thiourea system, raw paper is purified and turned into circular nanocellulose with a crystalline index of 48.85% and a standard size of 50 nm for a specific type of industrial residue. The use of ammonium persulfate under oxidizing circumstances to convert fibers in paper mills and pulp into crystalline cellulose nanoparticles 10 to 20 nm in width and 150 to 500 nm long is described in another study. Using a catalyst, inorganic nanoparticles were produced. For antibacterial and photocatalytic operations in paper mills or as an additive for water treatment and textile finishing, sol-gel-prepared cellulose nanocrystals. Enzymatic hydrolysis is a novel technique that can facilitate the extraction of nanocellulose from industrial fossil fuels that produce a soft and loose cellular structure, such as industrial fossil-producing leftovers like citrus pulp.

In addition to industrial nanocellulose emissions and biomass residues, the use of bacterial nanocellulose implants in water processing businesses is a viable alternative for producing nanocellulose from inexpensive biomass. Researchers have transformed lime pulp waste into high-quality bacteria nanocellulose using *Komagataeibacter europaeus* SGP37 with fermentation process in a static intermittent batch, establishing a novel method for transforming trash into high-value products. In addition, trash from other businesses and cities can serve as sources for the extraction of nanocellulose. In a separate investigation, nanocellulose crystals were recovered from discarded cigarette filters using ethanol extraction, bleaching, alkaline treatment, and acid hydrolysis. The released nanocellulose crystals had breadth, an average length, and crystallinity of 8 nm, 143 nm, and 96.77%, respectively. High-purity nanocellulose may have uses in the realm of biomedical chemicals. Using autoclave, high-pressure, and high-shear homogenization, nanofibers of cellulose were recovered from lime residues. Cellulose nano fibers having a diameter of 28 nm and a crystallinity of 44 to 46%, showing water replication, and a potential utilization in the packaging industry.

Cellulose

The most abundant substance in nature is cellulose, a non-combustible green substance produced by green plants from water, carbon dioxide, and sunlight. Cellulose can be considered a biodegradable and renewable source of energy, as well as an immature material for the synthesis of other compounds, because to its simple yet adaptable chemical structure, which can yield a wide range of active polymers fibers, and films. Cellulose's physical robustness is attributed to the fact that it is often a shiny polymer. Cellulose is a key component of biodegradable waste, and its effective utilization in the form of value addition may provide a glimpse into the promising future of biodegradable waste utilization.

Cellulose is a ringed glucose molecule having a linear chain with conformations resembling flat bands. It has a repeating unit (Fig. 1) composed of two anhydrous-glucose rings ($C_6H_{10}O_5$)_n, where n is between 10,000 and 15,000. n is dependent on the material source of cellulose coupled via covalent connections of oxygen to C1 of one glucose ring and C4 of the neighboring ring (1,4 linkages) and so-called 1,4 glucosidic bonds. The hydrogen interactions between oxygen and the hydroxyl groups of nearby ring molecules stabilize the bonds and give the cellulose chains a linear structure. This molecular arrangement encourages the parallel arrangement of the double cellulose chains that comprise the basic fibrils, which then aggregate into bigger microfibrils with a diameter of 5–50 nm and a length of several micron meters. The network of inter- and intra-chain hydrogen bonding renders cellulose fibrils a moderately stable polymer with strong axial stiffness. In the cellulose chain, the cellulose fibrils contain two parts, such as a highly organized (crystalline) structure and irregular (amorphous) regions. It serves as the fundamental phase of tissue reinforcement in plants, trees, marine organisms (Tunicata), algae, and bacteria (certain bacteria release cellulose fibrils that form exterior tissue structures) (Moon et al. 2011).

About 40 to 50% of wood is cellulose, while over 90% of cotton is cellulose (Hsieh 2006). Cellulose derived from wood fiber has numerous contaminants that can be removed by dissolving it in a solution of sodium hydroxide and carbon disulfide (CS₂). This dissolution procedure will produce a viscous liquid. When the liquid is introduced into the pipe in the acid bath, rayon fiber is produced. Cellophane paper is the result of a similar method for producing thin films from cellulose. Other forms of cellulose are referred to as Microcrystalline Cellulose (MCC), Nanocrystalline Cellulose (NCCs), Nanohiskers, BC, etc., based on their properties

Fig. 1 Cellulose chain repeating structure

and production procedure (Diez-Pascual and Diez-Vicente 2014). Cellulose and its derivatives may also be processed into various forms, such as BC, which employs important microorganisms in the manufacture of cellulose. Under moist conditions, the modulus of elasticity of homopolymer cellulose is around 134 GPa in the axial direction. Matrix polymers such as hemicellulose and lignin have an elastic modulus of 40 MPa and 2 GPa, respectively. The interaction between plant matrix polymers and rigid cellulose fibrils in the cell walls is one of the most difficult aspects of plant mechanical performance to comprehend (Pandey et al. 2010). The main sources of nanocellulose are plants, animals, and microbes. The extraction of nanocellulose from various biomass sources for usage in many fields has garnered increasing attention.

Nanocellulose includes mostly three categories: cellulose nanocrystals, also known as nano crystalline cellulose, nanocellulose whiskers, and cellulose microcrystals that are highly generated by acid hydrolysis from lignocellulose. Amorphous cellulose also leaves nanocrystalline cellulose behind. Mechanically, chemically, or enzymatically, cellulose nano fibers, as well as other microfibrillated cellulose, nanofibrils, and microfibrils, are treated. Defibrillation treatment of cellulosic fibers and bacterial cellulose, also known as bacterial nanocellulose, microbial cellulose, and biocellulose, is the major constituent of numerous *Acetobacteraceae* species. As a biodegradable and biodegradable substance, nanocellulose can be derived from the biomass of many plants, bacteria, algae, and other invertebrates by a variety of processes. Nanocellulose shares the inherent chemical structure of cellulose with a variety of hydroxy groups, aldehyde groups, and carboxy groups to maintain its activity. Due to nanocellulose's structure, it possesses a high surface area, crystallinity, mechanical strength, and active functional groups, making it applicable in a variety of situations. The nanocomposite uses of cellulose nano fibers, also known as microfibrillated cellulose, cellulose microfibril, and microfibril cellulose, are currently of interest to researchers. To manufacture these structures, cellulosic fiber must be subjected to mechanical dispersion to cause fiber delamination, thereby separating the nanometric fiber. This procedure has a significant energy requirement to ensure the efficient operation of the nanofibrillation process. Various treatments have been devised to integrate cellulose fiber prior to its nanofibrillation to reduce and enhance the process efficiency. There are a number of methods for obtaining glucose monosaccharides from cellulose. One of the most potential applications of cellulose, which degrades cellulose polymer into smaller polymer branches, particularly glucose and cellobiose dimer.

Enzymatic hydrolysis is a less advanced approach for creating nanocellulose than acid or alkaline procedures. However, this approach has some useful characteristics, so it is vital to develop and invest in enzymatic production methods. These enzymes are traditionally classified into three groups: cellobiohydrolases, exoglucanases, and endoglucanases. The resulting cellulose nanofibers are more homogeneous than those obtained solely through mechanical treatment. Due to a chemical interaction between cellulose and monochloroacetic acid in the presence of sodium hydroxide, the hydroxyl cellulose series is replaced by carboxymethyl groups during the carboxymethylation phase, which occurs in two stages. Carboxymethylation

generates a highly charged region around the fibrils, which aids their release during decontamination treatment.

Catalytic oxidation was carried out using 2,2,6,6-tetramethylpiperidine-1-oxyl (TEMPO) through the incorporation of the use of a selective oxidative catalyst that could negatively charge the fiber surface, resulting in electrostatic expulsion of anionic carboxyl groups between oxidized fibers, in order to bypass the binding forces. It is a widely used and effective treatment that reduces energy consumption by up to 100 times during the mechanical dispersion process and results in the fabrication of highly uniform cellulose nanofibers between 3–4 nm and several microns in length; nevertheless, it is expensive. The creation of nanofiber structure was facilitated by the TEMPO reagent. When this technique is paired with the action of sonication, cellulose is degraded significantly, resulting in fibers characterized by prolonged separation and facilitating stages of the defibering process. It was also discovered that the employment of the TEMPO agent in the treatment of oxidized cellulose pulp results in an increase in the level of polymerization, with the nanocellulose producing a light intensity as a result of post-oxidation.

Cellulose Feedstock

Primary natural cellulose sources include:

Plants

Plants are the primary potential source of cellulose since they are abundantly available and simple to harvest. The plant's cell wall is composed of stiff cellulose and non-cellulosic matrix polymers. The production and arrangement of cellulose microfibrils serve a crucial role in sustaining the physiological functions and stiffness of the cell walls during cell growth and development. Cellulose microfibrils production refers to the manufacturing of microfibrils from cellulose source plant materials such as sisal, cotton, flax, hemp, tubers, wheat straw, sugar beets, and so on. The cellulose microfibril of plants has a cross-sectional dimension of approximately 2–3 nm (Song et al. 2020). Wood is the primary source of cellulose fibrils, although cellulose microfibrils are strengthened by amorphous intracellular materials such as hemicellulose, lignin, pectin, etc. In order to extract pure cellulose microfibrils from lignocellulosic fibers, chemical processes such as alkalization, bleaching, and acid hydrolysis are required.

Tunicate

Tunicates are a family of marine animals known as “sea squirts” (Ascidacea). There are around 2300 species of this filter-feeding marine invertebrate species. These animals are an excellent source of cellulose microfibrils due to their thick, leathery

skin. There are several species in nature, and cellulose is extracted in diverse ways depending on the species. The properties and structures of the cellulose microfibrils of the tunicates species were not comparable; nonetheless, modest changes in the synthesis of cellulose microfibrils could alter microfibril properties (Thakur and Thakur 2015). It is anticipated that the Tunicate structure and characteristics of cellulose microfibrils are comparable amongst species. Due to the varied production of cellulose microfibrils, there may be slight changes in the structure of the resultant microfibrils. *Metandrocarpa uedai*, *Halocynthia papillosa*, and *Halocynthia roretzi* are the species that have been researched the most frequently (Pandey et al. 2010). Future isolation on a commercial scale of cellulose nanocrystals with a high aspect ratio (i.e., length/width) is most likely to be possible from tunicates, among the various natural cellulose sources. In the past, the lack of tunicates, the difficulty of harvesting tunicates on a large scale, and the paucity of information on cellulose separation were the greatest obstacles to increasing cellulose isolation.

Algae

The cell wall in cellulose nanofibrils is produced by algae. Algae produce microfibrils through the self-assembly of cellulose chains, which eventually aggregate into cellulose fibers, bigger assemblies. This cellulose fiber has sections of both irregular (amorphous) and regular (crystallite) structures. Their extracellular layers of algal taxa, such as the green algae/Chlorophyta (e.g., Chlorophyceae, Ulvophyceae, Trebouxiophyceae) and the red algae/Rhodophyta or Charophyta, are claimed to include hemicellulose and cellulose (e.g., Charophyceae). Within the Ochrophyta phylum, brown algae (class Phaeophyceae) are commonly known to contain hemicellulose and cellulose (e.g., xylofucoglucan sulfate), whereas a small number of species of golden algae (class Chrysophyceae) and yellow-green algae (class Xanthophyceae) have cellulose as a structural polysaccharide. Certain dinophytes (thecate dinoflagellates) contain a protective cellulose plate (theca) as a complex extracellular layer known as the amphiesma. Other polysaccharide matrices, such as ulvan, pectin, agar, alginate, and carrageenan, have been identified in the cell walls of brown, green, and red algae and may be ideal algal cellulose products for enhancing their economic viability (Zanchetta et al. 2021).

Bacteria

Certain bacteria, such as *G. xylinus*, which are prevalent contaminants in acid fermentation, create cellulose by exploiting a variety of carbon and nitrogen sources. Under optimal cultivation conditions, these bacteria generate dense pellets of cellulose microfibrils. BC is distinct from cellulose derived from other sources due to the fact that culture conditions can alter the microfibril formation process. In a bioreactor, cellulose microfibrils are secreted by bacteria at several stages of biosynthesis, including cellulose cultivation and pellicle management. Temperature, nutrients,

bacterial strain, pH, agitation rate, etc., can affect polymer network development and microfibril morphology during fermentation. Changing the shape of the bioreactor can also alter the pellicle form of cellulose-producing bacteria. Pellicle management refers to the chemical and mechanical procedures used to remove contaminants from pellicle. Alkaline sodium hydroxide, potassium hydroxide, and other solutions hydrolyze and eliminate contaminants from the pellicle. The mechanical defibrillation of cellulose tissue yields microfibrils that are pure (Thakur and Thakur 2015).

Bacterial Nanocellulose

The bacterium nanocellulose is one of the most specialized nanocellulose species, relative to other species, due to its creation via combining sugars for low molecular weight operations. During the separation of cellulose nanocrystals and nanofibers from lignocellulosic biomass, this nanocellulose is reconstituted with its own cellulose fiber package. The features of bacterial nanocellulose include great purity, including the structure of the nanofiber network, high water content of 99% and heat-stable hydrogel bodies produced by mechanical means. Due to the single filaments' thickness of ten nanometers, scanning electron microscopy is ideally suited for examining the morphological characteristics of bacterial nanocellulose. The primary benefit of this method is that it does not necessitate the restoration of extremely small particles, as is required for transmission electron microscopy. In addition, its great depth is incredibly useful for visualizing bacterial components with three-dimensional micro cellulose.

Although bacterial nanocellulose has the same chemical formula as cellulose isolated from plants, its features are unique in comparison to those of other nanocellulose species. Due to its biological compatibility, non-toxicity, biofunctionality, and simplicity of sterilizing, nanocellulose bacteria can give a biomaterial effect on the development of mechanical properties, depending on the system's intended purpose. The requirement for high-quality nanocellulose bacteria has prompted study into biotechnological strategies spanning from volatile to non-volatile pathways, employing techniques ranging from collection or grazing to sustainable cultural practices. These can include aerated fermenters, bubble columns, and rotating disc reactors in terms of materials. Depending on the intended application, the choice of growth method is crucial since the production method influences the structure and structure of the body and the cellulose machinery.

Therefore, the production of a bioprocess is determined by the employment of a certain type of bacteria, the construction of a traditional habitat, the concentration of dissolved oxygen, pH, and the temperature of the culture medium. The culture medium appears to be the most significant factor, as it has a significant impact on the overall cost of bacterial nanocellulose production; therefore, it is essential to identify a low-cost culture that can increase bacterial nanocellulose yields in order to define a commercially viable industrial-oriented solution applicable to numerous industries. The remarkable features of the bacterial nanocellulose material make it highly adaptable and functional; hence, it is anticipated that tissue engineering and

regenerative medicine will experience major advancements in the future. However, the greatest obstacles to using cellulose bacteria are its pricey manufacture, high media expenses, and limited industrial output. As previously stated, the use of bacterial nanocellulose in medical devices is expected to result in significant advancements in a variety of medical fields; however, this should not be done in the conventional manner; rather, due to the intense competition in the field, each application must be reviewed individually.

Bacterial Cellulose Biosynthesis

BC was discovered in 1886 by Adrien Brown, who observed the production of a white, gelatinous substance on the surface of a liquid medium, which had the ability to expand to a thickness of 25 millimetres and proved to be robust when he researched acetate fermentation. Brown further confirmed that the membrane of the bacteria was originally referred to as *Acetobacter xylinum*, but was later categorized as *A. xylinum* and is now known as *G. xylinus*. Multiple bacterial and cyanobacterial species have been identified as BC producers. *Acetobacter*, *Agrobacterium*, *Gluconacetobacter*, *Rhizobium*, *Pseudomonas*, *Alcaligenes*, and *Sarina* are cellulose-producing bacteria strains (Zou et al. 2017). The most effective producer is *G. xylinus*, a species known for its ability to synthesize cellulose commercially. Plant and bacterial cellulose have comparable chemical compositions, but their physical qualities and fiber structures are distinct. Plant cellulose consists primarily of cellulose I structure, whereas BC is thought to have distinct I and II crystalline forms (Torres et al. 2012). The distinctive features of BC include a high degree of polymerization, tensile strength, crystallinity, water-holding capacity in the range of 60 to 700 of dry weight, and an ultra-fine network nanofiber structure with a diameter of less than 19 nm (Chang et al. 2012). Further study revealed that cellulosic materials had the same chemical composition as plant-derived cellulose, and BC remains the purest form of natural cellulose to date (Brown 1886).

BC and plant cellulose are both constituted of polysaccharides including α -1,4-D linear chains of glucopyranose residues that vary in purity, degree of polymerization, and crystallinity (Yan et al. 2017). The benefits of BC fiber include simple manufacture and application (Esa et al. 2014; Tang et al. 2010), very high purity, and the absence of hemicellulose and lignin found in plant cellulose. It is considered a suitable material for the future of biomaterials. Conventional BC has an elastic modulus of 3.0 GPa and a strength of 70 MPa (Rahman and Netravali 2017). They consist of cellulose nanofibers with a network of interconnected fibrils that contain linkages and aggregation and form a three-dimensional structure (Suryanto 2017).

The bacterial production of cellulose is a multistep process including regulatory proteins, catalytic complexes, and specific enzymes. It has four enzymatic processes including glucose as the carbon source (Fig. 1). The enzymatic process consists of (i) glucokinase enzyme process for glucose phosphorylation, (ii) phosphoglucumutase enzyme process for isomerization of glucose - 6 - phosphate

(Glc-6-P) into glucose - 1 - phosphate (Glc-1-P), (iii) UDPG-pyrophosphorylase (UGPase) enzy UDPGlc is the immediate precursor to cellulose in many species. UG Pase is believed to play a crucial part in the manufacture of cellulose, as this enzyme is 100 times more active in cellulose-generating bacteria than in non-cellulose producing bacteria. When disaccharides, i.e., maltose and sucrose, fed into cellulose-BC biosynthesis, which produces bacteria as a carbon source, begins with the hydrolysis of disaccharides into glucose and fructose (monosaccharides) (Lee et al. 2014).

Gluconoacetobacter xylinus (*G. xylinus*) biosynthesis of cellulose begins with the creation of individual (14) chains between the outer membrane and plasma of the bacterial cell. One *G. xylinus* cell polymerizes up to 200,000 glucose molecules with (1,4) glucan chains, which are then discharged from the cell's surface pores (Thakur and Thakur 2015). The BC chains are subsequently interconnected to form protofibrils with a diameter of around 2–4 nm, which are eventually aggregated into microfibrils that are 3–15 nm thick and 70–80 nm wide (Helenius et al. 2006). Microfibrils essentially extend into crystalline cellulose bands, the interweaving of which produces a pellicle (Fig. 2a) containing a network of BC fibrous networks (Fig. 2b). It is unknown why these bacteria produce cellulose, but the mechanisms by which they maintain life are close to the surface of the fermentation medium because oxygen content is high close to the surface, preventing the entry of enemies and heavy metal ions into the cellulose culture and providing a protective layer against ultraviolet radiation. Moreover, the nutrients are easily digestible as bacterium meal (Thakur and Thakur 2015).

Production of Bacterial Cellulose from Agro-Industrial Waste

Utilizing industrial waste in production in British Columbia has numerous economic benefits. It can lower the prices of raw materials, waste disposal, and waste management for industrial applications on a big scale. Environmental accumulation issues are usually related to garbage accumulation. In order to obtain goods with additional value, the usage of these raw materials is geared toward environmentally responsible procedures. Agro-industrial wastes can be solids, slurries, or liquids, all of which are potential sources of environmental pollution. They come from cereals (barley, sorghum, corn, wheat, and rice), jute, groundnut, cotton, legumes (tomato, bean, soy), tea, chocolate, coffee, fruits (coco, mango, banana, apple), and palm oil. This waste is formed of cellulose compounds containing essential oils and fatty acids and lignocellulosic biomass including protein, carbohydrates, and nitrogen, depending on the type and method of agricultural labor. In the past decade, as shown in Table 1, numerous studies have employed agro-industrial wastes to create BC.

Producing BC nata or pellicle from agro-industrial particularly pineapple peel extract was accomplished by pulverizing clean pineapple peel in a blender (Fig. 2a) and then straining pineapple peel juice (Fig. 2b). The extract is next sterilized by boiling and placed in a fermenting pan (Fig. 2c and d). The nata was inoculated with bacteria, sealed, and fermented for 14 days. The nata is collected, cleaned, and used for other purposes after 14 days. The clean pellicle was refined with a 1% NaOH solution for 24 h to produce nanocellulose from BC pellicle. After being washed, the pellicle was sliced into little pieces to aid disintegration with a high-speed blender. Five minutes were spent alternating 50 g of pellicle with 100 ml of distilled water in a blender. After 3 min of mashing, add 1 l of water and continue mashing for an additional 2 min to obtain a satisfactory cellulose solution. Using High-Pressure Homogenizer (HPH) equipment, the homogenization procedure was carried out at 150 bar pressure five times for optimal results. The BNC slurries were then filtered to minimize their water content, poured into molds, and dried to produce a membrane or foam.

The HPH procedure data were then filtered for further use in calculating the BNC concentration in the nata solution (Fig. 3). Determine the concentration of the nanocellulose by placing it in distilled water and swirling it with a magnetic stirrer until it is uniform. The homogenization process was aided by an ultrasonic homogenizer. The homogenization products were poured into a flat mold and dried for 24 h at 70 °C in a drying oven or in a vacuum freeze dryer to produce a membrane or foam respectively.

The carbon source is the most expensive component of the cellulose synthesis process. It can account for up to 65% of the total cost of biotechnological processes (R. A. M. de S. Andrade et al. 2015). The yield of BNC synthesis is highly dependent on the medium components and the carbon source. Numerous scientists employ inexpensive waste materials as substrates in fermentation media to reduce the cellulose production cost. Furthermore, the use of waste

Table 1 Composition of fruit-industrial wastes

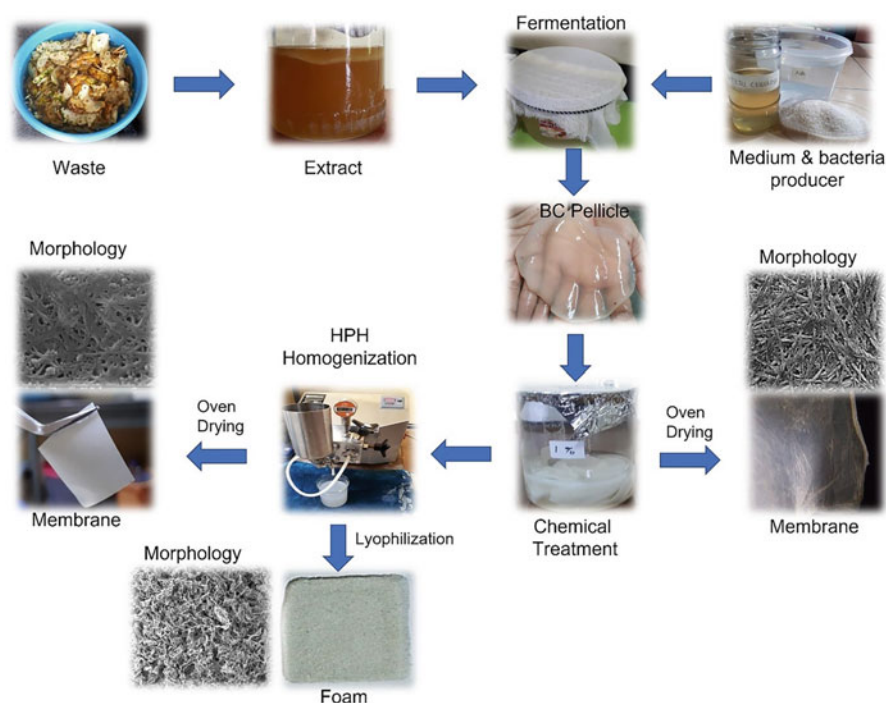

Fig. 3 Production of BC and processing methods

materials in fermentation media increased the efficiency of BNC biosynthesis compared to the use of monosaccharides as carbon sources (Wu and Liu 2012).

Numerous agro-industrial wastes, including potato peel waste, orange peel, coffee skin, pineapple peel, banana peel, cashew apple residue, coconut husk, dragon fruit foliage, and papaya skin, have been explored for the generation of BC. However, there is still much interest in discovering and employing inexpensive substrates that could increase the yield of BNC. In several instances, the culture media supplement, including extracted plant waste components, altered the structure of cellulose. The tensile strength of cellulose formed from rice husk-based medium, which contained hemicelluloses, lignin, and mineral salts, was 79% greater than that of cellulose derived from normal glucose-based medium or reference BC (Goelzer et al. 2009). In addition, the use of biomass waste in the synthesis of BC has positive environmental effects.

The majority of BC products use fruit extracts and coconut water (Suryanto et al. 2020). In 2020, Indonesia was the third largest exporter of processed pineapple in Southeast Asia, behind Thailand and the Philippines, producing approximately 2.45 million tonnes per year (BPS 2021). Supported by a suitable tropical climate, nearly all of Indonesia's area is devoted to pineapple production, resulting in a substantial volume of pineapple peel waste. Sugar, protein, organic acids, nitrogen, minerals,

water, and bromelain are all components of pineapple. It also contains trace levels of every vitamins, except vitamin D. Additionally, pineapple peel is frequently processed into syrup and extracted liquid for animal feed. Bacteria could potentially use pineapple peel as a source of nitrogen and carbon to produce cellulose.

Fermentation Methods

There are two distinct techniques of fermentation for producing cellulose, namely dynamic and static fermentation. In a dynamic fermentation with agitation procedure, BC pellicle is formed into pellets whose size and shape depend on the fermentation and agitation pace. In this instance, pellicle exhibit a greater water-retention capacity, reduced crystallinity, and a disordered structure (Kosseva et al. 2020; Algar et al. 2015). In static fermentation, the liquid/air interface of the liquid nutrient solution produces pellicle. Figure 2a demonstrates that, depending on the container used, multiple pellicle shapes can be created in the form of a film. The thickness of the pellicle is dependent on the fermentation period, which typically does not exceed 14 days, as inhibitory metabolites like as formic and glycolic acid accumulate during prolonged fermentation (Erbas Kiziltas et al. 2015). In this fermentation process, bacteria often form parallel layers of cellulose with a strong and rigid structure (Urbina et al. 2021).

Depending on the bacterial strain, oxygen, carbon sources (often saccharides), temperature, and pH must be added to the fermentation medium. Typically, fermentation occurs at a pH range of 4–7 and a temperature range of 28–30 °C. pH mediums below 4 are not conducive to bacterial development (Sadh et al. 2018). However, a newly identified strain of bacteria (*Gluconacetobacter medellensis*) is able to grow at an extremely acidic pH of 3.5 to manufacture BC with superior characteristics and in large quantities (Castro et al. 2011). This is advantageous in the fermentation process since most microorganisms cannot survive in low pH media, hence preventing contamination with bacteria, fungus, and other yeasts, particularly in large-scale manufacturing.

H–S media, which was created by Hestrin and Schramm, is the most often utilized medium for the production of BC. Citric acid, dibasic sodium phosphate, yeast extract, peptone, and D-glucose comprised the standard medium (Hestrin and Schramm 1954). Various carbon sources, such as sucrose, fructose, mannitol, and glycerol, among others, have been used to modify these compositions (Mohammadkazemi et al. 2015). However, when commercial nutrient sources are used as carbon additions, they increase production costs. Especially for industrial-scale production and BC applications, this is not economically practical. Consequently, a number of researchers have concentrated to develop the cost-effective carbon feedstocks derived from residues and byproducts of various industrial activities as well as agrowaste for the synthesis of BC.

There were multiple attempts to optimize the culture conditions, medium composition, and scaling-up procedure. BC is often synthesized on Hestrin-Schramm (HS) media, which contains glucose, peptone extract, and yeast as carbon and nitrogen sources, respectively. However, glucose is an expensive carbon source for the manufacture of BC. It results in the development of byproducts such as gluconic acid, which lowers the pH of the culture medium and, thus, reduces BC synthesis (Thakur and Thakur 2015).

Several industrial wastes, such as tea infusion, wheat fatty acid hydrolyzate (Hong et al. 2011), grape bagasse and raw glycerol, beet molasses, sugar cane, and corn steep liquor, Konjac powder, fruit juices, including oranges, Japanese pears, apples, pineapples, and grapes, grape juice extracts and sulfur berry liquor, and dried olive plant residues, have been investigated as potential sources of BC. Developing cultivating media based on less expensive raw ingredients will reduce the cost of BC production.

Increasing BC production by adding various chemicals to culture media. Alcohol, vitamin C, lignosulfonates, water-soluble polysaccharides, and thin stillage from wine distillation are examples of chemicals. Six alcohols were administered at varying concentrations during the static fermentation of *G. xylinus* cells (Lu et al. 2011) in order to determine the stimulant perspective of alcohol. All alcohols examined boosted BC production, with n-butanol being superior to ethylene glycol, glycerol, mannitol, methanol, and n-propanol. However, the results demonstrated that n-butanol increased BC synthesis only when added at concentrations below 1.5% v/v (maximum production of 132.60 mg per 100 ml, 56.00% higher than control). In contrast, mannitols only stimulated the bacteria to manufacture BC at a maximum concentration of 4% v/v (maximum production of 125.20 mg per 100 ml, 47.30% higher than control) (Thakur and Thakur 2015).

Gluconacetobacter, Sarcina, and Agrobacterium bacterial species have also produced cellulose. However, only Gluconacetobacter species produce commercial quantities of cellulose. *G. xylinus* continues to be utilized in cellulose synthesis and research. It is a nonpathogenic rod capable of synthesizing relatively large quantities of cellulose from carbon and nitrogen sources. The *G. xylinus* bacteria occurs naturally in unpasteurized fruit, juices, beer, and wine due to sugar fermentation. Recently, the generation of BC from a *G. sacchari* strain employing a carbon source yielded equivalent results to those obtained with *G. xylinus*. Due to their abundance, renewability, biocompatibility, biodegradability, and unique properties, the usage of BC has garnered substantial global attention over the past decade in an effort to raise awareness and demand for biobased eco-friendly functional materials (especially nanometric dimensions and nanostructured networks). The synthesis of nanocomposites with a variety of mixes, including synthetic polymers, natural bioactive substances, and inorganic compounds, is the subject of intensive research and development by British Columbia.

Bacterial Nanocellulose Fibrillation Using High-Pressure Homogenizer (HPH)

The first time Herrick and Turbak used this technique to separate Nano Fiber Cellulose (NFC) from wood fibers was in 1983. Homogenization is one of the mechanical processes involved in the manufacture of NFC. In addition to homogenization, reeving, cryo-crushing, milling, and microfluidization were utilized. A homogenizer-like mechanical use for isolation might also be considered another mechanical technique. Refining, cryo-crushing, and grinding are typically employed in conjunction with homogenization to lower the particle size from micro to nano. Pressure, varying transit periods through the engine (cycles), suspension concentration, and temperature (Kawee et al. 2018) are crucial elements that affect the characteristics of the produced nanofibers. The HPH application successfully enhances cellulose fiber, simplicity, efficiency, reproducibility, industrial scalability, and organic usage without chemical solvents (Li et al. 2012; Wang et al. 2015). However, homogenization is a simple process that does not require chemical solvents. Homogenization is not devoid of issues, but clogging is one of the most essential issues connected with non-uniform micro-sized particles in the early phases, leading to channel blockage. To overcome this issue, an early stage of treatment is required, including the use of pretreatments such as refining, cryo-crushing, and milling to lower the uniform fiber size to below 100 nm.

The high-pressure homogenizer is a device used to reduce and homogenize the particle size of both solids and liquids in solution. HPH is typically employed in the preparation of pharmaceutical and cosmetic components (Abdul Khalil et al. 2014). Figure 4 depicts the process in HPH equipment (Fig. 3) in which a solid particle combined with a solution is sucked into the cavity and subsequently pushed through a narrow gap by a pressure piston, as shown in Fig. 4b. The composite particles undergo dramatic variations in velocity in the material flow, known as cavitation force. Shear force refers to the fragmentation (crushing) of particles as a result of

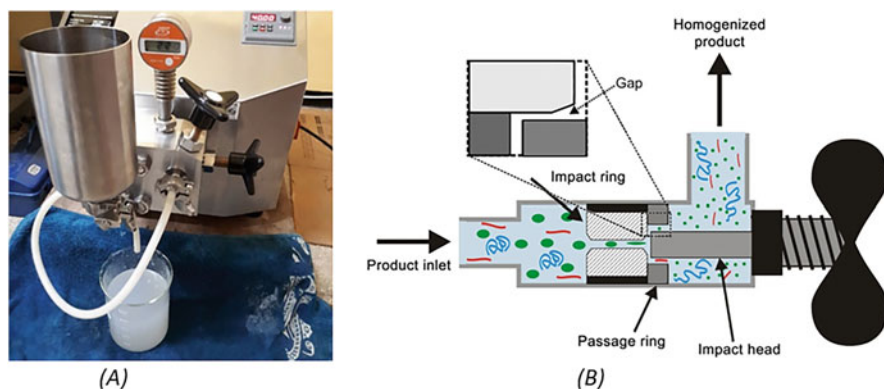

Fig. 4 (a) High-Pressure Homogenizer (HPH) equipment; (b) HPH working scheme (Augusto et al. 2017)

their high-velocity collision with the hollow or narrow slit wall. In addition, cavitation force and shear force contribute to the high velocity of particle impact between particles. The fragmentation of particles into smaller sizes produces a homogenized product (Kawee et al. 2018).

The utilized mechanism exerts high pressure on the solution and goes via a small opening in the pressure-regulating lever. In the homogenization process, HPH generated a combination of shear, impact, and cavitation forces based on precise system settings, including pressure settings and repetition (cycles).

Engineered Bacterial Nanocellulose

BC can be utilized in several forms, such as intact membranes (or pellets or fibers, depending on the production procedure), BC nanocrystals (BCNC), and deconstructed BC. BC was created to obtain particular qualities to fulfill the product's property requirements. Engineering of BC is accomplished by modifying BC using surface functionalization, functional material addition, nanoparticle combination, and polymer composites. Among the techniques for modifying BC are impregnation, disassembly, acid hydrolysis, and in-situ process (Azeredo et al. 2019). Different procedures involving the chemistry of the hydroxyl group can be used to functionalize surfaces (e.g., etherification, esterification, and oxidation). This will enable nanocellulose to have a variety of functional groups, including quaternary ammonium and aldehyde groups, which confer bacteriostatic and biocompatibility (Li et al. 2018).

BC has accomplished functional material addition utilizing an active chemical. Antiviral and antibacterial quaternary compounds (anionic and cationic) such as 4-vinyl pyridine, imidazolium, and pyridinium are added to BC to create antimicrobial agents. Aldehyde compounds are added to BC to increase its antibacterial properties for multiple uses. Oxidants like TEMPO can be used to convert hydroxyl groups to aldehyde and carboxyl functional groups.

Adding nanomaterials to BC typically has a significant effect on their function. BC has been augmented with nanomaterials like carbon nanotubes and graphene for use as electrodes for the direct electron transfer of glucose oxidase. They have numerous potential biomedical applications, including biosensors, biofuel cells, and bioelectronic devices (Kim et al. 2013). Several researchers mixed silver nanoparticles (CN101589854A), TiO₂, ZnO, and Al₂O₃ for antibacterial reasons in various filters. Copper nanoparticles in water filters (Szekeres et al. 2018) and coating materials (Zhou et al. 2020) act as antiviral/antibacterial agents. Copper surfaces can destroy viruses in as little as 8 h, whereas stainless steel and plastic surfaces require up to 72 h (van Doremalen et al. 2020).

BC is a biopolymer that has been included into composites with other polymeric substances. The majority of organic polymers have hydrogen bonding. This unique connection permits the creation of BC composites comprised of many polymers with distinct characteristics. BC composites containing biopolymers enhanced the biomedical uses, conductivity, and physicomechanical properties of BC. For instance,

the synthesis of BC-Chitosan composite was based on Chitosan's active involvement in biomedical domains as an anti-viral, anti-microbial, and anti-fungal agent, drug delivery vehicle, tissue engineering scaffold, wound healing agent, and wound exudate absorbent (Shah et al. 2013). BC-PAni composites were produced by in situ polymerization of PAni in a solution containing a BC pellicle, where PAni formed a layer on the BC surface. The composite possesses a high conductivity, which is increased by controlled acid doping (Shi et al. 2012).

Properties of Bacterial Nanocellulose Membrane

Morphology

Membrane structure is a network-like structure made of tiny fibrils that overlap and a membrane surface composed of several threads interwoven to form a layer of randomly arranged cellulose bands (Fig. 5). Ultrafine lengths of microbial cellulose ranging from 1 to 9 μm produce dense reticulate structures stabilized by hydrogen bonding. The degree of polymerization of plants ranges between 13,000 and 14,000, whereas the degree of polymerization of BC ranges between 2000 and 6000 and even reaches 20,000 (Bielecki et al. 2005).

The shape of BC is dependent by fermentation techniques and bacterial strain. Bacteria are capable of producing solid sphere-shaped BC or flock-shaped BC (Bi et al. 2014). The morphology of the BC film comprises of numerous micrometer-long cellulose nanofibers with an average diameter of approximately 70 nm. The shape of BC nanofibers is characterized by fibrils with linkages and aggregates that are interlinked. As demonstrated in Fig. 6, it generates a three-dimensional structure with variable cavity or pore diameters. These holes are acceptable for use as the composite system's matrix. However, the existence of pores can reduce the tensile strength of a membrane by trapping water molecules and weakening the structure of the fibers (Pa'e et al. 2014).

Fig. 5 Side view of BC membrane (Left) and top view of BC membrane (Right)

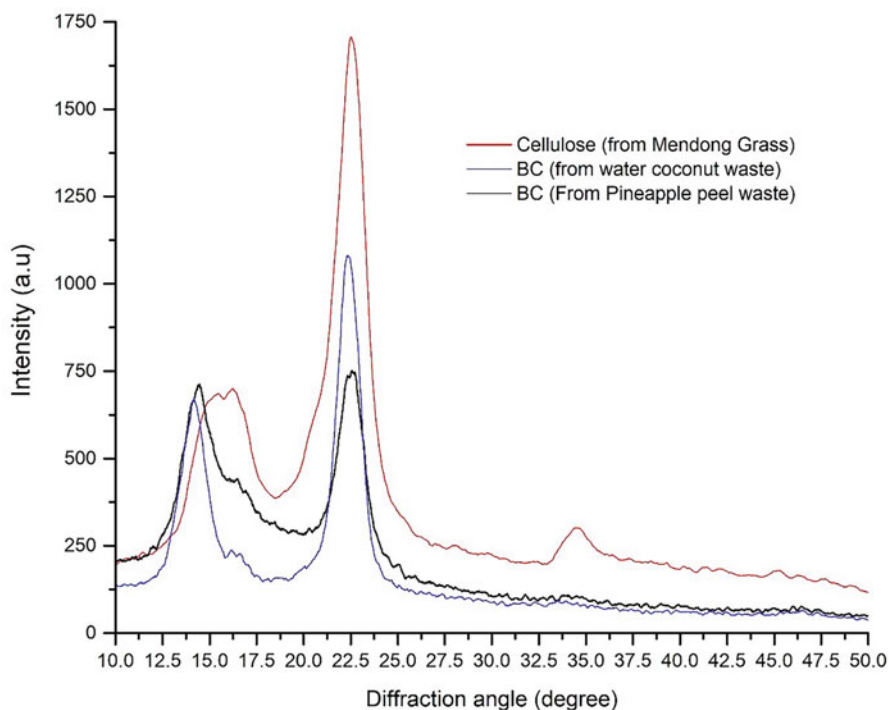

Fig. 6 Diffraction pattern of BC from agro-industry waste and the cellulose fiber from plant

Structure

Figure 6 displays the X-ray diffraction results comparing the structures of BC from waste coconut and pineapple peels with plant-derived cellulose. The bacterial cellulosic diffraction pattern has three peaks at 2θ angle: 14.20° , 16.70° , and 22.40° , but the cellulose fiber from the mendong plant has four peaks: 14.90° , 16.50° , 22.60° , and 34.50° . The first three diffraction peaks correspond to the 10, 110, and 002 crystal planes (Vicente et al. 2017), whereas the last three diffraction peaks from plant fibers correspond to the 040 crystal planes (Suryanto et al. 2018).

Diffractogram patterns can be used to determine the cellulose structure of fibers. The dip between the two peaks in the region at 2θ about 18° indicates the amorphous portion of the cellulose fiber structure, whereas the peaks between 22° and 23° are indicative of native cellulose (cellulose I) (Le Troedec et al. 2008). Therefore, cellulose I is the structure that forms bacteria from coconut water and cellulose. The two leading peaks denote an additional form of cellulose I, wherein the I cellulose structure has peak diffraction angles of 14.90° and 16.70° . In comparison, the structures of cellulose I exhibit peaks at 16.80° and 14.30° (Cheng et al. 2011). Observing the peak of the BC nanofiber diffraction angle revealed a high intensity

peak at 14.20° and a low intensity peak at 16.70° , indicating that the structure of the BC corresponds to cellulose I. The cellulose I has a triclinic structure with the following cell dimensions: $a = 0.674$ nm, $b = 0.593$ nm, $c = 1.036$ nm (chain axis), $\alpha = 117^\circ$, $\beta = 113^\circ$, $\gamma = 81^\circ$, one cellobiose residue per unit cell, a density of 1.582 cm⁻³, and a unit cell volume of 0.3395 nm³. It is known that cellulose derived from mendong fiber has a cellulose structure I with $a = 0.801$ nm, $b = 0.817$ nm, $c = 1.036$ nm (chain axis), $\alpha = 90.0^\circ$, $\beta = 97.3^\circ$, two cellobiose residues per unit cell, a density of 1.599 cm⁻³, and a unit cell volume of 0.6725 nm³ (Suryanto et al. 2014).

The conditions of a region influence the construction of BC structures. In addition to the type of bacteria (Bi et al. 2014), the culture in the reactor and the static culture determines the tendency of the static culture to make cellulose I (Zhou et al. 2007). Moreover, the drying process of BC products relies on the drying technique (Pa'e et al. 2014). The third peak of the cellulose diffraction pattern of plant fibers has a low intensity and is located at 34.5° with a low angle. This peak represents a quarter of the length of the cellobiose unit and emerges from the arrangement in the direction of the fiber. It is sensitive to the alignment of chains into fibrils. Moreover, this peak is an indication of monoclinic structure and is expected in all natural cellulose derived from plant sources (Clair et al. 2006).

The BC degree of crystalline waste pineapple peel was 83.0% and increased to 85.0% after being washed with 5% peroxide (Suryanto et al. 2018). In comparison to BC, nata de coco has a higher degree of crystallinity and crystalline index of 86.5%. In general, the degree of crystallinity of BC is between 87 and 90% (Pa'e et al. 2014). BC has superior crystalline characteristics to cellulose fiber of mendong grass, with a crystalline index and degree of crystallinity of 83.5% and 85.0%, respectively. It suggests that the BC fiber is purer and simpler to produce than plant fiber.

Functional Groups

Infra-red spectroscopy or Fourier Transform Infrared (FTIR) is used to analyze the functional group of cellulose and the characteristics of its chemical bonds. As depicted in Fig. 7, the functional group differences between bacterial and plant cellulose are minimal. Hydroxyl group stretching vibrations at 3481 – 3415 cm⁻¹, CH₂ stretching vibrations at 2902 cm⁻¹, and CH₂ stretching vibrations at 2902 cm⁻¹ dominate the distinctive absorption peak of cellulose. C-OH absorbed water at a frequency of 1633 – 1652 cm⁻¹, C-H bending vibration at 1444 cm⁻¹, C-O-C and C-OH stretching vibrations of the sugar ring at 1085 – 1093 cm⁻¹, and -glycosidic connection between glucose units at 890 cm⁻¹ (Shezad et al. 2010). All samples' spectra exhibited a specific band at approximately 894 cm⁻¹ and a band at 1444 cm⁻¹, thereby identifying them as type I cellulose (Kawee et al. 2018). The positions of the peaks in the FTIR spectra of all samples were not significantly changed, and the cellulose type did not change (type I).

In the process of creating BNC membrane, treatments such as sonication alter the FTIR pattern. For instance, the FTIR signals of sonicated and non-sonicated BC

Fig. 7 Functional groups of BC and plant cellulose

were largely same, indicating that its chemical structure was not significantly altered. However, ultrasonication of variable time altered the wave number and peak intensity of the principal BC spectra. This moving principal peak illustrates the loss of the long-chain BC structure resulting from ultrasonication. The OH-band emerges at 3340 cm^{-1} with an intensity of 24% in unsonicated BC. After 90 mins of sonication, the O-H band shifted to 3335 cm^{-1} at a 21% intensity. After ultrasonication, the bands at approximately 2950 cm^{-1} and 1641 cm^{-1} , which correspond to C-H and C-O stretching, respectively, also shift. The C-H stretch for unsonicated BC emerged at 2897 cm^{-1} with an intensity of 67%, but changed to 2902 cm^{-1} with an intensity of 56% after 90 mins of sonication (Abiral et al. 2018).

Mechanical Properties

In defining the application and technological procedure for employing BC films, the quality of BC is crucial. Depending on the polymer modification technique, cellulose's tensile strength can vary. BC possesses a favorable attribute known as film strength, which influences the strength of the end goods manufactured from this polymer. BC film offers greater strength qualities than other commonly used polymers when it is in film form. Comparatively, the tensile strength of BC films (200–300 MPa) is significantly greater than that of polypropylene (30–40 MPa)

and cellophane (20–100 MPa) (Betlej et al. 2021). The strength, hygroscopicity, and water vapor permeability of BC film are significantly altered by chemical reagent modification. Additionally, nonlinear BC networks can reduce the mechanical strength of BC films (Hsieh et al. 2008). By incorporating different substances into the polymer, the desired traits and characteristics can be achieved. The addition of montmorillonite to the cellulose-based composite decreased its tensile strength while increasing the polymer's permeability. The addition of BC to paper pulp increased the paper's tensile strength and affected its stiffness (Gao et al. 2011).

Water Holding Capacity and Water Release Rate

The water holding capacity and water release rate of a nano-bacterial compound's pellicles are of enormous importance, particularly if the substance is intended for medical applications such as wound binding and tissue engineering. As a result of their high porosity and surface area per unit, bacteria nanocompounds that are hydrogels retain the majority of the water. The highest water absorption capacity of nano-bacterial compounds measured 104 g/g, whereas the lowest water holding capacity measured 97.3 g/g. These behaviors indicate that the WHC profiles are consistent with the electron microscopy scan report and confirm that agricultural industry waste has a minimal effect on the size of the fibers and holes or the fibrous branching scheme. In contrast, the water content of nano-bacterial compound products over a period of 48 h affects the rate at which water exits the films. The ability of the bacterial nanocomposite to load water is mostly attributed to the glucan-forming hydrogen bonds. The drying response of a bacterial nanocomposite occurs in two stages: surface evaporation as a visible process dependent on temperature, humidity, and air velocity, followed by heat transfer and non-bonding of interior water molecules caused by the simultaneous breakdown of hydrogen bonds.

Bacterial Nanocellulose Composite Application

The BNC's unique feature is its broad usage potential for different applications. Due to its unique physicochemical and mechanical properties, BNC can be used in various specific fields, as follows:

Biomedical Application

Blood vessels, vascular, biosensing artificial cornea, artificial bone, artificial cartilage, artificial urethra, neural tissue, adipose tissue, wound dressings, controlled cell transfection, and drug administration can all be engineered using BC. Chondrocytes are the most abundant particles that make up cartilage in the field of cartilage engineering. Since Chondrocytes do not divide, cartilage tissue repair is very slow because there are not enough vessels and nerves to carry out the necessary

metabolism; therefore, this is a significant challenge in tissue engineering. Numerous BC characteristics can be employed as scaffolds to replace cartilage, induce the development of new tissue, and promote cell proliferation and growth. Using BNC for injured bone tissue is a rapidly emerging way of bone repair, as conventional procedures like as bone grafting have their own disadvantages, such as disease transmission and immunological rejection (Nemati and Gholami 2021).

The extraordinary efficacy of BC as a root canal filling material for intracanal asepsis in experimental animals. BNC demonstrated superior biological properties and compatibility for tooth canal therapy. Comparatively, BC has a greater expansion capacity and liquid absorption capacity than conventional methods employing conventional paper point materials (de Oliveira Barud et al. 2016).

BC membranes provide potential for nanostructured drug release systems for illegal substances or active compounds such as lidocaine hydrochloride, ibuprofen, and caffeine, while also providing an effective physical barrier against external infection. BC has also been regarded as an exceptional non-allergenic biomaterial for usage in the cosmetic sector as a facial mask for dry skincare and natural facial scrubs or as a cleansing agent (Dasan 2015).

Electronics Application

The application of BC in electronics has attracted significant interest in order to build new substrates with the required thermal stability, transparency, and flexibility, as well as sustainability and recyclability, for the development of electronic devices. Nanocellulose-based nanocomposite satisfies this criterion due to the BC features of superior mechanical qualities, thermal and surface stability. Its shape makes it desirable for use in electrical applications, such as dielectric material organic light emitting diodes (OLED), solar cells, capacitors and supercapacitors, and transistors.

Dielectric materials are insulators with interfaces that contact semiconductor or conducting materials. BC possesses good intrinsic insulation properties. Therefore, its application enhances the insulating property of standard paper. BC can be used as a fractional-order material to create electronic devices from polymer fractional-order BC-based materials.

BC also introduces innovative new features to OLED manufacture. OLED devices must be transparent and flexible because they are utilized in the screens of portable devices, monitors, and televisions. When the diameter of BC is less than one-tenth of the wavelength of visible light, it becomes a medium that scatters light freely. Consequently, BC with an ultrafine network was utilized to make translucent paper. The primary benefits of electronic paper are its high reflectivity, flexibility, contrast, and biodegradability in rewritable maps, paper, dynamic wallpapers, e-newspapers, e-book tablets, study tools, biosensors or actuators, and audio speaker diaphragm membranes. BC is also superior for membranes in headphones and loudspeakers (Dasan 2015; Tsalagkas 2015).

Energy Application

Solar energy harvesting devices with good charge transport capabilities and a large surface area can capture photons and transform them into electrical energy more efficiently. The mechanical properties of BC with a three-dimensional (3D) mesoporous structure are equivalent to those of other fibrous materials (e.g., glass fiber and carbon fiber) with a very large surface area. Therefore, BC can be utilized as a template or matrix in the production of photoelectrodes via 3D nanostructure processing. In addition, hydrophilic mesopores in cellulose films may serve as optimal host matrices for embedding catalyst nanoparticles with minimal agglomeration. So, BC networks can be condensed to generate optical characteristics that optimize photon absorption (Wang et al. 2017).

The photo-electrochemical separation of water is a novel technology for converting solar energy directly into hydrogen fuel. This approach is comparable to the creation of solar cells, comprising broad-band light absorption, a wide surface area for reduction-oxidation reactions, and rapid charge formation and separation. Consequently, photo-electrochemical cells also benefit from the structural benefits provided by 3D nanocellulose-based architectures.

Most lithium-ion (LiB) battery technologies use a PVDF membrane as a binder and a volatile and toxic chemical solvent for processing, such as N-methylpyrrolidone (NMP). Both NMP and PVDF are expensive and challenging to recycle materials. The replacement of organic solvents with carboxymethyl cellulose (CMC) to prevent economic, safety, and environmental issues. CMC is a water-soluble derivative of a linear polymer of cellulose with varying degrees of anionic substitution of carboxymethyl groups. Recent research has utilized 100% cellulose paper sheets for both the separator and electrode substrate of LIBs. These cellulose paper-based LIBs are flexible and thin, which gives them an advantage in several applications where conventional LIBs cannot perform, such as batteries for flexible electronics that require irregularly shaped batteries that can conform to the shape of a space, such as in electric vehicle door trims (Wang et al. 2017).

Widely used commercial alkaline batteries has high porosity, low cost and weight, strong mechanical qualities, and excellent wettability of cellulose paper sheets. Its use in LIB is restricted due to its poor thermal shutdown performance, which halts ion flow at high temperatures. Another worry is the hydrophilicity of cellulose paper, which can lead to lithium salt deterioration by absorbing a great deal of water. Nonetheless, some researchers resolve this issue by treating cellulose paper with extended heat treatment. The cost of manufacturing this separator is projected to exceed 20% of the entire cost of the LIB. In light of the relatively low cost of cellulose, attempts are underway to employ cellulose paper and its composites as LIB separators to replace the high cost of conventional membranes (polyethylene (PE)/polypropylene (PP)), particularly for low-power applications.

Piezoelectric nanogenerators based on cellulose are another use of the mechanical energy harvesting technique. Crystalline cellulose is the most recognized polymer piezoelectric material. Until the discovery of cellulose paper (also known as EAPap, which is an abbreviation for electro-active cellulose paper) that exhibits the

phenomena of actuation, piezoelectric qualities were first identified in natural wood. Polarity of the piezoelectric arises from the alignment of glucose units along the C2 monoclinic crystalline lattice via glycosidic bonds (Kim et al. 2006).

Food Application

As a component in traditional Southeast Asian desserts originating in the Philippines, BC is known as “nata de coco.” This meal has rapidly gained popularity and expanded around the globe. BC is made by fermenting coconut water to create nata, which is then sliced into pieces and soaking in sugar syrup. BC is also utilized in the food business as a possible stabilizer, stabilization, gel, and suspending agent. For instance, ice cream containing BC can retain its form for at least 60 min following removal from the freezer. There are numerous varieties of nata, including nata de pina made with pineapple juice, nata de coco made with coconut water, nata de soya made with tofu waste, and nata made with vegetable media. BC can reduce the risk of chronic diseases including diverticulitis, obesity, diabetes, and cardiovascular disease (Shi et al. 2014; Iguchi et al. 2000). BC has been utilized to generate low-fat ice cream with enhanced stability, emulsifier, rheological, and resistant capabilities in comparison to conventional ice cream. BC can also be added to mayonnaise products as a fat replacement with acceptable rheological and sensory properties.

BC has been investigated as a packaging material in the food packaging industry due to its strong web and barrier qualities. Paper is a significant material and is viewed as a good alternative to synthetic plastics; hence, paper-based materials are selected as packaging materials due to the fact that paper is both renewable and recyclable. Utilizing nanoparticles in papermaking technology allows for the production of paper with enhanced barrier and processing, strength, and hydrophobicity features. Due to the substantial reduction in oxygen molecule penetration through densely entangled fibrous structures, the paper manufactured from BNC possesses desirable qualities such as optical transparency, thermal stability, high strength, and superior oxygen barrier capabilities. With conventional micro-sized pulp paper, this feature could not be obtained. In certain items, color film is effective for both consumer appeal and food protection from the adverse effects of light. (Urbina et al. 2021) BNC nano paper (from biomass residue) coated with poly-hydroxyalkanoates (PHAs)/biomass extract is effective for food packing.

In addition, BC has been utilized as “active packaging” with components that absorb or release substances into or from packed foods or the surrounding environment to maintain freshness, extend shelf life, or improve the conditions of packaged goods. As a wrapping for ground beef, antimicrobial Nano paper has also been utilized by impregnating BNC with lyophilized post-biotic *Lactobacillus*. Additionally, the tailored films are antibacterial against *Listeria monocytogenes*. The addition of BC to food packaging manufactured from potato skin film can increase tensile strength and decrease moisture content, oxygen permeability, and water vapor permeability.

Environmental Application

Current environmental restrictions mandate the use of bio-based products and green materials in order to invest in green processes, industrial ecology, and sustainability. In addition, efforts should be made to create a healthy aquatic ecosystem because it is well recognized that water is the end destination of direct and indirect pollution (Pawar et al. 2018). The handling of wastewater containing heavy metals is one of the technological issues associated with preserving environmental quality. BC becomes a potential alternative material for wastewater purification and reuse technology due to its robust 3D nanofibrillar network with good structure. BC satisfies the requirements to develop a particular material for environmental applications and usher in a new era of biodegradable materials.

Various industrial processes in the battery, leather tanning, and fertilizer industries are frequently linked to heavy metal contamination in the environment. Heavy metals are extremely hazardous because they have the capacity to accumulate, resulting in greater exposure of organisms to these metals than can be found in the environment alone. Heavy metals are extremely hazardous since they can accumulate in organisms after being exposed to more of these metals than can be found in the environment alone; therefore, heavy metals from wastewater must be removed from polluted rivers. The BC membrane can serve as the template for this endeavor. BNC membranes are typically paired with chelating or absorbent agents such as ethylene diamine tetra acetic acid (EDTA), graphene oxide magnetic nanoparticles, chitosan, or chemical reagent modifications such as oxidation using 2,2,6,6-tetramethylpy-peridine-1-oxy radicals (TEMPO-oxidation). BC has been demonstrated to be an effective template for removing, among other elements, arsenic (As), chromium (Cr), iron (Fe), lead (Pb), strontium (Sr), and copper (Cu), with an antimony (Sb) removal effectiveness of up to 90% (Urbina et al. 2021).

Optical Materials

Nanocellulose can be modified with different top layers, polymer chains, or other nanoparticles to achieve biotechnological sensitivity at the lowest cost; these processes enable the detection of objects with interesting features and functions on their surface, particularly through optical applications. The primary objective may be the creation of chiral and metallic compounds from cellulose nanocrystals and other polymers or silica; this enables the component to be removed selectively or utilized in nanocomposites. Special removal of the nanocomposite's original component yields a chiral mesoporous material that can handle or act as a template for other materials. To improve the material, cellulose nanocrystals were employed to add upper plasmon, UV, and fluorescence inhibitors as well as lower light reflectors.

Wood Adhesives

In wood adhesion technology, the primary adhesives are formaldehyde-based adhesives such as phenol-formaldehyde resin, urea-formaldehyde resin, and melamine-formaldehyde. However, the usage of formaldehyde is problematic due to its extracts and other organic molecules that are flexible. Because of this, bio-based nanocellulosic materials are developed to alleviate these deficiencies, promote sustainable development, and deliver the benefits of their regeneration. In addition, cellulose nanomaterials in wood adhesion formulations considerably enhance adhesive bonding effectiveness and stability under both wet and dry circumstances and function as a stabilizing agent. However, the substantial increase in viscosity generated by its addition restricts its concentration. Nanocellulose's introduction of a nano-biomaterial that is stable, bulky, and inexpensive for material development is gaining appeal among common adhesives and, in particular, wood adhesives. Improving the mechanical and physical properties of panels, changing adhesive structures, and reducing formaldehyde emissions are, thus, the primary benefits of employing nanocellulose as a means of boosting the manufacture of sustainable wood panels. The addition of cellulose nanofibers to melamine-urea-formaldehyde and urea-formaldehyde adhesives strengthened the cellulose nanofibers environment, increased strength and durability, and enhanced the mechanical properties of the board.

Cosmetics

Additionally, nanocellulose has been utilized and promoted within the cosmetics business. In recent years, cellulose microfibrils have been included in candy bags and other cosmetic goods. On the other hand, micro cellulose bacteria have a few aesthetic applications because of their unique features, particularly as a skin-supporting substance or cosmetic agent in cosmetic production. Additionally, bacterial cellulose has been utilized as a medication delivery support, which is efficient for both hydrophobic and hydrophilic medicines. Consequently, a cellulose-coated bacterial film created in the converted region was successfully used to create a sheet mask that has the effect of hydrating and treating acne- and inflammation-prone skin. There is a potential that the use of 1,3-dihydroxy-2-propanone in the formulation of microbial nanocellulose compounds will not cause skin allergies in another patient with vitiligo. This substance applied to the skin with bacterial cellulose does not produce a distinct odor, a common adverse effect of commercial cosmetics.

Textile

Due to their cellular structure and vast functional location, nanocellulosic materials have proven useful in the textile industry, particularly for medicinal purposes.

Special characteristics include non-static behavior, low pollution, and humidity levels, and superior mechanical and liquid marketing properties. Antimicrobial activity is one of the most intriguing features of cellulose fibers. Currently, cellulose fiber surface modification is regarded as one of the most effective methods for enhancing the durability of medical fabrics. For instance, cellulose reacts with methylol-5, 5-dimethylhydantoin coupled with hypochlorite to generate chloramine on the fiber's surface, which has antibacterial properties. The manufacture of ethyl cellulose nanocompounds employing spiro oxazine as a light stabilizer is another approach. During the high-temperature printing process, nanoparticles of cellulose preserve their photochromic characteristics without sacrificing their physical qualities.

CO₂ Capture

These nanomaterials, particularly active nanocellulose aerogels, can be employed to store CO₂ selectively as adsorbents or membranes. In this way, nanocellulose has been utilized to substitute physical hydrogen bonds or chemical bonds, such as borax, epichlorohydrin, or glutaraldehyde cross-linked hydrogel, which can be transformed to aerogel in ice-free cycles. CO₂ capture by chemisorption is enhanced by the modification of nanocellulose aerogels containing silane such as 3-amino propyl methyldiethoxysilane, 3-silane derivative, and N-2-aminoethyl-3-silane derivative. Utilizing fibrillated nanocellulose aerogels produced with acetate-functionalized crystalline nanocellulose suspension, CO₂ storage via physisorption was also done.

Challenges

Once implemented, specific applications for the extraction of nanocellulose from diverse biomass wastes support the efficacy of novel technology in the production of certain high-value goods. However, technological obstacles and financial concerns must be resolved prior to mass manufacture and utilization. The collection, transportation, and storage of biomass waste, as well as the use of expensive enzymes or chemicals, as well as high energy consumption, are the most expensive barriers. To achieve manufacturing on an economic scale, it is important to develop efficient methods to produce nanocellulose with outstanding characteristics, the same size at cheap, low energy consumption, low-cost chemicals, and with active enzymes. In terms of technological obstacles, the creation of effective pre-treatment and precise change of structure and function stand out.

Preparing high-quality nanocellulose, especially for biomedical purposes, necessitates a process that effectively removes contaminants while leaving the cellulose unfinished. Because of the inherent features of nanocellulose, such as bioinertness, hydrophilic property, and heat dissipation, precise performance is needed to improve the performance for a specific application. In addition, choices must be taken to assess the advantages and downsides of employing micro cellulose. For instance, the

reinforcement using cellulose nanofibers to paper production can increase their strength, but it may also limit the slurry drainage capacity, so decreasing the efficiency of production. Even though there are some disadvantages to using nanocellulose, its superior mechanical qualities, high altitude, environmental friendliness, natural decay, recycling, and non-toxicity attract an increasing number of researchers to develop end-product applications with added value.

Conclusions

Agro-industrial wastes can be solids, slurries, or liquids, all of which are potential sources of environmental pollution. Utilizing agro-industrial waste for a variety of community uses contributes to the valorization and enhancement of the waste's value-added. There are numerous methods for utilizing agro-industrial waste to create goods with additional value in the sectors of biomedical application, energy harvesting and storage, food and packaging, and electronic materials. From a waste biomass extraction standpoint, cellulose can be synthesized via bacterial fermentation. It is possible to extract cellulose from plants, algae, tunicates, and bacteria. The cellulose manufacturing pathway in bacteria involves a multistep reaction involving regulatory proteins, catalytic complexes, and specific enzymes via both static and dynamic fermentation processes. Waste extracts used as carbon sources in a fermentation medium. BC was created to obtain particular qualities to fulfill the product's property requirements. Engineering of BC is carried out by modifying BC through surface functionalization, addition of functional material, combination with nanoparticles, and composite with other polymers, resulting in the enhancement of BCN properties. Future research must focus on the exploitation of BC synthesis and extraction so that this technique can be broadly used for nanocellulose-based products.

Acknowledgments The authors wish to thank the Universitas Negeri Malang for funding this activity through the 2021 PNPB funds.

Abstract

The marine ecosystem is a world of various microbial diversity having numerous bioresources that are relatively unexplored and require more studies for the isolation and identification of the natural novel products, especially biopolymers. Biopolymers are the polymers produced by living organisms, including bacteria, fungi, algae, and plants. The wide variety, renewable nature, lower toxicity, and unique structural and physicochemical behavior, etc., of biopolymers has gained attention in the scientific community and in various industrial sectors. These biopolymers from living organisms, composed of various monomers as building blocks for larger structures, bonded with covalent bonds. Most biopolymers are biodegradable materials. The biodegradable polymers are used in wide areas and have also resulted in the development of a variety of commercial products. Many of these biopolymers, such as polylactic acid, are naturally occurring polymers and poly beta hydroxybutyrate polymers are used as plastics; they may also be used as the need for polyethylene or polystyrene-supported plastics increases. The process of the synthesis of marine bacterial polymers and other prokaryotic biopolymer-based materials is influenced by marine environmental factors such as the microbial population, pH, and temperature. The natural biofilm producers are isolated from different marine habitats such as sediment, the Arctic, the Antarctic, deep sea, thermal vents, and cold ice, which have a higher quantity of bacterial exopolysaccharides.

Keywords

Exopolysaccharides · Biofilm · Bacterial EPS · Marine polymers · PLA · PHA

Introduction

Biopolymers are a type of polymers that are formed during/between the growth cycles of a living organism through various metabolic processes. Many of these biopolymers are discovered from prokaryotes and other natural sources. These biopolymers are biosynthesized or chemically synthesized from biomaterials by the organisms. Most of the biopolymers are derived from prokaryotes, mainly bacteria, plants, and fungi. Biological polymers attract more attention owing to their complexity, biodegradability, nontoxicity, abundance, biocompatibility, and their applications in various areas. Synthetic polymers such as plastics and other nonbiodegradable polymers cause environmental pollution. Around 140 million tonnes of synthetic nonbiodegradable polymers (man-made) are synthesized every

year for various purposes and cause major environmental issues. Biopolymers can be classified on the basis of various criteria such as origin, types, basis of degradability, number of monomeric units, heat responses, etc.

In prokaryotes such as bacteria, the intracellular polysaccharides are produced inside the cell as a cytoplasmic plasma membrane, whereas polysaccharides in bacterial cell walls act like a structural composition. Extracellular polymeric polysaccharides or exopolysaccharides (EPS) are covalently bound to the outer surface of a cell as capsule, sometimes these substances are loosely bound to cell surface as a form of slime. Most of bacterial cells capable for produce EPS in natural conditions to the extracellular surfaces and few microbes with greatly capable to secrete EPS in higher quantity when they are in stressful conditions (Papinutti 2010). Comparing with the production of hydroplant, bacterial EPS production is time saving i.e., take 2–3 days and the another advantage is that EPS production does not need land for cultivation and the waste products such as glycerols and hydrocarbon residues from industries are used as carbon substrates. These advantages in the production cost of EPS, is crucial factor that restraining the production and are industrially powerful substances. The main expenses are for the substrate required for the maximum growth of microbial cells on the bioreactor. Extensive studies are needed to optimize the ability of microbes to produce more EPS for the formulation of novel biocompounds, which is beneficial for multiple research areas. A comprehensive study is necessary to understand the physical and chemical properties of bacterial polysaccharides and could be more helpful for researchers in developing more useful compounds in various areas.

Biopolymers from marine sources such as bacteria and archaeobacteria, have novel biocompounds with higher biological activities and applications on a commercial level. The important characteristics of EPS from marine bacteria and the pigment produced by marine organisms such as carotenoids and melanins, can improve the survival/defensive mechanism of the organism. These biocompounds can be exploited for various products ranging such as adhesives, emulsifiers, and surfactants. Numerous marine biopolymers are significant, unidentified, unexplored, and undeveloped biological resources.

Bacterial Biofilm and Exopolysaccharides

In the marine ecosystems, microorganisms are the normal biota and are found in various areas in the oceans such as open oceans, marine sediments, marine organisms, and the other marine surfaces. The term ‘biofilm’ was first introduced by in 1978 by Corterson, and is a surface-attached (sessile) microbial community that are grown covered or surrounded by an EPS produced by itself. Biofilms are tightly packed communities of microbial colonies that can develop attached to a natural or synthetic surface, in an aquatic and soil environment, medical equipment, living tissues, water piping systems in potable and industrial usage, and are responsible for the formation of multicellular communities of biofilms (Dalton and March 1998). The colonization of bacterial cell on surfaces such as metal, concrete, biotic, and suspended particles, are survival strategies for microbes because this colonization gives more advantages in access to nutrients, protection from antibiotics and toxins,

maintaining the activities of extracellular enzymes, and protecting them from predation. The rates of the biofilm formation process vary widely depending on the type of microorganisms and environmental conditions such as the characteristic of a selected medium, temperature, pH, and ionic strength, factors that have an influence in changing the physicochemical properties of a bacterial surface and the microbial adhesion to the substrate (Hamadi et al. 2004).

As for the bacterial cells in a biofilm embedded in EPS, these extracellular polymeric substances comprise capsular polysaccharides, which produce a cohesive layer or capsule that is tightly linked to the cell surface, and the extracellular polymeric substances/ EPS secrete a layer of loosely attaching slime to the surface of the bacterial cells or into the outer environment. At the time of processing of the colonization on the surfaces, bacterial cells secrete extracellular polysaccharide substances that construct the biofilm matrix (Geesey and White 1990). Capsular EPS are produced mainly during the second phase of growth, i.e., the log phase, and slime EPS production mainly takes place during the stationary phase. Microbial cells commonly contain various polysaccharide structures and have a key role in maintaining shape and rigidity. Mainly they are able to produce polysaccharides characterized by the cellular location and their function. There are three mainly types:

- (a) Intracellular polysaccharides, are the storage form of carbon.
- (b) Cell wall polysaccharides such as teichoic acid and peptidoglycan.
- (c) Extracellular forms, EPS secreted in the growth medium and capsule in the outer side of the cell surface.

The outer capsular structure acts as a major protective cover of the cells from adverse environments such as toxic substances, osmotic pressure, temperature, oxygen tension, and may take part in the intake of the metal ions (Cerning 1990). The presence of EPS involved in biofilm formation also supports the interaction of bacteria. Almost all of the microbes are capable of producing a highly viscous layer surrounding the bacterial cell, which may give protection against phage attack or desiccation (Gruzdev et al. 2011) and some microbes are able to synthesize an EPS that gives the microbial cells protection from abiotic stress. EPS facilitate the free living organisms to attach and colonize on a biotic or abiotic surface where the nutrient components are accumulated. Some of the bacterial EPS are able to exhibit flocculating properties. Environmental factors such as heat shock, cold shock, acidic or alkali shock affect the productivity of secondary metabolites. Various studies have proved the involvement of environmental stimuli in the enhancement of the production of secondary metabolites. Microorganisms have the ability to adapt to the stressful situations in their natural environment.

A total of 32 bacterial species are isolated and identified based on physiological, biological, and molecular characteristics, mainly including the species of *Micrococcus*, *Klebsiella*, *Vibrio*, *Pseudomonas*, *Staphylococcus*, *Salmonella*, *Chromobacterium*, *E. coli*, *Halomonas*, *Bacillus*, etc. (Nisha et al. 2020). Some of the studies reported on the isolation and identification of bacteria from marine

biofilm attachment on the surfaces, isolated 11 bacterial strains from the ship hull, and identified morphological, biochemical, and molecular characteristics. Sravankumar et al. (2014) identified three genera of ten species, including *Bacillus* sp., *Vibrio* sp., and *Serratia* sp., from a marine biofilm attached to artificial surfaces (iron panels) based on Bergey. Marine organisms such as *Shewanella oneidensis*, *E. coli*, *Pseudomonas aeruginosa* (Lee and Newman 2003), *Vibrio proteolyticus* (Paul and Jeffrey 1985) and *Bacillus subtilis* (Omoike and Chorover 2004) were able to be involved in the process of biofouling. Marine bacterial species such as *Micrococcus*, *Halomonas*, and *Bacillus*, isolated from marine sediment, were studied by Abdelnasser Salah Shebl Ibrahim (2008). Most of the organisms that were subjected to screening were capable of producing biofilm on the steel surfaces except for some of them. *Micrococcus luteus* produced more biofilm than any other of the study organisms. A similar study reported that a marine *Micrococcus* sp. was able to attach onto steel surfaces (Nisha and Thangavel 2014). Attachment is the primary process in biofilm formation and the density of biofilm is dependent on the surface. Biofilm producing 82 bacterial species from the ship hull (MV-Balavan) at Cochin, Kerala. Another biofilm producer was analyzed using the crystal violet binding assay method and was identified as *Micrococcus luteus* by 16SrRNA sequencing (Nisha et al. 2020).

The bacterial EPS acts as a mechanical barrier between some bacteria and defense compounds of plants such as polymers from *Pseudomonas syringae* pv. *phaseolicola* and *Sinorhizobium meliloti*, which can be resistant against reactive oxygen species secreted by host plants at the time of infection (Lehman and Long 2013) and decrease oxidative stress. In some bacteria, polymers are involved in virulence and in pathogenicity. *Erwinia amylovora* shows high virulence owing to the production of levan and amylovoran and also decrease plant colonization. A study on *Rhizobium* NZP2037 reported that it is able to use its own poly-beta hydroxybutyrate and use EPS in carbon-restricted situations as a whole source of carbon and survived (Patel and Gerson 1974). The chemical characteristics of EPS such as pH, surface properties, metal content, ionic content, play a key role in metal biosorption (Fukushi 2012). These EPS can accumulate the other nutrients when grown under conditions of an additional supply of carbon. *Paenibacillus jamilae* produce EPS, and its biosorption capacity on various metals was studied and found to adsorb heavy metals such as Cd, Cu, Zn, Ni, Co, and Pb, and have maximum interaction with PB and a higher binding affinity of 303.03 mg/g (Morillo Pérez et al. 2008). Some of the studies on remediation in heavy metal areas for the recovery of the polluted environment revealed the capability of bacterial EPS on metal absorption. These microbial EPS are also capable of binding, absorbing or trapping some metal ion colloids, clay minerals, oxides, etc. The EPS from *Azotobacter chroococcum* XUI is capable of absorbing 47.87 and 40.48% Hg and PB respectively (Rasulov et al. 2013). The bacterial polymer xanthan showed Cu absorption with unusual biosorption and decreased pH 3.5 to 5.5 (Causse et al. 2016). Most of the bacterial EPS are composed of various components such as carboxyl groups and hydroxyl functional groups, EPS are negatively charged owing to these components (Ding et al. 2018). Another study on polymers from *Nostoc muscorum* and *Anabaena*

variabilis showed biosorption with Cu, Co, Zn, Cd, and Ni, with maximum affinity for Cu. Similarly, the EPS produced *Pseudomonas* sp. CU-1 to protect the cells from heavy metals because it has an ability to bind with Cu (Lau et al. 2005).

Microbes producing EPS got an advantage from the stress of drought environmental conditions. The EPS from *Pseudomonas* spp. from soil have a higher water-holding capacity and had altered moisture when added to sanded soil (Roberson and Firestone 1992). Some cyanobacteria, including *Nostoc calcicola* and *Phormidium* 94a, were isolated from a desiccated area producing EPS, which is also capable of nutrients, water retention, and a survival mechanism (Bhatnagar et al. 2014). EPS produced from *Planococcus rifietoensis* RT₄ and *Halomonas variabilis* HT₁ were inoculated into chickpea plants and various factors were studied. The results showed increased plant growth, that soil aggregation improves more than 75% in elevated salt stress, and protected the plants from salinity (Qurashi and Sabri 2012). Bacterial EPS produced by plant-associated organisms was also able to involve the plants in salt stress tolerance. The biopolymer from NaCl-tolerant bacterial species can decrease the uptake quantity of Na by the plants by decreasing the amount of ions (Upadhyay et al. 2011) and preventing osmotic stress, which can also promote the survival of microbes and is useful for plants. Bacterial EPS protect the cells from desiccation/drought like a protective soft sponge and show structural modifications during desiccation and can trapped nutrients and water, also act as a protecting factor for the survival of the microbial cells (Roberson et al. 1993).

Microbial extracellular polysaccharides can protect the thermophiles, they cannot dissolve at high temperatures, and acts as shielding for the microbes. These characteristics were studied in thermophiles such as *Geobacillus tepidamans* V264 and *Bacillus* sp. B3-72 (Kambourova et al. 2009). Microbes producing EPS can alter the microstructure and desalination and improve the habitability and survivability of the microbes (Krembs et al. 2011). These extracellular polymeric substances from archaea and thermophiles have a unique slime layer/EPS with a large number of potential applications in various industries. Microbes living in sea-ice can produce EPS, play a key role in cryoprotection, and have adaptations at low temperatures and also high salt concentrations. Higher EPS production was shown by organisms isolated from Arctic sea-ice and they are capable of protecting the microbial cells from harsh environmental conditions (Caruso et al. 2018). Extracellular polymeric substances can be a protection factor for thermophilic bacteria by shielding microorganisms from very high temperatures. The polymers produced by *Bacillus* sp. strain B3-72 and *Geobacillus tepidamans* V264 are not easily dissolved at high temperatures (Nicolaus et al. 2000). Biofilm producers have lower susceptibility to antimicrobials than the microbes than free living ones. These biofilms possess negative charge and are capable of binding with positive charges molecules and protect the cells. Numerous studies reported the potential capacity of bacterial EPS against antimicrobial agents and pathogens. The EPS produced by *Acinetobacter baumannii* have antibiotic sensitivity against tobramycin (Davenport et al. 2014) and a similar study on slime/EPS from *Staphylococcus* spp. showed effective antagonistic activity against pefloxacin, tobramycin, and teicoplanin (Souli and Giamarellou 1998) (Table 1).

Physical and Chemical Properties of Biopolymers

Polymers or macromolecules from microbes are classified by different possibilities such as by source, structure, synthesis, and molecular forces. These macromolecules are high molecular compounds 10,000 to 10,000,000 Da in mass. The polymers are mainly of two major groups of polysaccharides depending upon structural unit, homopolysaccharides, which consist of only one sugar component, and heteropolysaccharides, which consists of two or more sugar components.

Also, there are two types based on source, natural polymers, e.g., nucleic acids, proteins, polysaccharides, and natural rubbers, and synthetic polymers, e.g., Teflon, polyethylene, PVC, and polystyrene.

The biopolymers are classified based on structures in to three groups: linear polymers, where monomers are joined to form a straight long chain, owing to the close packing of polymer chains (these polymers have high tensile strength, a high melting point, and high densities; branched chain polymers, where monomer units are combined to produce a main chain or a linear chain that also forms a branch along the main chain; cross-linked polymers, three-dimensional (3D) networks polymers, where a linear chain is initially formed, which are joined together to form cross-linked polymers.

Depending on the molecule formed the polymers are of two types, globular and fiber, and by the nature of the atom, polymers are classified in to carbon-containing polymers, heteropolymers, organic element, and inorganic polymers.

The biopolymers from bacteria are in various classes such as polysaccharides, composed of sugars with glycosidic linkage; polyamides, composed of amino acids with peptide bonds; polyesters, composed of a hydroxy fatty acid linked by ester bonds; polyphosphates, composed of inorganic phosphates linked with anhydride bonds.

Bacterial polysaccharide synthesis consumes nutrients and chemical energy, is maintained by bacterial cells, and are responsible for growing and persisting in unfavorable conditions. Bacterial polymers that are high-molecular-weight polymers are responsible for forming helical strands, are present commonly in a double-stranded forms such as xanthan, kappa carrageenan, gellan, and succinoglycan, or otherwise triple-stranded structures such as curdlan and *Schizophyllum* (Nishinari and Takahashi 2003). Various condensation linkages in polysaccharides with variations of monomeric sequences give a wide range of structural architecture and shapes. Sometimes, polymer chains are in high-molecular-weight substances, which results in complex determined physical properties. The common monosaccharides in the bacterial cells are D-glucose, D-galactose, D-mannose, L-fucose, L-rhamnose, and N-acetyl hexosamines, and N-acetyl D-galactosamine. In some organisms, uronic acids such as D-glucuronic acid could be present. Many other sugars are present in microbial polysaccharides, such as acetate with ester linkage or pyruvate linked with ketal, and influence the structural and physical characteristics of polymeric substances. Other ester-linked substituents such as propionyl, succinyl ester, hydroxybutanyl, glyceryl residues, and a few of the amino acid substituents

have been characterized in microbes (Sutherland 1998). Ester-linked O-acetyl groups are the organic substituent in bacterial polysaccharide in some microbes. Ketal pyruvate is also one of the important constituents in bacterial polysaccharides that are imparted in the charge of these polymers. Knowledge of the physical and chemical properties and composition of polysaccharides from microbes could help to exploit and invent new hydrocolloids in various areas such as cosmetics, food, and biomedical applications. Bacterial polysaccharides that have been industrially commercialized include gellan gum (*Sphingomonas elodea*) (Gonçalves et al. 2009), dextran (*Leuconostoc mesenteroides*) (Mollet 1996), and succinoglycan (*Rhizobium* sp.) (Chouly et al. 1995).

Types of Biopolymers in Prokaryotes (Bacteria)

The historical evidence on polymers is from 1886, the finding of a cellulose biomaterial produced by a bacterial species was reported, the first polymer from bacteria *Leuconostoc mesenteroides*, is dextran, which was found in a microbial product. Louis Pasteur discovered this in the mid-nineteenth century (Van Tieghem 1878). After discovering EPS, the first intracellular polymer-like polyamide cyanophycin was discovered (Borzi 1887). After 40 years, polyhydroxybutyrate was found in *Bacillus megaterium* (Lemoigne 1926) and some of the other polymers with medical industrial applications were discovered from various bacterial species in the twentieth century such as alginates (Linker and Jones 1966), xanthan (Leach et al. 1957), polyglutamate (Ivanovics and Erdos 1937) and polyphosphate (Kornberg et al. 1956). These, started a new trend in research into diverse biomaterials. After these discoveries of biopolymers, overall research interests into the purification, different biological activities and synthesis, and metabolic activities were also studied. These areas of research were at a molecular level such as DNA sequencing, gene clusters, cloning of genes, identification analysis of genes of biopolymers between 1970 and 2000. As continuation, the reactions involved in mechanisms of particular enzymes including, synthases, synthetases, polymerases, and the functions of proteins, co-polymerases were studied. Various types such as intracellular and extracellular biopolymers were isolated and characterized by researchers from the through the decades, whereas numerous organisms with high potential novel biopolymers should be exploited. Biopolymers such as starch, glycogen, polyphosphate, polyhydroxyalkanoates (PHAs), etc., are accumulated in cell cytoplasm. There is a limitation to the availability of space in cytoplasm, which limits the amount of biopolymer produced by an organism. Many of the polysaccharides such as dextran, curdlan, xanthan, alginates, pullulan, chitosan, cellulose, and poly (β -D glutamate) are the polymers secreted extracellularly. Polylactic acid and PHAs, has been produced on a large scale for biotechnological applications.

Xanthan

Xanthan is a copolymer with a complex structure produced by some bacterial species as a part of metabolism and is the first commercially produced bacterial polysaccharide through fermentation. These xanthan polymer building blocks mainly contain five different sugar groups produced by *Xanthomonas campestris*. Xanthan is used extensively in food items such as cheese spreads, ice creams, deserts, and puddings as a gelling agent and in nonfood industrial applications such as the mineral ore processing, oil recovery, agriculture, paper manufacturing, cosmetics, and pharmaceutical sectors.

Dextran

Dextran is a polysaccharide with a large family of bacterial polysaccharides that polymerized outside of the cell by an enzyme called dextran sucrose. It has monomers of simple sugars and is stored in bacteria and in yeasts. These polymers have various medical applications, including blood volume expanders, wound covering, improvement of blood flow, wound coverings, surgical sutures, and in the treatment of anemia. Dextran hemoglobin compounds may be used as blood substitutes owing to the capability as plasma expanders and ability to deliver oxygen.

Cellulose

Cellulose is a complex structural sugar compound and can be produced by some bacterial species such as *Cellulomonas* and *Micrococcus*, etc., having unique properties. Cellulose is the homopolymer unbranched β (1,4)-linked glucose units. *Salmonella enterica*, *Rhizobium* spp., *Agrobacterium* spp., and *Pseudomonas aeruginosa* produce cellulose polymer. Bacterial cellulose has Generally Recognized As Safe (GRAS) status and is widely used in biomedical and packaging products and also in food. Bacterial cellulose has a very large surface area and is able to absorb liquids. A very low quantity of bacterial cellulose can be used as thickening, binding, and coating agents.

Pullulan

Pullulan is a polymer made by repeating units of maltotriose residues with α -1,6 glycosidic bonds. Microbial pullulan secretes extracellularly to the outer surface as EPS. Pullulan is a water-soluble polysaccharide produced by some species of *Aureobasidium pullulans*. Pullulan is a biodegradable, nontoxic, odorless, tasteless, and bioactive polymer. The main application of pullulan is the use as a food additive

that is in low-calorie foods and drinks, and it can also be used instead of starch. The pullulan biopolymer can be used as a flocculating agent for the precipitation of uranium clays, potash clays, and in mineral ores. Pullulan compounds can serve as drug carriers in the medical field, pullulan can work as a plasma expander without undesired side effects and is completely excreted out after metabolic conversions. Pullulan compounds can also serve as medical adhesives.

Glucans

Glucans are mainly produced by *Saccharomyces cerevisiae*, and are a homopolymer of the simple sugar glucose. Glucans are purified from yeasts and are used as immunomodulators, antiviral agents in plants, and inhibit tumor growth. *Schizophyllum*, lentinan, and grifolan are isolated from *Schizophyllum commune*, *Lentinus edodes*, and *Grifola frondosa* respectively, are β (1–3) (1,6)-glucans, and are effective as antitumor agents.

Glycogen

Various types of bacteria produce polysaccharides and excessive polysaccharides are stored as glycogen in the cells. These polysaccharides show water solubility with a 1,4-glycosidic bond in linear and α 1,6-glycosidic bonds in side chains. In bacterial cells, glycogen is accumulated as in limited growth conditions with excessive carbon sources and other nutrients are in deficient quantities. This glycogen is a common potential indicator of a bacterial lifestyle.

Alginate

Alginates are nonrepeating, negatively charged heteropolymers with β -(1,4)-linked β -D-mannuronic acid and guluronic acid. Alginate acts as a survival mechanism by protecting the bacterial cells from phagocytes when the cells are in a biofilm matrix, e.g., *Pseudomonas aeruginosa*. These polymers interact with divalent cation and form dense hydrogels with a high water-holding capability. The EPS produced by *Pseudomonas aeruginosa* also enhance bacterial survival in chlorinated water. Bacterial alginates are widely used as biobased materials in food and for pharmaceutical and cosmetic purposes, for example. Alginates produced by *Pseudomonas aeruginosa* are able to protect bacteria against inflammation in hosts, phagocytosis, etc.

Hyaluronic Acid (Hyaluronate)

Hyaluronates are negatively charged, unbranched heteropolymers with β -(1,4)-linked repeating heteropolymers of glucuronate and N-acetyl glucosamine. It is a

component of biofilm and has antiphagocytic action. Hyaluronates are found in *Streptococcus* spp., *Pasteurella*, and *Bacillus cereus*.

Polyesters

Polyesters are PHAs, highly reduced biopolyesters, and function as an electron sink in an anaerobic zone of biofilm. Some of the PHAs, such as polyhydroxybutyrates are naturally found polyesters formed into spherical inclusions with hydrophobicity.

Polyamides

Polyamides are highly charged polycationic (ϵ -PL) and polyanionic (γ -PGA) materials and are nontoxic, biodegradable, and renewable. Polyamides are composed of amino acids and are produced by synthetases. Some of the nonpathogenic organisms such as *Bacillus megaterium* and *B. licheniformis* produce polyamide-based materials. Polyamides function as capsules or slime layers in bacterial cells to protect them, and also act as intracellular storage materials. In industries, polyphosphates are used as substitutes for chemical polymers.

Polyphosphate

Polyphosphates are chains with condensed phosphates that functions as a storehouse with negatively charged, high-energy rich bonds. The metabolic activity of this polyphosphate is positively related to the virulence factor production of the microbe. These polyphosphates function as phosphate storage molecules, acts as buffers, and give energy to the metabolic pathways. Polyphosphates regulate cell signaling and are involved in growth, viability, virulence, and stress tolerance, etc.

Curdlan

Curdlan is a bacterial EPS, comprises β -(1,3)-glucan, has various applications. These materials are insoluble in water, and have gelling activity. This biopolymer is approved by the FDA for safe use as dietary fiber in Taiwan, Korea, and Japan, and also as food additives. The fermentative production of curdlan on a commercial scale uses *Alcaligenes faecalis* var. *myxogenes*, reclassified as *Agrobacterium* spp.

Gellan

Gellan is an extracellular polysaccharide with high molecular weight, composed of 1,3-beta found in *Sphingomonas elodea*, *S. paucimobilis*, and *Pseudomonas elodea*. Two main types of gellan are used. “KELCOGEL” is an industrial food product and purified “Gel-Gro” gellan gum is used in the pharmaceutical and biomedical fields.

Prokaryotic (Bacterial) Biopolymers from Various Marine Sources

Marine bacterial EPS contain heteropolysaccharides with various monosaccharides such as pentoses (D-ribose, D-arabinose, D-xylose), hexoses (D-glucose, D-mannose, D-galactose, D-allose, L-rhamnose, and L-fucose), amino sugars (D-galactosamine, D-glucosamine) or uronic acids (D-glucuronic acid, D-galacturonic acids). Other inorganic substances such as phosphates, sulphates, succinic acids, acetic acids, and pyruvic acids may also be present. The marine polymers with other macromolecules such as lipids, proteins, and nucleic acids, comprise the organic matrix present in the intracellular space of bacterial biofilms, and act as the largest reservoir of reduced carbon. In recent years, the marine habitat has attracted great attention, especially in extreme environments and extremophiles has raised its peak. Several studies have reported on ice cold microbial marine communities, and found that these organisms produce EPS and play a key role in cryoprotection. The production quantity of EPS as a capsular form in bacterial pathogens. The production rate and the amount of EPS accumulated influences the pathogenicity of an organism.

Exopolysaccharides play a key role in biofilm matrix production by bacterial cells, and are involved in cell-to-cell communication in between microbial cells and its close cells. The nutrients also interact with EPS to increase the rate of intake of substances/molecules, dissolved compounds, and support microbial growth. Hydrated biofilm acts as stable microenvironment and here, the extracellular enzymes can find storage and ease the uptake of molecules. Bacterial strains from deep sea hydrothermal vents showing resistant to heavy-metal substances and the purified form of EPS have the capability to bind the metals and toxic substances (Wuertz et al. 2000). These EPS exhibit the polymeric state in the marine environment and show binding affinity toward cations and trace metals. EPS isolated from Antarctic regions and sulfate groups act as anchoring agents for cations, and are found as trace metals in the Southern Ocean (SO). This improves the bacterial communities in areas with limited availability of trace metals such as iron (Mancuso Nichols et al. 2005).

Exopolysaccharide from *Alteromonas* strain 1644 are found in annelids in deep sea thermal vents, and showed a low viscosity at a low ionic concentration (Samain et al. 1997). This organism has the ability to secrete two types of polysaccharides and are differentiated by their gelling property. Marine bacteria are capable of higher production of various EPS when growing with limited quantities of nutrients such as phosphorus and nitrogen under laboratory conditions. *Hahella chejuensis*, from the marine sediment of Marado, Republic of Korea, can produce the highest yield of EPS in sucrose-enriched culture media (Ko et al. 2000), whereas haloalkaliphilic bacteria from saline lakes in Antarctica, *Halomonas alkaliantartica* CRSS, was a potentially greater producer of EPS in the presence of acetate as a carbon source (Poli et al. 2004). Microbes from volcanic hydrothermal vents, deep sea hydrothermal vents, and shallow thermal springs have a novel EPS producer, *Pseudoalteromonas* strain 721, producing EPS with octasaccharide repeating units with

two side chains. These EPS show gel formation and viscoelastic behavior at increasing temperature (Rougeaux et al. 1999).

In a study on CMG607w and CMG1421 two strains of *Pseudomonas aeruginosa* produce commercially usable biopolymers. CMG607w was from the sediment of the Lyari River outfall of the Arabian Sea, and can produce the medium-chain-length PHAs. PHA production was increased with an increase in incubation period (Jamil and Ahmed 2008). PHA has a fascinating source of various biomolecules and are highly potential interest to several industrial applications. Marine sponge and bacterial interactions are very complex, Nowadays, these mutualistic relationships attract attention because of the production of a bacterial biopolymer (polyesters) such as intracellular PHAs by the bacterial cell. These PHAs act as a carbon, an energy reservoir, and as the alternative to the fossil fuel-based polymers. The PHA production by these sponge-associated microbes are under stressful sponge mesophyl microenvironments. In this review, the researchers try to explore the industrial outlook for marine bacteria for the synthesis of PHA at a commercial level (Ganesan Sathiyarayanan et al. 2016). PHA production is highly expensive compared with petrochemical-based plastics and is too hazardous to the ecosystem. Easily and cheaply available carbon sources/raw materials such as coconut cake and rice bran are used to overcome this issue. The potential PHA-producing bacterial strains M6 and S6 are isolated from different seaweeds, and identified by 16SrRNA sequencing as *Bacillus cereus* RBL6 and *Pseudomonas pseudoalcaligenes* RBL7 respectively (Ramya et al. 2017).

Many of the bacterial species produce EPS as a survival mechanism in adverse conditions, a strategy for growth, and to adhere to solid surfaces. New research is ongoing in the area of the isolation of EPS-producing bacteria from the marine environment, especially from extreme environments such as the deep sea hydrothermal vents with high temperature, pressure, and the presence of heavy metals. Various marine EPS-producing bacterial species are also isolated from several extreme niches such as cold environments, especially Arctic and Antarctic sea ice with extreme environmental conditions such as temperature, nutrient concentration, and salinity in marine, aquatic, and terrestrial ecosystems. Bacterial EPS from these extreme environments are heteropolysaccharides that have three to four different monosaccharides. This work gives an overview of current knowledge on EPS-producing marine organisms has a symbiotic association with marine annelid worms that were living in an extreme niche (Poli et al. 2010). The psychrophilic bacterial isolates from South Ocean produce their EPS as an extracellular response to the environmental constraints. These EPS production responses of bacterial species in relation to cold and sea environments were explained.

In the study on marine *Micrococcus luteus* EPS and Fourier transform infrared (FTIR) results observed the presence of carboxyl groups, glucans, O-H, NH₂, C=O, C=N groups, etc. (Nisha et al. 2020). Various studies were reported on the spectral analysis of EPS from microbial strains. In EPS from *Micrococcus luteus* analyzed using FTIR, the results showed various peaks, a broad stretched peak 3423 cm⁻¹ has the presence of a hydroxyl group. The weak band at 2925 cm⁻¹ revealed the C-H

group, and a peak at 1739 cm^{-1} indicated the presence of uronic acid. Overall results reveal the presence of the carboxyl group and uronic acid (Patil et al. 2009). A similar study reporting an *α -Proteobacterium* group included the functional group from crude EPS, a broad band at 4000 cm^{-1} to 650 cm^{-1} with a resolution of 4 cm^{-1} and a sharp band at 2989.89 cm^{-1} , indicating the presence of O-H, carboxylic acid, and H-bonded groups. C-O, alcohol, ether, and phenol groups are observed from the peak at 1038.92 cm^{-1} (Sunil Pawar et al. 2013). Ortega Morales et al. (2007) studied EPS and reported that the existence of ^-OH (2800 cm^{-1} to 3600 cm^{-1}) groups, also COOH groups (1600 cm^{-1} to 1725 cm^{-1}). B3 strain displayed the occurrence of an OH band at 3415 cm^{-1} and the presence of a band at 1631.48 cm^{-1} (Ashok Kumar et al. 2011). Similar results are reported by Anita Iyer et al. (2005): the FTIR result of EPS produced from marine *Enterobacter cloacae* revealed the existence of O-H, COOH, C-H, C-O, S=O groups. Bragadeeswaran et al. (2011) studied EPS from *Bacillus cereus* GU 812900, with peaks at 2853.98 to 2923.88 cm^{-1} , the presence of C-H stretching in an aliphatic compound in the cell wall such as carbohydrates and fatty acids is identified and spectral peaks at 1645.79 cm^{-1} showing the presence of an amide II band. Another peak at 1560.53 cm^{-1} revealed the NH_2 bending, C=O, C=N stretching amide I band. The results showed (1, 3) glucan linkages, the values are close to 1000, 2000, 3000, 15,000, and 1600 cm^{-1} (Vijayabaskar et al. 2011). Related work studying the FTIR results of *Paenibacillus polymyxa* JB115-BG showed the peaks at 3420 cm^{-1} O-H stretching, 2938 cm^{-1} C-H band, and 1634 cm^{-1} indicates C=O bond (Jung et al. 2007), and a similar result was reported, which revealed the peaks to have protein conjugated glucan at 1242 cm^{-1} (Gonzaga et al. 2005).

The microbes live in deep marine environment and can survive under extreme ecological and harsh environments such as high salinity, low temperature, and high atmospheric pressure. These characteristics lead them to be of scientific interest. Banerjee et al. (2019) studied the microbes from the SO, a deep marine ecosystem with a diverse group of microbes. They isolate EPS producers, optimize the production of EPS and characterize EPS, results shown that, three different EPS showing structural confirmation, having porous structure to powerful flakes same as polymeric compounds with C:N ratio between 4 to 11. The FTIR characterization showed the existence of carbohydrate, water molecules, and protein-associated amides. EPS of a microbe are biopolymeric in nature and help in biofilm formation, providing a protection layer to microbes by forming a complex interrelationship between cells and entrapping the nutrients (Di Donato et al. 2016). In this way they assist bacterial microcolonies to withstand extreme environmental conditions and allow easy accessibility of nutrients between bacterial cells. Marine prokaryotic organisms produce biopolymers with an important property as biomaterials with suitable industrial materials. By examining these structural and physicochemical properties it was found that they had a large field of possibilities such as pharmaceuticals, food processing, bioremediation of petrochemical spillage, etc. Gray and Biddlestone (1973) reported that *Halomonas hydrothermalis* MB-45 is a good EPS producer, isolated from the SO (Indian Sector) and the higher production of 5.26 g/L and with a carbon nitrogen (C/N) ratio between 4 and 11. A similar study on

Pseudoalteromonas spp. from the SO showed the same range of C/N ratio. The surface morphology of the EPS-producing *Zunongwangia profunda* MB24 had similarities to *Pseudoalteromonas* spp., having porous and smooth regions in the EPS (Sengupta et al. 2019). This EPS was polysaccharide macromolecules with α -glycosidic bonds, polysaccharides, and amine-substituted. These compact structures indicate their potential applications as thickener, viscosifier, stabilizing agent, etc. The porous characteristics of EPS have been proven to be a key factor for heavy metal biosorption and has the ability to hold more water. The fibrous pores of bacterial EPS help the cells to attach to each other with high-affinity interactions. The FTIR spectra of three bacterial species showed a functional group in polysaccharide macromolecules. Here, EPS from *Marinobacter algicola* MB-44 showed highly complex aminated branching polysaccharides (Fan et al. 2012). The bacterial EPS of SO origin have different applications in food industries as anticoagulant, thickening agent, biodegradation for waste water treatment, and anti-HIV activity, as well as having UV protection capacity.

Alteromonas macleodii subsp. *Fijiensis* is a potent EPS producer, which was isolated from the hydrothermal vent at a depth of 2600 m in the North Fiji Basin (Rougeaux et al. 1998). A valuable source of bacterial EPS was isolated from volcanic and hydrothermal marine areas including *Methanosarcina*, *Haloferax*, *Haloarcula*, *Sulfolobus*, *Bacillus* spp., *Thermotoga maritima*, and *Thermococcus litoralis* (Maugeri et al. 2002; Manca et al. 1996) and their biopolymers were studied. The thermophilic bacteria *Geobacillus* spp. from Phlegraean in Italy are found in shallow hydrothermal vents of the marine area and determined as a higher EPS producer (Nicolaus et al. 2002). Similarly, EPS production and characterization was done by using a thermophilic strain of *Geobacillus* sp. isolated from the marine sediment from a hot spring near the seashore of Maronti, Italy. Previous studies demonstrate the bacterial populations in Port di Livante, where the habitat was deep, and the hydrothermal vents of these communities. The studies reported that those bacteria are thermophilic, chemosynthetic, archaeal strains (Gugliandolo and Maugeri 1998). Thermophilic aerobic microbe can compete to make two exopolysaccharides (EPS-1 and EPS-2), isolated from a marine hydrothermal vent at Vulcano Island, Italy. The thermotolerant *Bacillus licheniformis* strain (B3-15) was isolated from a shallow marine hydrothermal vent at Vulcano Island, and is capable of producing EPS with immunomodulating properties, with a maximum production of 165 mg/L EPS on a liquid mineral medium (Maugeri et al. 2002) (Table 2 and Fig. 1).

Functions of Bacterial Biopolymers/Exopolysaccharides

Bacterial EPS is getting in this decade because of the rheological properties and the fermented food products (Cerning and Marshall 1999). Bacterial EPS have quite a lot of medicinal applications, such as antiviral and antitumor activity, lowering the level of blood cholesterol, and they also act as immunostimulation agents such as polysaccharide vaccine. With unique structural and physical properties, microbial

EPS have a broad range of applications in various industries, such as food, pharmaceutical, and other industries. These biopolymers have various applications in that they are used as stabilizers, binding agents, gelling agents, lubricants, coagulants, film formers, and thickening agents (Sutherland [1997](#)). EPS are composed mainly of monosaccharides and several other noncarbohydrate substituents such as succinate and acetate. These EPS molecules are extremely pure, have regular structures, and possess unique rheological properties. Another characteristic feature of EPS that they are acidic or basic in nature. Dextran, produced by *Leuconostoc mesenteroides*,

Fig. 1 Flow chart of bacterial exopolysaccharides production

is used in plasma substitutes for shock and loss of blood (Silver et al. 1998). The lactic acid bacteria (LAB)-producing EPS, used as a stabilizer and thickener, also produced commercially (Singh and Das 2011). *Xanthomonas campestris* produces xanthan with a highly industrially valuable polymer. These bacterial EPS have wide industrial applications such as in the food, oil recovery, cosmetics, and toiletries industries. The fantastic rheological properties of this xanthan gum allows it to be used as stabilizing agent in suspensions and emulsions, and it is used in aqueous systems as a rheological control agent (Roberts 1996). Xanthan is also added to the uniformly suspended solid component in formulations used to improve the flowing ability of insecticides, herbicides, and fungicides in the agricultural field (De Angelis 2012).

Various studies put forward that EPS from *Spirulina* was composed of polysaccharides and used as anti-inflammatory and therapeutic agents. Spirulan, which is produced by *Arthrospira platensis*, is a sulphated polysaccharide, and has been

recognized to have the ability to inhibit pulmonary metastasis in humans. It is also involved in the prevention of adhesion and proliferation of cancer cells (De Morais et al. 2010). Similarly, the polysaccharide produced by the marine microbe *Vibrio diabolicus* is hyaluronic acid and is commercially known as the trade name 'Hyalurift.' These polysaccharides are important in bone integrity, and they show restoration activity (De Morais et al. 2010). Two bacterial EPS, GalactoPol, produced from *Pseudomonas oleovorans*, which is mainly composed of galactose (Freitas et al. 2009), and FucoPol, a fucose containing EPS synthesized from *Enterobacter* A47, were newly reported and have various applications. As a part of the investigation of new biopolymers with potential sources, several microbes are isolated from extreme environments, such as Antarctic ecosystems, deep sea hydrothermal vents, saline lakes and geothermal (Poli et al. 2010). Biofilm-producing *Micrococcus luteus* from the ship hull at Cochin, India, quantified and optimized EPS production. The higher production of EPS was at 56.7gm/L, at 96 h of incubation time, 27 °C incubation temperature, and EPS showing antimicrobial activities against the human pathogens (Nisha et al. 2020).

Exopolysaccharides from *Bifidobacterium bifidum* WBIN03 and *Lactobacillus plantarum* R315 showing antimicrobial activity against *Cronobacter sakazakii*, *E. coli*, *Listeria monocytogenes*, *Staphylococcus aureus*, *Bacillus cereus*, *Candida albicans*, *Salmonella typhimurium*, and *Shigella sonnei* were reported by Li et al. (2014). Crude EPS from *Lentinus subnudus* was tested for its antibacterial activity in Swiss albino rats infected with *E. coli* and *Pseudomonas aeruginosa* and it was found that EPS possess antibacterial activity (Majolagbe et al. 2013). Mahendran et al. (2013) reported similar study on potential antibacterial effects of EPS from *Ganoderma lucidum* and *Lysinibacillus fusiformis*. Rajasree et al. (2014) studied EPS from marine *Exiguobacterium* spp., and results showed inhibition activity on *Alteromonas* spp. and *Gallionella* spp.

Broadly characterized, studied, and commercially profitable EPS xanthan gum, which is an initially produced biopolymer (Rosalam and England 2006) from a microbial polymer produced by *Xanthomonas* spp., is a most extensively studied and widely accepted commercial microbial polymer. Gellan, rhamsan, welan, and diutan are EPS that are distinguished by differences in composition and side chain linkage. Alginate is a polymer secreted by the genera *Pseudomonas* and *Azotobacter* and is a linear polysaccharide that is composed of guluronic acids and mannuronic acids and forms mixed and poly-mannuronic acid sequences. Alginates from bacteria and algae show differences in acetylated alginates (Rehm 2009). Glucans – glucose homopolysaccharides – vary in glycosidic linkage, chain length, degree and type of branching, confirmation of polymer, and a molecular mass. There are two types of glucans, β -glucan and curdlan and α -glucans. Several microbes from the genera *Gluconacetobacter*, *Agrobacterium*, *Achromobacter*, *Aerobacter*, *Rhizobium*, *Sarcina*, and *Salmonella* are capable of producing cellulose (Chawla et al. 2009). α -Glucans is an extracellular enzyme produced by dextranucrase from sucrose, by numerous bacteria of the genera *Leuconostoc*, *Streptococcus* and *Lactobacillus*. Hyaluron from respective bacterial strains such as *Pseudomonas aeruginosa* and *Streptococcus* A and B attenuated strains (Rehm 2009), is composed of glucuronic

acid and a linear polymer composed of a repeating disaccharide. N-acetylglucosamine is a linear polymer with repeating disaccharide units (Ruffing and Chen 2006). Microbial succinoglycan – are secreted by some soil bacterial species such as *Rhizobium*, *Alcaligenes*, *Pseudomonas*, and *Agrobacterium* (Glenn et al. 2007). It is a branched EPS with a galactose and glucose backbone and the side chain tetrasaccharide composed of glucose residues. Levan is an extracellular enzyme produced from diverse bacterial species such as *Bacillus*, *Rahnella*, *Aerobacter*, *Erwinia*, *Streptococcus*, *Pseudomonas*, and *Zymomonas*, and is a highly branched fructose homopolysaccharide synthesized by an enzyme levan sucrose from sucrose.

Extracellular polymeric substances/exopolysaccharides are accountable for the adhesiveness of biofilm on the biotic/abiotic solid surfaces, the cohesion of microorganisms, influencing spatial organization, acting as adhesive in cells, allowing interactions among microorganisms, and some of the resistant actions, etc. Such biological functions are essential for formation and other activities. The EPS /biopolymers stabilize the bacterial aggregation via various interactions among macromolecules, such as dispersion forces, electrostatic interactions, and hydrogen bonds. The outer secretion of a jelly like 3D structure in the microbes allows them to develop a strong consortium (Flemming et al. 2000). EPS produced from *Sphingomonas paucimobilis* have properties such as surface activity, which promotes and influences adhesion through secretion of an extracellular polymeric substance (Azeredo and Oliveira 2000). Some of the protein adhesins play a key role in the attachment of microbes to the surfaces. The EPS produced from *Caulobacter crescentus*, known as holdfast, is mainly influenced by the initial surface attachment together with other cellular structures (Wan et al. 2013). The

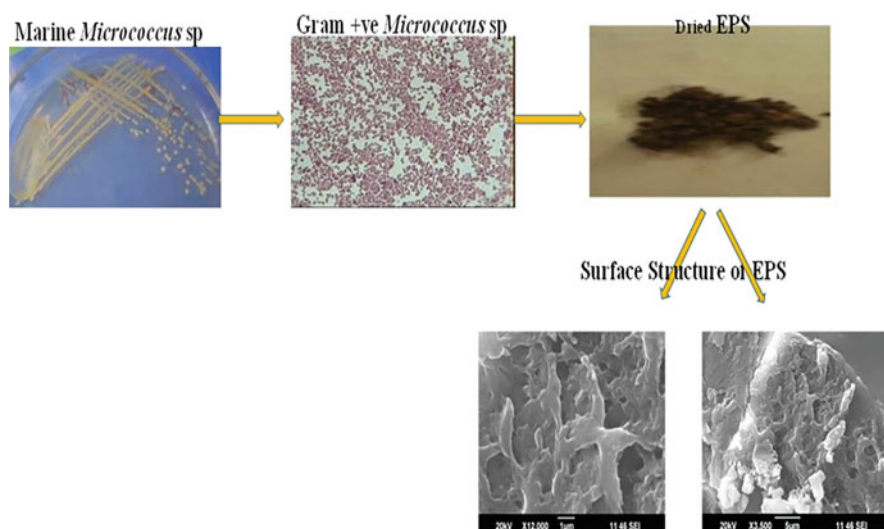

Fig. 2 Exopolysaccharides production by marine *Micrococcus luteus*

higher production of EPS by microbes can influence the cell adhesions. Large quantities of EPS enhance the attachment via interaction in between the functional groups such as uronic acid and acetyl groups; this statement has been confirmed by evaluating 27 bacterial species. The process of the interactions between the EPS and functional groups is unknown and the matrix formed by EPS can influence the chemical communication (Flemming et al. 2007).

In a few of bacterial cells, ex-DNA seems to be answerable for the adhesion capabilities of EPS rather than the presence of polysaccharide. The structural and functional activities of ex-DNA studies have not been reported entirely, whereas a few works show the responsibility of the structural properties and cohesion of EPS involved in the process of adhesion onto the solid surfaces and signaling. In the biofilm formation of *Staphylococcus aureus*, *Pseudomonas aeruginosa*, and *Ralstonia solanacearum* ex-DNA is an important structural component. Active secretion of EPS by the microorganisms (Whitchurch et al. 2002) however, it is not essential in the formation of biofilm by *Streptococcus epidermidis* (Flemming and Wingender 2010). This statement is dependent upon the treatment with DNA-ase1, which inhibits the formation of biofilm by *S. aureus* but not *S. epidermidis* (Izano et al. 2007).

Ex-DNA are very important in the components of biofilms produced by different microbes, these biofilm microbes are surrounded by an EPS. There is a much less detailed understanding on this area because less research has been done. In bacterial cells, the rate of transformation and the rate of conjugation are higher in biofilms. *Campylobacter jejuni* transfer antibiotic-resistant genes by transformation and show a higher rate in the biofilm than they do in planktonic cells (Bae et al. 2014). Related studies reported that the age of biofilm and the concentration of DNA influence the frequent rate of transformations, whereas the higher density of planktonic cells inhibits the transformation in biofilm. Moreover, the number of events used to observe can depend on the techniques, which are used here to detect the conjugative gene transfer in a biofilm. 100-fold higher rates of conjugation were detected by the use of confocal laser scanning microscopy. It is higher than when plating techniques are used (Hausner and Wuerztz 1999). Some of the research discussed and suggested on ex-DNA can be used as an alternative to bioactivity measurements in environmental studies. The fraction separation of ex-DNA and the evaluation/analysis in the case of complex samples such as soils have not been developed.

Studies on polymers reported that, surface active agents are amphiphilic substances that are used in various sectors in the modern industry, most of these are synthesized by organochemical synthesis. Biosurfactants and bioemulsifiers are produced by the biological sources and have gained more interest in the past decades owing to the structural and functional diversity. These compounds are mainly of high biodegradability, and less toxic when compared with chemically synthesized compounds. Research reviews on this substance give an overall summing-up of the classification of various types of biomolecules with surface active abilities, and more of these molecules are awaiting discovery, some of them with production on an industrial scale. The marine environment is a mostly unexploited source of novel surface-active agents. Microbes from marine sources, mainly bacteria that are living

in association with microalgae are potential sources of surface-active agents with various biotechnological applications. In the production of a surface-active agent from a different microbe, the yield can be too low to meet the quantity demanded by the industries. This is major problem remains an important part of their future commercial development.

Applications of Biopolymers

Polymers from microbial sources have unique properties with abundant materials and applications in various sectors.

Industrial Applications

Microbial polymers are mainly used as industry standard material, in combined with other materials to enhance their desired properties and applications. These polymers are widely used in packaging in various sectors, PHA, polylactic acid and starch being easily available, water resistant, and inexpensive. Microbial polymers are used as a biocement during concrete preparations for industrial construction and interior decoration. Some of these biopolymers are able to remove metals from water and is beneficial in waste water treatment. Biopolymers are used in the automotive industry as a component for making interior and exterior parts, engines, exhausts, steering wheels, electrical components, etc. These polymers are also used in food industries as thickening agents, gelling agents, and stabilizers.

Biomedical Applications

Most of the biopolymers are widely used in the biomedical field and are nontoxic, degradable, biocompatible, and can be applied in drug delivery, tissue engineering, and the pharmaceutical industries. They are very porous and are used as wound healers, for example. Microbial polymers/polypeptides are easily available and inexpensive materials; therefore, they increasingly used as biomedical materials. Many studies reported the ortho-dental applications of bacterial polymers, hydrogels, etc., and their suitability. Biocompatible polymeric substances including polysaccharides, polyamides, polyesters, and polyphosphates have diverse applications such as antioxidant, antibacterial, antifungal, and antitumor wound healing.

Dextran is a potential drug carrier polymer, with targeting approaches in several organ therapies, such as colon-centered therapies and other intestinal/alimentary tract therapies, owing to its degradability. Liver-targeted drug therapies are also successfully completed with dextran-based nanomaterials.

Gellan and its derivatives have wide applications such as tissue engineering, gene therapy, protein carriers, regenerative medicine, and drug delivery. Gellan is mainly

used as a gel or capsule coating, which helps to release the drugs with a modified profile. These are used against gastric and peptic ulcers, inflammation, arthritis, etc. Gellan gum beads are used against diabetes as hypoglycemic agents. Gellan can be fabricated/modified into fibers, films, and 3D structures.

Curdlan is a potential wound-healing agent with reduced pain, speedy healing, and lowering of the number of dressings of wounds used when compared with the standard treatments.

Polyhydroxyalkanoates have been mainly used in soft-tissue engineering, such as heart valves, tendons, nerves, and blood vessels, and are also used in life-saving areas such as cardiac muscle regeneration, successfully mimicking myocardial muscle activity. These PHAs are used to encapsulate a drug for controlled drug delivery.

Cosmetic Applications

Biopolymers can be used as cleaning agents for pedicures and manicures and are used as the natural ingredient for hair care products, sunscreen lotion/creams, and in beauty creams/lotions.

Nanotechnology

Biopolymers are biomaterials used in the production of nanomaterials and are in higher demand in green chemistry. Green synthesis of various nanomaterials constitutes a new trend in research on nanotechnology.

Agriculture/Fishery

Bacterial EPS play an important role in symbiotic relation between nitrogen-fixing bacteria such as *Rhizobium* and the leguminous plants. *Sinorhizobium meliloti* is able to produce a polymer, succinoglycan. Some of the studies reported that the plants are capable of identifying the structure of rhizobial EPS and the expressions of the receptors. Biopolymers can be utilized for making fishing nets, beehives, fishing traps, and fertilizers.

Other Applications

Biopolymers are used to produce footballs and other hollow balls, golf and badminton equipment, etc. These materials are also used for the manufacturing of insulated wires, cables, electronic devices, printed circuit boards, etc.

Conclusion

Many studies are continuing to explore alternatives to petroleum-based products that would be biodegradable or renewable to reduce the risk of pollution. Biopolymers are the best solution to the problem; hence there are so many challenges such as the limited rate of production, cost of production, and sustainability. Prokaryotes, especially bacteria, are the superior cell factories that have the ability to convert carbon and nitrogen sources into various intracellular and extracellular biopolymers, such as polysaccharides, polyphosphates, polyamides, and polyesters. Microbial polysaccharides are renewable sources for the formation of hydrocolloids and can be used in the food industries, pharmaceutical industries, and in various other industrial applications, e.g., xanthan, dextran, alginate, and gellan. In the case of microbial polymers, only few of these are commercialized. Microbial biopolymers play an important role in their pathogenicity/virulence. These microbial biopolymers have diverse characteristics and properties, and are suitable for medical and industrial applications.

Abstract

Humic substances are complex biopolymers found in soils, water bodies, and sediments. The application of humus-based materials in biomedicine is emerging because of its medicinal properties. Specifically, humic acid could demonstrate antiviral action against several viruses. This chapter summarizes recent advances on the effect of several interventions on humus composition, properties, and structures. It also highlights the biomedical applications of humic substances, especially in drug delivery.

Introduction

Humus is a common organic compound present in the environment. It occurs in concentrations between 1 mg(C)/L to over 100 mg(C)/L in water bodies (Maier 2015). It is also found in soils, water, and sediments since it can be obtained from plants, algal, and microorganisms (Pandey et al. 2000) when it undergoes physical, chemical, and biochemical changes. In brief, humus is got from decomposing plants and biomasses. As such, it is considered ubiquitous and heterogeneous because of several reasons, including formation mechanisms and processes, as illustrated in Fig. 1.

Recent advances have examined the effects of several interventions on humus composition, properties, and structural characteristics in different locations under varying environmental conditions. First, research on identifying humic substances based on a nonconventional transformational process was investigated. Bezuglova and coworkers (Bezuglova and Komarov 2022) identified humus through its unique characteristics during peat's conversion. They studied this conversion process based on some growing seedlings for about 5 years. The conversion processes were identified as hydrolysis of organic products, initial transformation process, and humidification of the lignin structures. Building on this, Ndzelu et al. (2021) examined the effect of tillage on the composition of soil humus and humic acid structural characteristics in soil. The study showed that avoiding soil tillage was a better alternative to tillage in enhancing the sequestration and stability of soil carbon. Similarly, Raiesi (2021) reported on the effects of wheat dry farming as well as abandonment of the same on the quantity and quality of humic substances in an ecosystem. These factors were used to determine the “soil degradation and

Fig. 1 Illustration of humus formation mechanisms. (Reproduced with permission from Mazzei and Piccolo (2012))

ecological restoration in semi-humid pastures.” As such, land-use changes were shown to affect soil organic matter. Depending on the location, the (bio) chemistry of soil humus and humic substances could differ (Baveye and Wander 2019). In Kuban rice crops, Sheudzhen and Gutorova (Sheudzhen and Gutorova 2021) investigated the influence of liquid manure on the humus state of gleyic and chernozem soil grown with rice. The study reports increased soil humic acid in the region of Krasnoarmeysky district of Krasnodar territory. Another recent study (Levshina and Matyushkina 2021) presented different concentration distributions of dissolved aluminum, iron, copper, chromium, vanadium, nickel, and zinc, and their humus complexes in Zeya reservoir water. When compared to iron, the latter had the highest concentration distribution. Similarly, few studies have also reported properties of humic substances in Eastern Siberia (Milkheev and Tsybenov 2021), Uzbekistan (Kamilov et al. 2021), and others (Sarapulova 2021).

Humus is a complex polymer formed from polymerization reaction of several monomers that are considered decomposing organic products, which can be repolymerized, as shown in Fig. 2. Therefore, humus undergoes a dynamic equilibrium state in nature (Selyanina et al. 2012). This is also because the humus content of several soils hardly changes, which makes the rate of formation similar to the turnover (Varga et al. 2008). This turnover (2–5% per annum) is basically a function of climate changes (Yuan and Chen 2010). Though biomolecules could be obtained from different sources, we have focused on soil and microalgae-based biomolecules. Furthermore, the chemical properties and biomedical applications of the same have been presented. In conclusion, we have examined recent advances in polysaccharide-based naturally occurring biomolecules.

Table 1 Overview of fungicides in soils, with their chemical names

Fungicides	Chemical names
Azoxystrobin	Methyl (E)-2-[2-[6-(2-cyanophenoxy)pyrimidin-4-yloxy]-3-methoxyacrylate
Cyprodinil	4-Cyclopropyl-6-methyl- <i>N</i> -phenylpyrimidin-2-amine
Fludioxonil	4-(2,2-Difluoro-1,3-benzodioxol-4-yl)th-pyrrole-3-carbonitrile
Mancozeb	Zinc manganese ethylenebisdithiocarbamate
Metalaxyl	Methyl <i>N</i> -(methoxyacetyl)- <i>N</i> -(2,6-xylyl)-DL-alaninate
Penconazole	(RS)-1-[2-(2,4-Dichlorophenyl)pentyl]-1H-1,2,4 triazole
Procymidone	<i>N</i> -(3,5-Dichlorophenyl)-1,2-dimethylcyclopropane-1,2-dicarboximide
Tebuconazole	(RS)-1- <i>p</i> -Chlorophenyl)-4,4-dimethyl-3-(1H-1,2,4,-triazol-1-yl-methyl) pentan-3-ol
Vinclozolin	(RS)-3-(3,5-Dichlorophenyl)-5-methyl-5-vinyl-1,3-oxazolidine-2,4-dione
Propiconazole	(2RS,4RS; 2RS,4RS)-1-[2-(2,4-Dichlorophenyl)-4-propyl-1,3-dioxolan-2-ylmethyl]-1H-1,2,4-triazole
Pyrimethanil	<i>N</i> -(4,6-Dimethylpyrimidin-2-yl) aniline
Quinoxifen	5,7-Dichloro-4-quinolyl-4-fluorophenyl ether

Toxicology: Fungicides in Vineyard Soils

Ensuring toxic-free soils is the desired goal in several agricultural regions. However, the presence of pesticides in soils raises serious concerns. This is because studies have shown that numerous dangers and risks are associated with their extensive usage in soils. So, the sorption of pesticides is an important process that could be affected by their solubility in soils. Generally, several fungicides are slightly soluble at a temperature range of 20–30 °C. For example, azoxystrobin, cyprodinil, fludioxonil, mancozeb, penconazole, procymidone, tebuconazole, and vinclozolin have solubility ranging between 1 and 100 mg/L, while quinoxifen is exceptionally insoluble with less than 1 mg/L. At the same temperature range of 20–30 °C, metalaxyl, propiconazole, and pyrimethanil have a notably higher solubility of 100–10,000 mg/L (Kamrin 1997). The chemical names of these specific fungicides are shown in Table 1.

Several studies have reported that the increasing “use of pesticides in areas of wet subtropical climate” causes a high incidence of copper concentration. Thus, copper-based pesticides are also vineyard soil contaminants. In the upper layers, Brazilian soils have one of the highest concentrations of copper contents ranging from 37 to 3216 mgCu/kg (Casali et al. 2008; Mirlean et al. 2007), according to the findings. Depending on the depth, Bulgarian soils have been shown to contain least copper contents in their upper layers, while Spanish soils could be also least in increased depths.

Properties and Composition of Humic Substances

Humic substances can be characterized by their color, total exchangeable acidity, alpha amino nitrogen, nitrogen, methoxyl, vanillin, and carboxyl and phenolic contents (Rashad et al. 2022; Lawrence 2017). Humic substances are usually black

in color, with low methoxyl and nitrogen contents of about 3–6% for the latter. Alternatively, humic substances could contain high carboxyl and phenolic hydroxyl contents, with over 150 cmo/kg total exchangeable acidity. Specifically, humic substances consist of lignin, proteins, and humic and fulvic acids. As per the basic composition, lignin contains 62–69% carbon, 5.0–6.5% hydrogen, and 26–33% oxygen, with no nitrogen content. Similarly, humic acids are composed of 52–62% carbon, 3.0–5.5% hydrogen, 3.5–5% nitrogen, and 30–35% oxygen. Also, proteins contain same carbon, hydrogen, oxygen, and nitrogen in proportions of 50–55%, 6.5–7.3%, 19–24%, and 15–19%, respectively.

Humic substances are composed of peat, sapropel, oxifulvic acid, potassium humate, and carbohydrate-derived fulvic acid. Peat is a biomass mainly made of organic matter (about 65%) and inorganic matter (about 35%). They mostly occur in wetland regions (Bujang et al. 2011). Properties of peat include moisture content, bulk density, specific gravity, void ratio, permeability, compressibility, and shear strength. These properties represent “the engineering behavior of peat,” which can be enhanced using fiber reinforcement, sodium silicate grout system, and others (Sina et al. 2011).

Sapropels are products of accumulated biomass materials, usually located under freshwater bodies (Bogush et al. 2022; Ivanova et al. 1997). Peat, as well as sapropels and other humic substances, are basically used in the treatment of dermatitis (Wolina 2009), psoriasis (Codish et al. 2005), rheumatoid arthritis (Gungen et al. 2012), and wounds (Vysokogorskii et al. 2009).

Studies have been conducted on the size of the humic substances. For instance, Guo et al. (2016) report HS from dairy manure and sugarcane pressmud compost as 300–600 nm. Calvo et al. (2016) also have noted that HS could demonstrate a molecular weight of 500–1000,000 Da due to their hydrophobic interactions and hydrogen bonding with heterogeneous polymers (Liu et al. 2011; Canellas et al. 2015).

Applications/Prospects of Humic Substances in Pharmaceutical Research

When humic substances are dissolved, they produce humic acid. Humic acids possess desirable medicinal properties of antiviral action, anti-inflammation, and others (Yamada et al. 1998), which demonstrate their usefulness in biomedical applications. Some of these areas of biomedical applications include the treatment of ulcers and herpes virus infection (Mishra et al. 2015). However, humic substances could also be used to detoxify toxic sites (such as metal-polluted lakes (Petit 2004; Tan 1994), sequest metals (Pandey et al. 1999), enhance crop production (Mishra et al. 2015), extract organic substances from water (Biggs et al. 1985), energy provision (Talmage et al. 2007), and cleaning up of nuclear power plants (Sollins et al. 1996)).

Humic substances could play a significant role in cancer treatment due to their “biochemical and molecular effects.” This is because the emerging role of molecular

simulations involving humic substances could guide new experimental designs, as well as “predicting properties and phenomena at the molecular scale” (Jacob et al. 2019). Other areas include their role in cancer etiology.

Conclusion

Humic substances have unique structures and composition, with dynamic formation and turnover rates. The main advantage of humus materials is that they can be obtained from different sources, unlike polysaccharides. Since only 20% of humus in certain soils occur as lipids, more research is needed to investigate the role of ecological restoration in enhancing the yield. The effects of crop dry farming and abandonment on the humic composition should be investigated.

Abstract

The use of polymers based on biological materials, rather than those that are based on petroleum, to create ecofriendly biologically degradable materials has gained popularity in recent years. Since they are less expensive and easier to produce than natural polymers, synthetic polymers are widely used. But they cause environmental contamination and are not biodegradable. Therefore, scientists advised choosing polymers that are naturally eco-friendly. This idea explains why soy protein, a cheap, easily accessible, and biodegradable ingredient, is so popular. It has superior biocompatibility, biodegradability, and better processing qualities and is 90% protein. Another appealing aspect of it is its use in numerous industrial fields. The aim of this chapter is focused on discussion of history of soy protein, composition, physicochemical properties, abiotic factors involved in improving the mechanical properties of soy protein, soy product production methods, and bio-nanocomposites. Moreover, some applications of soy protein polymer are also discussed.

Introduction

Biopolymers are natural polymers produced by or made from living things. They can be produced by chemical process from biological materials or can be synthesized solely from living organisms. Among the earliest modern biomaterials manufactured from natural biopolymers were rubber, linoleum, celluloid, and cellophane. Cellulose, the most common organic substance and most abundant biopolymer on the earth, is used to make celluloid and cellophane (Hassan et al. 2019). Various plants, including maize and soybeans, as well as different species of trees and even bacteria, may be the source of this resource. Concerns over the damage that pollution, from fossil fuels and petrochemical wastes which are the natural and traditional source of biopolymers, has on the environment are increasing. Several researches have been conducted to investigate various other alternatives to petroleum-based goods that are renewable and biodegradable, resulting in a lower risk of environmental damage. Since biopolymers are typically biodegradable materials produced from renewable basic resources, the possibilities of new product derivation are the hot topic in various fields like

health, pharmaceuticals, nanotechnology, food industries, enzyme kinetics, etc. Following are major categories for biopolymers:

1. Classification based on monomeric unit used and the structure of the biopolymers formed (Reddy and Yang 2011)
 - Long polymers of nucleotides like DNA and RNA with at least 13 or more polymers of amino acids
 - Polymers of carbohydrates with linear bonds
2. Classification according to their origin (Tansaz and Boccaccini 2016)
 - Polyesters: polyhydroxyalkanoates, poly lactic acid
 - Proteins: silk, collagen/gelatin, elastin, rexlin, adhesic, and polymonoacid; soy, zein, wheat, gluten, casein, and serum album
 - Polysaccharides (bacterial): xanthan, polygalactosamine, dextran, gellan, and cellulose
 - Polysaccharides (fungal): pullulan, chitin, and yeast glucan
 - Polysaccharides (plant/algal): starch, cellulose, agar, alginate, carageenan, pectin, konjan, and various gums
 - Polysaccharides (animal): chitin, hyaluronic acid
 - Lipids/surfactants: acetoglycerides, waxes, and emulsion
 - Polyphenols: lignin, tannins, and humic acid
3. Classification based on the type of origin
 - Synthetic biopolymers are biodegradable polymers made from renewable materials like polylactic acid.
 - Natural biopolymers are biopolymers produced spontaneously by living organisms.
 - Microbial polymers: produced by microorganisms such as bacteria, fungi, and algae.

Biopolymers can either be categorized as thermoplastics, thermosets, or elastomers based on how they react to heat. Biobased thermoset biopolymers have recently outpaced biobased thermoplastic biopolymers in volume (Post et al. 2020). Likewise, one more classification is based on their combination as blends, composites, or laminator. Blends of biopolymers include a mixture of polymer-like ElovioR (BASE.AG) which is said to be a mixture of PLA and PBAT. Biocomposites are biopolymers which are synthetically polymer strengthened using fibers of natural origin such as hemp, flax, banana, wood, jute, number of grass-like materials and flax, hemp, jute, banana, wood, various grasses, and condiments (Rajeswari et al. 2021).

It is advantageous to have a biodegradable plastic that undergoes microbial decomposition in the soil for numerous biomedical, agricultural, and ecological purposes. Many scientific investigations and efforts have been made to improve plastics' biodegradability. However, their efforts have been focused mostly on the following areas. Biodegradable polymers, synthetic polymer modification, and biodegradable polymer composites are all examples of new biodegradable polymers. Biopolymers as starting materials have received a lot of interest in the search

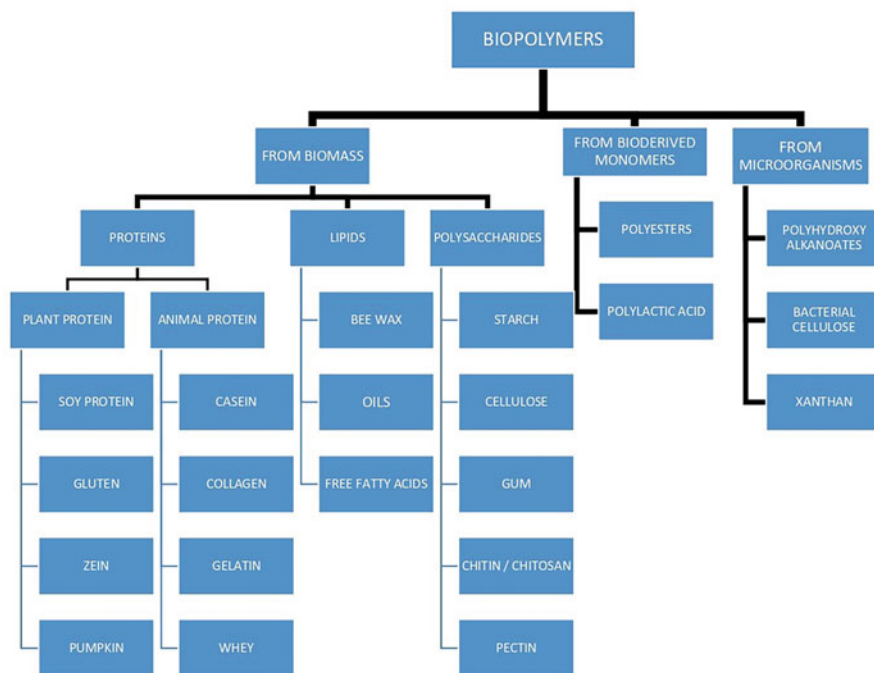

Fig. 1 Classification and components of biopolymers

for biodegradable polymers made from renewable resources. Green composites are a particular type of biocomposite that are reinforced with natural fibers using a biobased polymer matrix. We can rid our environment of plastic waste by substituting green composite items for synthetic plastic ones. Biobased polymers have played a significant part in the evolution of the plastics sector today. Biopolymers have been utilized by humans for food, clothing, and furniture throughout history. Among these, soy protein has gained much scientific interest for being developed as ecofriendly protein material with efficient properties like biodegradability, biocompatibility, regeneration, etc. (Echeverría et al. 2014). Plant proteins are polymers that are biodegradable as well as renewable. Soy protein is used as starting material for making plastics (Fig. 1). It is also used as filler or expender to reduce the price of plastics originated from petroleum products to assure the eco-friendly biodegradability. Apart from these characteristics, it is used as food ingredient, and also it has attracted great attention in nonfood application as polymeric materials. Composites made of soy protein were frequently utilized for hard packaging, transportation, and housing. Green composites were created using soy protein resins for a variety of uses, including glues or adhesives, plastic films, coverings or coats, emulsifiers, and blended hydrogels. They are also being considered to be substances which have immense use in biotechnology and medicine (Reddy and Yang 2011) (Figs. 2 and 3).

Fig. 2 Diagrammatic representation showing stages of producing soy products from young soya plants (Song et al. 2011)

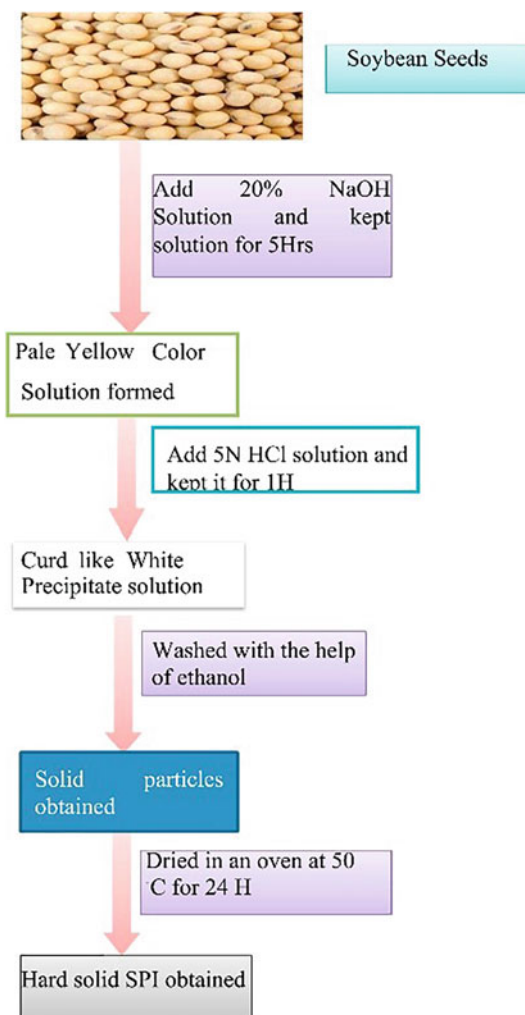

History of Soy Protein (Dupare et al. 2008)

See Table 1.

Composition of Soy Protein

Soyproteins (SP) are extracted from soybeans. It belongs to the plant species *Glycine max*, family Fabacea. They contain ~38% protein, ~30% of carbohydrates, ~14% moisture and minerals, and ~18% oil (Tansaz et al. 2016). It is a globular protein. The main components of soy protein are glycinin and β -conglycinin. Their content, rates, and biosynthetic dynamics vary depending on the type of soybean and the environment in which they live. The molecular weight of glycinin and conglycinin is between 300–400 KDa and 150–250 KDa. β -conglycinin is a trimer or a hexamer when in solution, while glycinin is a hexamer (Hammond et al. 2003). Glycinin is a protein having quaternary structure that is stabilized by disulfide, electrostatic, and hydrophilic interaction. 6 A-SS-B subunits are made up of polymers of acidic and basic proteins bonded by di sulfide linkages. The subunits of the same are found to be arranged as double hexagon stacks and result in a shape of hollow horizontal cylinder. Glycinin has acidic or basic polypeptides linked by disulfide bond. Inner portions of the glycinin molecule are rich in proteins containing basic amino acids. Meanwhile, beta conglycinin forms important portion of 7S and is having 150–180 KDa which contains 3 sub units such as α , α' and β . They are linked through hydrophobic interactions. They interact to produce 7 isomers. Molecular weight of these subunits is 72 KDa, 68 KDa, and 52 KDa. The N-terminal aspartic acid residue of the original β conglycinin is glycoprotein consisting of carbohydrates linked as a single unit. Per protein molecule, the carbohydrate moiety consists of 12 glucosamine residues and 38 mannose residues. So their structure is different, and that

Fig. 3 Extractions of soy protein isolate (Gautam et al. 2021)

reflects in their physicochemical properties too. The isoelectric point of conglycinin is 4.8, and that of glycinin is 6.4. The amino acid property in soya protein is like 18% basic and 20% acidic in nature (Gorissen et al. 2018). The amino acid content in soy protein is given in Table 1. It divides into fractions 2S, 7S, 11S, or 15S depending on the molecular weight and sedimentation coefficient. Of the soy proteins, the 7S and 11S globulins account for 37% and 21%, respectively. Glycinin serves as a gelling, emulsifying, and foaming agent when combined with other film-forming proteins. In comparison to glycinin, β -conglycinin is less heat stable and denatures between 70 °C and 80 °C (Table 2).

Table 1 The timeline of commercialization of soy protein

Time period	Contributions
700 BC	First written record of soybean cultivation record of soybean cultivation for China
1712	Soybean included in Europe
1804	Soybean was introduced to the USA from Asia/China
1900	Research on agricultural sources for plastic production including soy protein
1913	Britain and France bagged patents for generating bioplastics from soy protein
1917	First US patent for soy protein
1933	As a result of Henry Ford's soy bean experiment, it was discovered that soy protein could be shaped into miniature plastic car parts and that soybean oil produced outstanding paint for painting automobiles and binding molds
1936–42	Regional Soybean Industrial Products Laboratory, Urbana, published a continual series of studies on its initiative to produce polymers from soy protein and meal
1942	150 million lbs. of soy-meal plastic was produced which was a derivative of phenol-formaldehyde, soy, and wood flour
1960s	Although the worldwide soya bean market has declined, Japan's booming livestock sector has begun to employ soy protein meal as a protein and energy source
1970s	Soybean consumption in Europe increased gradually
1976–2005	Soybean plantings increased by 50% in the USA, while national average soybean yields increased by about the same amount
1980s	In Europe, demand for soy meal and soy oil fueled expansion of processing capacity
1990s	Demand for soybean products spread to China, South Korea, Mexico, Indonesia, Turkey, and Philippines
2000s	China's overall capacity for processing soy beans has quadrupled

Types of Soya Protein Product

Soy protein products are mainly produced in 3 forms. They are flour, concentrate, and isolates of soy protein. The major difference among the above components is in the content of proteins, in which SPI has uppermost and soy protein flour has the lower most percentage of protein. The carbohydrate content is high in soy protein flour. At the time of production of soy protein concentrate, the soluble carbohydrates are removed leaving the insoluble types. But during soy protein isolate production, both soluble and insoluble carbohydrates were removed.

Soy Flour

Soy flour contains about 56% protein. The fraction is like 11S fraction and 7S fraction; each contains ~35% of the protein. Storage globulins, glycinin and conglycinin, are the major components of the two fractions. The native glycinin contains tightly folded polypeptides linked by disulfide bonds. Soy protein flour is

Table 2 Amino acid content in soya protein concentrates

Sl. No.	Amino acid	Soya protein concentrate (mg/100 g)	% of total amino acids
1.	Alanine	2677	4.3
2.	Arginine	4642	7.4
3.	Aspartic acid	7249	11.5
4.	Cysteine	886	1.4
5.	Glutamic acid	12,013	19.1
6.	Glycine	2688	4.3
7.	Histidine	1578	2.5
8.	Isoleucine	2942	4.7
9.	Leucine	4917	7.8
10.	Lysine	3929	6.2
11.	Methionine	814	1.3
12.	Phenyl alanine	3278	5.2
13.	Proline	3298	5.2
14.	Serine	3369	5.4
15.	Threonine	2474	3.9
16.	Tryptophan	835	1.3
17.	Tyrosine	2301	3.7
18.	Valine	3064	4.9
19.	Total amino acids	62,954	100
20.	Total EAA % total	23,832	37.9
21.	Total BC AAA % total	10,923	17.4

produced using defatted and fine ground shavings or flakes and meals after passing over meshed screen of standard sizes of 100. For manufacturing flakes with lesser fat content, clean, dry soya beans are subjected to deshelling and finally cracked. These cracked beans will be heating at 74 °C and flaked. The most widely used method is solvent extraction using hexane for extracting oil. About 1% or less amount of oil is reduced, and the solvent solubilizes the soy bean fat content. Later, the organic content in the flake product will be removed. A flash solventizing system can be used for the production of edible and industrial soy protein (Vavlitis and Milligan 1993). This method provides mild heating condition, minimum retention time to minimize protein denaturation, and low moisture condition. Finally, high soluble and nonfat containing de oiled flakes called white flakes. Soy flours are available in three forms like highly dispersible soy flour and in between these two forms of soy flour type.

Soy Protein Concentrate

Soy protein concentrate is a form of soy protein product. It contains about 70% protein. These are usually produced by separating majority of nonproteinaceous components in the soy flakes having high protein solubility which were subjected for

previous dehushing and fat-removal processing. This contains mainly soluble carbohydrates and some low molecular nitrogenous substances and minerals. The amino acid composition of soy protein concentrate differs somewhat from the original soy flour. Commonly, three methods exist for manufacturing soy protein concentrate. Each process produces a different type of concentrate with different properties. These processes include aqueous-alcohol wash, aqueous extraction combined with thermal denaturation and acid wash. The first two methods result in the denaturation of the final soy protein product; in contrast, acid wash will not denature soy proteins. pH of the dispersed water will be adjusted to an acidic range (4.2–4.5) using HCl in order to dissolve the soluble sugars. Hence this will help not to go for other specific solvents. Concentrate of solids is usually neutralized and then spray dried.

Soy-Protein Isolate

This is one of the popularly available soy-protein product containing 90% of proteins and is usually produced by utilizing the property of isoelectric point. Soy flakes which were subjected to fat content removal will be mixed with warm water at a pH of 7.5 to 9. By centrifugation, the soluble proteins and carbohydrates were partially recovered from the insoluble fractions. In order to precipitate the majority of the proteins, HCl is added to the solution, lowering the pH to 4.2–4.5. The precipitated proteins are rinsed clean of the soluble sugars. The addition of NaOH suspends and neutralizes the precipitated proteins. The product was then eventually frozen dried (Gupta and Nayak 2014).

Physicochemical Properties Soy Protein

The chemical ratio of soya protein is that it has both polar and nonpolar side chain. As a result, intra- and intermolecular interaction will be strengthened due to hydrogen bond formation, dipole interaction, and hydrophobic interactions. The stiffness, yield point, and limit strength of soy protein films are increased as a result of the side chains of soy protein molecules' strong charges and polar interactions with one another (Zhang and Jane 2001). In aqueous solution, pH 4.5 causes the precipitation of the soy protein, and hence it is decided as the isoelectric point for soy protein. Film formation at or near the isoelectric point due to coagulation was not reported. But it can be bypassed and deployed at pH values far from its quiescent point.

Therefore, their functional groups have been exposed and intermolecular interactions will increase. Therefore, it is clear that the mechanical properties of soil proteins can be affected by their pH. Physical properties during processing are better under alkaline conditions (Kim and Netravali 2011). Both soy protein and soy protein isolate were naturally brittle when processed without plasticizers or modifiers. The interaction between protein and some smaller molecules like plasticizers, water, lipids, and certain additives influences the mechanical strength of

network of proteins. The structural stability and mechanical behavior of SPI films are, on the other hand, influenced by various functions such as length of the polymer chains, water resistance, and charges in the surface of the polypeptide chains. SPI films have durable O₂-resistant properties and permeable parameters which are less than approximately 500 times in lower relative humidity atmospheres (Song et al. 2011).

Many methods are being investigated to enhance the functioning of soy protein, and one of them is to use natural fibers from a composite material to strengthen soy protein films. Due to the natural fibers' eco-friendliness, biodegradability, sustainability, low cost, and density, as well as their ability to be produced from waste streams, these composites with natural fiber incorporation are a desirable option. Utilizing additives like cross-linking agents and plasticizers to enhance the mechanical characteristics and moisture sensitivity of soy protein films is another method for combining protein with other natural polymers.

Methods to Improve the Mechanical Properties of Soy Protein

pH Treatment

Utsumi et al. (1997) reported that soy protein isolates have good gelating ability, and emulsification foaming and water absorption properties. It is poorly soluble in acidic pH condition. At isoelectric point, the SPI was almost insoluble. So at alkaline pH (8–11) that means far from the isoelectric point, the soy protein differs its film-forming capacity. At this pH, the denaturation of soy protein was promoted that leads to unfolding, and solubilization of protein assists the formation of rigid structures. The Kim and Netrasvali designed reinforced green composite with soy protein-hemp yarn. They also discovered that the interfacial shear strength of SPC resin/hemp yarn was raised with pH, rising from 17.7 MPa at pH 7 to 28.0 MPa at pH 10. As a result of the exposed reactive groups in the peptide chain caused by the addition of NaOH, the soy protein underwent another modification that boosted intermolecular contact with the hydroxyl group of the cellulose hemp yarn. If the alkaline state is exceeded past pH 10, soy protein molecules and electrostatic repulsive forces appear to grow, which reduces the interaction with cellulose fibers.

Thermal Treatment

Ryan et al. in 2008 studied that pH, protein concentration, and calcium supplementation affect the thermal stability of soy protein isolate and whey protein hydroxate. Thermal treatment is the oldest method used for the modification of soy protein. Thermal treatment decreases the action of protease inhibitors, eliminates lipoxygenase and volatile chemicals, and improves the functional qualities of the product (Barac et al. 2004). Studied thermal properties of soy protein isolates are investigated by thermo gravimetric (TG) and derivative TG (DTG) analysis.

Actually, SPI materials without any secondary components have no satisfactory physicochemical and mechanical properties for industrial-level applications (Park and Hettiarachchy 2000). Especially the soy protein biopolymers' thermal stability can be increased by blending with other 2 biodegradable polymers; chemicals or enzymatic modification has been applied (Pathak et al. 2009).

Yulong et al. have studied about the thermal degradation of sodium alginate-incorporated soya protein isolate/glycerol composite membranes. This was done by thermal gravimetric analysis method (TGA) and differential thermal analysis (DTA). The samples were heated from ambient up to 1050 K with temperature programmed at certain heating rates in air at a flow rate of 30 ml/min. Thermal degradation in oxidative atmosphere, the normal SPI- and SPI-SA-integrated biomaterials, exhibited a 3-stage decomposition. At 400 K, an initial weight loss occurred mainly due to the physical water loss from the sample, but during second-stage main weight loss happened. The pure SPI losses into weight in the temperature range from 540 to 630 K. But in SPI /SA composite, the main weight loss happened in the range of 480-600 K. Several reviews reported that the inter and intra molecular linkage in proteins is caused by treating the soy protein using heat at basic pH. Studies also revealed that the heating of SP films at 80–95 °C for various periods increased tensile strengths. The soy protein isolate seems to get aggregated via strong forces of interactions like hydrogen bond formation and disulfide bridges within the protein molecules and was experimentally proved by checking the solubilization of film heated at 65 °C for 6, 18, and 24 h and also at 50 °C for 6 h. It was also reported that the solubility founded more than 95% dissolution of the protein sample in the urea buffer. Here, the component urea serves as an H-bond breaker and 2 mercapto ethanol as an S-S bond-breaking agent. The resultant SDS-PAGE patterns of the respective proteins showed protein aggregates.

Tensile Strength Modification

Tensile tests are the most often used methods for figuring out the mechanical characteristics of biopolymer components as well as their structural layout. The ratio of stress to strain (stiffeners) in a material at the elastic stage of a tensile strength is known as the “Young's modulus” (Azammi et al. 2020). Due to the rigid, brittle physical properties and little flow ability soy protein isolate is reinforced with reducing agent, a starch filler, plasticizer, water etc. to increase the tensile properties. Studies revealed that soya protein concentrate reinforced with ramie fiber showed tensile properties similar to steel (Netravali and Chabba 2003). Soy protein films made from purely soy protein isolate bend to the brittle. So there is a need of converting them into composite from using functional nanomolecules. The dimension of nanoparticle approaches the Fermi wavelength of elusion and metal nanoclusters (NCs) where size is less than 2 nm as a novel functional nanomaterial. They are composed of a few to 100 atoms. Studies by

Husseinsyah et al. (2014) clearly studied that the tensile strength of SPI has increased by modifying with kapok husk films (KH).

The Kapok Husk filler, which serves as a reinforcing component, is to blame for the increase. From the SPI measurements to the Kapok Husk filler phase, it can facilitate the transfer of stress. This is a result of the hydroxyl and carbonyl groups in the SPI matrix and the hydroxyl group in the Kapok Husk filler forming intermolecular hydrogen bonds with one another. Huang and Netravali's experimental study from 2009 revealed that modified SPI with Kapok Husk filler and Glutaraldehyde reinforcement had greater tensile strength than unmodified SPI cross-link using reactions involving a Schiff base. This linkage strengthened the interaction on interfaces and the wetting property of SPI matrix and KH filler. The tensile strength of the glutaraldehyde-treated SPI films is better than that of untreated SPI films because of the imine linkages (Jin et al. 2013).

Water Barrier Properties Modification

The low-moisture barrier properties of the soy protein films arise due to their hydrophilic nature. Studies have been focused on minimizing the hydrophilicity and stabilizing the mechanical properties in order to enhance the physical characteristics of biopolymer bond films. Addition of hydrophobic chemicals is a new technique for enhancing biopolymer's moisture barrier qualities (Hernandez 1994). The moisture barrier properties of biopolymer films have been enhanced by the incorporation of lipid components like neutral lipids, fatty acids, or waxes. Studies also proved that additives of Eugenol (Eu) into SPI film improve the barrier properties. An alternative method to make soy protein films more functional is to alter the network arrangement of proteins majorly via cross-linking a protein chain. The soya protein isolate has low-oxygen permeability values, and this property provides an opportunity for preserving foods from oxidative deterioration. Experimental works also become successful by using glycyrrhizin alginate nanogel particles (GI-ALG NGPs) incorporated with SPI matrix which form a continuous and cohesive network and also act as a water barrier. In earlier times, the studies on rheology and water absorption properties of soy protein isolate with alginate have conducted many, but the nanogel particles in place of alginate is a recent work (Aritrasinha 2021), and it proved best as a moisture barrier.

Water-Holding Capacity Modification (WHC)

The term "WHC," which stands for "water holding capacity," refers to the total amount of water that can be absorbed per gram of protein powder. Actually, this is the result of proteins directly interacting with solutes like water. There are three distinct phases of water absorption that define soy protein's water absorption. The ionic and high-energy site surfaces on the polypeptide are bound by approximately

1 g of water for every 100 g of solid during the first phase, resulting in a highly structured monolayer. Apart from this monolayer, 25 g of water is hydrogen bound to the polar groups, changing the conformation and causing the protein matrix to swell at first. In essence, the polar group is connected to the water retention of proteins (Nguyen et al. 2015).

Blending

The best method to increase the physical properties of SPI materials, a practice of binding soy protein with polymers like polysaccharide proteins and synthetic, is followed which results in better products. Natural polymers used for blending are sodium alginate, calcium, cellulose, chitin, chitosan, glutan, whey protein isolate, and gelatin. Poly vinyl alcohol (PVA) is proved as a good blend for getting SPI film strength, flexible and better adhesive properties (Chen et al. 2013). Natural polymers are hydrophilic in nature, so the blends made by natural polymers cannot solve the moisture sensitivity problems of soy protein films. So the solution for this is to use synthetic polymers in place of natural polymers. Synthetic polymers like polyvinyl alcohol, poly lactic acid, and poly butylene adipate- co- tetra phthalate were used for blending and are biodegradable. Also they are hydrophobic in nature and do not have good interfaced adhesive (Chen and Zhang 2012). Another study using bioabsorbable polyphosphate filler as a blending agent revealed that this leads to changing the failed micromechanism of the blended soy plastic to a pseudo ductile way from being fragile. It enhances properties such as water resistance, strength, stiffness, etc., (Otaigbe and Adams 1997). Interpretation of gelatin also processes between successful blending agents. It results in gearing up the limited strength of elastic modulus and the increases the limit strength elastic modulus and ability to swell by the soy protein films. As a result, the transparency of the soy protein films increases and becomes easy to manage. Flexibility also increased. Some natural oils were also used as blending agents like Epoxydized soya bean oil (ESO), virgin extra olive oil, and lactic acid (LA) which were added to SPI-based films, and this improved hydrophobic character of film.

Plasticizers

The brittleness nature of SPI has been removed by adding plasticizers because they have the ability to reduce internal hydrogen bonding. Three theories are there to elucidate the effect of plasticizer mechanism: (a) Theory of Lubricity which says that plasticizers can enhance the interactive motions of macromolecules as does a lubricant; (b) Gel Theory which says that weak interactions such as H bonding, Vander Waals, and ionic bonds can be interrupted by polymeric interactions; (c) Free Volume Theory which says that an increase in the free volume of polymer can lead to depression of transition temperatures of glass. One of the basic perceptions underneath these theories is that behind these theories plasticizers are able to interpolate themselves between polymeric chains and can result in decreasing force of attraction which held the chains. The molecular weight and number and position of hydroxyl

groups of plasticizers are all variable that affects the ability to plasticize soybean protein-based polymer.

Wan et al. in 1996 proved that polyols from the ethylene glycol series are a good plasticizer due to their similar polarity to soy protein. Studies also proved different outcomes of plasticizers on the SPI film characteristics. Glycerol and sorbitol in 1:1 concentration result in the increase of moisture sorption content. Glycerol is found to be a good plasticizer, but adding 2,2-diphenol-2-hydroxy ethanoic acid (DPHEAC) and various amounts of salicylic acid again improves the properties of SPI like the increase in tensile strength and modulus with lower water sorption.

Surfactants

The most common surfactant used is Sodium Dodecyl Sulfate (SDS). A study of Sessa et al. proposed the effect of control of viscosity of zein by sodium dodecyl sulfate (SDS) during the time of thermal processing. In their experiment, they blend zein between water and TEG (Tri ethylene Glycol) followed by a heat treatment and shearing inside a torque rheometer to observe the change in viscosity. However, following the addition of SDS, there are reports explaining a diminishing tendency to the increase in viscosity of the zein/water/TEG in parallel to the addition of SDS. At the same time, when there is an increase in the quantity of SDS, the tensile strength and Young man modulus were found to be decreased with an elongation in bioplastics made up of zein. The application of SDS with soy protein isolate ensured a ductile material. Another study by Veerbeek and Van Den Berg in 2011 used a combination of SDS and urea for the processing of thermoplastic blood meal bioplastic extrusion. Results showed that the consolidation of the bioplastic was strongly dependent on the amount of SDS, and it is required for bioprocessing and consolidation. But in higher concentration, it hinders the formation of new intermolecular forces. Use of SDS leads to the improvement as process ability and the processing window get expanded. The blood meal is processed by injection molding with the addition of SDS and urea. Apart from SDS, adding different types of fatty acids like palmitic acid, stearic acid, and oleic acid in the film-forming solution is an efficient method to get thick SPI films with a white color and lesser chances of shrinking followed by drying of the film.

Biodegradable Polymers

Biodegradable polymers are low-cost good processability materials belonging to a family of polymer materials. There are 2 types of biodegradable polymers. They are natural and synthetic polymers. Natural polymers are basically polysaccharide or protein.

Chitin is a natural polymer having hard and elastic property which is employed for combining SPI in the presence of glycerol. Chitin has some rigidity which enhances the tensile strength and Young's modulus of SPI films (Denavi et al. 2009).

Chitosan is also a natural polymer made up of β -1,4 linkages between 2 amino 2 deoxy – D glucopyranose as monomers. It is used as a blending agent. It is less hydrophilic than SPI film. So its blending results an increase in water content angle and decrease in surface energy.

Propyleneglycolalginate (PGA) is a biodegradable polymer used to combine with SPI. The water stability of the film is improved by the formation of covalent bonds between propyleneglycolalginate and SPI. Total 10% addition of PGA is found to increase the resistance of water vapors and ductability of the film.

Cellulose is also a natural polymer which on adding SPI increases the oxygen and carbon dioxide barrier properties and also its mechanical strength. Apart from other blending agents, the cellulose needs a cosolvent due to its amorphous nature, so here 1-butyl-3-methylimidazolium chloride (BmimCl) is used.

Gelatin is a natural biodegradable polymer which on combination with soya proteins leads to a better blended product. The presence of sugar rings in the polysaccharide chain limits the flow and sliding moment of polymeric chain over each other. That increases the stiffness and brittleness. The porous nature of this combined form extend its application in the medical field very successfully in skin tissue regeneration purpose.

Caesin-incorporated SPI is also a better option to contribute to the features of SPI film. The transparency of the film can be increased by either sodium or calcium casienate. In addition, calcium caseinate also plays an important role in improving the elasticity and tensile strength of the blended films.

Poly lactic acid (PLA) is thermoplastic polyester used as a blending agent. SPI-PLA blends can be created using a screw extruder vent and poly (2-ethyl 2-oxazoline) as a compatibilizer.

Poly butylene succinate (PBS) is semicrystalline thermoplastic polyester with good elongation and physical properties. Direct blending of PSB with SPI is not so successful. So first, PBS is reacted with toluene diisocyanate (TDI) at different ratios to prepare methane group containing PBS. The remaining -NCO group on the PBS reacts further with the functional group in SPI when it is introduced.

Polycaprolactone (PCL) is a type of synthetic aliphatic polyester. The blending of PCL with SPI can be enhanced using some molecules having reactive ability such as MDI (Methylene Di pheny Di isocyanate) and TDI (Toluene 2, di isocyanate). Coconut oil also has plasticizing ability and compatibility in SPI and PCL blend and possesses highly effective mechanical properties, biodegradable properties, and adhesive properties.

Polyurethane (PU) is a blending agent having dual properties like elastomeric and thermoplastic character. An experimental work was done by Zhang et al. in 2003 by preparing prepolymers. A series of SPI-PU composites were created by compression molding a series of polyurethane prepolymers (PUP) that include NCO groups. The prepolymers' -NCO groups reacted with the SPI's -NO₂, -NH, and -OH groups, enhancing the blends' toughness, thermal stability, and water resistance. Additionally, ionic waterborne polyurethane (WPU) can be blended with SPI to enhance thermal stability, optical transmittance, and water resistance. Waterborne polyurethane, which is nontoxic and inflammable, increasingly replaced organic solvent-borne polyurethane once the environmental and health issues were taken into account.

Polyvinyl alcohol artificial polymer is hydrophilic. It is widely produced all throughout the world. In order to create biodegradable composites, it is mixed with organic polymers.

Effect of Plasticizers

Plasticizer is an addition that is added to a plastic or an elastomer to make the material softer or pliable. They actually break the intermolecular linking and thereby stabilizer protein in their primitive structure (Gurgel et al. 2011) and made the protein chains movable. Various researches were conducted for studying the effect of plasticizer. Due to its small size and hydrophilic character, glycerol is one of the most commonly utilized plasticizers for soy protein modification and has become increasingly compatible with soy protein. The influence of glycerol content on SPI plastic is investigated using Fourier Transform Infrared Analysis (FTIR), thermo gravimetric analysis (TGA), and differential scanning calorimetry (DSC). The results show that flexible films with good mechanical properties can contain between 25 and 35% of glycerol by weight. The tensile strength decreases as more glycerol is added, yet the elongation at break increases. This is as a result of glycerol's ability to reduce links between protein chains while enhancing chain mobility (Guerrero et al. 2014). A study was conducted using water as plasticizer for biopolymeric materials and was found to be effective (Reddy and Yang 2011). Plasticizers like stearic acid, sodium dodecyl sulfate, ferulic acid, waterborne polythene, etc. were reported to improve the water vapor barrier properties of soy protein.

Effect of Cross-Linking Agent

The mechanical and water resistance qualities of soy protein polymers are improved by yet another addition. Zinc sulfate, formaldehyde, acetic anhydride, glyoxal, and glutaraldehyde are a few examples of cross-linking agents. Studies showed that using glutaraldehyde (GA) as a cross-linking agent increased SPC strength and decreased moisture absorption (Chabba et al. 2005). In recent years, an unique natural cross-linking substance known as 1, 2, 3-propanetriol-diglycidyl-ether (PTGE), which is formaldehyde-free, practical, and easily accessible, has been added and shown to have an extremely high tensile strength.

Enzymatic Treatment

Enzymatic treatment for processing of soya protein is found to be a good method, for mainly oxidoreductase enzyme was used. The enzymes such as laccase (EC1.10.3.2), catechol oxidase (EC1.10.3.1), O-amino phenol oxidase (EC I. 10. 34) or peroxidase, glucose oxides (EC 1.1.3.4), hex oxidase (EC I. I. 3.5), or a cellobiose oxidase (EC1.1.3.25) were used for treatment. An oxidoreductase may be from plant, animal, bacteria, or fungi (including filamentous fungi and yeast). Some of the fungus-secreting laccase enzymes are *Aspergillus*, *Neurospora*, *T. Verscefan*, *M. thermophore*, *C. comaties*, *R. solani*, etc. Example for bacteria-secreting laccase is from the strain of *Bacillus*. Sometimes, oxido-reduction is produced by a method of cultivating a host cell shear forced with a recombinant DNA vector which carrier is a

DNA sequence encoding the oxidoreductase and also DNA sequence-encoding functions permitting the expression of the DNA sequence encoding the oxidoreductase, in a culture medium under conditions permitting the expression of the oxidoreductases. Studies using polyethylene glycol diacrylate (PEGDA) found a good concentration reduces the viscosity of soy protein and increases the water resistance capacity.

Incorporation of Other Biopolymers

Different types of cellulose can be incorporated with soy protein plastic to improve its mechanical properties. The type of biopolymers used for this purpose is commonly known as fillers. Microcrystalline, short fiber, and long fiber celluloses were the principal fillers utilized. The elongation, young's modulus, and tensile strength for soy protein without cellulose filler were reported to be 4.1%, 1481 MPa, and 37 MPa, respectively. In reality, adding microcrystalline cellulose to soy isolate promotes stiffness rather than tensile strength. Young's modulus rises along increasing short filler cellulose concentration, reaching a maximum of 2250 MPa at 20% cellulose. With 5% short fiber cellulose, elongation falls to 29%, and it slightly rises with 16 and 20% short fiber cellulose. When long fiber cellulose is added, the plastic becomes stiffer, has lower tensile strength, and has less elongation. Water absorption studies on these fibers' ability to absorb water also showed that soy proteins without fibers can absorb up to 32% of water after 26 h of immersion in water at ambient temperature. Soy protein with a 20% microcrystalline content absorbs about 28% of the water. Short-fiber cellulose increases water absorption to 34% when added at a 20% concentration, but only up to a 15% reduction in water absorption. So this rise may attribute to the fluffiness of the structure of the material that is because of the short fiber cellulose at this particular concentration. At the same time, no significant change in water absorption is noted in long fiber cellulose-incorporated soy protein.

Soy Protein Bio-nanocomposite

Soy protein isolate (SPI) gained significant attraction in the package technology field because of super easy biodegradability and film forming properties. But SPI-based films are always susceptible to inner mechanical functioning and higher sensitivity to moisture and limit its practical applications. Concerning these matters, several studies have been conducted to develop biobased nanocomposite films. Reinforcement units cellulose nanofiber (CNF) and nanosilica (NS) particles were studied, and results showed an increase in mechanical properties, aqueous services, barrier peptides, etc. of SPI-based composites. The CNF and NS particles were incorporated with soy protein film with low help of a silane reagent (KH 560). It bridges CNF and NS and forms a nanohybrid skeleton. It also enhances the interfacial interactions between nanofiller and SPI matrix by

exposing the exsposed functional group. This soy protein isolates cellulose nanofiller, and nanosilica nanocomposite films were developed. An experimental study was conducted using a copper nanocrystal for developing soy protein bio-nanocomposite. To improve the mechanical properties of SPI-based films, water-disposed CuNCs (Copper nanoclusters) were applied with the soy protein isolate with facile method. To improve the mechanical properties of SPI-based films, water-disposed CuNCs (Copper nano556 clusters) were applied with the soy protein isolate with facile method and along with chitosan is also attached. When checking about the tensile strength and EB (Elongation break) values of SPI -CS - CuNCs films, they were about 118.78% and 74.93% increased, respectively. The compatibility between SPI and chitosan was found to be increased by adding CuNC, hence micro structure of the SPI-based film becomes more homogeneous and the hydrophobicity and thermal stability also get better. The water vapor barrier ability got decreased, and so the nanocomposite film is found best in food-packaging materials. Nanocomposite films were formulated isolates of soy, clays (Na + -MMT), and eugenol (antimicrobial agent). The shear thinning behavior and consistency in SPI enhance with the addition of Na + MMT. Because it is inexpensive and readily available, nanocomposite (MMT) is a popular nanoparticle for soy protein plastic. Melt extrusion of SPI/Montmorillonite (MMT) bio-nanocomposite films revealed appreciable improvements in the films' tensile strength, storage modulus, water barrier performance, and thermal stability. The pH of film-forming solutions essentially determines which qualities are superior criteria for extrusion and MMT content (Kumar et al. 2010). The soy protein isolate/cellulose sans composite's tensile strength and young's modules were improved as a consequence of an experiment using cellulose whiskers to strengthen the soy protein isolate. Since the cellulose whisker content is increased, the thermal stability and water resistance capacity of the SOPI matrix increased, and the reason behind this phenomenon was found to be the intermolecular hydrogen-bonding interaction between the cellulose whiskers and the SPI matrix (Wang et al. 2006).

Soy Plastics

Polyurethane and polyester thermoset includes the common types of soy bean-derived plastics. Soy polyols, which are polymers found in soybean oil, are used to manufacture adhesives, coatings, sealants, inks, and car panels, among other things. Polyols stability and endurance can be improved by using the right ingredients in their formulation. Due to the inclusion of various compounds that lend durability and strength to the final products, soy-based plastics appear to be nonbiodegradable in some situations. Soy protein plastics are made at considerably lower temperatures than conventional plastics, it appear and feel like petroleum-based plastics. They are generally are freezer safe and may tolerate hot foods and liquids up to around 90 degree celsius. Polymerization is a chemical process that involves the discovery of monomers in the presence of heat or a change in pH,

resulting in huge networks of linked chains known as polymers. The same thing happens with bioplastics, but they must first be treated before they can be used. In the case of soya, a variety of derivatives can be employed to make plastic. 60 pounds of soy generates 11 pounds of oil, 48 pounds of soy meal and/or 38 pounds of fat-removed soy flour, 20 pounds of protein concentrate, and 12 pounds of soy protein isolate. After dehulling and meal grinding, dehulled soybeans are ground into soy flour, which is subsequently loaded with varying degrees of protein solubility. Soy protein concentrate is made from soy flour that has had the water- or alcohol-soluble carbohydrates leached out of it. The next step is acidification of soy protein concentrate to pH 4.5 followed by dissolving the soy protein concentrate in caustic 12 solution of pH 9. That forms the purest soy protein in the market containing 90% protein and virtually ready to be converted into a plastic, but there is one additional thing to think about: the moisture content. Ford's team (who invented the world's first plastic automobile) found that if plastic swells are left in the rain, moisture content affects the mechanical properties of the final material. An option for controlling moisture content is by adding plasticizers such as glycerol or by oven or air drying methods. Once the moisture content is controlled, then the protein isolate can be tuned into a plastic using heat and pressure. At the same time, compression modeling and extrusion are also done. Many chemical modifications have been made during processing to improve the mechanical properties and moisture sensitivity of soy protein plastics (Nanda et al. [2022](#)).

Methods for the Formulation of Soy Protein Product

Soluble sugars are typically left out of defatted soya flakes, or flocs, when making soy protein concentrates. The majority of the remaining substance is made up of insoluble polysaccharides and proteins. The remaining soy product's protein level increased naturally as a result of the removal of soluble sugars, and the unwanted oligosaccharides that cause flatulence were also removed. To remove soluble sugars and produce soy protein concentrates, a variety of leaching techniques are being investigated. The starting material's quality, the yield, and the extraction conditions all have an impact on the leaching process. Hexane was used to extract the oil from the whole flat flakes of soy to create soya concentrate. For improving the quality of the product, research study by Russin et al. in [2011](#) reported that a solvent mixture of hexane, ethanol, and water can be used for the oil extraction of full flat flakes. It has also had the capacity to remove substantial amount of undesirable glycerides, phosphatides, and off-flavor components which are not removed during hexane extraction. Heat is an abiotic factor which affects the quality and yield of soya protein concentrate. Excessive toasting of defatted flakes leads to reduce the amount of soluble sugars to leach out, and that results in lesser amount of protein content in the final product. There are three methods for manufacturing soya protein concentrate aqueous wash, acid wash, hot water leaching, and enzymatic treatment:

Aqueous Alcohol Wash

This method is employed in case of commercial production of soy protein concentrate. Total 50 to 70% of aqueous alcohol is used in this method, and it extracts soluble sugar and small amount of soluble protein. As the aqueous alcohol has the capacity to denature the protein, the protein becomes insoluble and the insoluble polysaccharides also remain. The alcohol is finally recovered by flash desolventizing. The water/alcohol ratio is an interesting parameter for controlling the protein composition, yield, and functional properties of the SPC. The most interesting functional properties were obtained when using either water-only solvent or solvent with high water/alcohol ratios.

Hot Water Leaching

Heat denatures proteins, and soy protein does too, rendering it insoluble in water. Moist heat has greater denaturation potential than dry heat. Small molecular weight components, such as soluble sugars, were removed from the insoluble protein and polysaccharide matrix using high temperature-heated water. The quality of soy protein products is crucial. This trait can be found in things like the ability to influence flavor, texture, and water binding.

Application of Soy Protein

In Biomedical Field

The lower price, vegan nature, guaranteed safety from transmissible diseases, longer shelf life, and permanence, and biodegradable abilities gain the attraction of soy protein as a cheaper and best source of biopolymers (Deepmala et al. 2017). The applications of biopolymers in medical field include revitalization of tissues, preparation of biologically active bone fillers, and dressings for mini and major surgeries. It has the capacity to incorporate them into the blood clot and enhances the responses of collagens leading to countable depositions with great potential for healing of wounds. Soya hydrogel manufactured by various processes is getting popularized for delivery of molecules and other clinical needs. In the studies of Synders et al., combination of soy protein and PEG (Poly ethylene glycol) hydrogel can be used to prepare wet mout wound dressing and also can be employed for transdermal drug delivery system. The ability to incorporate into various drugs by soy protein biopolymers is greatly enhanced by augmenting it with polar and nonpolar amino acids in a modest ratio (Chien et al. 2014).

For Wound Healing

A wound is an injury that causes an external or internal rupture of body tissue, usually skin. Based on the type of repair mechanism, wounds are divided into acute (mechanical injuries and burns) and chronic wounds. Acute wounds generally heal within 8–12 weeks with minimal scarring. Because of the long duration for breakages, wound healing time is not found to be satisfiable for chronic wounds. The cascade of healing is classified into four overlapping phases like homeostasis, inflammation, proliferative, and maturation. The first response to injury is to build damaged blood vessels and activate platelets to form fibrin clots, which stop blood flow and create a scaffold for incoming inflammatory cells. Neutrophils are immediately recruited to the clot as the first line of defense against bacteria. Monocytes are recruited within 48–96 h after injury and converted to tissue-activated macrophages at the site of injury. Macrophages and fibroblasts release various growth factors to aid wound healing and generate granulation tissue. Healing time depends on the depth, size, type, location, and stage of infection of the wound. Apart from that, it also depends on the health condition and age of the patient. A potent wound dressing should manage the wound without causing a secondary infection and should be able to create an aseptic enA potent wound dressing should manage the wound without causing a secondary infection. It absorbs exudates from wound, resists wound desiccation, stimulates growth factors, stays elastic and flexible, and also is antigenic and biocompatible. Conventional wound dressings are designed to create a closed wound environment to prevent infection and a moist environment to facilitate the wound-healing process. Recent discoveries in the development of advanced wound dressings have demonstrated the use of materials or incorporation of biologics that can promote wound healing events ranging from cell migration to generation of extracellular matrix components. Another option for wound healing is by applying tissue grafts, but studies reported that it has some limitation because of rejection or possibility of transferring diseases, and also they are very expensive. Because of the characteristics nature like high biodegradability, biocompatibility, and similar property of extra cellular matrix components the natural polymers have high demand in use as wound dressing materials. Among these plant-derived proteins, soy has been considered for burns and wound dressings. It was studied that reepithelialization at the wound site is affected by the inflammatory response of the wound tissue because of the dressing materials, so it can resist inflammatory responses at the early stage, and so scar formation possibility can be reduced. In this particular context, the genistein and daidzein commonly known as phytoestrogen is well known in promoting the wound-healing attributes during the inflammation mechanism mainly due to the immune modulatory activities (Pierzynowska et al. 2021). By this way, the activity of lymphocytes, macrophages, and monocytes can be reduced. It promotes the blood clotting and deposition of collagen to start the healing process. Different forms of soy proteins were studied as the application of soy protein in wound dressing. Some of them are discussed below:

(A) Films

Soy protein isolate films are very brittle and are made by solvent casting. The globular structure and internal hydrogen bonding between chain is especially the strong inter- and intrainteraction between components which is the reason for easy brittling. A better way to improve the flexibility is by adding plasticizers such as glycerol, sorbitol, etc. Biodegradable blending agents like sodium dodecyl sulfate and polycaprolactone- triol are also used. In vitro studies revealed that plasticizers will increase the flexibility and ductility of the films as they have the hydroxyl components and they can reduce the internal hydrogen bonding between the polymer chains and initiate the space area between the molecules (Suyatma et al. 2005). Blended with hydrophobic polymers leads to the effect on water absorption properties and degradation behavior. In addition to this, a combination of chitosan and soy protein membranes is also used in the medical field as wound dressings. Silva et al. studied on such blending and added glutaraldehyde to function as a cross-linking agent to get biologically compact membrane for wound dressings. In vivo studies in wounded rats model resulted in the combination of chitosan-soy protein which can induce fresh tissues to form which can accelerate the healing of wound when compared to control. They also reported that the chitosan soy protein combination improves induced anti-inflammatory properties and positive host responses which also trigger wound healing.

(B) Hydrogels

Conventional wound-dressing materials like bandage and gauzes are effective in controlling hemorrhages, but they have limitations that they are non-biodegradable and susceptible to infection. Another drawback is it is not suitable for shapeless wounds, it uses secondary tissue infections, and it is found ineffective for wound healing. We can overcome these limitations by using hydrogels which can manage moist-free wound conditions because of the water-absorbing nature of the materials. It also has a positive impact regarding the oxygen permeability, and thus it provides a barrier against bacteria. Studies by Synders et al. revealed that only soy powder mixed in water can be formed to gel form without adding any cross-linking agent. In drug delivery system, also these hydrogels were used nowadays. Total 12% of soy protein concentration is better for making hydrogels because in this higher concentration the network is improved and modified and thereby the mechanical properties were automatically improved. The residues from soy protein hydrogel degradation are non-toxic and were shown to excite deposition of collagens in the fibroblastic cells of culture. This proves that soy protein has intrinsic bioactivity. Commercially, the most popular hydrogel type is the alginate hydrogel (Tansaz et al. 2016).

(C) Fibers

Micro- or nanofibers are made from soy polymer by electrospinning technique. Electro-spun mats are best suited for wound healing because of their high surface area and porosity nature (Ratchada et al. 2017). Soy protein blending using PEO (poly ethylene oxide) in various concentrations such as 20:80; 40:60; and 60:40 helped in the fabrication of fibers. The efficiency of fibers were tested

by analyzing the moisture vapor transmission rate (MVTR). The basic mechanism behind the water absorption property of soy protein is that increased concentration of soy protein can decrease the MVTR. Thus it creates an atmosphere of moistness for healing of wounds. Antibacterial test is found to be most promising: The activity of SOY-PEO fibers inhibits the growth of *S. aureus* and *P. aeruginosa* (Phillips et al. 2015). Alginate SPI blend fibers were coagulated with calcium chloride; hydrochloric acid and ethanol were used in wound dressings. As the concentration of ethanol is increased, the mechanical properties of fibers in the wet state also increased.

In the Food-Packaging Field

Due to ready availability, unique structure property, and renewable character, soy protein is used in the food-packaging field. Bioplastics can be made from soy protein. So it is considered as a natural plastic that can form an amorphous 3D structure. Consumers always try to find compostable or biodegradable packaging material, so they can just dispose of the plastic or put it in green bins after use, and there is no need to worry about spending more energy in recycling the material. Biodegradable soy protein thus offers an option for consumers to choose “healthy packaging” thus creating an opportunity to reduce one’s carbon foot print and dependence on petroleum-based plastics.

Used As Adhesives

The adhesive property of soy protein helps to replace formaldehyde used in making wood-based panels used in house construction. Products made with UF resins like particle board, hard wood plywood, and paneling contain the chemical formaldehyde. Most of the consumer products contain formaldehyde-based resins that release formaldehyde and cause health-related problems. However soybean-based adhesives have been used to replace UF to reduce the emission of formaldehyde (Jisoo Jeon et al. 2011). Soy protein-Kymene[®], Soy baby[®] and Ozero[®], Soyad[™], and Cargill’s Prolia[™] are some commercially available soy-based adhesives. The volatile organic compounds present in the products will be reduced by the activity of soy ingredients in the adhesives used. It is also important to know that adhesives made by soy protein possess significant resistance to water with a wide range of binding capacity. The main advantage of soya adhesives was as follows:

- A soy-derived bonding adhesive designed to replace formaldehyde-based adhesives in fiberglass insulation applications.
- A combination of low cost soy phenol formaldehyde resins for core-oriented particle board applications. Up to 20% replacement of powdered PF and p-MDI by soybean flour in OSB boards was achieved without significant loss of overall properties, including moisture property performance.

- Improvement of soybean properties in wood bonding by jet cooking.
- Soy flour replaces animal blood-derived protein as blowing agent in phenol-formaldehyde resin, foam adhesive extrusion system for laminated plywood veneers.
- Formaldehyde-free resins containing soy flour or meal in wood composite systems such as plywood, panels, plywood, and parquet.
- A chemically modified soy protein-based adhesive that creates a strong, heat-resistant bond when bonding paper substrates.
- Liquid fast-curing soy-based adhesives for packaging.
- A strong, sound absorbing, easy-to-lay soy-based floor adhesive.

Conclusion

Soy protein is proved to be one of the best plant proteins used as biopolymer. Its flexibility in changing the chemical structure using various chemical agents makes it more strong and durable. Soy products can be made from soya using physical, chemical or biological, or enzymatic method. Making soy plastic and further modifying it using chemicals is also a marked characteristic feature. By modifying the soy protein polymer product to some extent, we can increase its mechanical strength that makes it a powerful ecofriendly material. The emerging fields of applications of soy protein in biomedical and material industry in the last few years indicate that research efforts in this area will increase in the near future application of soy-protein-based products. The recent development of soy protein applications in the biomedical and food materials industries suggests that future soy-protein-based products will see a rise in research efforts in this arena.

Abstract

Biopolymers with piezoelectric properties are widely attractive nowadays owing to their direct and indirect effects of piezoelectric behavior in addition to biocompatibility and biodegradability. Although a wide range of polymers such as polyvinylidene fluoride, are used to enhance the power generation, conversion efficiency, and storage capacity of different piezoelectric devices, biocompatibility is the significant property when bio-nanogenerators are considered. Biopolymers are notable for their wide availability, ease of handling and biodegradability, however durability and poor mechanical strength are some of the challenges associated with them. This chapter briefly illustrates the recent advances in developing biopolymer nanocomposites for piezoelectric applications and the influence of different nanomaterials in regulating the piezoelectric properties of biopolymers.

Introduction

With new technological advancements in day-to-day life, the strength, resources, and environmental issues faced by people are becoming increasingly extreme. Owing to the resource limitations of conventional nonrenewable power sources and the environmental damage they cause when in use, renewable energy is a popular area for development and research. Accordingly, different electricity assets together with solar energy, wind power, and ocean strength have been advanced hastily, but they nonetheless have positive boundaries inside the method of series and operation. In particular, they are unable to miniaturize or sensitize in any way.

The piezoelectric nanogenerator (PENG) is constructed with a piezoelectric material because it has evolved to collate and transform mechanical energy into electrical energy. Piezoelectric ceramics, such as lead zirconate titanate (PZT) (Hubbe et al. 2008; Mariano et al. 2014), barium titanium oxide (Hernández-Flores et al. 2020; Harrison et al. 2014), zinc oxide (ZnO) (Lu et al. 2019), and piezoelectric polymers, such as polyvinylidene fluoride (PVDF) (Lin et al. 2008; Xue et al. 2012), polyamide (PA) (Prokhorov et al. 2020; Qi et al. 2018), are the most common types of piezoelectric materials. The outstanding contribution of these compounds is the wide usage of piezoelectric mills in electricity harvesting, in biomedical domains such as high-risk heart diseases such as implantable, self-powered sensors and in wearable electronics. Wearable and implantable self-powered sensor devices require raw materials to be nontoxic, exceedingly flexible, biodegradable, and harmless to humans. Piezoelectric and triboelectric gadgets based on flexible natural polymers with the described advantages are advanced choices and involve a variety of considerations (Jahan et al. 2018). But, in addition, they also have certain risks, which include ecological issues, terrible biocompatibility, excessive cost, and nonrenewability, which limit their huge utility. Therefore, the improvement of excessive overall performance, renewability, good value, recyclable, and biocompatibility, and thus natural piezoelectric composite materials with biopolymers and PENGs, has been growing (Kopycinska et al. 2003). This chapter includes a few recent case studies on the piezoelectric properties of certain biopolymers such as cellulose, chitosan, and polylactic acid, etc.

Piezoelectricity at a Glance

The electricity that is the by-product of any electro-mechanical interactions is termed piezoelectricity and is basically the result of electrical and mechanical fluctuations. The materials that have no inversion symmetry for the mentioned parameters generate a transducer effect according to their need for mechanical stress. A material can produce a mechanical compression after it is subjected to an electric field, owing

to the centrosymmetric quality, and the converse piezoelectric behavior is always reasonable. Piezoelectricity can be scientifically denoted as a linear relationship between the mechanical factors of strain, compliance, and stress, and the electrical parameters of electric movement, permeability, and the intensity of the electric field. Generally, choosing of the exact crystal class and polymer to boost the mechanical requirements collectively yield implausible consequences in the design (Harrison et al. 2014). A substance is said to be piezoelectric if it can generate an electrical charge in response to mechanical stress. The term piezoelectric is extracted from a Greek word “*piezein*,” which relates the compression or pressure, and *piezo*, the Greek word for “push.” One of the distinguishing features of the piezoelectric effect is that it is conversable, that is the substances exhibiting direct piezoelectric effect, (production of electricity with the applied stress) shows the reverse piezoelectric behavior (formation of stress with the applied electric field).

Piezoelectricity, can also be defined as pressure electricity, by which the production of electric separation is spread over a mechanical stress. Ceramics, which commonly show high piezoelectric strain constant, and have many peculiarities such as hardness, elasticity, being lightweight, and piezoelectric stress constant, which is lower in natural polymers. Overall, a substance must possess stable molecular dipoles, have the ability to arrange or adapt the dipoles, be able to sustain the dipole orientation, and be able to withstand high stresses depending on the mechanical stress being applied (Ponnamma et al. 2017). The semicrystalline structured polymers have different advantages such as mechanical arrangement, polymorphic phases, thermal annealing, and excessive voltage treatment, bringing crystalline phase alteration close to the piezoelectricity outcomes.

The piezoelectric coefficient and piezoelectricity mechanism in a semicrystalline polymer are illustrated in Fig. 1. When a square crystalline material with either negative or positive charges is squeezed, there is no change in polarization. This is because the occurrence in the relative center of charges remains exactly at the same point. For a hexagon, given stress varies like the center of charge, thereby developing the variation in polarization. As the majority of semicrystalline structured polymers contain randomly organized tiny crystals in an amorphous framework, some crystallites are reoriented using poling techniques.

Figure 2 illustrates piezoelectric polymers such as bulk piezopolymers, which are classified as two. They are semicrystalline structured polymers and piezoelectric; next are amorphous dipolar polymers or polymer composites, which are certain piezoelectric particles implanted in any polymer or any piezoelectric pillars within a polymer and a voided charged polymer. In corona poling of the composite film, fibers from the same polar poly- γ -benzyl-L-glutamate (PBLG)/poly (methylmethacrylate) biopolymer composite film and piezoelectric films were reported (Cernea et al. 2012). Such composite provided 20 pC/N piezo coefficient d_{33} value. The fibers were oriented and were compared with the electrospinning process, then accomplished approximately 100% orientation of those electric dipoles inside the given structure of PBLG. Similarly piezoelectric characteristics of composite films are enhanced with different kinds of fiber reinforcement.

Fig. 2 The representation of various types of piezoelectric polymer

Fig. 3 The piezoelectric effect in quartz

The positive and negative charge centers within a piezoelectric material move in response to mechanical stress, creating an external electric field. The piezoelectric material is stretched or compressed when the direction of the external electric field is reversed. Piezoelectric effect is necessary in a variety of applications that include sound production and identification, high voltage production, extremely fine electronic frequency generation, and microbalances optical assembly observation. It also serves as the foundation for many atomic-resolution scientific instrumentation techniques, including scanning probe microscope (Fig. 3).

Piezoelectric effects are also used in more general applications, such as ignition sources in cigarette lighters. Free limits of volumetric expansion or contraction can preserve piezoelectricity and potentially improve nanometer-scale performance (Lu et al. 2019).

Piezoelectric Properties of Biopolymers and Nanocomposites

Nanocellulose has become a notable biomaterial in recent times because of the outstanding mechanical properties, renewability, biocompatibility, low cost, etc. (Prokhorov et al. 2020). Because of great abundance in nature, wood is an available base substance for the preparation of nanocellulose. However, the separation normally needs a process of a different stage that includes intensive chemical as well as mechanical processing for cellulose nanofibers, crystalline whiskers, and any other nearby structures of pure cellulose, those having a minimum dimension range of 1–100 nm (Hubbe et al. 2008). This makes the cellulosic material preparations very complicated and time consuming. The cellulose nanocomposites further show distinct qualities, because of the nanometric size effect in bulk media compared with conventional composites, even at low concentrations (Mariano et al. 2014). Properties and specialties of such nanocomposites include extreme chemical stability, mechanical properties, bio-compatibility, low cytotoxicity, cost effectiveness, and availability (Joseph et al. 2020).

It is simple to enhance the piezoelectric property of PVDF by using graphene (Xue et al. 2012). The solution casting method was used to create (rGO)/PVDF nanocomposites with rGO content ranging from 0.0 wt% to 2 wt%. A nanocomposite film was strained at a ratio of 4:5 and polarized using a step-field method to create a piezoelectric-phase crystal structure. The output voltages of the rGO/PVDF nanocomposite films were evaluated using substantial vibration tests and several experiments to examine the characteristics of developed piezoelectric. Compared with other fillers in the nanocomposite film, rGO at 0.05 wt%, possesses a significant voltage output that is roughly 293% of the pure PVDF. In addition, the output voltage enhances with increasing rGO content from 0 wt% to 0.2 wt%. More β -crystalline phase forms in these rGO depositions, which is confirmed by FTIR and powdered XRD spectrum analyses.

Recently emerging piezoelectric materials provide green solutions for the development of lightweight, biocompatible, flexible, and ecologically adaptable mechanical harvest energy. Such devices are used as independent power supplies for robotics, electronic skin sensors, and medical monitoring systems (Song et al. 2021). PENGs can use mechanical vibrations to power liquid crystal displays and LED by harvesting energy from human activity and sound waves (AlAhzm et al. 2021). The piezoelectric properties of composite fibers were tested the implementation of nanogenerators using PET substrates, aluminum foil, copper wires and similar components, and rectangular fibers (25×25 mm) were arranged parallel in between the copper wires and aluminum foils and then connected using a conducting tape on either parts. Usually, PET substrates were typically wrapped on the two sides of the given model using an adhesive on both sides. The PENG was tested for piezoelectric output voltage by testing under a load of 2.5 N and a resistance of 1 Mega Ohm. As the vibration frequency increases, the output voltage rises until it reaches a point where the voltage is balanced. In comparison with all other composite fibers, PENG manufactured from 3% composition of the hybrid nanofiller performs exceptionally well, which is due to the filler's ability to strengthen the material.

The excellent piezoelectric and ferroelectric properties of PVDF have led to practical applications in the fields of flexible detectors, sensors, and actuators in the up-to-date information and industries of electronics in recent years. The nonpolar phase is the most advanced stable crystalline phase, whereas the polar phase with the highest dipolar density and the strongest piezoelectric property.

The effect of the hybrid filler's micro- CaCO_3 content (Jahan et al. 2018) and subsequent uniaxial stretching at various ratios R (4–5) of elongation on the electrical, piezoelectric, mechanical, and dielectric characteristics of the hybrid nanocomposites. A hybrid nanocomposite typically consists of 40 parts CaCO_3 and 3 parts (wt.) of Mt., with a d_{33} of 7.4 pC/N, which is a high value for piezoelectric coefficient. The pressurized-type hybrid nanocomposites dependably exhibited an enhanced piezoelectricity with the greatest d_{33} value of 30.6 pC/N formed at R of 5, and it was assigned to the almost 100% β phase content and dipolar arrangement formed by extending and subsequent poling. Melt extrusion manufacturing for the hybrid filler added to PVDF nanocomposite has been illustrated with enhanced

piezoelectric properties and then it was extended to different draw ratios, R. Hybrid fillers always contribute to enhance the polar β phase in PVDF composites.

The metal oxides permit the electrical energy transfer and mechanical vibration transfer by forming interconnected networks throughout a particularly selected sample. This occurs as the ZnO and FeO filler materials have ferroelectric characteristics and distinct dipole orientation helping to produce the piezoelectricity. Electrospinning always permits the dipole alignment, and is responsible for the piezoelectricity. The dipoles in the ZnO and FeO subsidize to the improved piezoelectric performance. Furthermore, the nanoparticles act as stress junctions and differentiate the electrospun PVDF fibers into different segments. This increases the local deformation and makes the piezoelectric output voltage very large.

Cellulose nanofibers and nanocomposites are notable for exhibiting mechanical energy harvesting properties or piezoelectricity (Kalia et al. 2011). Composite material with an isolation structure has excellent electrical properties (Qi et al. 2018). At a frequency range of about 1 kHz, the polyamide/barium titanate/carbon nanotube ternary nanocomposites (PBCNCs)-3D components displayed a dielectric constant of 16.2, which is regarded as being two times greater than that of SLS-printed composite parts (PBCNCs) without an isolated structure. After comparing with PBCNCs, the strain coefficient of piezoelectricity increased from 1.7 to 2.1 pC/N. These outcomes will not only provide a way for the construction of 3D segregated percolation channels, which will improve the overall performance of polymer composites powered by piezoelectricity, in addition to offering a new material for SLS processing (Fig. 4).

Zinc oxide nanoparticles (ZnO-NPs) are one of the most eye-catching materials because of their exceptional optical, antibacterial, piezoelectric, and mechanical capabilities (Prokhorov et al. 2020). The dielectric, mechanical, and piezoelectric properties of chitosan nanocomposites can be varied by altering the concentration of ZnO-NPs in accordance with the applications. The structural characteristics of CS-ZnO films, including their conductivity, mechanical, dielectric and piezoelectric properties, can be changed by varying the concentration of ZnO-NPs. Moreover, CS-ZnO films with 15% NPs show a greater piezoelectric coefficient d_{33} value than films with 20% NPs (Fig. 5).

Fig. 4 RGO-PVDF nanocomposite films

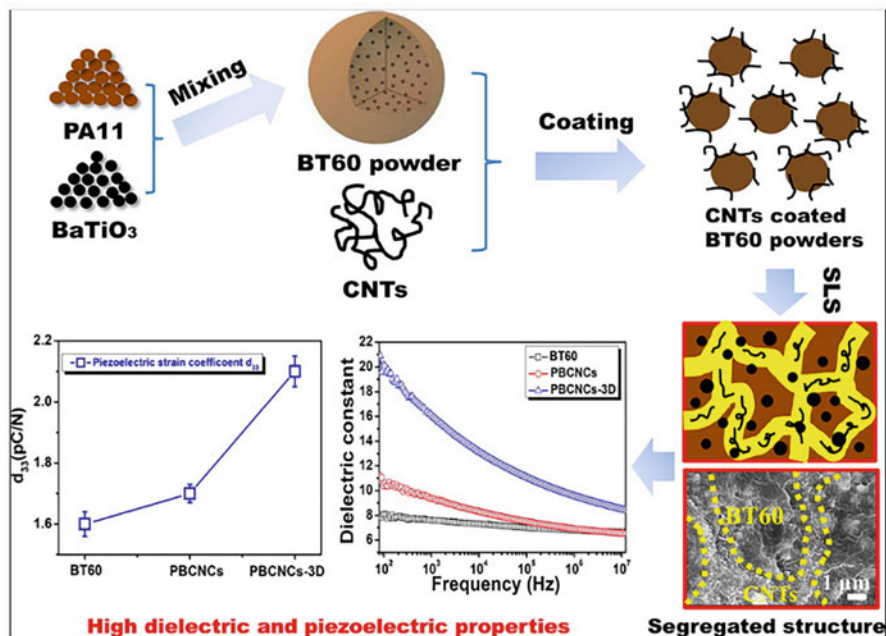

Fig. 5 Piezoelectric and dielectric characteristics in ternary polyamide11/BaTiO₃/CNT nanocomposites sintered by a selective laser

(Figure 6) shows the operation of a PENG based on boron nitride nano tubes (BNNT)-ZnO quantum dot (QD) (Shim et al. 2022) nanocomposites. Compared with BNNT, the features of BNNT-ZnO QDs' piezoelectric coefficient rise significantly. For various piezoelectric applications, the unique features of BNNTs can be demoralized. In contrast to the longitudinal direction, it is still exceedingly challenging to improve the piezoelectric capabilities in the radial direction. To extract the performance of piezoelectric characteristics, a design utilizing BNNT inorganic composites with outstanding inorganic piezoelectric materials is required.

The piezoelectric constants of the BNNT-ZnO QD nanocomposites and the distinction between out-of-plane and in-plane piezoelectric behavior were examined using traditional piezoelectric force microscopy (PFM) analysis in relation to the significant piezoelectric properties. Furthermore, using the SEM-PFM technique, the piezoelectric effect is induced by applying a specific radial force to a single wire of the BNNT-ZnO-QD nanocomposite. The effective single-line piezoelectric coefficient of BNNT-ZnO-QDs and the radial increases in the piezoelectric charge coefficient of BNNT-ZnO-QD films were 41.9% (-60.3 pC/N) compared with a single wire of BNNT and BNNT foil. At a low volume of 0.18 wt%, a transparent and flexible piezoelectric device based on BNNT-ZnO-QD nanocomposites exhibits excellent piezoelectric properties. The performance of PENGs using electrically poled BNNT-ZnO-QD nanocomposites improved by more than 140% and 45% compared to native BNNT-ZnO-QD nanocomposites and BNNTs respectively.

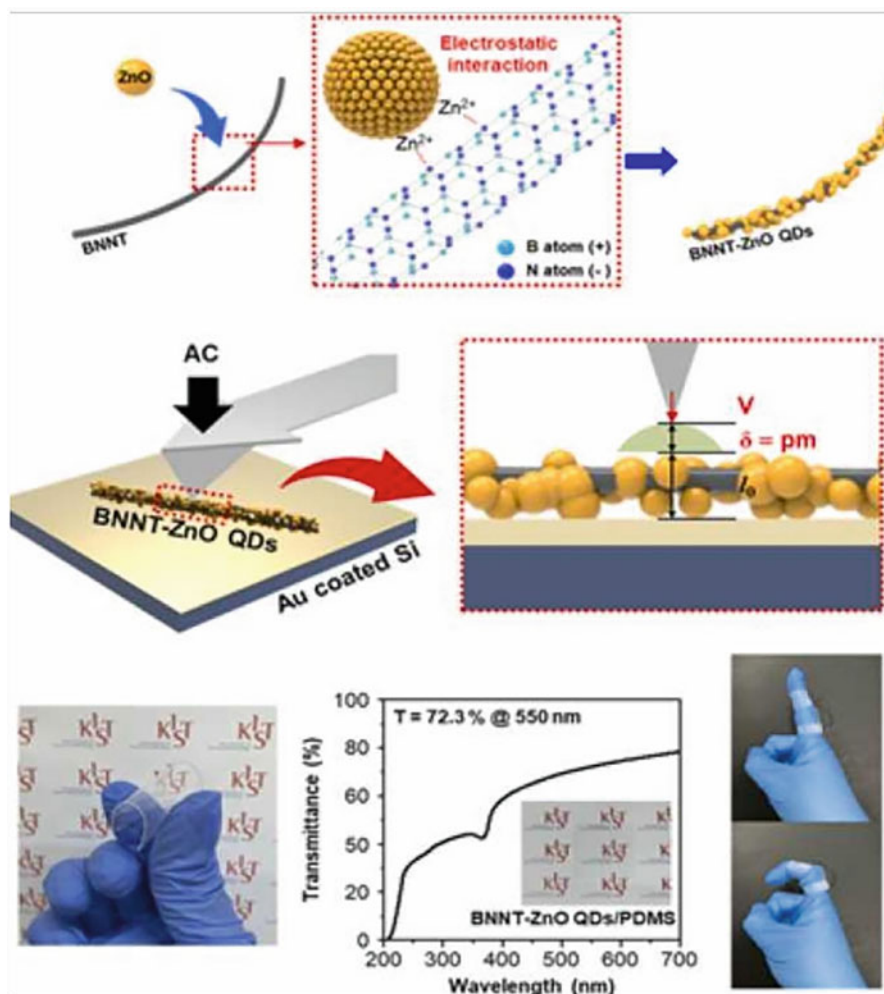

Fig. 6 BNNT-ZnO-QD nanocomposites for enhancing PENG and boron nitride nanotube piezoelectric properties

Therefore, there are new avenues for developing innovative materials and devices for generating renewable energy (Fig. 6).

Milled nanocomposite parts made of PA11/BaTiO₃ (Qi et al. 2017) possessed dielectric and piezoelectric properties. The solid-state shear milling technique improved the sintering window of the PA11/BaTiO₃ nanocomposites, especially for the nanocomposites containing 40% BaTiO₃ particles, and the broad sintering window varied from 10.1 °C to 14.6 °C. Second, after milling treatment, the dielectric constant (ϵ), piezoelectric strain coefficient (d_{33}), and piezoelectric stress coefficient (g_{33}) of SLS-printed PA11/BaTiO₃ nanocomposite parts were improved.

Finally, this SLS machine was used to create complex PA11/BaTiO₃ nanocomposite parts with improved dimensional accuracy and mechanical properties.

Natural polymer-based piezoelectric materials always have poor piezoelectric performance. We used TEMPO oxidized cellulose nanofibrils (TOCN) (Song et al. 2022b) and MoS₂ nanosheets to create flexible porous piezoelectric air gel films. Air gel membranes have mesopores and large specific surface areas. Moreover, using an electric field strength of 20 MV/m it polarizes the air inside the MoS₂ nanosheets and mesopores, showing better piezoelectric properties. The TOCN/MoS₂ air gel film PENG with 6 wt% MoS₂ demonstrated good power performance when arranged into a PENG. It produced a maximum volumetric power density of 0.143 $\mu\text{W}/\text{cm}$, an open-circuit voltage of 42 V, a short-circuit current of 1.1 μA , and a maximum areal power density of 1.29 $\mu\text{W}/\text{cm}$. These properties make them promising piezoelectric materials for harvesting energy.

Ferroelectric antimony sulfide (SbSI) nanowires are used to create composite materials for the fabrication of energy harvesting and sensor devices. SbSI is an excellent material for nanogenerators and nanosensors that require high piezoelectric coefficients ($d_{33} = 650 \text{ pC/N}$) and electromechanical coefficients ($k_{33} = 0.9$). In these composites, cellulose and epoxy resins serve as matrix materials, with SbSI nanowires filling the matrix. A piezoelectric response to vibration was demonstrated. We then constructed a fiber-reinforced polymer piezoelectric sensor using a composite material containing epoxy resin as an element. A comparison of the piezoelectric properties of cellulose/SbSI and epoxy resin/SbSI nanocomposite is done. Subsequently, the effect of the concentration of SbSI nanowires in the fiber-reinforced polymer with detailed properties of epoxy resin/SbSI nanocomposites were detailed.

Mechanical energy is the most common available energy source, and the piezoelectric effect is widely used to harvest it. To convert mechanical energy to electrical energy, a piezoelectric generator based on ZnO nanowires is used. Different investigations such as vibrations, human body motion, acoustic waves, wind, and other mechanical energy forms have all been studied using PENGs. Different materials and nanocomposites, particularly PZT, ZnO, BaTiO₃, and numerous substances, are used to build PENGs (Sun et al. 2020). As a matrix material, these composites use epoxy resins or various types of cellulose. Mechanical energy, which is frequently derived from the piezoelectric effect, is the most commonly available energy source. To construct PENGs, various materials and their composites, particularly PZT, ZnO, BaTiO₃, and various compounds, are used. These composite materials use epoxy resins and various celluloses as matrices (Fig. 7).

Elastic and piezoelectric properties of thin-film lead calcium titanate samples' were investigated using modified atomic force microscopy techniques such as atomic force acoustic microscopy, tapping mode, and ultrasonic piezo mode (Kopycinska et al. 2003). The morphology of thin films indicates whether they are nanocrystalline, amorphous, polycrystalline, as well as having the imaging capabilities using dynamic force microscopy techniques. The relationship between the strain dynamics and polarization gradient (Csoka et al. 2012) of these obtained films was studied by monitoring their deflection with an atomic force microscope

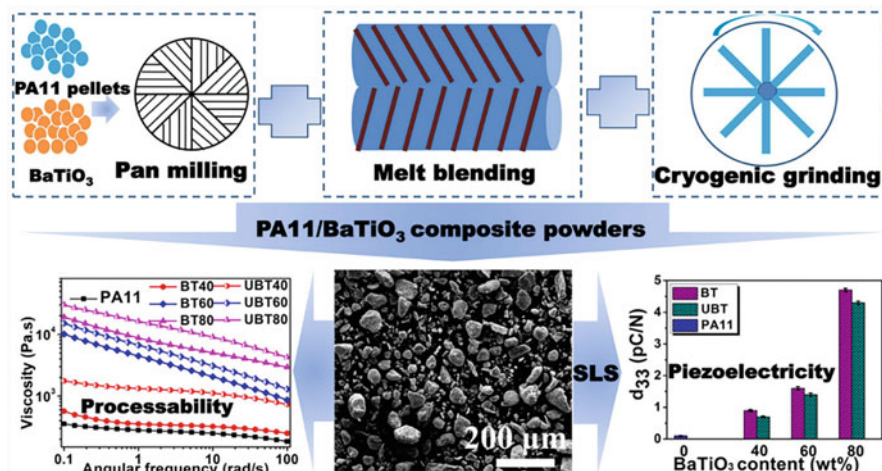

Fig. 7 Piezoelectric properties for selective laser sintering and PA11/BaTiO₃ nanocomposite powder preparation with improved processability

operating in contact mode. The piezoelectric response of the film is related to the direct investment of the cellulose asymmetric crystal structure. The effective piezoelectric shear constant (d_{25}) for highly ordered CNC films was found to be 2.1 pm/V. This value is comparable with the piezoelectric metal oxide reference film (Fig. 8).

An applied uniform strain in piezoelectric materials can induce electrical polarization and vice versa. This technical property is restricted to noncentrosymmetric systems owing to crystallographic considerations. Even in nonpiezoelectric dielectrics, non-uniform loading can break inversion symmetry and induce polarization. The key idea is that all dielectrics exhibit the above-mentioned (Sharma et al. 2007) coupling between polarization and strain gradient. The flexoelectric effect is an experimentally verified phenomenon. This flexoelectric coupling is very small and cannot be detected experimentally unless very large strain gradients are present. Based on the field theoretical framework and the related green functional solutions developed, there is an opportunity to engineer 'piezoelectricity', i.e., large strain gradients present inside composites containing nanoscale heterogeneities. Total polarization can only be achieved if the shape and distribution of the heterogeneity are not centrosymmetric. Based on restrictive assumptions about the shape, distribution of the heterogeneities and limited material data, unoptimized quantitative results show an apparent piezoelectric behavior of nearly 10% of the quartz for heterogeneity sizes within 4-nm range. Improved performance based on geometry, proper material selection, and topology optimization is not unreasonable.

Low-temperature, screen-printable piezoelectric nanocomposite films with piezoelectric and dielectric properties made on flexible plastic and textile substrates are reported. The improvement in piezoelectricity is due to the addition of silver nanoparticles (Almusallam et al. 2017) and the use of an additional post-treatment, cold pressing. These developments increased the self-supporting piezoelectric

Fig. 8 Cellulose nanocrystal thin films have a piezoelectric effect

charge coefficient d_{33} by 18% to a value of 98 pC/N. The peak output voltage of the composite film decreased as the dielectric constant of the piezoelectric film changed. The theoretical and experimental potential of this material to harvest mechanical energy from various fibers under compressive and bending forces are investigated. Under 800 N compressive force, the maximum energy density of the modified piezoelectric material was determined to be 34 J/m³ for Kermel textile.

On cotton cloth, the maximum energy density of the modified piezoelectric material after bending was found to be 14.3 J/m³. For a 100-mm × 100-mm piezoelectric element with a thickness of 100 μm, this corresponds to the energy produced per mechanical motion of 14.3 μJ or 38 μJ, which is a potentially useful amount of energy. The process is illustrated briefly in Fig. 9.

Composites of MWCNT/cellulose (M/C) are formed by covalently grafting multiwalled carbon nanotubes (Yun and Kim 2011) onto cellulose. Mechanical stretching was used to create oriented M/C composites. By examining the morphology of M/C composites and measuring their electrical, mechanical, and piezoelectric properties, the strain effect was demonstrated. The effects of aligned MWCNTs on M/C composite actuator performance in terms of resonance frequency and bending displacement as a function of strain ratio and ambient humidity were investigated. Aligned MWCNTs improved mechanical and piezoelectric properties, but they also changed the actuator performance of M/C composites.

A confinement cell technique was used to produce colloidal opal structures to vertically align large CNC rods. Because of the high interfacial energy between the surface of CNC poly (tetrafluoroethylene) (PTFE) (Wang et al. 2020) and the torque induced by shear force, CNC rods are vertically aligned to a high degree. An external

Fig. 9 Piezoelectric nanocomposite films for textile kinetic energy harvesting

DC electrical field was introduced to further align the dipole moments of each CNC in the same direction.

The CNC film with a piezoelectric coefficient of 19.3 pm/V, has excellent piezoelectric performance, which is comparable to poly (vinylidene fluoride), d33 (20–30 pm/V). This is plotted in the graph; this research introduces a new class of high-performance piezoelectric polymer materials derived from biocompatible and renewable natural resources (Fig. 10).

The frequency constants (N_p , N_t), piezoelectric voltage coefficient (g_{31}), and piezoelectric charge coefficient (d_{31}) of BNT-BT0.08 ceramic have maximum values, whereas the piezoelectric charge coefficient (d_{33}) and electromechanical coupling factor (k_p) have minimum values. ($\text{Bi}_{0.5}\text{Na}_{0.5}\text{TiO}_3$ (Cernea et al. 2012) was prepared using 5, 8, and 11 mol% BaTiO_3 (BNT-BTx; $x = 0.05, 0.08$, and 0.11) with the given sol-gel technique. It was prepared in situ using the resulting gel precursor and exhibited a microstructure composed of a crystalline perovskite and nano-sized particles. High-density (98–99% ρ_{theor}) BNT-BTx ceramics were fabricated from this nanopowder using the spark plasma sintering (SPS) technique. The results confirm the SPS method applied to the nanoscale powders obtained by sol-gel as a viable method for fabricating nanostructured ceramics. We have studied the changes in the structural and electrical properties of ceramics with BaTiO_3 concentration (x). The dielectric constant of the BNT-BT0.08 ceramic = 2090, 100 kHz) is higher than those at $x = 0.05$ ($\epsilon_r = 1350$) and $x = 0.11$ ($\epsilon_r = 1800$). BNT BT0.

The electrical properties of ceramics are affected by grain size, oxygen deficiency, and uneven residual stress caused by this oxygen deficiency. BNT-BTx ceramics sintered by SPS appear to be excellent ceramic resonators with high mechanical quality factors (Q_m). The piezoelectricity of wood, or the change in electrical polarization caused by mechanical stress (Tuukkanen and Rajala 2018), has been known for decades. Looking at an isolated crystalline wood block CNC, the piezoelectric effect is greatly enhanced. A related issue has received limited attention in the scientific literature, with little recent evidence for CNC piezoelectricity. The charge density produced by a given applied voltage is described by the piezoelectric coefficient d_{mn} . A 3×6 matrix can represent the components of a cubic tensor with

Fig. 10 Large-scale vertical crystal alignment in piezoelectric nanocellulose thin film

piezoelectric coefficients d_{mn} , where $m = 1, 2, 3$ are electrical axes and $n = 1, 2, 6$ are mechanical axes. The length, width, and thickness are represented by principal axes 1, 2, and 3 respectively, and shear around these axes is represented by indices 4, 5, and 6.

The symmetry of a cellulose crystal lattice, formed by unit cells of cellulose molecules, can be used to calculate the piezoelectric tensor d_{mn} for a single cellulose crystal ($[C_6H_{10}O_5]_n$). The cellulose has a monoclinic symmetry with a space group of $C2 \parallel x3$ and the piezoelectric tensor:

$$d_{mn} = \begin{pmatrix} 0 & 0 & 0 & d_{14} & d_{15} & 0 \\ 0 & 0 & 0 & d_{24} & d_{25} & 0 \\ d_{31} & d_{32} & d_{33} & 0 & 0 & d_{36} \end{pmatrix} \quad (E1)$$

It should be noted that this tensor is only valid for single-cellulose crystals and randomly oriented crystal arrangements, such as in cellulose nanofiber (CNF) films. Combining different coefficient yields the overall piezoelectric response. Aggregation of fibers and associated cellulose crystals, for example, has been shown to significantly reduce the effective piezoelectric tensor in wood.

$$d_{mn} = \begin{pmatrix} 0 & 0 & 0 & d_{14} & 0 & 0 \\ 0 & 0 & 0 & 0 & d_{25} & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \end{pmatrix} \quad (E2)$$

where $d_{14} = -d_{25}$.

As piezoelectricity is closely related to ferroelectricity, we also measured the ferroelectric hysteresis of the CNF films using a ferroelectric tester. The piezoelectric

sensitivity of the sensor was determined by applying a dynamic excitation force (1.4 N peak-to-peak; frequency 2 Hz) to the sensor while it was resting on a metal plate (Hänninen et al. 2016). A commercially available, highly sensitive dynamic force sensor was used as a reference for the excitation force. The measurements were repeated three times per side, and each sensor was excited six times. After each measurement, the sensor was repositioned on the metal plate. Piezoelectric sensitivity (in pC/N) was obtained by dividing the charge generated by the sensor by the force of the dynamic force sensor.

The piezoelectric behavior is highly dependent on the chosen combination of nanocellulose and chitosan. In particular, chitosan and CNC can be mixed to produce films with strong lateral dependence. This effect was not seen in the chitosan + CNF films with the minimal piezoelectric sensitivity values. The purest chitosan produced the best results (Pongampai et al. 2021). The piezoelectric properties of various films appear to benefit a wide range of sensor and actuator applications. However, differences in sensitivity values between individual sensors were observed in all films studied, indicating the need to optimize manufacturing parameters such as pH, solution concentration, and mixture composition (Song et al. 2022a).

Piezoelectric materials can be employed as embedded sensors as well. Composite laminates are fundamental innovative construction materials. They are frequently used to assess structural strain and deformation. The effect of SbSI nanowire concentration on the properties of epoxy resin/nanowire composite (ESNC) and its fiber-reinforced polymer was also demonstrated. The observations of this previous work on the alignment of SbSI nanowires within an epoxy resin matrix during the electrical field curing process are discussed in the literature review of this work (Torón et al. 2020).

Figure 11 shows the schematic representation of sonochemical fabrication of composites of epoxy resin/SbSI nanowires, SbSI nanowires, cellulose/SbSI nanowires, fiber-reinforced polymer (FRP) laminate, and generator/sensor assembly with an integrated sensor.

A nondestructive three-point bending test was used to describe the piezoelectric properties of FRP laminate sensors. The experiments were carried out on an INSTRON 4469 machine (INSTRON, Norwood, MA, USA). The distance between the stanchions was 200 mm. The samples were bent with different speeds of load bar travel (1, 2, 5, 10, 20, 40, 60, 80, 100, 150, and 300 mm/min) up to a deflection of 1.0 mm. The sample was then flexed for 120 s before being reloaded at the same rate. After 30 s (the time required to discharge the sensor), the next charge rate charge-recharge cycle was performed (Fig. 11).

The electrical signal of the FRP laminate was recorded with a Keithley 6517A electrometer (Cleveland, OH, USA). During nondestructive deflection, load-deflection curves were recorded. Agglomeration of SbSI nanowires means less random distribution within the matrix and piezoelectric charges discharged unevenly at the electrodes through the nonconducting epoxy (or cellulose) matrix. Both ESNC and FRP laminates have a lower piezoelectric response. The mechanical response of the composite is reduced as the content of SbSI nanowires increases.

Three orientation methods were used to understand the effect of orientation (Zhai et al. 2020) on the piezoelectric properties of CNF ultrathin films in the thickness

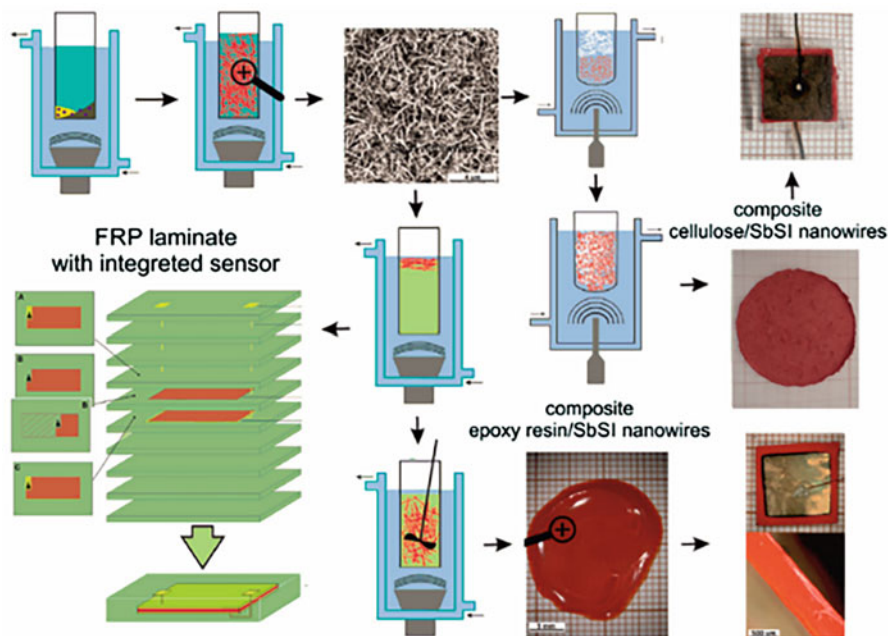

Fig. 11 Scheme of sono-chemical preparation

direction: in-plane electrical orientation, high magnetic field orientation (HiMA), and corona poling. Piezoelectric properties were analyzed using piezo response force microscopy (PFM). The vertical displacement of an extremely thin CNF film surface was captured and converted to the piezoelectric coefficient d_{33} by applying an AC voltage with PFM. The piezoelectric coefficients have different aligned CNF ultrathin films. Corona poled CNF ultrathin films exhibit the largest piezoelectric coefficient among the three orientation methods. Water contact angle measurement proves that the through-thickness piezoelectric constant is related to the hydroxyl groups appearing on the surface of the CNF ultrathin films. Quantitative PFM is generally limited by the presence of an offset in the amplitude of the piezo response. The amplitude of the piezo response should be recorded as a function of the applied AC voltage. An AC voltage up to 10 V was applied to the AFM probe with a frequency of 600 kHz and an amplitude of 2-V steps. Five different areas measuring $10 \times 10 \mu\text{m}^2$ were scanned for each sample. The sampling rate was kept at 0.5 Hz. The PFM standard sample periodically poled lithium niobate (PPLN) was obtained from Bruker and has a nominal piezoelectric coefficient of 7.5 pm/V. PPLN was used as a reference to calculate the piezoelectric coefficient of ultrathin CNF films.

Experimental conditions were similar to those described above. The amplitude signal (Aamp) obtained from the sample, is expressed in mV. Using the piezoelectric coefficients of the reference sample PPLN and equation (S1), the calibration

parameters can be determined. Once the calibration parameters are obtained, the PFM signal Aamp from the CNF ultrathin film can be used to calculate its piezoelectric coefficient d_{33} . This is because 3 represents the thickness direction and d_{33} is the piezoelectric coefficient in the thickness direction.

Yang et al. introduced BT and graphene into poly-L lactic acid (PLLA) scaffolds with the aim of imparting precise piezoelectric properties to the scaffolds. PLLA was used as a biodegradable polymer as the matrix fabric. Scaffolds were fabricated using selective laser sintering (SLS). This is a typical additive manufacturing process that can produce scaffolds with complex pore geometries and customized geometries. It was thought that a porous structure might need to provide a microenvironment for the mobile boom, whereas a personalized shape might need to fit the disease site perfectly. This can reduce bone loss during implantation. The PLLA framework had a very low open circuit voltage as well as a modern short circuit. As a result of the high piezoelectric properties of BT nanoparticles, the PLLA/BT composite scaffold provided an increased open-circuit voltage of 0.76 V and a short-circuit current of 5.1 nA. More significantly, the open-circuit voltage and fast switching are similarly increased to ~ 1.4 V and ~ 10 nA respectively, indicating stronger piezoelectricity. The overall piezoelectric performance of PLLA/BT composites was highly dependent on the polarization performance of BT nanoparticles.

Prior to polarization, the orientation of the domain names of the BT nanoparticles was disordered within the framework matrix. In this situation, the scaffold did not exhibit piezoelectric shock. Therefore, to rearrange the domain orientation of BT, polarization by an externally powered domain was required. However, the large dielectric difference between BT and polymer degraded the polarization performance of the piezoceramic. In general, the incorporated graphene creates a conducting channel for the polarization field, thereby facilitating electrical energy transfer to nearby BT nanoparticles. Under these circumstances, additional powered regions within the BT were relocated along the direction of the polarization order, resulting in enhanced piezoelectric response of the composite (Shim et al. 2022).

Cai et al. (2019) reported the application of electrospinning technology to develop piezoelectric polyhydroxybutyrate (PHB) nanocomposites. PHB is a biopolymer that is used commercially in agriculture, parcel stores, and biomedical fields. Bacterial diffusion can biosynthesize it on a large scale. Because of the high stereoregularity of the biosynthesized molecules, PHB has an excessive crystallinity (up to 75–85%). The crystal structure of PHB is an α -phase with two left-handed helical molecules made up of double axes along the crystalline state chain. The unit cell is orthorhombic: P212121-D42 with $a = 5.76$ Å, $b = 13.20$ Å, c (fiber period) = 5.96 Å. PHB is a piezoelectric biopolymer with suitable properties such as biodegradability, biocompatibility, and optical interest. Compared with PHB nanofibers, the nanofibers of PHB/MWCNT have a higher content of β -type crystals, improving the piezoelectric charge constant of PHB/MWCNT (25.7 pC/N), much higher than that of pure PHB (3.25 pC/N). For biomedical applications, mechanical interactions between cells and material surfaces are driven by cell adhesion, motility, cytoskeletal organization, cell

migration, differentiation, and tissue morphogenesis. Several studies have shown that some cell lines require external stimuli to promote tissue repair, thus the use of electromechanically active materials has attracted attention. Micro- and nanotechnology have been used to aid in the fabrication of TE scaffolds and provide a more suitable environment for potential tissue regeneration by controlling their morphology and chemistry at the micro- and nanoscale. The origin of PE was based on a non-centrosymmetric structure, and PLA had this noncentrosymmetric structure even in the amorphous state owing to its chiral conformation. For materials performing PE, displacement is produced without an external electrical field, regardless of whether there is a barrier to control the stimulation. The importance of interfaces between bioelectronic devices and the human body underscores biosecurity concerns. Biodegradability of organic and synthetic materials is one of the highly desirable properties that should be considered to avoid additional surgical intervention. A process that largely mimics biological PE is the stretching of intrinsic piezoelectric materials, which can degrade under similar body conditions. An advantage of PE in tissue regeneration is that polarized polymers exhibit more pronounced protein adsorption and improved cell adhesion and proliferation. Natural polymers are an interesting next-generation triboelectric friction material, and in recent years there has been a dramatic increase in reports of triboelectric nanogenerators based on natural polymers.

Conclusions

After referring to a wide variety of related articles the scope of cellulose nanocomposites that utilize the piezoelectric properties is obvious. In earlier times, only the applications of nanocomposites were considered based on their durability and availability; later, by considering the internal properties such as ductility, mechanical properties, and piezoelectric properties, the areas of application also changed. Now, the piezoelectric behavior of cellulose nanocomposites consists of applications in day-to-day life, biomedical applications, most particularly concentrating on health-related applications. The piezoelectric behavior of cellulose varies by layering, thickness, and components. This property can be considered catalytical, as its dimensions can vary with the constituents added to the base materials such as nanocellulose or biopolymers. This chapter illustrates the collective advances in developing a biopolymer nanocomposite for piezoelectric applications and the contributions of biopolymers with piezoelectric properties. There is a great scope of biopolymers in different practical applications, with their unique properties other than the piezoelectric effect.

Abstract

Biopolymers are receiving much attention in material science and biomedical engineering fields because of their renewable nature, anisotropic form, exceptional mechanical capabilities, high biocompatibility, tailored surface chemistry, and intriguing optical properties. The surprising inherent features of biopolymers, including chemical inertness, amphiphilicity, mechanical strength, high stiffness, and low density, allow it to be used in a broad array of optical-electronic devices. In this chapter, we focus mostly on theoretical and experimental advances of the optical properties of various biopolymers and their applications in devices like LEDs, solar cells, printed electronics, thermal transistors.

Keywords

Biopolymer · Optical properties · Nanocellulose · Bionanocomposites

Introduction

Electronic devices are getting widespread acceptance for their applications in medical field, energy harvesting, remote monitoring, etc. In the last 10 years, the convenience and value that the function devices have brought to the everyday lives of people has been remarkable.

However, the environmental problems caused by persistent materials used in electronic gadgets are increasingly severe, for example, plastics. These materials are highly stable, which will not break down in long periods without using high-temperature treatment or a harsh chemical.

Hence, academic studies of green, degradable materials to build electronics have been very significant for scientific community. In an effort to substitute for conventional resources and to minimize environmental harm caused by synthetic materials, there is an increasing desire to use commonly degradable biopolymers in electronic devices Agate et al. (2018).

Biopolymers are polymeric biological compounds in which covalent connections connect monomeric units to form bigger molecules. The word bio indicates that the materials are biodegradable and derived from living beings. Biopolymer can be used to describe a variety of materials often produced from bio sources, such as microbes, vegetables, sugar, fat, proteins, plants, and trees, among others Ahmadi et al. (2017). Biopolymers provide functional electronics with novel opportunities due to their biocompatibility, biodegradability, natural abundance, mechanical flexibility, and light weight, thereby providing the final inspiration and an alluring ingredient for the development of flexible, wearable, implantable, and/or environmentally friendly electronics.

In particular, a broad range of molecular engineering strategies has been proposed for modification of biological molecules or the utilization of molecular assemblies for achieving new optical-electrical properties, functions, and applications through noncovalent/covalent bonds with functional groups, such as hydroxyl, carboxylic, amino, and amine. Moreover, biopolymers also possess certain unique electrical properties, which motivate them to become an ideal choice for electronics devices, having high electric conductivity, good ion conductivity, versatility, and stability, etc. So far, a number of natural or synthetic biopolymers for electronics devices like batteries, PV, sensors, displays, transistors, memories, friction generators as substrates, active layers, and electrodes, give the bioelectronics the ability to be manufactured on large scales with lower costs, maintaining high performance. Moreover, the molecules of biopolymers possess an abundance of functional groups, which allows stable dispersion or high solubility in ordinary fluids, including water, for forming solvable electronic inks.

This characteristic makes them an ideal candidate to be manufactured into electronic DEVICES using low-temperature fabrication techniques, protecting them against degradation by harsh conditions from any patterning techniques like photolithography on semiconductors of organic origin. Among various fabrication techniques, solution-coating and patterning processes are the beneficial enabler technologies to develop cheap, large-area, and flexible bioelectronic devices. Recently, several common printing techniques, such as intaglio, screen, inkjet, and 3D printing, are being extensively applied to different applications, such as health care, power devices, memory, and sensors, showing high promise in developing flexible devices.

Biopolymers can be prepared using renewable materials, such as plants, crops, trees, and their components, using physical, chemical, and biological methods. Biopolymers containing natural bioactive components have outstanding features, such as high mechanical strength, biocompatibility, and biodegradability, as well as a large number of active bonding sites, which provide unique benefits for the production of flexible electronics. For instance, biopolymers' unique multilayer structures possess an adjustable stretch modulus, offering great mechanical flexibility and enhanced strength for adaptation on various dynamic surfaces and bent interfaces.

In addition, a variety of functional groups in biopolymers, such as hydroxyl, carboxylic, amino, and amine, impart diverse functionalities on electronic elements based on biologicals, including selective adsorption, sensing, and ultra-hydrophobicity. In addition, biopolymers are suitable for the creation of implantable devices because of their low cost, biodegradability, and biocompatibility. Moreover, biopolymers also possess certain unique electrical properties which make them an ideal choice for electronics devices, such as high electric conductivity, high resistance to dielectric breakdown, superior ion conductivity, etc. However, inherent limitations in the biomolecules including instability, difficulties to sustain the activity of biomolecules, and limited functionalization hamper practical applications of biomolecules for the design of bioelectronic devices Chung et al. (2019).

Unlike synthetic polymers, biopolymers are assembled by molecular means, leading to well-defined three-dimensional structures. Biopolymers are

environmentally benign in nature and are easy for the microorganisms to break down. The term “biopolymer” refers to synthetic polymers that are produced bio-based from living things. Their molecular structures are mostly made of repeated units of amino acids, sugars, or nucleic acids, along with chemical side chains to aid their functioning.

Because of growing ecological concerns stemming from the use of chemicals and products made of oil, synthesizing refined chemicals and functional materials from natural resources is a matter of great social importance. Because of their intrinsic qualities, renewable nature, and abundant nature, nanocellulose could prove one of the most promising green materials in the current era, from sourcing, production, and surface modification of nanocellulose, to materials creation and applications. Biomass, plants, or microorganisms could be used as sources for nanocellulose, using relatively simple, scalable, and efficient isolation procedures. Nanocellulose can be extracted from natural sources using a combination of mechanical, chemical, and enzymatic processes. The source, the extraction methods, and the potential subsequent surface modifications affect nanocellulose characteristics. When materials are required for material strength, flexibility, and/or nano-structured specialty, nanocellulose is a viable material. Applications include tissue scaffolds, biomedical applications, biosensing, ultracapacitors, catalysis, environmental monitoring, optical electronics, antibacterial coatings, functional papers, packaging, mechanically reinforced polymer composites, and electrochemically controlled deposition. Techniques to alter nanocellulose surfaces include esterification, amidation, polymerization, etherification, silylation, sulfonation, and phosphorylation. These methods are typically applied to introduce charge- or hydrophobic-like moieties. The optical properties of nanocellulose provide a broad design and application opportunity for optoelectronics, including solar cells (Lasrado et al. 2020), displays, flexible electronics, and touchscreens (Hu et al. 2013). Because they allow the flow of light, cellulose-based materials are naturally transparent. However, if the light is presented as fibers that are of similar sizes as light wavelengths, then they may scatter substantially. Due to its intriguing characteristics and potential applications, nanocellulose has received much attention recently as a biogenic, biorenewable material. It can be extracted from various materials that contain cellulose, of which wood is the most prevalent source. Natural wood fiber has a distinct, layered, hollow structure. The cell walls of individual wood grain are composed of numerous nanofibers. Nanocellulose fibers can be woven out of pulps made of wood using mechanical techniques like homogenizers, microfluidizers, and milling machines. Flexible electrically conducting sheets that have high surface conductivity, wide optical absorption, and outstanding chemical and thermal stability are required for optical electronics applications. Silver nanowires (AgNWs) bonded on the surfaces of hybrid membranes made from cellulose nanofibers (CNFs) and graphene oxide (GO) were created using an easy vacuum-filtering technique, layer-by-layer, and were developed by Changshun Wang and collaborators (Wang et al. 2020). The AgNWs layers are capable of developing condensed, Stratiform structures based on a flexible, robust base provided by intermediate CNF/GO layers. The measurement of light in nanocellulose and its optical properties with respect to the dielectric

materials are covered in this chapter. The chapter also covers materials based on nanocellulose for environmental protection, plasmonics, photoreduction, and in energy-saving buildings and systems. Furthermore, it offers opportunities to develop cutting-edge strategies to build unique materials based on nanocellulose, which possess different dimensions and have novel applications. Lightweight, flexible supercapacitors are the most important potential optical-electronic application for nanocellulosic materials. When combined with conductive substance – typically a polymer – nanocellulose provides requisite mechanical support for flexing, freely standing structures and produces a large volumetric capacity. Modifications to nanocelluloses optoelectronic properties can be made through modifications to conductive polymers. Polypyrrole, polyaniline, and polycarbonate are the most commonly used conductive polymers. Polypyrrole has been applied on to the fibers of cellulose in order to produce a CNF-based electroactive composite, created by Nystrom et al. This composite is not only electroactive, it is also conductive as well as having power storage capabilities. The enhanced polypyrrole/nanocellulose composite produced an almost perfect pseudocapacitive response.

Bionanocomposites

Using conventional chemical methods, like polylactic acid, or by direct enzymatic action within a microorganism or a genetically modified organism, like polyhydroxyalkanoate, a biopolymer could be created based on biomonomers. The biotechnological creation of biopolymers with customized properties that are suitable for high-value medical applications, such as tissue engineering and medication delivery, is enabled via genetic modification of microorganisms.

Biopolymers have been used by humans for the most part throughout history in the form of food, clothes, and furniture. Since the start of the Industrial Revolution, fossil fuels like petroleum have been the most prominent sources for the invention and production of virtually all commercial products, especially plastics, now in widespread use (Sundar et al. 2010). However, these resources are finite, and ecological considerations have to be taken into account for all aspects of the usage of fossil fuels in manufacturing and power. Biopolymers need to compete against fossil-fuel-derived polymers, not only based on function, but also on price. Biopolymers are competitive in this respect when oil prices are high, while the prices of biomass, like maize starch, are low.

Bionanocomposites are worthy of a specific investigation, since they constitute an exciting multidisciplinary field combining biology, materials science, and nanotechnology. Polymer nanocomposites are composed of polymers and inorganic/organic fillers, which are combined on the nanoscale. The broad array of available biopolymers and fillers, such as clays, cellulose whittling, and metallic nanoparticles, gives these new materials exceptional tailorability. Nanocomposites are pursued by biomedical technologies such as tissue engineering, medical implants, dental uses, and controlled drug delivery.

However, widespread application of these significant bionanocomposites in our everyday lives is achievable only when it is available to consumers in bulk. Biopolymers or bionanocomposite is biocompatible as well as biodegradable, which is readily absorbed or eliminated by metabolic processes from the body. Biopolymers could offer competitive advantage in replacing petroleum-based polymer materials sustainably. They also possess unique characteristics, which cannot be replicated with conventional polymers. Biopolymer properties are strongly affected by polymer structure, which is crucial in producing polymers for their intended uses.

Biopolymers are used in a wide variety of medical applications. Packaging, engineering, environment, agriculture, and food-related industries are also seeing an increase. Adding porosity to a biomaterial broadens its possible applications. Biopolymers and their metabolites are abundant, diverse, and essential for living things; they possess unique characteristics that make them most useful for various applications. Biopolymers are a good choice for industrial applications due to their characteristics and because they can be made from renewable resources.

When one compares the performance properties and manufacturing costs of biopolymers with those of fossil fuel-based equivalents, the situation is one of the perfect competitions. Although it is quite cheap to manufacture biopolymers, continuous efforts are being made to improve their beneficial properties. Recently, a wide range of biopolymer applications have been identified, including additives and bioplastic blends, as well as personal care, food, and pharmaceutical goods, all with an eco-friendly degrading benefit (Sadasivuni et al. 2019).

According to K. Winkworth-Smith and T. J. Foster (2013), the target for a chosen biopolymer (emulsion-and-foam-surface activity, viscosity formation, or gelation), its structural development process, and its collaborative efforts with any complementary building materials play roles in the determination of biopolymers function in different fields. Two types of biopolymers are biodegradable and non-biodegradable. The above groups emphasize on the importance of conducting a comprehensive study on biopolymers, because this is necessary for developing eminent products, which can safely be biodegraded.

This has enabled the development of biocomposites, which are essentially polymers created from biologically based or fossil-fuel-based components reinforced with natural fibers such as flax, hemp, sisal, wood, and jute, thereby improving the biopolymer's composition. Biocomposites have generated enormous interest in the current research marketplace, providing the means for the resolution of a number of obstacles while trying to produce new products S.J.Eichhorn et al. (2020).

Classification of Biopolymers

Biopolymers are divided into two categories according to their sources of origin: natural – derived from plants, animals, and microorganisms, or fossil fuels – and synthetic – derived through the chemical process of synthesis. When measured on the basis of their usability, nondegradable biobase biopolymers are superior to biobase-degradable biopolymers on different functional fields (Ravenstijn 2010).

Biopolymers are classified as elastic, thermoset, or thermoplastic depending on their capacity to react under thermal conditions. Elastomers motivated many scientists to create new materials that possess their own set of desired properties, while thermosets from biological sources recently have attracted greater interest for manufacturing components than bioplastics from biological sources.

Biopolymers may also be classified as mixtures, laminates, or composites depending on their composition. Many biopolymers have demonstrated their ability to be blended with another biopolymer, whether biodegradable or nonbiodegradable, either natural or synthetically generated (Vroman and Tiggert 2009). Several biopolymers have proven the ability to be blended with another biopolymer, either biodegradable or nonbiodegradable, naturally or synthetically generated.

Additionally, biopolymers are categorized based on the monomeric units used and the structure of biopolymer forms. DNA and RNA are longer polymers made up of at least 13 nucleotide monomers.

Electronic Fabrication Techniques Using Biopolymers

Biopolymers are susceptible to degrade in the presence of high-light, heat, and chemical corrosion, and therefore, conventional top-down photolithography and thermal vaporization are ill-suited for the fabrication of electronic devices made of biopolymers because of the dissolution in the washing process with organic/acid solvents, or the warping in the thermal processing. Printing is an additive technology that has the capability to deposit various materials simultaneously and pattern them to produce flexible devices like medical monitors, human-machine interfaces, electronic displays, transistors at a low cost, high volume, and high yield. Biopolymers are not dissoluble in organic, acidic, or aqueous solutions, so they may be applied to solution-processing printing processes. Through printing procedures, biopolymer inks can be easily converted into functional electronics without the need for severe chemical or thermal processing, thereby preventing the loss of bioactive components and enabling the production of stable, high-performance electronics.

In addition, printing is one of the most promising technologies for processing solutions, covering both contact printing and contactless printing. As with screen and gravure printing, contact printing requires a mask to be in contact with a substrate, restricting its applicability to curved or complex surfaces. In contrast, contactless printing eliminates the need for masks and enables the direct printing of various surfaces. Therefore, depending on the surface qualities, the precise biopolymer ink patterns and high-performance electronics can be printed using the most suitable methods.

Screen Printing

Screen printing is a printing process in which ink is applied onto a substrate by pushing a viscous, high-viscosity ink across a screen in the shape of a pattern. In recent years, screen printing has received considerable attention for the printing of

photoelectric devices such as printed solar cells, organic light-emitting diodes, organic field-effect transistors, and radio frequency tags. For example, PEDOT:PSS printed by screens onto the electrode surfaces has been proven an efficient conductor and redox mediator for biosensors, which has a high sensitivity for the detection of phenolic compounds in water. Furthermore, the screen-printed PEDOT:PSS circuits on fabrics have shown a high sensitivity for the electrocardiography signals as an electronic and an ionic conductor.

As expected, screen-printed polyfunctional electronics textiles, which have intrinsic biocompatibility and flexibility, have a high potential of application to the smart wearable electronics of the future. Therefore, the screen-printing technologies are extremely promising for the production of biopolymer-based electronics at a lower cost and with less impact on the environment.

Spray Printing

At the moment, the spin-coating technique is still one of the important methods for the process to shape solution films. However, the spin-coating technique has very high requirements to fit surface characteristics of rotating materials to substrate surfaces.

In addition, a poor utilization rate and nonuniform films restrict its applications to devices with a lower price and a greater yield. Spray-coating has been extensively utilized to flexible electron devices because of its improved compatibility with biopolymers, high-efficiency manufacturing, and lower-cost manufacturing procedures in order to address the disadvantages of spin-coating. For instance, it is compatible with the mass production of the industrial powder, for instance, with large-scale fabrication of biopolymer electronics films by rolling-to-roll.

Inkjet Printing

Currently, the biopolymer films coated by aerosol spray are being extensively studied for electronics. In brief, there are big prospects in spray-coating for the field of integrated circuits at scale. As a contactless technology, inkjet printing works by dropping an ink gradually onto the substrate, to create a patterned predesigned film, and has been used extensively for fabricating a wide variety of devices such as transistors, solar cells, and sensors S.Conti et al. (2020). Unlike the above two print methods, inkjet printing is capable of producing highly resolved prints of electronic functional biopolymer inks onto different substrates, showing promise in fabricating micrometer-scale devices with custom patterns.

By using inkjet printing, the electrode structures can be freely inked into any geometry, a significant improvement over conventional processes like as photolithography or thermal vaporization via shadowmask. In addition, inkjet printing is suitable for fabricating thin, homogeneous layers at moderate processing temperatures that are compatible with biopolymers and flexible biopolymer substrates. Inkjet

printing is thus a highly promising route to build complex, inexpensive electronic devices with biopolymers.

3D Printing

As a significant advanced additive manufacturing technology, 3D printing is capable of producing accurate complex 3D architectures with no material waste to fulfill a variety of practical applications. Moreover, 3D printing can be used for biopolymer-based inks, avoiding damage to biological activity, and importation of toxic materials, to produce biomedical devices and nonplantable electronics J.Ferri et al. 2019. Therefore, introducing 3D printing in smart materials and biopolymers becomes crucial for the further expansion of 3D-flexible electronics for tissue engineering, soft robotics, and stretchable electronics.

Moreover, 3D printing is utilized extensively in tissue engineering, thermonuclear delivery, and other biological applications. Thus, 3D printing provides advantages such as superior print flexibility, biocompatibility, and environmental friendliness, allowing it to be applied to a variety of biobased electrical devices. Great advances in biopolymer-based electronics have been achieved in preparation of printed methods.

When considering to select the most suitable technology, following issues are addressed, depending on biopolymer inks and fabrication technique: biopolymers for printing that have the right rheological properties, such as viscosity, concentration, and plasticity of the biopolymer inks, as well as the compatibility of printing technology with biopolymers, to prevent the loss of bioactive components and the corresponding performances. In addition, the wetting and dewetting kinetic mechanisms of biopolymer inks on various substrates are not entirely known, necessitating additional research to achieve regulated and precise patterning using biopolymer inks. Therefore, greater emphasis must be placed on optimizing the printing methods depending on different biopolymer inks, which is crucial for realizing biopolymer applications for electronics.

Application of Biopolymers

Due to characteristics such as biocompatibility, degradation by microbes into non-toxic end products, maximization of biological activities, lower immunogenicity, ability to support cell proliferation with the proper mechanical properties, transposition into complex shapes with the appropriate porosity, and preservation, biopolymers are utilized most frequently in the medical field. Examples include targeted drug delivery, surgical stent devices, wound healing products, and closed-end products. Biopolymers are generally used in applications such as food containers, soil holding sheets, agricultural films, garbage bags, and common packaging materials because of their film-forming and barrier properties. They are also found applications in hazardous waste disposal, automobile material production, the paper industry, and even the development of new construction materials.

Three-dimensional scaffolds to form tissues, packaging, delivery systems, environmentally friendly insulation materials are some of these applications (Gavillon and Budtova 2007). Biomedical applications, due to the higher importance of their entities, attract much of the interest in biopolymer applications in comparison with other fields. The most common applications for biodegradable polymers in disease treatment are orthopedic and vascular reconstructive implants and surgical sutures that aid in the integration of damaged tissues.

These threads may work throughout tissue regeneration, before being either physically removed or allowed to disintegrate naturally within the body. They are also highly durable, easily sterilized, and strong. Because of their stable tensile strength and outstanding flexibility, poly-(glycolic acid), poly-(l-lactic acid), and their copolymers are commonly used as stitches. Bone fixation implants made from biopolymers allow unrestricted, dynamic bone regeneration, and they do not have to be removed by surgery once bone has healed, as the whole implant structure disintegrates.

Because they are highly bioactive, metabolic, and toxic when compared with their synthetic counterparts, biopolymer nanoparticles potentially become an essential material in drug delivery systems and facilitate the release and uptake of drugs. Biopolymers having poly-(hydroxy acids) and poly-(ortho esters) groups are usually employed for drug delivery systems. Polyurethanes are classified as a blood-compatible material due to their hard, flexible, and wear-resistant properties, which are essential in scaffolds of blood vessels simulations by the artificial grafts (Zhu and Xu 2010). Biopolymers have attracted interest from the agriculture industry because of their nature-based degradation and soil-improvement properties, with significant potential for the development of mulches and plant containers.

By maintaining moisture, decreasing the weed growth, maintaining proper soil temperature, and – most importantly – photodegrading, organic fertilizers contribute to plant growth and remove the need for removing them and associated costs (Raj et al. 2011). Fertilizers are created using polymer films comprised of poly(vinyl chloride), low-density polyethylene, poly(vinyl alcohol), or polybutylene. With the help of soil microbes, or by adding fine particles that promote the films termination, these films are modified so they may begin breaking down only after the growing season has ended. In farm settings, composting lessens the need to farm, meaning that root injuries and plant stunting/destruction are reduced further.

Because of their physical characteristics that enable modifications of molecular weight, chemical composition, and manufacturing conditions, yet achieving desired properties, packing polymers are of great interest. These desired properties are determined by the product to be packaged and its storage environment. The possibility to combine properties from several biopolymers in one biodegradable film has been established in order to create packing materials that possess features quite notable compared with synthetic equivalents, although the latter do enjoy some advantages compared to their bioderived counterparts.

Potential packaging films are being created using polyethylene copolymers and biopolymers based on starch, cellulose, and other polysaccharides. Natural fillers, such as starch, are now mixed with synthetic polymers in order to enhance the degradation-free qualities of the packaging laminates. Food-storage bags, storage

containers, throwaway plates, glasses, and silverware, and even textiles are among the preferred types of packaging that are made with biopolymer sources. Biopolymer packaging of foods and condiments assures the quality and appetizing qualities of packaged items are maintained from production time until sampling.

The automobile industry has seen a major shift to produce today's cars, focusing on reducing fuel use and emissions. The forgone goals were supposed to be achieved by making vehicles lighter to meet motoring laws. Most manufacturers are racing towards producing plastic car components made from bio-derived polymers like polyamide, polyester, and polypropylene, among others.

Scale	Methods	Variables	Outcomes	Limitations
Quantum scale	Quantum mechanics (QM) Density functional theory (DFT), Coupled cluster method (CCSD(T))	Crystal symmetries	Thermal properties, chemical reactions, and electrical qualities based on band structure and density of states	Timescale and system size constraints imposed by computing performance.
Mesoscale	Coarse-grained methods. Quasicontinuum method, Kinetic Monte-Carlo method, dissipative particle dynamics (DPD), coarse-grained molecular dynamics	Structure flaws and defects, molecular weight, thermal fluctuation, hydrophilic-hydrophobic – ratio	Hydrodynamic radius, fracture properties, radius of gyration, self-assembly and size effects	Either restrictions in accuracy or size
Molecular scale	Energy conservation and equilibrium, steered molecular dynamics (SMD), replicate exchange molecular dynamics (REMD), molecular dynamics (MD), well-tempered metadynamics, umbrella sampling, and reactive force-fields	Sequence, pH, ions, force, velocity, temperature	Conformation, chemical reactions, mechanical properties	Restrictions in time scale and system size due to constraints in computational performance

(continued)

Scale	Methods	Variables	Outcomes	Limitations
Macroscale	Continuum methods such as solid and CFD (FEM, FVM, BEM, FDM) MBS-simulation	Process conditions (thermal, mechanical, and electrical), the global structure, and dynamic mechanical properties	Global thermal and electrical analysis, multibody problems, and nonlinear structure analysis	Description via partial differential equations, the restriction which arises due to homogenization of structure or properties

We review the current state-of-the-art of biopolymer design, highlighting materials-design approaches combining experimental and computational studies. Exploring a variety of parameters effects on biopolymer synthesis and processing, we argue, provides opportunities for developing mechanistic models and exploring design spaces for novel materials. As such, we purposely excluded studies which focus solely on structure analysis and the characterization of natural biomaterials.

This research begins by reviewing the general methods for the manufacture, processing, and modeling of biopolymers, emphasizing what parameters may be handled or studied using these methods. Then, we examine the structural-to-processing-property relationships for collagen, elastic, and silk-inspired biopolymers, as well as the methodology employed to arrive at these conclusions. Combining experimental and computational investigations, we then discuss challenges and opportunities in the field of biopolymer design.

Biopolymers in Biomedical Applications

Collagen

Collagen, which was discovered by Paine in 1838, is a significant structural component of vertebrates and the most prevalent mammalian protein, comprising 20–30% of the total body protein. Collagen is produced by fibroblasts, which are normally derived from pluripotent adventitial cells or reticulum cells.

The primary collagen molecules are rod-shaped, with an approximate length and breadth of 3000 and 15Å, respectively, and a molecular mass of roughly 300 KDA. It is easily absorbed by the body and possesses a negligible antigenicity. In addition, the material is nontoxic, biocompatible, and biodegradable. It possesses a high ratio of strength to weight and a high affinity for water.

Gelatin

Gelatin is a water-soluble substance derived from the degradation of the tertiary, secondary, and to some extent primary structures of natural collagen via the partial hydrolysis of collagens extracted from animal skin, white connective tissue, and

bones. The majority of hydrocolloids are polysaccharides, whereas gelatin is a protein that is edible and contains all essential amino acids with the exception of tryptophan. Gelatin can be derived from a variety of collagen sources. The primary commercial sources are cattle bones, skins, pig hides, and fish. Due to its surface-active qualities, gelatin is utilized as a foaming, emulsifying, and moistening agent in food, pharmaceutical, medicinal, and technical applications.

Chitosan

Chitosan is generated from chitin, a polymer found in nature. Chitin was originally isolated and characterized in 1811 by French scientist Henri Braconnot from mushrooms. It comes second in the world's most abundant biopolymer. Other than cellulose, chitin is the most prevalent polysaccharide in nature. It is a major component of crustacean and insect exoskeletons, as well as the cell walls of nematodes, yeasts, and fungi. Chitin is superb for biocompatibility; it has high bioactivity, biodegradability, selective permeability, polyelectrolyte activity, antimicrobial activity, the capacity for forming gels and films, and the ability for chelation ability and absorption capability. Chitosan can be used as a pharmaceutical carrier to manage drug release, to act antibacterially and antiacidic, to inhibit bacterial plaque formation and the decalcification of dental enamel, to contribute to osteogenesis, to absorb fat, and to promote healing of ulcers and lesions due to its unique properties.

Cellulose

It is the most common naturally occurring glucose polymer, being the primary component of plants and natural fibers such as cotton and flax. Additionally, some bacteria (such as *Acetobacter xylinum*) may manufacture cellulose. Chemically, plant-based cellulose is identical to that of microorganisms and bacteria; yet, its macromolecular structure and physical properties are distinct. Cellulosic fiber has the chemical formula $(C_6H_{10}O_5)_n$ and is a polysaccharide with a linear chain consisting of several hundred to over 10,000 D-glucose units linked by B(1–4) bonds. Cellulose and its derivatives are harmless to the environment. Natural cotton fibers and other recycled (man-made) celluloid fibers, such as viscose, modatim, and lyocell, are the most important celluloid fibers for medical purposes.

Xylan

Xylan, a naturally abundant hemicellulose, is regarded to be the second most prevalent polysaccharide, behind cellulose. Xylans are a predominant hemicellulose in hardwoods, as well as annual plants and grains, constituting up to 30% of cell wall material and 25–35% of lignocellulosic materials. Because it is biodegraded by enzymes produced by colonic bacteria, xylan has been deemed a promising

feedstock for the production of gastrointestinal drug delivery systems. Xylan's physiological effects: The viscous structure of fiber polysaccharides in grains contributes to the bulking effect of feces as well as reductions in blood cholesterol levels, postprandial glucose, and insulin responses. Cereals' water-extractable polysaccharides are said to alleviate alcohol-induced liver problems. Arabino-glucuronoxylan, a substance with immunostimulating properties, has been isolated from various plant sources. Several of these xylans have demonstrated antiphlogistic properties. Hemicellulose extracts rich in xylans from plant residues, such as bamboo leaves, wheat straw, and maize stalks, have been shown to inhibit the growth of sarcomas¹⁸⁰ and other tumors, most likely by the indirect, nonspecific stimulation of the host's immunological responses. T cells and immunological cells are stimulated by carboxymethylated hemicelluloses derived from wood.

Alginate

Alginate is a water-soluble polymer derived from brown algae, one of the most abundant biosynthesized substances. Alginate is utilized to support tissue healing and regeneration matrix or delivery systems. Due to its biocompatibility, biodegradability, nonantigenity, and chelating ability, alginate is widely employed in a variety of biomedical applications, such as tissue engineering, drug delivery, and, in particular formulations, to avoid gastrointestinal reflux. It is a U.S. Food and Drug Administration (FDA)-approved polymer; thus, alginate has emerged as one of the most prominent biomaterials in regenerative medicine, nutritional supplements, and other uses. Due to its easiness of manipulation, alginate is also often employed in dental impression production.

Carrageenan

Carrageenan is extracted from various species of rhodophyte marine algae. Carrageenan is the generic name for a family of polysaccharides with a gel-like consistency and viscosity. Carrageenan is a sulfated polygalactan whose ester-sulfate content ranges from 15% to 40%. Carrageenan is regarded as a suitable alternative for gelatine (products derived from animals) in both solid and soft-gel capsules. Its addition to glycerin-water mixes conceals the chalkiness of antiacidic gels. It can be applied topically as well as sublingually. It functions as a thickening and binder agent in dental products and keeps the liquid and solid from separating.

Gum Arabic

Gum arabic is a dry, edible, gelatinous substance obtained from the stems and branches of *Acacia senegal* and *Acacia seyal*, which are rich in soluble nonviscous fiber. GA is used topically to cover inflammatory surfaces and orally to alleviate

intestinal mucosal inflammation in folk medicine. According to studies, GA possesses antioxidant and nephroprotective effects. Nevertheless, these results are not universally recognized. Due to its physical qualities, it reduces glucose uptake, increases the mass of feces and Bile acids, and has the ability to modify human physiology in a beneficial manner. Some research has shown that gum arabic inhibits the growth of some pathogenic species, such as *Porphyromonas gingivalis* and *Prevotella intermedia* (agents implicated in the creation of dental plaque). According to one study, GA can promote tooth remineralization and reduce plaque production, making it a viable agent for preventing the formation of plaque. These effects were linked to the high Ca^{+2} , Mg^{+2} , and K^{+} salt content of the polysaccharides of GA, as well as the effects of the gum on the metabolism of Ca, and maybe phosphate as well. Adding gum arabic to plaster goods increases their stiffness. Small amounts of gum arabic added to hemihydrate calcium carbonate lower the quantity of water required to combine plasters and stones.

Xanthan Gum

Xanthan gum is a naturally occurring polymer generated by *Xanthomonas campestris* bacteria. Repeated pentasaccharide units consisting of two D-glucopyranosyl units, two D-mannopyranosyl units, and one D-glucopyranosyluronic unit make up the fundamental structure of xanthan. Viscosity is correlated with the ability of xanthan to thicken liquids; higher viscosity resists flow. The viscosity of xanthan solutions decreases as shear speed increases, exhibiting a pseudoplastic or shear-thinning feature. In toothpastes and cosmetics, xanthan gum is a frequent ingredient. It can be easily emptied from the tube. Additionally, it ensures that toothpaste remains stable when placed on a toothbrush. Additionally, the thinning properties of shears improve dispersion onto teeth and rinse off. Denser toothpastes containing xanthan gum have a brilliant, glossy, stringy appearance and a reduced flow rate. In pharmaceutical emulsions and suspensions, xanthan gum prevents the separation of insoluble components.

Pectin

Pectin is a heteropolysaccharide structural component of the main cell walls of terrestrial plants. Pectin consists of a complex collection of polysaccharides found in the majority of primary cell walls and is particularly common in the nonwoody sections of nearly all terrestrial plants. Commercial pectin is nearly exclusively obtained from citrus peels or apple pomace, both of which are byproducts of fruit juice manufacture. Pectins are believed to be mostly made of D-galacturonic acid (GalA) units linked into chains by A-(1–4) glycosidic bonds. Combined with carbopol and chitosan, pectin is used to generate mucoadhesive patches. It exerts its effect by making close contact with tissues, enveloping polymer-mucin chains, and forming a weak connection between the chains. Pectin functions as a natural

preventative against cation toxicity. Pectin is efficient at eliminating lead and mercury from the respiratory and digestive systems. Pectin improves blood coagulation; hence, it is useful for hemostasis regulation. Pectin is useful in the treatment of overeating because it slows digestion by keeping food components in the intestines, resulting in less food absorption. Pectin hydrogels are employed as binders in tablet formulations and in controlled-release matrix tablet formulations. Pectin is currently being studied as a material for the development of medication delivery systems tailored to the gastrointestinal tract. Some pectins have demonstrated *in vitro* anti-inflammatory capabilities, which is a promising and advantageous property for device modification. Due to its ability to stimulate immunological responses *in vitro*, pectin is currently being intensively studied as a potential candidate in soft and hard tissue engineering as well as dental titanium coatings.

Factors Affecting the Optical Properties of Biopolymers

Biopolymers have attracted much interest as an ingredient for flexible display devices. Flat-panel display (FPD) technology is moving away from a wet-bulk process towards a continuous roll-to-roll due to manufacturing cost considerations.

The traditional technology involves stacking onto a large substrate, usually made from glass, then, slicing up the panels to different sizes, depending on available tools. So, a normal way to manufacture the panes into different sizes proved to be most economical.

Plastics were used instead of glass for the substrates in the rolling-to-roll process, due to their flexibility. When the process is not being used, the plastics flexibility allows it to be bent over and folded over to store. As a result, a rolling-to-rolling approach has a number of advantages, such as cost-effectiveness and simplicity. Coefficient of Linear Thermal Expansion (CTE) is an important element of a roll-to-roll process.

If a substrate is not capable of withstanding the high temperatures of the process, then functional materials that are deposited on substrates will suffer damage and destruction due to a mismatch of material CTE. Even though the CTE of glass used as the substrate is sufficient to withstand the temperatures in the manufacturing process, the glass is impossibly brittle and cannot fold. Plastic bracing needs to be used in order to improve CTE.

When reinforcing the plastic, this reduces the plastics CTE, but does not lose optical transmission. The reduced CTE associated with nanocellulose offsets higher CTE from the polymers. On the other hand, the high Youngs modulus associated with nanocellulose is balanced out by low Youngs moduli associated with polymers.

As crystallinity increases, the intermolecular hydrogen bonding among molecular chains in the cellulose increases. Because thermal expansion is constrained by the intermolecular hydrogen bonds, higher degrees of crystallinity indicate lower CTE. Increased milling causes a degradation and breakdown of the fibrillated fibers as multiple passes are made through the mill. In conclusion, CTE and the material modulus are affected by the level of crystallinity. Furthermore, since cellulose

contains nanofibers which are connected through hydrogen bonds among the intermolecular bonds, these nanofibers are hard to disassemble using mechanical processes such as milling, homogenization, etc. So using blender-style homogenizers, they produced the nanofibers of the TEMPO-oxidized cellulose (TOCN). The CTE of TOCN (2.7 ppm K^{-1}) was lower than that of glass (about 9 ppm K^{-1}) and compared to silicon (3 ppm K^{-1}).

The nanofibers are denser, with smaller pores within fibers, suppressing light-scattering properties, while the bacteria nanocellulose is translucent to light-scattering at the surface. The nanocellulose is treated with emery paper for increasing transparency.

The surface of the nanocellulose needs to be smoothed uniformly in order to enhance light surface scattering. There are different methods to smooth the nanocellulose surfaces. The earliest technique involves coating sheets of nanocellulose with optically transparent polymers. Impregnation into a plastic has been the second method and has been mostly used.

The optical transparency of nanocomposites made from nanocellulose and plastics is enhanced because nanocellulose has smaller diameters than visible light wavelengths. The difference between the refractive index (RI) of nanocellulose and plastics is minimized in order to improve light transmission in the nanocomposites. Chemical processing changes the RI of nanocellulose. Therefore, careful management of the optical transparencies of CTEs and substrates is essential, with acetylation being the most prevalent chemical treatment.

Also, nanocomposites that contain high-DS BCs exhibit superior transmission, as BCs have lower RIs as the DS increases. Furthermore, because of the enhanced bonds acetylation created between the cellulose and the polymer, the acetylated BC was successfully incorporated. Insertion of the large groups of acetyl into nanocellulose caused a thickness increase in the material, allowing thickened nanocellulose to interact with transduction. Furthermore, excessively acetylated nanocellulose will have lower RIs compared with that of plastics. The adaptability of nanocellulose supports has several advantages, including the ease of manufacturing and storage.

The bendable, flexible substrates show lower modulus and higher extension when broken than the nanocellulose, which shows the adaptability of the nanocomposites offered by plastics. Pure acrylic resin has a very high elongation at break; however, the material is susceptible to even a small crack; hence, sheet breaks at folding. In nanocomposites, the nanocellulose (BC) stops the growth of fractures; thus, the material can fold without breaking. However, if used in dry BC, elongation at breaking increases, reducing the strength and increasing the Young's modulus. The properties of BC-containing nanocomposites are also affected by plasticization methods.

The earliest technique for introduction is "in situ" technique, involving plastic addition directly to BC development environment. The second technique of introduction involves the "impregnating" of the BC in the plastic solution. The nanocelluloses tapered structure is different depending on the nanocomposite creation process. The hydrogen bonding among the nanofibers is broken off when the PVA is coated onto BC surfaces, increasing elongation upon breaking when compared with uncoated BC.

The Young Modulus and the strain at the yield, which is affected by the number of passes in the mill, were both affected for the MFC. Young's modulus and yield strain are reduced by making more passes. These results suggested the linkage of intermolecular hydrogen bonds with the fibrillated fibers at the number of passes.

The fiber form is a source of reduced strain at the yield. First, additional grinding treatments caused fibrillated fibers to break down, as well as increasing hydrogen bonding. Second, aspect ratios of fibers decreased due to the shear forces reducing fiber length.

Optical Applications of Biopolymers

Optical components are utilized for light transmission, detection, and conversion. They include optically active coatings like sensors, photonic coatings, Bragg reflectors, and several other devices, as well as waveguides (a physical structure that conducts electromagnetic waves of the optical spectrum). The materials used to create optical elements must have the ability to modulate or control electromagnetic radiation in the UV, visible, and IR spectral ranges. Materials must possess specific mechanical, chemical, and biological (biocompatibility, biodegradability) qualities in addition to optical properties in order to be used in photonics. The degree of transparency, refractive index, and their spectrum dependence are the most crucial factors in choosing an optical material. High transparency materials exhibit comparatively little light reflection, absorption, and scattering, resulting in minimal optical losses. However, biopolymers substantially absorb light at short wavelengths of 250–400 nm, which is common for many organic compounds. As a result, the optical use of materials based on biopolymers is constrained. The biopolymers poly(limonene carbonate), silk fibroin, chitosan, gelatin, nanocellulose, alginate, polylactic acid, and polyhydroxyalkanoates are ideal for optical applications. The creation of materials with novel functionalities and programmable properties is made possible by the abundance of functional groups present and the potential for manipulating the supramolecular organization of the biopolymers. Here are a few examples of how biopolymers can be used in optical applications.

Displays

Various flat panel display (FPD) technologies, including active matrix liquid crystal displays (AM-LCDs), active matrix organic light emitting displays (AM-OLEDs), and others, are being mass-produced for flexible displays and lighting panels at this time. Organic light emitting diode (OLED) has been adopted as the preferred technology for flexible or conformal displays in the mobile display market due to its inherent advantages of being lightweight, having a high brightness, having a low power consumption, having a broad color gamut, having a quick response time, and having a high degree of flexibility. It is of tremendous practical importance to improve OLED with biocompatibility and human affinity given the demands of

flexible and wearable technology for device biocompatibility and the advancement of bio-photonic research. When electric current travels through a light-emitting diode, it creates monochromatic light, or light with a single wavelength. The semiconductor device produces a P-N junction, with the P-side referred to as the anode and the N-side referred to as the cathode; the region between the two is referred to as the depletion region. Forward bias results in recombination of holes from p-types and electrons from n-types, which results in energy being released as light B. Geffroy et al. (2009).

Being renewable, the enhanced properties of biopolymers are emerging as a promising replacement for inorganic LEDs. Deoxyribose nucleic acid is a remarkable molecule both from the perspective of structure and properties. They are electrically conductive and cheap and are promising materials for use in optical devices. Gupta et al. (2011) and Kobayashi et al. revealed the dipping-coating technology that embeds Ru(bpy)₃²⁺ DNA doping into LEDs as soluble water-soluble DNA polyaniline complexes. OLEDs are traditionally made on rigid glass substrate, and the polymer substrate offers an alternative as flexible material.

Natural biopolymers can be used as substrates for flexible green electronic devices because of their nontoxicity, high mechanical strength, strong biocompatibility, and biodegradability. A translucent paper made of self-assembled chitin nanofibers (CHnF) with strong hydrogen bonds was introduced by Jin et al. The use of low-cost coating is an effective method for LED source conversion, but the lack of reliable and stable white light emitting diodes (WLEDs) in the display industry is one of the significant technological obstacles. Gotta and colleagues used biocomposites of biological (crystalline nano-cellulose and porcine gastric mucus) and organic (luminescent dye) materials to generate white light emission in blue LEDs. Thanks to both the encapsulation properties of proteins (mucin selectively binds to dye molecules through molecular disulfide bonds) and the excellent host matrix of cellulose nanocrystals, the resulting composite material has excellent optical and mechanical properties as well as resistance to heat, humidity, and ultraviolet radiation (self-assembled into nanoscale or layered ordered films may include active ingredients such as nanoparticles). This study lays the path for the development of nonluminescent coatings devoid of rare earth elements for WLED technology.

Additionally, organic thin film transistors (OTFTs), essential parts of electronic displays, are crucial in regulating pixel resolution. Biopolymers have received a lot of attention recently as potential building blocks for flexible TFTs. For instance, the effective preparation of high performance OTFTs was made possible by the use of biocompatible human hair keratin as a supporting substrate and high capacitance dielectric layer. Proton conduction is facilitated by the formation of hydrogen bonds between amino groups and absorbed water molecules in keratin, which has extraordinarily high dipole properties and hygroscopicity. Due to protein denaturing at basic conditions, the constructed devices may also degrade in alkaline solutions. In addition, keratin is a promising carrier material for environmentally friendly, completely printable, and low-cost photo-electric devices due to the abundance of hydrogen bonds and ease of structural alteration in its molecules. As a substrate or gate dielectric for OTFTs or other functional electron devices, cellulose nanofibers (CNF) have also been used.

Solar Panel

Sustainable energy is provided by solar cells, which are also an essential part of energy-conversion machinery and are popular due to their low price and environmental friendliness. Flexible solar cells have recently experienced significant development as a result of their special advantages related to their ability to survive complex manufacturing processes and de-forming. Solar cells are a semiconductor device that provides a steady source of power using sunlight. Due to its low cost and resilience, it has gained wide popularity. Biopolymers such as cellulose, chitosan, pectin, and silk fibroins are increasingly being sought after as optical and electronic devices because they possess lower density and thermal expansion coefficient, higher strength, and elasticity moduli, which reveal tremendous potential for solar cells. Yuqiang and co-workers built flexible organic solar cells using silk fiber fibers that are biocompatible and have silver nanowire grids.

Inverted organic solar cells were used to electrostatically self-assemble chitosan molecules into a highly ordered layer-by-layer (LbL) cathode interlayer film (OSCs). The ordered LbL structure of the chitosan coating decreased the work function of the electrode and enhanced device performance as a result of the formation of interfacial and molecular dipoles. Electronic devices are becoming increasingly interested in biopolymers such as chitosan, pectin, cellulose, and silk fibroin due to their low density, low thermal expansion coefficient, high tensile strength, and elastic modulus. This has demonstrated the immense potential of inexpensive and ecologically friendly solar cells. Moreover, the development of thin protein/peptidyl-based solar cells during the past few decades has paved the path for biocompatible interfaces for wearable electronics.

The silk fibroin (SF) film is a ground-breaking transparent solar cell substrate. The high transmittance of SF film is attributed to a motif consisting of a sequence of amino acids that appears to have weak absorption in the 400–1200 nm spectral range. In order to construct organic solar cells, Liu and colleagues used natural silk fibroin film with silver nanowire as the conductive substrate, achieving superior conductivity, transmittance, and degradation compared to the conventional flexible ITO-PEN substrate. In addition, conductive composites comprised of DNA and bacterial cellulose can serve as the base material, active layer, and bioelectrode for solar cells. Therefore, biopolymers with diverse molecular configurations and topologies offer them with beneficial electric capabilities, robust mechanical qualities, and good transparency, boosting their usage in wearable and smart energy electronics as well as biomedical energy electronics.

Sensors

In the last few years, the development of high-performance, flexible electronics, which are capable of accurately sensing the outside signals, has been a major field of study. Chemical sensors detect chemical substances by translating chemical reactions into electrical signals, playing a major role in food and environmental safety.

Biosensors are sensitive to bioanalytical fields, like diagnostics, therapeutics, and forensics. A high-sensitivity biosensor of alpha-fetoprotein, the tumor-forming protein, was developed by Min et al. The sensor showed favorable selectivity, sensitivity, ultra-low detection limits, high hydrophilic, and good antifouling capability; thus, it was found a high-viability potential in clinical diagnosis. High performance flexible and extensible sensors that can precisely sense external signals have recently emerged as a key study area because of advancements in flexible electronics, materials science, and micro-/nano-processing technology. As an active sensing layer, conductive electrode, and substrate, natural biopolymers and chemically produced polymers with inherent bio-compatibility have been widely used in a range of sensors. In addition to giving the sensors high flexibility, the inclusion of functional biopolymers through doping, surface modification, and chemical group design also enhances the charge transfer in the active sensing layer, raising the sensitivity and detection threshold of the sensors. This section primarily introduces chemical sensors, biosensors, and strain sensors with enhanced performance through molecular modification of biopolymers.

By converting chemical processes into electrical impulses, chemical sensors are sensitive to a variety of substances. This technology is vital for intelligent agriculture, food security, environmental monitoring, and medical diagnosis. Wang et al. developed a functional polysaccharide film-based humidity sensor with high humidity sensitivity by forming a network of hydrogen bonds between water and polysaccharides, which accelerates proton transport in humid environments and exhibits strong responses to humidity. Keratin is an outstanding biopolymer for humidity sensors as an active material for ionic/electrical transduction due to the abundance of functional groups (C = O, C-O, and O-H) on its side chains. These groups enhance the chemisorption of water molecules and facilitate proton transfer in humid environments.

The presence of functional groups such as NH₂, OH, C-N, and C=O on the surface of chitosan film enhances the adsorption of certain active molecules, hence enhancing the sensitivity of sensors. Shantini et al. employed chitosan as the active sensing layer in the creation of a chemical sensor to detect hexanal. For chemical sensing applications, biopolymers with many functional groups that can accurately detect analytes are hence suitable. In the realm of bioanalysis, biosensors have been widely explored for forensic analysis, drug release monitoring, and biomarker identification. By correctly grafting or adding conducting polymers or molecules to biopolymers, which can supplement and improve the performance of biopolymers in biosensors, it may be possible to achieve greater electrochemical activity for the purposes of biological sensing. Wei et al. utilized HA to bind CD44 receptors in order to develop a photoelectrochemical biosensor for the detection of CD44-related cancer with excellent sensitivity. Consequently, the creation of intrinsically biocompatible and electrochemical biopolymers is a potential strategy for producing high-performance biosensors.

Strain sensors, and particularly wearable strain sensors, have attracted a great deal of interest because they may play a significant role in future flexible and wearable electronic systems. In order to perform long-term monitoring of human health and activities, mechanical stretchability has emerged as one of the most essential

characteristics for strain sensors. Rarely these are the vast majority of naturally brittle and chemically unstable biopolymers utilized in flexible strain sensors.

In addition, silk possesses outstanding optical properties, such as high transparency and the capacity to alter sheet crystallinity, highlighting the protein's potential in organic photonics and electronics. Constructing functional biopolymers utilizing simple doping and heating procedures that provide excellent mechanical properties without losing sensing ability is an effective method for producing high-performance, flexible strain sensors.

Diverse chemical and physical alterations equip biopolymers with functional molecular structures that have greater sensitivity, greater optical resolving power, and more flexible features, hence enhancing their eligibility for usage in a variety of functional sensors. It is still challenging to satisfy all practical needs without compromising biocompatibility and sensor performance.

Flexible Electronics

Biodegradable and reproducible biopolymers are in an increasing demand in flexible electronics to replace nonrenewable resources and reduce electronic waste disposal. Several nanomaterials have been combined with biopolymers to offer additional functionality in order to meet the requirements of emerging new technologies that require the combination of mechanical, optical, and electrical capabilities, as well as sustainability and ecologically friendly ways. Natural biopolymers have a variety of exceptional characteristics, including low cost, biocompatibility, superior mechanical properties, and light weight. As a result of these remarkable features, natural functional biopolymers can be developed and enhanced for the production of high-performance flexible electronic devices.

Silks, a family of biopolymer fiber materials, are produced by numerous species, most notably arthropods like spiders, worms, and butterflies. These proteins have a unique nanoarchitecture that provides them with particular properties such as rigidity, strength, and toughness. In comparison to synthetic polymers, they possess superior mechanical properties, biocompatibility, biodegradability, and processability in a variety of macro- to nanoscale shapes and geometries. Silk materials are creating new opportunities in optics, photonics, and flexible electronics due to its transparency, flexibility, and surface patterning simplicity. The ease with which silk can be functionalized with organic and inorganic dopants utilizing either a controlled mesoscopic assembly or a straightforward macroscopic mixing of water-based solutions is one of its primary advantages. Transparent, conductive AgNW/CNF paper for flexible electronics was created using a hot-pressing process. In terms of electrical conductivity, the outcomes were comparable to ITO and sufficient for the development of organic solar cells.

Electronic skins (sometimes referred to as “e-skins”) and flexible strain sensors are fundamental components of flexible electronics and have a wide variety of applications for monitoring human daily activities, HMI, AI, and the prevention and treatment of human diseases. Soft, elastic e-skins may contain an array of

sensors that can mimic the features of human skin and detect ambient conditions. These sensors include of pressure, temperature, humidity, and strain sensors, among others. In an ion gel, Zhao et al. demonstrated cellulose-based electronic skins composed of cellulose, ions, and water (Cel-IL dynamic gel). E-skins exhibited a microstructure resembling brambles with ionic conductivity, high adhesion, and rapid self-healing properties. The biomimetic e-skins were also highly sensitive to certain mechanical strains and human movements, making them a promising tool for monitoring human mobility.

Despite the substantial advances made in recent research on biopolymers and biopolymer-based sensors, integrating the practical application of biopolymers in flexible electronics presents various challenges. While natural biopolymers have been developed as nontoxic, biocompatible, and biodegradable substrates for flexible electronics, other integrated components have limits in this field. To offer biopolymers new extraordinary qualities, such as electronic conductivity, bioactivity, thermostability, 3D conformal properties, and high ion mobility on skins and curved surfaces, more mechanistic research and synthetic methodologies must be created for innovative biopolymers. Finally, it is necessary to develop surface/interface engineering methodologies, substrate fabrication technology, and multifunctional integration of biopolymers-based flexible electronics. Unquestionably, biopolymers offer an exciting opportunity to take advantage of new functional flexible electronics, which are vital to enhancing their application in eco-friendly, durable, and intelligent electronic devices.

Bioimaging

Bioimaging is necessary for comprehending the appearance, structure, metabolism, and functions of cells. Consider sensitivity, specificity, efficacy, optimal clearance, and response to disease biomarkers for the appropriate imaging agent to aid in the diagnosis, evaluation, and treatment of diseases.

Hyaluronic acid (HA) is the only nonsulfated glycosaminoglycan (GAG) that is common in synovial fluid and extracellular matrix (ECM). The range of molecular weights (MW) for HA is vast, from 1000 to 10,000,000 Da. HA degrades into minute molecules as it traverses successively through tissues, lymphatics, lymph nodes, blood, liver, and kidney. Depending on its MW, HA has a number of physiological functions in the body. For example, high MW HA, which is frequently found in loose connective tissues, serves to maintain the water content and cell integrity of the extracellular matrix (ECM), whereas oligosaccharide HA, a degraded form of MW HA, is known to stimulate angiogenic signals in endothelial cells. The concentration of HA in the blood is generally low, with the exception of an abnormal increase caused by altered cell activities such as carcinogenesis, inflammatory response, and immunological reaction. Concerning cancer, HA's biological actions have been extensively researched. Kim et al. reported employing HAQDot conjugates *in vivo* to investigate the effect of chemically modifying HA's distribution within the body. HA-QDot conjugates with a near-infrared emission wavelength and a red emission wavelength were employed for real-time bioimaging of HA derivatives in naked mice. Bioimaging

the temporal evolution of HA derivatives has traditionally required the successive slaughter of multiple animals. Our research provides long-term real-time monitoring of HA-QDot conjugates without the use of naked mice. Regarding their application in tissue engineering and drug delivery, it was described how HA derivatives are dispersed throughout the body according on the degree of HA modification.

Recent research on biopolymers, such as polysaccharides, has centered on the development of novel nanomaterials. Cellulose derivatives, such as carboxymethylcellulose (CMC), are among the promising possibilities for the production of semiconductor nanocrystals. CMC is a pH-sensitive, nontoxic, biocompatible, and ecologically friendly anionic water-soluble polysaccharide synthesized from cellulose with various amounts of carboxymethyl groups (known as the degree of substitution, DS). Consequently, these CMC features provide a vast array of potential for biomedical applications, such as the production of functional capping ligands for illuminating nanoprobe intended for cancer research. Anderson et al. created unique ZnS quantum dots that were stabilized and functionalized by carboxymethylcellulose using an environmentally friendly aqueous colloidal method. In addition, they meticulously characterized the novel ZnS quantum dots. Keeping in mind the colloidal chemistry technique, a thorough analysis and interpretation of the optical properties' dependence on the synthesis parameters (pH of the solution and concentration of precursors) were conducted.

For the regeneration of damaged or infected tissue, biopolymeric in situ hydrogels are crucial. Despite its exceptional biodegradability and biocompatibility in the biological system, only a few number of biopolymeric in situ hydrogels have achieved clinical approval. Hydrogels are networks of hydrophilic polymers that may absorb up to 2000 times their dry weight in water. Hydrogels are formed by hydrogen bonds, hydrophobic forces, and secondary forces such as ionic or molecular entanglements binding polymeric networks. Some hydrogels may have an inhomogeneous physical structure due to clusters of molecular entrapment, ionically connected domains, or hydrophobicity. Due to their injectable matrices, ease of therapeutic agent encapsulation during hydrogel network creation, and little invasiveness into the target location, in situ-generated hydrogels have garnered considerable interest. Chen et al. demonstrated that injectable, in situ-produced hydrogel-based bone scaffolds may be monitored and evaluated nondestructively and noninvasively using ultrasound. In addition, they demonstrated how to produce in situ hydrogels from nanohydroxyapatite, collagen, and chitosan that display good stiffness, low degradation rates, and enhanced blood flow in vivo as determined by ultrasonography. The outstanding features of the bio-polymer-based carbon dots make them excellent for usage in bio-sensing, biological labeling, medical diagnostics, optoelectronic devices, and bioimaging.

Data Storage

Importance is increasing for the creation of functional memory components for information technology, where data storage components are used as building blocks. Data can be stored using electrical bistability, which emerges in devices as two states

with different conductivities at the same applied voltage. Using organic materials for memory devices coupled with solution processing enables large-scale and cost-effective implementation. Several approaches for constructing the active layer of organic memory devices have been proposed. In one arrangement, polymers combined with metal NPs in the polymer-nanoparticle (NP) system exhibit electrical bistability. Given that the optical and electrical properties may be manipulated by varying the composition and size/shape of the nano components, polymer-NPs combinations are attractive as functional materials for a variety of applications. Due to its affinity for metal ions, deoxyribonucleic acid (DNA) is a well-known good template for the production of metal nanoparticles (NPs). Recent research has shown that the processing of DNA for thin-film optoelectronic applications is perfectly compatible with that of conventional polymers, making it an additional interesting optical material.

Hung et al. demonstrated a DNA biopolymer nanocomposite-based photoinduced write-once read-many-times (WORM) organic memory device. The device consists of a single layer of biopolymer sandwiched between electrodes, and electrical bistability is activated by the in situ production of silver nanoparticles embedded in the biopolymer after exposure to light. The device exhibits a switching effect to high conductivity and an excellent retention characteristic above a threshold of 2.6 V. This straightforward technique has the potential to optically alter the properties of DNA nanocomposite thin films, which has promise for optical storage and plasmonic applications. This is accomplished by utilizing DNA's affinity for metals and solution processing.

Optical circuitry, optical data storage, three-dimensional mechanical actuators, birefringent structures, photonic crystals, and bone replacement can all benefit from the fabrication of three-dimensional structures with dimensions ranging from micrometers to nanometers by means of two-photon polymerization. Since the nonlinear nature of multiphoton absorption limits polymerization to the laser's focal volume, structures can be created by scanning a focused laser beam across the resin. Due to optical nonlinearity and the photo-polymerization threshold energy requirement, multiphoton polymerization techniques provide resolutions superior to the laser beam diffraction limit. Correa et al. described building structures with the biopolymer chitosan utilizing two photons and a resolution of around 700 nm.

Conclusion

Today, molecular engineering is one of the most effective methods for resolving inherent limits and enhancing a system's distinctive properties by physical or chemical alterations, hence opening creative paths for the creation of multifunctional bioelectronic devices. In today's culture, electronic devices are ubiquitous, permeating every facet of human activity. Nonetheless, an increasing volume of e-waste is causing environmental difficulties. Therefore, biodegradable electronics has emerged as the most practical and desirable solution to environmental issues, and the biopolymers used in recent applications for functional electronics are examined

in detail in terms of molecular engineering. The notion of bio-based electronics refers to the incorporation of bio-based components into specific electronic equipment, resulting in increased electrical efficiency and a reduction of environmental issues. Several fields, including organic electronics, materials chemistry, and printed electronics, are currently being merged in order to accelerate the development of flexible electronics toward the creation of new, environmentally friendly electronics. Although challenges remain in the biopolymer field for real-world applications, it is highly significant for electronic waste reduction, thus creating novel electronic devices that are environmentally friendly and sustainably designed.

Here, we review the current status of biopolymer design and highlight theoretical and experimental advances in building novel materials. We believe that investigating different parameters effects in biopolymer synthesis and processing offers opportunities for building mechanistic models and exploring the design possibilities of novel materials.

Abstract

There are close similarities between biopolymers and native tissues. The properties of these materials make them suitable for application in regenerative medicine. This chapter includes current research works and reports on the influence of water vapor annealing process, cellulose nanomaterials, pectin materials, cross-linking effects, and others on the mechanical properties of silk fibroin, collagen,

chitosan, gelatin, and alginate biopolymers. While several arguments have been included, the use of these cellulose- and pectin-based materials is undisputed. Recent experiments on mechanical characterization techniques including resilience, hardness, fatigue, torsion, bending, traction, and compression have been highlighted.

Introduction

The increasing environmental awareness combined with a circular economy policy backed by new rules is pushing plastic manufacturers and consumers to choose environmentally friendly raw materials for their product (Aliotta et al. 2019). State-of-the-art researches based on properties especially in regard to the aspect of environmental sustainability and protection indicate great possible benefits in different industrial applications (Pellicer et al. 2017).

Biomaterials are essential components made from proteins (collagens, gelatin, caseins, albumins), polysaccharides (starch, cellulose, chitin, alginate, hyaluronate), and biodegradable synthetic polymers (polylactic acid, polyglycolic acid) which have been used in several applications due to their advantages, features that include cytocompatibility, high strength and stiffness, recyclable, biodegradable, renewable, and do not cause skin irritation (Horney et al. 2018; Bakshi et al. 2019). However, there are some drawbacks, including moisture absorption, the existence of color, the presence of odor when heated or burned during processing, quality inconsistencies, and limited thermal stability (Oksman et al. 2012).

Interestingly, these problems highlight the need to study the properties of the biopolymers, especially the mechanical properties, making it one of the most important properties needed in industrial application like in packaging industry; a global production capacity of 0.21 million ton was recorded in 2016, 0.5 million ton in 2020, and a further increase in million ton will be expected by the year 2023 (Aeschelmann and Carus 2016–2021).

Recent advances on mechanical properties of biopolymers have focused on the development of biopolymer composite materials for varied applications. For example, (Kaewprachu et al. 2022) synthesized “carboxymethyl cellulose/rice flour composites from palm fruit husk film.” The rice flour could reduce the film strength and flexibility when available at high amounts. Also, Bejagam et al. (2022) examined the different mechanical properties of polyhydroxyalkanoates via molecular dynamics simulations. Synthesis of other composites based on casein, glycerin, enzymes, and synthetic polymers has similarly been reported (Prochon et al. 2022; Zaccone et al. 2022).

Over the years, several researches have focused on the mechanical properties of biopolymer with poly(lactic acid) (PLA) as one of the most commercially successful

bio-based and biodegradable polymers due to its good processability and mechanical properties (Jem and Bowen 2020). Beltra et al. (2007) performed two mechanical recycling processes on PLA to investigate their effects on the degradation, in consideration of the structure and properties during the processes. The first recycling process consists of two steps, namely, accelerated aging and melt processing, while the second recycling process consists of three steps such as accelerated aging, demanding washing process, and melt processing. Instead of a change in the structure and properties, the study revealed that the new introduced process, that is, “demanding washing process,” contributed a negligible decrease on the molecular weight of the PLA. Rather, it was the melt processing that gave rise to the thermo-mechanical degradation. This corresponds to the studies of Hopmann et al. (2015). Therefore, this chapter presents the mechanical properties of biopolymers such as silk fibroin, collagen, chitosan, gelatin, and alginate biopolymers. Recent experiments on mechanical characterization techniques including resilience, hardness, fatigue, torsion, bending, traction, and compression have been highlighted.

Mechanical Properties of Biopolymers

Gelatin

Ge et al. (2017) designed a nanocomposite hydrogel of gelatin reinforced with chitin whiskers. They examined the role of the combination in improving the mechanical properties and gelling ability of gelatin. At different concentrations, the mechanical strength, hardness, fracture stress, and strain were more stable than when tested for pure gelatin. Furthermore, Nuvoli et al. (2020) reported on the structural, thermal, and mechanical properties of fish gelatin reinforced with milled tara gum and glycerol. The gelatin-based films having a high glycerol content could exhibit good thermal stability. However, an excessive increase of the glycerol was also found to have negative impacts on the mechanical properties. In brief, this reinforcement increased the thermal stability and mechanical properties of the composite. Another recent study has also reported the use of “nonequilibrium atmospheric pressure plasma in stabilizing gelatin nanofibers.” In the study, gelatin nanofibers were cross-linked using low-pressure treatment, instead of the usual chemical agents, to address the poor mechanical properties and solubilization associated with gelatin. Figure 1 shows a general overview of the plasma-cross-linked gelatin.

Based on these earlier findings, current researches are investigating the facile approaches and synergistic effects of enhancing the properties. For example, Zheng et al. (2022) immersed cooling-induced gelatin hydrogels into a $\text{Zr}(\text{SO}_4)_2$ dilute solution to resolve the challenge of gelatin poor mechanical properties, which limits the versatile application of the hydrogel. Mechanical tests showed that the properties of elastic modulus, compressive modulus, and strength were about 400, 1192, and 476 KPa, respectively. These values are about 100, 11, and 5 times, respectively, larger than those of pure gelatin.

Fig. 1 General overview of plasma-cross-linked gelatin (Liguori et al. 2016)

Current research is also examining the use of other new methods for graphene preparation and mechanical properties, through nano-indentation experiments using atomic force microscopy (Weiss et al. 2018). Similarly, more studies on improving the physical as well as mechanical properties of gelatin after cross-linking with transglutaminase (MTG) are underway (Liu et al. 2020). Its effects on texture properties would also be considered. Helical conformation and coiled conformation of gelatin chains when immersed in water exist in gelatin products, and their ratio influences the mechanical properties of the final material (Rivero et al. 2010). Further, Cai and coworkers (2019) have built on the recent review of (Ebhodaghe 2022). They examined the effect of electrospinning, coaxial electrospinning, and

Fig. 2 SEM images of gelatin/chitosan films with and without DAS (Cai et al. 2019)

Fig. 3 Influence of water content on polysaccharide-based biopolymer. (Reproduced with permission from Yakimets et al. 2007)

others on the properties and structure of gelatin/chitosan films incorporated with docosahexaenoic acids. Notably, they report that electrospinning and coaxial electrospinning enhanced the mechanical properties and solubilization of the films. Figure 2 shows these in detail.

Effect of water content on biopolymers is shown in Fig. 3.

Silk Fibroin (SF)

Hong et al. (2019) investigated the use of chondrocytes-based silk-GMA hydrogel for the repair of cartilage defect using digital light processing for the 3D printing of the hydrogel. This resulted in good biocompatibility and mechanical strength being

impacted to the hydrogel for sustained tissue regeneration. Similarly, Rajput et al. (2022) prepared photocurable methacrylated SF which resembles the mechanical properties of human tissues. Using the same method as Hong et al. they also report that this scaffold had the same compressive modulus (12 KPa–96 KPa) and degradation (48–91%, in 21 days). This was somewhat similar to those of human tissues. Furthermore, research is ongoing on the possibility of adjusting the mechanical properties of Mo_3Se_3 -PVA-SF nanowire to provide regeneration in tenocytes obtainable from the human bone marrow stem cells. SF and PVA could enhance the mechanical properties of the nanowire, which gives prospects for application in tendon tissue engineering. This is because the molybdenum-based nanowire contributes mechanical strength, reinforcement, high porosity, and biocompatibility to the blend (Subramanian et al. 2022). Moreover, Liu et al. (2022) have examined the synthesis of SF and PLLA electrospun fibers through a hot stretching process to develop textile tissues. While this process enhances the fiber alignment, crystalline nature, and mechanical properties, the SF/PLLA mass ratio reduced their crystallinity and mechanical properties though with increasing degradation rate and surface hydrophilic nature. Overall, the properties of physical, biological, and mechanical strength were enhanced for advanced nanotextile tissue construction. Taking a different approach, Cho et al. (2022) investigated the influence of water vapor-annealed SF on the indentation modulus and hardness of graphene oxide-SF through nano-indentation experiments and finite element analysis (FEA). Water vapor annealing process can be used to enhance the indentation modulus and hardness of the bionanofilms because of close similarity of the FEA and the nano-indentation. Another recent development is the use of cellulose nanocrystals (CNC) in enhancing the mechanical properties of SF (Poggi et al. 2022). Result of the study on mechanical response and yielding transition of composite gels by Poggi et al. showed that gelation occurs rapidly and viscoelastic response was more in the presence of CNC. Yield strain of the gels reduced at higher shear rates probably due to the shear-induced compaction.

Collagen (COL)

The normal human body consists of one-third COL, even as it provides structural and mechanical stability. This is why COL films usually find applications in tissue engineering and regenerative medicine (Ebhodaghe 2021, 2022). Studies have shown that collagenous materials show different mechanical properties in different conditions. The effect of cross-linking on tensile properties of COL is shown in Table 1. More so, the fact that the same COL materials could display different mechanical properties influencing their usability (while depending upon their states) makes case for a closer study.

The effects of cellulose-based nanofibers have been intensely investigated for different biopolymers, as shown in Fig. 2. On COL, the compression strength and fracture strain were improved upon when the nanofibers were impregnated on COL (Lohrasbi et al. 2020).

Table 1 Effect of cross-linking on tensile strength of collagen biopolymer

Cross-linking treatment	Nature of collagen	Control (MPa)	Time (h)	Amount (%)	Tensile strength (MPa)	References
Proanthocyanidin PBS solution	Demineralized	10.8 ± 4.9	4	0.5	17.7 ± 9.4	Elango et al. (2016)
EDC in 70% ethanol	Demineralized	–	24	–	408 ± 39.5	Sheu et al. (2001)
Glutaraldehyde	Dentinum reinforced	37.7 ± 4.5	0.083	1	37.3 ± 5.6	Leung et al. (2012)
Glutaraldehyde	Electrospun	43.70	24	5	44.13	Gillette et al. (2010)
Sorbitol	Fish collagen	2.3 ± 0.4	–	0.05	4.8 ± 0.8	Gobeaux et al. (2008)
Glycerol	Fish collagen	2.3 ± 0.4	–	0.05	4.1 ± 0.7	

Bose et al. (2020a) examined the properties and performance of COL films in both dry and wet conditions under different loading and environmental conditions (in air and in water). In water, the samples show an increased stiffness condition, while reduction in modulus was reported in dry condition. Also, the Tan values were 0.05–0.75 for dry samples and 0.12–0.24 for hydrated ones. Further, they investigated the fracture behavior of COL in water and in dry conditions. The utilized specimens of COL films (i.e., a single-edged notched tension) displayed reduced tensile strength and fracture energy, while failure strain was significantly increased in wet conditions (Bose et al. 2020b). Building on these findings, Ma et al. (2022) studied the effect of calcium spraying on the mechanical properties of COL. The samples were sprayed with Ca before and after drying. When sprayed with Ca before drying, the samples displayed improved elasticity and stiffness, while spraying after drying only improved toughness of the samples. These were because Ca penetrated the film in the former, while it only generated a protective covering of Ca/alginate on the membrane surface of the latter. Also, the study shows that while the samples developed a protective layer, the COL retained their integrity for the latter.

Taking a different approach, Andonegi et al. (2022) examined the role of ionic liquids and wool on the mechanical properties of COL, for possible varied applications. The composites were obtained by compression molding, and this made the COL films homogeneous. This presence of ionic liquids in the composites enhanced the mechanical properties of COL, because of the obvious increase in tensile strength.

Chitosan (CS)

Presently, studies are exploring several techniques of enhancing the mechanical properties of CS. One of such is the use of atomic force microscopy (AFM). AFM is a microscopic technique that can be used to investigate a wider range of samples than the scanning electron microscopy (SEM). This is because it can be used in air or liquid unlike the SEM, which is usually adopted in vacuum. The usefulness of the former in tissue engineering lies in the ability to measure more physical parameters than pure topography (Joshi et al. 2022). As such, Luna et al. (2022) examined the influence of temperature and pH on the mechanical properties of CS films. PeakForce-QNM AFM was used for this, with CS being at nanoscale. Minute changes in pH and temperature had effects on the structure and mechanics of the film, though this was not the cause of changes in the COL film surface free energy. Also, another study (Gotla et al. 2022) combined CS hydrogel at different pH values and anionic sodium dodecyl sulfate (SDS) which was added. These ionic surfactants hold potential to improve the mechanical strength of CS. At acidic pH conditions, CS possesses superior mechanical strength unlike when the conditions are basic. The study showed that CS composite hydrogels are similar to stretched rubber and can undergo load-dependent crystallization at basic pH conditions. This enhancement can inspire new mechanical applications based on the combinations. Also, the role of

pectin on mechanical properties of CS was observed when Akalin et al. (2022) synthesized CS-based and CS-/pectin-based silver nanoparticle films and confirmed that the presence of pectin improved the mechanical properties of CS.

Alginate

Alginate is an ubiquitous polysaccharide present in brown seaweed. As a common viscosifier and gelling agent, it can be used in different industries, ranging from food to pharmaceutical and biotechnology.

Considering the effect of gel network on mechanical properties of alginate, Schuster et al. (2017) examined the relationship between network structure and functional properties of capillary alginate gels for muscle fiber formation. They found a correlation existing between the nanostructure of gels and mechanical properties of the biopolymer. Moving forward, Notermans et al. (2019) also examined the relationship between the mechano-biological adaptation of rat Achilles tendons and changes in their constitutive mechanical properties and biomechanical behavior. They compared creep and stress relaxation to experimental data to generate a generalized computational model for the Achilles tendon. Also similarly, the effect of high sugar content on microstructure mechanics and release of calcium-alginate gels have been reported (Lopez-Sanchez et al. 2018). Sugar contents greater than 15 wt% reduced the extensibility of alginate molecules. They showed the structure-function relationship of the gels. The release of sugar from calcium alginate gels having sugars of 15 wt% and 30 wt% was similar to Fickian diffusion mechanism and others. Recently, Matthew et al. (2022) developed an alginate-hyperbranched polymer complex (HBP) from its addition to alginate structure. A vortex fluidic device was used to control the physicochemical, structural, and mechanical properties of the hydrogel. Incorporating the HBP complex to the hydrogel structure increased their swelling, diffusion coefficient, and failure mechanical properties though the bulk structure was the same. This was similar to the rate of degradation which also was largely unaffected. Overall, the HBP changed the structural and mechanical properties of alginate, while the degradation property was modified.

Mechanical Characterization Techniques

These refer to recent experiments conducted on resilience, hardness, fatigue, torsion, bending, traction, and compression of materials. Some of these techniques are shown in Fig. 5.

Resilience

Recent studies have reported experiments on the impact of amylases on biopolymer dynamics during storage of straight-dough wheat bread (Bosmans et al. 2013) and

Fig. 4 Cellulose nanocomposite-based biopolymer source. (Reproduced with permission from Anna et al. 2011)

the shear modulus and fracture properties of biopolymer double networks (Lwin et al. 2022). Results from this latter experimentation showed that mechanical properties could be changed from being compliant and ductile to stiffness by a secondary network of flexible fibers, which occur only when a primary network of stiff fibers is rigid. This observation is responsible for the resilience and tenability of biopolymer double networks.

On the optical and mechanical properties of self-repairing pectin biopolymers, the influence of water on pectin repair has been reported (Pierce et al. 2022). This water-induced self-repair of pectin was enhanced by its physicochemical properties which are related to some reparative and regenerative processes.

Hardness

Factors that could influence the hardness of biopolymers obtained from potato and plantain peels have been examined (Castro et al. 2021), as shown in Fig. 4. The recent study related the combination of urea, glycerine, acetic acid, and water. Also, reports on the maximum hardness of albumin, COL, and CS with single-walled carbon nanotube (CNT) concentrations of 0.01 wt%, 482 ± 10 , 425 ± 10 , and 407 ± 15 MPa, respectively, have been presented (Gerasimenko et al. 2021).

Torsion

A recent study designed a mechanical system to determine the torsion modulus of polymers. They further subjected polytetrafluoroethylene to torsional stresses. This was important because of the possibility to design polymer products and determine if the strength needed to prevent fatigue was present in the polymers (Piedade et al. 2020).

Bending

It is possible to enhance the bending mechanical properties of hydroxyapatite (HA)/PLCL sandwich beam scaffold for use in tissue engineering applications. The presence of the beam was needed to enhance the critical stress and the fracture absorbed energy. Also, the bending mechanical properties were improved by sandwiching the HA/PCL scaffold with the PLCL layers (Hazwani and Todo [2022](#)).

Furthermore, Hazwani and Todo ([2021](#)) designed composite HA/PLLA and HA/PLCL via template and freeze-drying methods. Here, the three-point bending was used to determine the bending mechanical and fracture properties of the porous composite beams. The presence of PLLA and PLCL enhanced the flexural mechanical properties of the HA. Specifically, PLLA caused a higher modulus and fracture strength while PLCL a higher fracture energy. By extension, (Alvarez-Blanco et al. [2022](#)) recently examined the failure of additive manufacturing components when subjected to three-point bending tests of strength and crack morphology. In other words, they analyzed the fracture morphology of 3D printed lattice core PLA samples. In brief, process parameters can influence the mechanical behavior and failure of the components made from additive manufacturing.

Traction

Researches have estimated the effect of cellular traction forces on the morphogenesis of capillaries via advanced modeling of fibrous biopolymers (Ah-Hing [2022](#)). The study highlights independence among density, displacements, and tractions.

Compression

Chen et al. ([2022](#)) has considered the combination of biopolymers and fiber inclusions as an alternative to reinforcing soft soil. They presented the synergistic effect on failure pattern, strength enhancement, stress-strain characteristics, and the reinforcement mechanism of soft soil. Overall, the biopolymer enhanced particle bonding force and reinforcement efficiency of soil fibers, while fibers reduced soil brittleness with residual resistance after post-peak failure.

Fatigue

Ni et al. ([2020](#)) investigated the performance of soils enhanced with economically adopted natural polymers in unconfined compression strength tests and fatigue loading tests (Peron et al. [2018](#)). This is because biopolymers can affect ground improvement depending on their types. The study argues that as a biopolymer soil strengthener, xanthan gum can enhance the stabilization and fatigue life of soils even

Fig. 5 Mechanical characterization techniques. (Reproduced with permission from Meng et al. 2019)

when they are subjected to continuous loading. Also, Luo et al. (2020) performed fatigue-to-failure experiments for fatigue life assessment of filled rubber by hysteresis-induced self-heating temperature. It became possible to examine the fatigue life of the rubber under the condition of steady-state temperature increase. This is due to a possible relationship between temperature increase and fatigue life. The fatigue parameter used was the maximum principal strain, and this was important in deciding the S-N curve (Fig. 5).

Conclusion

Recent studies on enhancing the physical and mechanical properties of biopolymers have been presented. Notably, pectin- and cellulose-based nanocrystals are materials that can be applied to improve the mechanical properties of several biopolymers. Also, well-organized hierarchical structures have no real effect on the interfacial combinations of molecules. While water vapor annealing process could be widely employed for several biopolymers with poor mechanical properties, more research is needed to investigate how the annealing process could directly affect the interfacial properties between graphene oxide and silk fibroin layers. Challenges of processing biopolymers include intrinsic limitations in experimental methods (Jung et al. 2015), cost-competitiveness, and polymer choice limitations to density and temperature-based properties (Van de Velde and Kiekens 2022).

Abstract

In the context of sustainable development, the use of polymers of natural origin has gained a lot of significance. Degradability, nontoxicity, a wealth of natural resources available as raw materials, and renewable nature are the main characteristics that are prioritized when employing biopolymers. These polymers have a wide range of applications, including medication administration, tissue engineering, tumor ablation, biomedicine, and food packaging. Their weak thermal and mechanical stability, however, is a drawback. The four most studied biopolymers, cellulose, starch, chitosan, and poly(lactic acid), have all been the subject of thermal investigations, which have been attempted to be analyzed in this chapter.

The thermogravimetric analysis and differential scanning calorimetric methods gave an idea on the thermal stability, degradation steps, and glass transition temperature and crystallinity of the samples. Various studies on effect of different parameter affecting the thermal degradation are also highlighted. Studies have proved that the use of other polymers, crosslinking agents, and nanofillers blended along with biopolymer has improved the thermal stability. These studies would provide an insight into further development of methodologies to improve upon the properties of natural polymers.

Introduction

Biopolymers have recently gained popularity in industry because of their compatibility, renewable nature, nontoxicity, biodegradability, sustainability, and environmental friendliness. More and more polymeric biomaterials from synthetic and natural sources are being developed as a result of many applications in tissue engineering and restoration, as well as specialized fields like drug supply, nanotechnology, and therapeutical applications. They are extensively utilized in farm products, biomedical gadgets, dental implants, food additives, smart food containers, and other hygiene products on the commercial market. Biopolymers are mostly used in implantations, particularly those with electrical components and those whose temperature-dependent features are crucial for interacting with biological tissues. The majority of biopolymers used in implants has electrical components and/or possess temperature-dependent properties that are essential for interfacing with biological tissues (Ebnesajjad 2013).

Before being used, plant and animal resources must be modified to have qualities that are acceptable for a number of reasons. High molecular weight polymers usually require additives like antioxidants, plasticizers, lubricants, mold release agents, reinforcing agents, and UV stabilizers in order to alter the properties of the polymers and produce novel compounds. A material's thermal behavior is a key factor in defining its characteristics because it is closely related to morphology and has an impact on its therapeutic efficacy (Yaashikaa et al. 2022). Thermal analysis should be performed across a wide temperature range so as to assess various process parameters such as thermal degradation rate, stability, polymer shrinkage, glass transition temperature (T_g), melting temperature (T_m), reaction crystallization temperature, amount of crystallinity, effect of sterilization methods, expansion, insulation, and storage. Mechanical characteristics and thermal behavior are related because below T_g , a polymer is glassy, and above T_g , a polymer is rubbery and a polymer with a regular chain structure can be recognized with a characteristic melting temperature (T_m).

The naturally derived polymers are classified based on a variety of variables, including biodegradability (biodegradable and nonbiodegradable biopolymers), origin (made from natural sources and fossil fuels), thermal condition response (elastomers, thermoplastics, and thermosets), composition (blends, laminates, and composites), and raw material source (natural, synthetic, and microbiological biopolymers) (Van de Velde and Kiekens 2002).

This chapter provides an insight into the different studies carried out in analyzing the thermal behavior and thermal stability of the most relevant and significant biopolymers that had been researched the most. Four biopolymers, namely, Cellulose, Starch, Chitosan, and Polylactic acid, were chosen from among the various biodegradable polymers available. Due to their low thermal stability, these polymers cannot be applied to a wide variety of biological applications, despite their widespread use in such fields. Modern calorimetric techniques, such as differential scanning calorimetry (DSC), temperature-modulated differential scanning calorimetry (TMDSC), adiabatic calorimetry (AC), and fast scanning chip calorimetry (FSC), are employed for proper quantitative thermal analysis of the metastable, semicrystalline, and amorphous biopolymers. Thermal analyses enlighten many transitions in the polymeric matrices and among them, melting, crystal rearrangements, decomposition, enthalpy relaxation, glass transition, crystallization are only a few.

Cellulose

An important factor contributing to global warming is rising carbon emissions. The use of biodegradable and eco-friendly materials initiates substantial change in global climate. The need for composite manufacture has been steadily rising in a number of industries, which has led to an issue with the accumulation of a vast quantity of wasted composites that also requires safe disposal. Therefore, reducing these issues, without compromising on the advantages is a challenging area of research. Due to important benefits including biodegradability, ease of handling, low energy consumption during processing, abundant availability, and high-specific strength, fibers made from natural resources are widely employed in the manufacture of composite materials (Almedia et al. 2006). A linear homopolysaccharide with -D-glucopyranose units connected by -1-4-glycosidic linkages makes up the main component of cellulose (Fig. 1).

Fig. 1 Structure of cellulose

The mechanical properties of naturally available fibers depend on the chemical constituents, growing environment, the lifetime of the species, and retting techniques (Athijayamani et al. 2015). According to studies, mixing cellulose with other polysaccharides like pectin and chitosan may increase flexibility, steadiness, and transparency (Yaradoddi et al. 2020). Additionally, cellulose has poor interfacial adhesion, thermal instability, and water sensitivity, which reduces the appeal of cellulose-based composites. Such technical challenges can be overcome by suitable functionalization and prior treatments of cellulose (Polman et al. 2021). The resources for cellulose are plentiful in many nations, and cellulosic material made from agricultural production can be used to create pure cellulose. Comparing the properties of pure cellulose with corresponding composites showed that the thermal and mechanical properties become promising in the latter. Due to the nature of the materials used to make composites, the production of nanocomposites enhances the qualities. In terms of the applications for these materials, the thermal characteristics of composites are crucial.

Thermal Properties of Cellulose

Various researchers observed that heating dry cellulose from 120 to 470 K using DSC does not exhibit a first-order phase transition. As a result, only flat sample baselines are possible to acquire in DSC curves. A significant endothermic peak caused by water vaporization can be seen in the temperature range of 273 to 400 K when cellulose that has absorbed a little amount of water is examined by DSC. The amount of water determines the peak temperature of vaporization. Any excess moisture in dried cellulose can be assessed by taking the endothermic peak of vaporization as a suitable index. Natural cellulose is a crystalline polymer with a 20–90% crystallinity range. Natural cellulose's crystallinity varies depending on the type of plant it comes from; for instance, kapok's crystallinity is only about 30%, whereas jute's is over 70%. In most cases, solid-state NMR, infrared spectroscopy, and X-ray diffractometry are used to determine crystallinity.

Thermal Properties of Cellulose Composites

Thermal stability is an important element when evaluating the possible applications of composites in several industries (Pyda 2001). Researchers were able to construct composites with improved design and processing parameters and create high-performance polymers with improved thermal stability by studying degradation behavior (Pyda 2002). The two main processes in the thermal deterioration of polymeric composites are the removal of volatile matter and the depolymerization process (Cheremisinoff and Cheremisinoff 1996). Low-molecular-weight molecules, like water, evaporate as the initial stage of thermal breakdown. A reduction in thermal stability could be the result of the hydrolysis of the polymer due to the water absorbed by hydrophilic cellulose (Yano et al. 1976). The highest weight loss

occurs during the second degradation stage, which is also the most important indicator of the heat stability of polymer composites. Researchers were able to create composites with the best possible design and processing circumstances by studying degradation behavior. They were also able to create high-performance polymers with improved thermal stability (Li et al. 2014).

Thermal Properties of Nano Cellulose Composites

While thinking about prospective applications, it is also crucial to understand the thermal behavior of nanocellulose and its thermoplastic composites during mixing and extrusion. Nanocellulose degrades at a temperature between 200 °C and 300 °C; thus, during the manufacturing process, the compounding temperature must be kept under control at 200 °C to avoid the degradation of nanocellulose (Nepomuceno et al. 2017). The thermal stability of the nanocomposites may highly varied by the source of the nanocellulose, the kind of matrix, the processing methods, and the drying method. Thermal stability of nanocomposites is affected by incorporation of nanocellulose. There are often two main steps to the thermal degradation of polymeric composites: the removal of volatile substances or the evaporation of water and the depolymerization process, respectively (Lizundia et al. 2015). Low-molecular-weight molecules, like water vapor, are typically vaporized as part of the first stage of heat degradation. A decrease in thermal stability could result from the hydrolysis of polymers caused by the water absorbed by hydrophilic nanocellulose (Srithep et al. 2013). The highest weight loss occurs in the second degradation stage, which is also the most important indicator of the heat stability of polymer composites. Kilzer and Broido postulated two distinct mechanisms for cellulose degradation: cellulose dehydration, an endothermic process that results in “dehydrocellulose,” and cellulose depolymerization, which competes with evaporation or dehydration. The first mechanism produces dehydrocellulose which will break down into gases and char residue (Kilzer and Broido 1965). The intermolecular interaction between the nanocellulose and the polymer matrix has a significant impact on the thermal stability of composite materials. Strong intermolecular bonds may increase the bond dissociation energy required for macromolecule chain cleavage (Maiti et al. 2013). Therefore, high degree of dispersion of nanocellulose and significant interfacial adhesion between polymer and nanocellulose are necessary for enhancing the thermal stability. The addition of nanocellulose enhanced the thermal properties of the composites, with increases in its crystalline phase and T_m being especially noticeable. As a result, the thermal characteristics of nanocellulose composites may be improved. The integration of nanocellulose as a nucleating agent may boost the overall crystallinity and crystallization rate of nanocomposites. The thermal characteristics of nanocomposites were, however, impacted by the poor dispersion and clustering of nanocellulose, particularly at high concentrations. The distribution of nanocellulose and the interaction of nanocellulose with the polymer matrix can be improved through layer-by-layer deposition, which eliminates agglomeration and considerably enhances the characteristics of the composites.

Cellulosic nanofibers were investigated using TGA as a reinforcing phase in PLA/CNF composites. Investigated was the thermal degrading behavior of the membrane with and without the inclusion of cellulose nanofibers (Wang et al. 2020). The initial breakdown temperature of every PLA/CNF composite was greater than that of PLA, which suggests that the addition of cellulose nanofibers improved the composites' thermal stability. The derivative thermogram (DTG) analysis shows that cellulose nanofibers have two temperature peaks, one at about 40 °C, which is associated with the hydrophilic groups of the nanofibers, and the other at about 346 °C, which was related to the dehydration processes and volatile product generation through chain scission and degradation. There is only one decomposition peak for PLA at 331 °C. Moreover, the initial degradation temperature and maximum degradation temperature of PLA/CNF composites were increased by 20 °C and 10 °C after the addition of PLA/Cellulose composites, 5.0 wt% of CNF, respectively. It can be concluded that the PLA/CNF composites have an improved thermal property compared to the PLA.

TGA measurements were used to assess the thermal stability of cellulose, PVA, and its nanocomposites. Similar patterns may be seen in the TGA thermographs of PVA and their nanocomposites, specifically three primary regions of weight loss. Due to water evaporation, the initial zone (75–160 °C) shows about 5–10% weight loss. The structural degradation of PVA nanocomposite films causes the second transition region (260–390 °C), which has a total weight loss of about 74%. The third region, which was around 390 °C, was caused by the dissolution of carbonaceous materials or the cleavage of backbone of bio composite films. At 500 °C, the overall weight loss in this range exceeded 95%. This demonstrates that cellulose and nanocellulose fiber can increase the thermal stability of PVA, proving that the PVA matrix's increased thermal stability is caused by a strong hydrogen bond between the hydroxyl groups of nanocellulose (Sultana et al. 2020).

The poly(3-hydroxybutyrate-co-3-hydroxyvalerate) (PHBV) matrix was used to combine the rigid rod-shaped CNC with flexible CNF to create the nanocomposites. The T_c and T_m of PHBV composites increased as a result of the addition of CNC and CNF. A decrease in the X_c results from the addition of cellulose nanoparticle, which stimulated the nucleation of PHBV matrix crystallization. However, compared to the CNC/PHBV composites, the CNF/PHBV composite displayed an enhanced crystallinity (Jun et al. 2017).

Thermal analysis of NCC/gelatin bio-nanocomposites revealed that the addition of NCC raised the degradation temperature by 7–9 °C, enhancing the thermal stability. The thermal stability of CNF/PVOH nanocomposites was reported to have significantly increased. The thermal breakdown temperature of composites rose from 273 °C to 340 °C in comparison to pure PVOH with the incorporation of 10% CNF. Generally, introducing nanocellulose to hydrophilic composites improved their thermal properties (Ben Cheikh et al. 2018).

Studies using TGA and DTG for PVA/NCF composites and pure PVA show a three stage process. These occur between 50 °C and 181.7 °C, between 181.7 °C and 342.7 °C, and between 342.7 °C and 500 °C. The PVA/NCF composite experienced

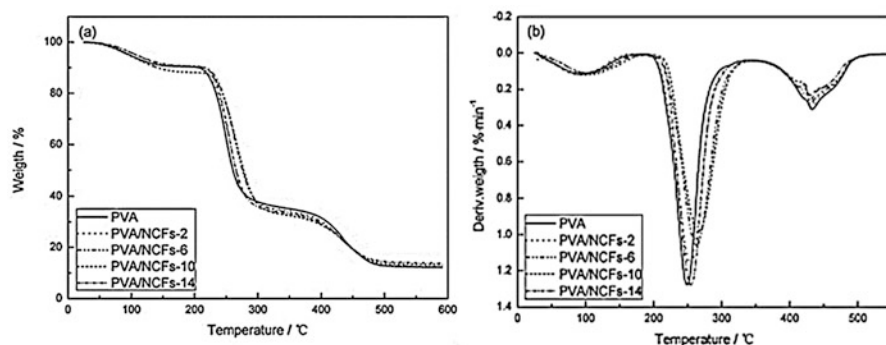

Fig. 2 TGA (a) and DTG (b) curves for the PVA and PVA/NCF composite. (Adapted from reference Li et al. 2014)

its first degrading phase at a temperature that was a bit higher than that of pure PVA (Fig. 2).

The second degradation process in PVA/NCF occurred at a temperature that was higher than that of pure PVA, indicating greater thermal stability for PVA/NCF. With the addition of NCFs to PVA, the maximum decomposition temperatures for the first step increased by 0.4 to 9.1 °C and those for the second process increased by 4.9 to 16.9 °C. This means that a significant increase in the thermal stability of PVA/NCF was observed by the addition of small quantities of NCF (Li et al. 2014).

Starch

Starch is a biodegradable semicrystalline polymer made up of 1, 4- α -D glucopyranosyl fragments present in amylose and amylopectin moieties. Both amylose and amylopectin are formed by chain polymerization techniques of D-glucose repeating units, but the only difference is that the first one is a straight chain polymer and the latter is branched. The amorphous character of starch is caused by amylose, whereas the crystalline nature is caused by amylopectin. The content of amylose and amylopectin varies in starch obtained from various sources (Table 1) (Fig. 3).

Starch-based polymers are promising and drew attention because of their easy availability, low cost, and biodegradability. However, native starch owns poor mechanical and thermal stabilities, excessive hydrophilicity, and brittleness. The properties of starch could be improvised by making modifications such as derivatization of the hydroxyl groups or making composites with other additives. To increase the flexibility and decrease the brittleness, plasticizers are added to starch (Vieria et al. 2011). Common plasticizers for the starch biopolymers are polyols (glycerol, sorbitol, polyethylene glycol etc.), formamide, urea, and citric acid. Starch-based thermoplastics have applications in food packaging or in agriculture (Molavi et al. 2015).

Table 1 Amylose-amylopectin composition of starch from different sources

Source	Amylose (in %)	Amylopectin (in %)	Crystallinity
Rice	20–30	70–80	38
Potato	23–31	69–77	23–53
Cassava	16–25	75–84	31–59
Wheat	30	70	36–39
Corn	28	72	43–48

**Fig. 3** Structure of (a) amylose and (b) amylopectin

Thermal Properties of Starch and Its Esters

When starch is heated in water to 60–70 °C, it loses its crystalline nature and becomes a semisolid and the process is called gelatinization (Donowan 1979). In general, the thermal properties of polymers consist of the determination of melting point, decomposition temperature, glass transition temperature, thermal expansion coefficient, modulus of elasticity, thermal conductivity, specific heat, and density. There is a correlation between the amylopectin/amylose ratios with the thermal stability (Liu et al. 2013). Thermal decomposition temperature and the sequence of activation energy increase with amylopectin/amylose ratio.

Glass transition temperature T_g is an essential parameter used for identification of plastics. The transformation from hard to soft in amorphous polymers occurs at this temperature. Shorgen, R. L. has prepared starch acetates with varying degrees of substitution (Shorgen 1996). Derivatization of starch hydroxyl groups helps to provide water repellent nature to the polymeric film. The acetylation of amylose-rich starch gave a more flexible film compared to the fully acetylated normal starch. This is because of the reduction of the crystalline structure of amylose after derivatization. He arrived at the conclusion on basis of his observations that the T_g decreases with increase in the degrees of substitution for dry starch acetate. In addition the T_g decreases with the increase in moisture content.

Rudnik et al. carried out thermal analysis of starch succinates and obtained a result that indicates the thermal stability of starch succinates increases with increase

in the substitution (Rudnik et al. 2005). Stabilities of succinates of starch obtained from different sources are comparable. Similar results have been reported in the literature (Thiebaud et al. 1997). Thermal stability of esters of starch is attributed to the lower number of free starch hydroxyl groups since the decomposition mechanism involves the dehydration between the hydroxyl groups of starch.

Thermal Properties of Starch Composites

The thermal decomposition of starch-based polymers is one of the main difficulties we encounter while employing them. Thermogravimetric analysis (TGA) is a method for measuring the heat stability of polymers that is often employed. A fine controlling over the heating rate, atmosphere, and mass of the substance gives a better analytical result. Thermal experiments are done in excess water condition as well as in water free condition in order to simulate their uses in aqueous and dry processes.

The cautious application of additives can adjust the thermal characteristics of starch-based polymers. The fabrication of nanocomposites of starch with various clays such as montmorillonite, hectorite, and kaolinite improves the thermal degradation temperature (Banna et al. 2020). Incorporation of TiO₂ nanoparticle along with starch causes advancement in the thermal stability.

The inclusion of Aloe Vera gel with starch-based composite films has made significant enhancement in the antimicrobial nature of the film. Since the components of Aloe Vera have antimicrobial activities, it is an efficient substitute for other inorganic antimicrobial agents (Bastarrachea et al. 2011). Hence, it increases the resistance and shelf life of the film, as it is important when it is used as a packing material. The thermal stability of a film of starch-chitosan was achieved by Bajer et al. and made a comparison with the influence of inclusion of Aloe Vera gel in the film (Bajer et al. 2020). The maximum degradation temperatures obtained for starch film, starch-chitosan film, and AV gel-incorporated starch-chitosan film were 293 °C, 298 °C, and 302 °C, respectively. The alteration of the thermal resistance of starch-based films by the inclusion of AV gel is attributed to several reasons like their aggregation, intercalation, and active impact within the starch medium. The thermal stability of pure starch with varying concentrations of AV gel was evaluated by Gutiérrez and Alvarez and found that the weight loss during heating is less with the one with higher composition of AV gel (Gutiérrez and Alvarez 2016). The impact of curcumin-loaded nanoparticles and AV gel on banana starch was examined by Nieto-Suaza et al., and they were able to derivatize banana starch. In all cases, they observed three stages of decomposition, first stage at 105 °C, due to the loss of water molecules. Second stage observed in a range of 180 °C and 250 °C and the third stage is above 250 °C, which is attributed to the complex degradation process in the structure of starch.

For enhanced efficiency, starch-based polymers are compounded with synthetic polymers including polylactic acid (PLA), polyvinyl alcohol (PVA), and polyester. Such plastics are made soft by the inclusion of plasticizers. Among various

plasticizers, ascorbic acid has antioxidant properties and is found in various vegetables and fruits. Hence, ascorbic acid-blended films find applications in packaging, edible films, etc. Yoon, S-D reported that the ascorbic acid inclusion improves the thermal properties of starch-PVA polymer films. And it is found that ascorbic acid is better than poly-ols in getting films with good thermal properties (Yoon 2014).

Chitosan

With numerous biological and therapeutic uses, chitosan is another resourceful natural biopolymer. Chitin and its deacetylated derivative chitosan are natural biopolymers composed of *N*-acetyl-D-glucosamine (acetylated unit) and β -(1-4)-linked D-glucosamine (deacetylated unit) connected in a random manner (Rinaudo 2006). Deacetylating of chitin by hydrolyzing the acetamide groups with concentrated NaOH or KOH at temperatures above 100 °C produces chitosan. This reaction occurs in a heterogeneous environment most of the time. It is a white powder that dissolves in 1% acetic acid and has a particle size of less than 120 mesh. Chitosan can link to negatively charged molecules because of the presence of positive amine groups. It does, however, have several disadvantages, such as low mechanical strength and a slow processing speed. In applications based on polymer materials, mechanical properties of polymers and polymer mixes are most important, but their thermal properties must also be considered. The temperature at which polymers degrade must be determined before they may be used in thermal applications. This natural biopolymer contains amine groups in its structure, has a positive charge, and can thus bond to negatively charged molecules (Fig. 4).

Chitosan is used in a variety of industries, including biotechnology, pharmaceuticals, environmental chemistry, and tissue engineering (Kumar et al. 2004). Unlike cellulose, chitosan is a simple polysaccharide with distinct characteristics that may be easily tweaked through functionalization techniques such as N-acylation, production of aldimines and ketimines, interaction with keto-acids, and N-carboxymethylation. Due to the ability of its amino groups to function as chelation sites, it can adsorb a range of toxic metals (Jha et al. 1988). For the majority of heavy metals, chitosan-based sorbents have demonstrated relatively strong sorption capacities and kinetics due to their high nitrogen content and porosity. Acid, vat, and

Fig. 4 Formation of chitosan from chitin

naphthol dyes have a strong affinity for chitosan (Shin et al. 2022). Another field in which chitosan can serve is in solid-state batteries in acid media due to its ionic conductivity (Ravi Kumar 2000), and it is also a suitable matrix for controlled medication release with minimal adverse effects. Chitosan hydrogels that are p^H -sensitive aid in medication delivery. Chitosan is used to make biodegradable wound dressing bandages because it inhibits microbial, fungal, and bacterial growth Chandy and Sharma (1990). Understanding their thermal stability and pyrolysis could help them comprehend and organize their industrial processes more effectively.

According to Emilia Szymańska and Winnicka (2015), chitosan is quite sensitive to environmental factors, so it is best to keep it in well-sealed containers at low temperatures (2–8 °C). It is critical to undertake stability tests during the preparation process of chitosan-based applications to determine the product's shelf-life. Chitosan (medium molecular weight), Aldrich, had a melting point of around 290 °C. It is determined by the degree of deacetylation as well as the molecular weight (10,000–1,000,000 g/mol). It is an amorphous material with a T_g value of 203 °C. Chitosan is extremely sensitive to a variety of degradation processes, including thermo-degradation. It can be biodegraded into harmless residues, with the amount of degradation being inversely proportional to the molecular weight of the substance. Understanding their thermal stability and pyrolysis could aid in better understanding and planning their industrial processes.

Chitosan is comparable in structure and properties to glycosaminoglycan (GAG), a natural polysaccharide that is a main constituent of the external matrix of cells. The degree of deacetylation is found to tune the properties like molecular weight, solubility, and viscosity. Chitosan deacetylation ranges from 50% to 100%, with the latter being entirely deacetylated chitin. Chitosan has a molar mass of 50–2000 kDa on an average. The structural analysis of chitosan produced from shrimp exoskeleton was carried out by E. Onsosen and O. Skaugrud (1990) using several instrumental techniques including FTIR, XRD, and SEM analysis, and the key features are listed below in Table 2 and Fig. 5.

Despite the fact that chitosan is a biocompatible polymer, it has a low heat resistance. Heat is frequently used in the creation of medication formulations for delivery of drugs. High temperature exposure can alter the structure of a polymer, influencing its solubility and viscosity. The temperature at which glass transition occurs for the chitosan moieties was observed to move to a larger value with an increase in its molecular mass, indicating that thermal degradation of the chitosan structure is a complicated process, which involving two or more decomposition steps. Based on these findings, it may be concluded that chitosan can be heated

Table 2 Structural analyses data of chitosan from FT-IR and XRD

below its glass transition temperature without losing its physicochemical features. The loss of water as a result of thermal treatment is thought to be the cause of lowering the T_g , making the material more temperature-dependent, and, as a result, reducing its storage steadiness. In chitosan-based systems, the inclusion of medication, plasticizer, or other additives tends to lower the polymer glass transition temperature. Tissue engineering (Croiser and Jerome 2013) is one of the most important usages for chitosan polymer blends. Novel chitosan/polyol-phosphate compositions have received numerous applications in the biomedical field due to the altered chitosan's ability to become heat sensitive in diluted acids and go through gelation at body temperature. These characteristics make it an appealing tool for a variety of uses, including local drug injecting systems and sophisticated tissue-engineering vehicles. Some of the chitosan thermal investigations have been described, indicating that there is still room for improvement in the thermal stability of the most cost-effective biopolymer.

Thermal Analysis of Chitosan: Effect of Various Factors

Thermogravimetric analysis and differential scanning calorimetric experiment results are summarized here. Thermogravimetric research offers accurate data on physicochemical parameters, solid process transformation, and solid participation in

Fig. 6 TGA of chitosan. (Adapted from Dey et al. 2016)

isothermal and nonisothermal heating. According to studies by Nieto et al. (1991), there were two stages in the TG plot (Fig. 6).

The analysis shows a moisture loss in the temperature range of 22–100 °C, and vaporization and removal of volatile products occur at 248–600 °C. The polysaccharide glycosidic linkages in chitosan are randomly split during pyrolysis and converted into various fatty acids. According to DSC analysis, it is observed that an endothermic peak occurs at 77–80 °C which is caused by the loss of water bonded with hydrophilic groups. A second peak around 303–304 °C is an exothermic peak which occurs due to chitosan network degradation.

The nonisothermal ultrasound-assisted deacetylation process (NIUSAD) was used to produce chitosan samples with a variety of characteristics, such as an average degree of acetylation ranging from 7.5% to 25.0%, an average molecular weight measured from viscosity measurements that varied from $1.17 \times 10^5 \text{ g mol}^{-1}$ to $6.45 \times 10^5 \text{ g mol}^{-1}$ and crystallinity index average (19.1%– CI -52.7%). The findings showed that each of these variables has an impact on the thermal stability of NIUSAD chitosan, with the crystallinity index having the greatest influence on the temperature at which deterioration really starts.

Several investigations on chitosan and its modification have revealed that a number of parameters influence heat deterioration (Georgieva et al. 2012). One such factor is the rate at which the sample is heated. The effect of the rate of heating on thermal degradation was performed by Peng-Zhi Hong et al. They used thermogravimetric analysis to investigate the temperature-dependent breakdown of

chitosan at various rate of heating in nitrogen. The findings suggest that chitosan thermal breakdown in nitrogen is a one-step process. Temperatures of deterioration rise as rate of heating(B) increases. The temperature at the maximum rate of degradation, or the peak temperature on a differential thermogravimetry curve (T_p), is $1.291B + 355.2$ °C, and the temperature at which the maximum rate of degradation ends (T_f) is $1.505B + 369.7$ °C. B has little effect on the strongest thermal degradation reactions at T_p and T_f , which have average values of 50.17% and 72.16%, respectively. The peak height on a differential thermogravimetry curve (R_p), which represents the greatest thermal degradation reaction rate, rises with B. The frequency factor, A, and activation energy for the reaction, E, dramatically rise during the reaction's initial phase, then it remains largely constant before reaching a peak value during the final phase. The thermal degradation's rate constants alter with the level of decomposition and rise as the reaction temperature rises. The variation in the decomposition curve with heating rate is illustrated in Fig. 7.

The temperature of maximal reaction rate for the first stage of thermal degradation increased from 294 °C to 328 °C in another investigation by Douglas de Britto et al., when the heating rate was changed from 2.5 °C/min to 15 °C/min. It was also discovered that E_a (Activation energy) is independent of the heating method used,

Fig. 7 TG curves of the thermal degradation of chitosan at heating rates (a) 5 K/min, (b) 10 K/min, (c) 15 K/min, and (d) 20 K/min. (Adapted from Moussout et al. 2016)

whether it is isothermal or dynamic. However, it has been hypothesized that it may be dependent on the average degree of deacetylation and the polymer's physical state (powder or film). Depolymerization and deacetylation were found to have an effect on thermal degradation as observed by significant changes in the TG-curve at temperatures exceeding $380\text{ }^{\circ}\text{C}$. It could be due to a change in the material's structure as well as a change in the mechanism of its thermal degradation process. Two peaks were seen in the DTG and DTA curves, at 295 and $545\text{ }^{\circ}\text{C}$, respectively. Both of these steps are highly exothermic. The first stage, which ends at $400\text{ }^{\circ}\text{C}$, is associated with a weight loss of 43.5% , whereas the next stage is associated with a mass loss of 35% . The first stage, according to some writers Hong et al. (2007), is associated with chitosan deacetylation and depolymerization. The second step is due to a degradation of residual cross-links in polymer (Fig. 8).

An investigation on the effect of different acid solvents on thermal behavior of chitosan films was evaluated by Hugo Yves et al. (2019). The impact of different acids on the thermal characteristics of chitosan films was studied. Polymer solutions of $100\text{ }\mu\text{m}$ thick films were created in a variety of acids, such as hydrochloric, nitric, and organic acids like tartaric, acetic, citric, lactic, and maleic acids. Infrared spectroscopy, X-ray diffraction, and thermal analysis were used to examine the films. They were less crystalline and more clear than chitosan powder. The intra- and intermolecular interactions in chitosan films were altered by the acid's nature, as evidenced by the shift to higher frequencies of the bands at $2942\text{--}2784\text{ cm}^{-1}$ and the shift to lower frequencies of the bands at 1650 , 1590 , 1420 , and 1376 cm^{-1} in the infrared spectra. Films had lesser thermal stability than chitosan, and each acid was affecting the thermal stability differently (Fig. 9).

Fig. 9 Degradation behavior of different molecular mass of chitosans measured by thermo gravimetric analysis: (a) 400 kDa, (b) 250 kDa, (c) 100 kDa, (d) 50 kDa, (e) 25 kDa, (f) 5 kDa, and (g) 2.5 kDa. (Adapted from reference Mao et al. 2004)

Degradation temperature was dependent on molecular weight according to the observation made on chitosan of different molecular weights. According to S. Mao et al., molecular weight is a factor to consider while studying thermal behavior. Low molecular mass chitosan decomposes at a low temperature than large molecular weight chitosan. Chitosan of molecular weight of 250–500 kDa showed a highest degradation temperature of roughly 280 °C. 100–250 MW requires 220 °C and MW 25–100 and 2.5–5 kDa is 180 °C. Chitosan solubility increased as molecular weight decreased, and chitosan breakdown temperature was also affected by molecular weight.

Methods to Improve the Thermal Stability

Certain applications for which polymers have been used thermal stability are major criteria. One method to improve the stability is to blend it with polymer. The commonly used polymers are starch, poly(vinyl alcohol), poly(ethyleneoxide), and polyvinylpyrrolidone. A study carried out on using these polymers as blends showed that blending with PVA (Mao et al. 2004) increased the moisture stability and this can be due to higher structural packing attained due to cross-linking. According to the study conducted on PVA-chitosan blends (Cui et al. 2018) for drug delivery application, it was seen that two endothermic peaks were observed at 160 °C and 220 °C and shifted to higher temperatures. The shift to a higher temperature of the

first peak is the replacement of the amino and hydroxyl group of chitosan by crosslinking agents. This shows that PVA cross-linked with chitosan was a better option than the composite of PVA- chitosan for high temperature applications. In comparison to pure chitosan, PVA addition on chitosan/polyvinylpyrrolidone films was found to have a higher initial temperature of thermal decomposition.

When a natural polymer, such as carboxymethyl cellulose (Thomas et al. 2016), is blended with glycerol and formaldehyde, the thermal stability is improved. When comparing pure chitosan to chitosan cross-linked with formaldehyde, it is clear that the weight loss (percent) of chitosan cross-linked with formaldehyde was larger. The temperature at which pure chitosan degrades is 120 °C. Chitosan cross-linked with 0.2% formaldehyde had the best thermal stability up to 220 °C. When chitosan is combined with an excessive amount of crosslinking agent, a hydrogel is formed. When compared to pure CMC, CMC crosslinked with formaldehyde improves thermal stability. The temperature at which pure CMC degrades is 240 °C. At 260 °C, CMC crosslinked with 0.4% formaldehyde provided the best thermal stability.

In order to study the thermal properties of cross-linking, studies were conducted on chitosan, chitosan cross-linked with glutaraldehyde, and blended poly (ethyleneoxide) polymer. It was found the on cross-linking and blending the thermal stability was improved. It was found that there was more hydrophilicity for the cross linked chitosan and thermal stability decreased. According to Zhang et al. (2021), combining CS and polycaprolactone at the optimal ratio of 9:1 significantly improved the membranes' thermal stability, hydrophilicity, and dynamic mechanical viscoelasticity. By using dynamic mechanical thermal analysis, all of the samples in the experimental range showed strong elasticity at low temperatures and high viscosity at high temperatures (DMTA). The glass transition temperature of polycaprolactone increased from 64.8 to 76 and the initial degradation temperature increased up to 86 °C. The most significant variation was seen in crystallinity and porosity which increased up to 30% and 86%. The elongation on breakage was 200%. So these properties make this membrane blend suitable for tissue engineering. Further studies were performed by adding acrylic acid along with poly caprolactone to chitosan (PCL-g-AA). The compatibility of PCL-g-AA with chitosan and, subsequently, the characteristics of the blend were both significantly improved as a result of the production of ester and imide groups, which improved the dispersion and homogeneity of chitosan in the matrix. Furthermore, PCL-g-AA/chitosan was easier to process than PCL/chitosan because it had a lower melt temperature. The PCL-g-AA/chitosan combination had greater water resistance, which also affected how resistant it was to degrading in soil and in an enzymatic environment. However, weight loss of the blends after being buried in soil or exposed to an enzymatic environment suggests that both blends were biodegradable, particularly at high chitosan concentration levels. When polyamide was blended in, the thermal stability was also enhanced.

The cross linkage methodology applied can be chemical or physical factors. Usually chemical cross linking increases the stability due to covalent bonding and hydrophilic and hydrophobic interaction. The cross-linkers used are glutaraldehyde,

cinnamic acid, and glyoxal. Three component chitosan/sodium alginate/pentasodium tripolyphosphate (Ch/NaAlg/TPP) membranes, as well as one component chitosan (Ch), two component chitosan/sodium alginate (Ch/NaAlg), and chitosan/pentasodium tripolyphosphate (Ch/TPP) membranes, were examined. It was shown from the above study that the thermal stability increases in the following order: Ch/NaAlg < Ch/NaAlg/TPP < Ch/TPPNaAlgChTPP if the temperature at which thermal deterioration begins is used as a criterion for the thermal stability. A study on the chemical reaction between chitosan and cinnamic acid showed that the stability of the polymer was decreased (Dieb et.al. 2012). On reacting cinnamic acid with chitosan gave the corresponding N-cinnamoyl chitosan (NCC) polymer. NCC polymer was having less thermal stability when compared to chitosan polymer according to a thermogravimetric study. Using the Arrhenius relationship, the activation energies for heat degradation of chitosan and NCC polymers were calculated. Research on the heat degradation of NCC polymer revealed that the removal of low-molecular-weight radicals is the mechanism through which NCC polymer degrades and this might be the reason for low heat stability.

With advancements in nanochemistry, attempts have been made to improve chitosan's thermal and mechanical properties by incorporation of nanoparticles. The main advantage of chitosan is that it is a cost-effective matrix with a biocompatible character that may be used to create hybrid products. Silica is one of the cost effective material, which can be used in combination with chitosan to prepare biosensors and catalyst and also find application in analytical field. It can easily be prepared using sol-gel method. Narrower distribution of particles and reduced particle size and development of oxide of the metal in situ leads to improved strength and increased glass transition temperature. The hydroxyl and amino groups in chitosan helps in the formation of gel network. The chitosan dissolved in 2% HAG and hydrolysis of TEOS resulted in the formation of gel network. The % of silica was varied and flexible chitosan-silica hybrids were produced. Characteristic absorption in FTIR corresponding to N-H stretching (3249 cm^{-1}) showed a decrease in intensity and shift to lesser frequency and showed more interfacial interaction between chitosan matrix and inorganic phase. A new absorption band at 960 cm^{-1} related Si-OH due to H-bonding to amide and oxy group of chitosan. The particle size of silica was 2 to 7 nm. Thermogravimetric investigation revealed that the first stage weight loss between $100\text{ }^{\circ}\text{C}$ and $160\text{ }^{\circ}\text{C}$ appears to be caused by the loss of absorbed water on the surface of chitosan as well as a side product of the subsequent condensation of the Si-OH groups (Al-sageer and Muslim 2010). Because low molecular weight species decompose more slowly between $160\text{ }^{\circ}\text{C}$ and $270\text{ }^{\circ}\text{C}$, chitosan loses weight more slowly. The complex dehydration of the saccharide rings, depolymerization, and thermal degradation of the acetylated and deacetylated units of the polymer all occur in the range between $170\text{ }^{\circ}\text{C}$ and $450\text{ }^{\circ}\text{C}$. The silica network's incorporation and interaction with the polymer raise the hybrids' thermal resistance, which also raises the temperature at which they decompose thermally. The mass of residue retained at $750\text{ }^{\circ}\text{C}$ indicates the amount of silica content incorporated in the hybrids. The displacement in the glass transition temperature

(T_g) of the composites from the maxima of the transition curves has been measured using dynamic mechanical thermal analysis (DMTA). As the silica content rises, so do the storage modulus and glass transition temperature. With 30 weight percent silica, the T_g value rises to its highest point, which is 159.37 °C.

A number of properties of chitosan have been modified by addition of nano-fillers of metal oxide. Metal oxides such ZnO, Fe₃O₄, and TiO₂ were found to increase the magnetic properties and tensile properties. The studies using MgO (De Silva et al. 2017), which is prepared easily from economical raw materials like brine, magnesium salts, etc., are limited. In a study a new magnesium carbonate/poly (methylmethacrylate) (PMMA) composite precursor was successfully heat-treated to produce spherical MgO nanoparticles for the first time. Chitosan-MgO composites were synthesized by solution casting technique. TG analysis showed that there were three mass loss stages. First was around 100 °C due to absorbed moisture, which was followed by the second mass loss at 200–300 °C which could be due to the thermal decomposition of amine and -CH₂OH groups of chitosan, and the final step at 525–650 °C could be due to the degradation of the glucosamine ring. The addition of MgO to chitosan films increased their thermal stability substantially. For example, the degradation temperature of pure chitosan film is 325 °C at 50% mass loss, but it has shifted to 450 °C and 529 °C with the addition of 5 and 10 (w/w percent) MgO, which is a 27% and 59% increase, respectively. This increase has been attributed to the high dispersion of MgO which hinders the diffusion and the great thermal stability of MgO above 250 °C as well as the homogeneous dispersion of MgO could explain these improvements.

The effect of nanoalumina (Aziz et al. 2011) on the glass transition was studied on films of chitosan and its complexes prepared using solution-casting technique. Varying amounts of Al₂O₃ (3, 4.5, 6, 7.5, 9, 12, and 15 wt%) were added to the highest room temperature conducting sample in the chitosan–salt system, that is, sample containing 60 wt% chitosan–40 wt% NH₄SCN. The glass transition temperature was studied using differential scanning calorimetry and T_g for the highest conducting composite is 190 °C. The increase in T_g with increase in more than 6 wt % filler content is attributed to the increase in degree of crystallinity. Thus, research is still going on to improve the thermal stability of chitosan, the most versatile natural polymer.

Polylactic Acid (PLA)

Polylactic acid (PLA), also known as the first generation biobased biodegradable polyester, is the most widely used biopolymer and is originated from renewable materials like sugar and corn starch. In the food packaging sector, tissue scaffolding, and biomedical devices, the aliphatic polyester polylactic acid (PLA) (Scheme 1), made from lactic acid (2-hydroxypropionic acid), finds widespread use. The PLA monomer lactic acid comes in two optical isomeric structures: Levorotary or L isomer and Dextrorotary or D isomer, which results in the polymers PLLA and

Fig. 10 Production of PLA

PDLA (Wuisman and Smit 2006). PLA is a particularly desirable material to employ in substitution of petroleum-based polymers, because of its strong mechanical qualities and good processability. However, PLA is hydrophobic in nature with low thermal stability, sluggish to degrade, poor toughness, and less reactive side chain groups (Barkhad et al. 2020). PLA has a wide variety of applications which includes automotive parts, mechanical parts, electrical and electronic devices, and materials for 3D printing, etc. (Fig. 10).

PLA can be produced by sensibly controlling the polymerization of its D- and L-isomers to obtain highly crystalline and amorphous polymers with high molecular weight distribution which is generally recognized as safe for food packaging applications. As this polymer readily undergoes hydrolysis, no major processing techniques can be used to produce them in large scales and for that, high molecular weight polymers with good thermal stability are required.

Thermal Properties of PLA

The thermal degradation temperature of PLA starts around 200 °C according to the thermo gravimetric (TGA) analysis and is caused by a variety of factors, including reformation of the lactide structure, hydrolysis, oxidative scission of the polymer chain, etc. However, there have been reports of two degradation phases for PLA, at 300 °C and 340 °C, as a result of the stereoisomeric structure (D- and L-forms) of the polymer, which can affect the polymer's thermal characteristics (Aoyagi et al. 2002). According to Varol's TGA analysis, the degradation temperatures of PLLA and PDLA pellets were found to be 296 °C and 321 °C respectively (Fig. 11). The average molecular weight of the two PLAs, 53 and 56 kDa for PLLA and PDLA respectively, explains this difference (Varol 2019) (Fig. 11).

The melting temperature (T_m) and glass transition temperature (T_g) of PLA significantly affect the physical-chemical stability of foods in food packaging applications. The possibility of heat-treated packaging of PLA is very less as the T_m of PLA is low. Homopolymers of PLA showed a glass transition temperature of around 60 °C, the specific heat capacity C_p is 0.51 J/(g °C), and the melt temperature is around 175 °C.

Poly(lactid acid) is a slower-crystallizing material; however, pure PLA crystallizes at the highest rates, producing crystalline spherulitic morphology in the

Fig. 11 TGA curves of PLLA and PDLA (a) thermograms and (b) derivative curves as a function of temperature. (Adapted from reference Varol 2019)

temperature range of 110–130 °C. The impact of the co-monomer length, its content, and architectural characteristics on the PLA crystallization should also be taken into account for the copolymers based on PLA. In general, the crystallization process is related to the nuclei formation and consequent crystal growth. For commercial applications, a specific amount of crystallinity is necessary; however, it is difficult to produce high crystallinity. A variety of formulations or modifications are essential to fasten the PLA's crystallization. Some of them are addition of nucleating agents for inducing crystallization at higher temperatures, use of plasticizers to increase the segmental mobility by reducing the chain folding energy, and also the production of the stereocomplex crystallites of the enantiomeric forms of PLA. In recent years, the last formulation, that is, the making of stereocomplex crystallites, has got wide attention since they have superior properties compared to the D- and L- forms of PLA. PLA exists in four diverse crystalline forms α , β , γ , and δ based on the different crystallization conditions and the PLA composition. Recently, stereocomplex crystallites received much attention and the melting temperature of the same is about 50 °C higher than that of PLA homochiral crystallites. Peaks for X-ray diffraction can be seen in the most typical form that crystallizes from melt or solution at 14.8°, 16.9°, 19.1°, and 22.5°. The disordered α form crystal or γ form crystal is generated below 120 °C and has comparable diffraction patterns to the α form crystals.

The controls of processing parameters on the thermal insulation behavior of melt-processed PLA revealed a considerable rise in the degree of crystallization with an increase in annealing time, which had a direct impact on the glass transition temperature, density, and thermal conductivity. Typically, PLA's thermal properties were established by the Carslaw and Jaeger mathematical model, and this model was for a real heat source with definite power and negligible losses. The thermal conductance (λ) is expressed using the equation, $\lambda = \frac{P}{\Delta T} \frac{h}{S}$, where P is the power of the electric heat source, S is its surface area, h is the distance from the heat source to the temperature sensor, and ΔT is the temperature difference between them.

Thermal Behavior of Blends of PLA with Other Polymers

Numerous studies on PLA blends have been conducted in an effort to enhance some PLA characteristics, such as crystallinity index, biodegradability, or mechanical properties for packaging use. The Gordon–Taylor equation, $Tg^b = \frac{W_1 Tg_1 + k W_2 Tg_2}{W_1 + k W_2}$, where Tg^b , Tg_1 , and Tg_2 are the glass transition temperatures of the blend, and the neat components, W is the weight fraction, and k is a parameter that can be adjusted and is a measure of miscibility which can be correlated to the strength of interaction between the individual blend components.

The thermal behavior of PLA/starch blends that have been annealed at various temperatures was compared by Shanshan and coworkers (Shanshan et al. 2015). It was discovered that annealing helped to reduce or perhaps completely eradicate the enthalpy relaxation at Tg . DSC was used to determine the degree of crystallinity (X_c), using the equation, $X_c = \frac{1}{W_f} \left[\frac{\Delta H_m - \Delta H_c}{\Delta H_{m0}} \right]$, where ΔH_m is the enthalpy for melting, ΔH_c is the enthalpy for cold crystallization, ΔH_{m0} is the melting enthalpy of the 100% crystalline PLA, and W_f is the weight fraction of PLA in the composites. The findings show that with increase in the annealing temperatures, the samples' crystallinity gets elevated. It was established that during the annealing process, the disordered crystal had a tendency to transform into the ordered crystal. In addition to the behavior showed by pure PLA, all of the PLA/starch blends also demonstrated a double melting behavior. The lower melting temperature ($Tm1$) increased as the annealing temperature was elevated, while the $Tm2$ did not significantly alter. The XRD patterns additionally demonstrated that annealing helped the materials to increase crystallinity. The thermal stability of the annealed samples was much less than that of the virgin samples which was supported by the activation energy values obtained from the Flynn–Wall–Ozawa method.

Similar to PLA, the biopolyester polyhydroxybutyrate (PHB) is also produced through bacterial fermentation from renewable resources like corn or sugar. Even though PLA and PHB's low thermal stability restricts their commercial applications, introducing PHB to PLA has been proven to increase PLA's mechanical strength and crystallinity (Armentano et al. 2015). In their review, Kervran and coworkers reported that in contrast to PHB, which has stronger thermal stability in PLA/PHB blend, PLA showed a poor thermal stability in the PLA/PHB blend than the pure PLA (Kervran et al. 2022). Dynamic study of the PLA/PHB blends TGA curves showed that the blends degraded in two stages. PHB degradation was thought to be responsible for the first stage of mass loss, and PLA was thought to be responsible for the second (Aydemir and Gardner 2020).

Several studies investigated the PLA systems, by adding additives such as cellulose-based reinforcements, plasticizers, crosslinking agents, etc., to increase the mechanical characteristics, flexibility, and physicochemical properties of the PLA/PHB blends for improved performance in superior applications (Trusca and Panaitescu 2019). Different plasticizers, comprising acetyl tributyl citrate (ATBC), oligomeric lactic acid, vegetable oils, and polyethylene glycol, are employed to plasticize PLA/PHB blends. However, the dynamic analyses revealed that the

addition of ATBC had no appreciable impact on the T_{\max} values of PLA and PHB. In comparison to lower molecular weight polyethylene glycol (PEG) (Mw 4000), the higher molecular weight PEG (Mw 6000) showed better thermal stability in PHB/PLA blends. So the thermal stability of PHB/PLA can be varied by the addition of polyethylene glycol with different molecular weights (Panaitescu et al. 2017). A similar improvement in PHB's thermal stability was seen when epoxidized soybean oil (ESBO) or epoxidized linseed oil were added to vegetable oils used for plasticizing PLA/PHB blends (Garcia et al. 2016; Lopera-Valle et al. 2019). This may be accounted for by the fact that vegetable oils may enhance the interaction between their molecular fragments and the polymeric backbones, resulting in the development of a thin physical barrier on the surface of the material and a subsequent reduction in the permeability of volatile substances. Additionally, the capacity of the epoxidized vegetable oils to scavenge acid groups during the breakdown improves the thermal stability. In the same way, in order to establish bonds between the chains of PHB and PLA polymeric chains, many works were reported showing the use of many crosslinking agents, such as maleic anhydride (MA), dicumyl peroxide (DCP). Based on different interpretations, inserting MA in the PLA/PHB blends can serve as a bridge by forming covalent connections by dipole-dipole interaction, hydrogen bonding or transesterification reaction, which leads to the enhanced interactions of PLA and PHB chains. While just a modest improvement in thermal characteristics was seen with no appreciable change in T_{\max} , this could improve the mechanical as well as morphological aspects. Frone and coworkers noticed that adding 1 wt.% of DCP to a 75/25 PLA/PHB blend did not significantly alter the T_{\max} values, but that the T_{onset} and $T_{10\%}$ values decreased for the blends with and without DCP by 5 °C and 17 °C, respectively. When MA and DCP were evaluated on PLA/PHB blends, the first one improved the blend's thermal stability, especially the thermal stability of the PHB in the blends, while the second one decreased the $T_{10\%}$ and T_{\max} values (Frone et al. 2019). Graphene oxide (GO)-based crosslinker was prepared with PLA in a very recent research by Sujana and coworkers, and a modest improvement in thermal stability was noted, which may be related to the interfacial contacts between the GO-based crosslinker and the polymer chains. The TGA, DTG, and DSC analyses all showed that the inclusion of GO-LA crosslinker increased the thermal stability of GO cross linked PLA (Sujana et al. 2021).

Extruded films are seen as alternatives to conventional synthetic-polymer films because of their exceptional mechanical and thermal properties and immediate prospective applications in extrusion-method large-scale manufacture of biodegradable polymers. Castillo et al. produced films made of polypropylene, poly(lactic acid), and chitosan using a solvent-free extrusion technique, using glycerol and polypropylene-graft maleic anhydride as plasticizer and compatibilizer, respectively. The thermal and mechanical qualities of extruded films containing up to 50% by weight of biopolymers are acceptable, and the addition of a compatibilizer enhances the processing features (Castillo et al. 2020).

In addition to that a lot of researchers reported the incorporation of agricultural fibers into PLA which could enhance the flame retardancy and thermal stability of the fiber reinforced PLA and which varies according to the kind and pretreatment

technique of the agricultural fibers used in creating fiber-reinforced PLA. (Yiga et al. 2021). Tej Singh et al. explored the consequences of *Dalbergia sissoo* wood waste on the glass transition and cold crystallization temperatures of the PLA-based composites, whereas with the increase of wood waste content, the crystallinity was found to be increasing after a first reduction in the value (Singh et al. 2021). A similar work recently reported to evaluate the feasibility of wood leachate (WL) constituents especially phenol and lignin as an additive in PLA-based biocomposites, and they reported that the thermal stability of PLA and its crystallization behavior were found to be improved with the addition of WL as a filler (Shahavi et al. 2022).

The fire resistance and UV stability properties of PLA and its composites are becoming significant because of their relevance in commercial applications. The mechanical and fire resistance of the PLA matrix was significantly enhanced by the addition of nano-ZnO and cellulose nanocrystals (CNC) to the polymer matrix. The studies confirmed that ZnO nanoparticles can display fire-retardant qualities, and the 1.5% CNC and 1.5% ZnO nanocomposites outperformed all others in terms of having the least amount of mass loss. Due to substantial char generation, oxidative combustion did not exhibit a clearly defined single decomposition, indicating two distinct decomposition processes. The shielding effect from ZnO acts as an insulator and causes noncontinuous burning, which boosts the fire retardancy of nanocomposites in addition to the use of CNCs (Bajwa et al. 2021).

Due to their low weight and simplicity of production, thermally conductive polymer composites are frequently employed as heat dissipation materials in LEDs and electronic packaging. Typically, high thermal conductivity fillers like metal, ceramic, and carbon are incorporated into a polymer matrix to create thermally conductive nanocomposites.

Conclusion

In many industries, biodegradable polymers have emerged as superior substitutes for traditional polymers. It is ascribed to their simplicity in production, low cost, and ease in degradation. The majority of biopolymers used in implants has electrical components and/or possess temperature-dependent properties that are essential for interacting with biological tissues. Being directly tied to morphology and having a direct impact on a material's therapeutic performance, a material's thermal behavior plays a significant role in characterizing its properties.

Based on quantitative and qualitative thermal assessments, this chapter covers some of the thermal characteristics of four pertinent biopolymers that were most extensively explored in the literature. Relying on apparent heat capacity, quantitative thermal analyses of semicrystalline and amorphous biopolymers were carried out and the findings were interpreted in terms of the molecular mobility in the microscopic level throughout the whole temperature range, including several transition zones. The facts presented in this chapter were carried out using the conventional DSC, conventional TMDSC, adiabatic calorimetry, quasi-isothermal TMDSC, etc. The discrete phases and phase transitions, such as the melt and cold crystallization,

the enthalpy of relaxation, crystal rearrangement, melting, glass transition, etc., could be characterized by these thermal analyses. Quantitative measurements gave an idea about the amount of crystalline, amorphous, and semicrystalline fractions. With the inclusion of nanocellulose, the thermal properties of nanocomposites have typically improved. Since nanocellulose degrades at a temperature of about 200–300 °C, processing temperatures should be kept below that range. The two primary issues that still exist with cellulose are its ability to break down into nanoscale particles and its compatibility with other polymeric materials. Similar to cellulose, derivatization or the creation of composites can be used to alter the thermal characteristics of starch. Esterification of hydroxyl groups of starch will help in improving the thermal stability. Blended composites of starch with various plasticizers and other additives exhibit variable thermal properties. Chitosan and PLA also have restricted applications due to its poor thermal stability. To enhance the thermal characteristics, the utilization of cross-linking agents, nanofillers, blending with polymers, and several other methods were applied and some are illustrated in this chapter.

In a nutshell, it is possible to improve the thermal conductivity of bio-based polymers by incorporating various structural parameters. In particular, structural modification through noncovalent functionalization offers an effective method for creating nanocomposites with high thermal conductivity, which makes them highly desirable in a variety of heat management applications, including lighting systems, the automotive industry, and next-generation microelectronics.

Abstract

Growing environmental consciousness has made the development of biobased, biodegradable, high-performance packaging materials increasingly popular. Biobased packaging materials, as opposed to those made from fossil carbon, constitute a solution that can significantly improve the environment because of their sustainability, biodegradability, biocompatibility, availability, and lack of toxicity. Since the passage of oxygen or moisture can cause the contents of packaging to degrade, gas barrier qualities are essential. Various criteria used to evaluate the barrier properties, evaluation methods, and methods utilized to enhance gas barrier properties of packaging films are covered in this chapter. A few significant biopolymers' oxygen and water vapor barrier characteristics are thoroughly explored. Recent studies on the use of cellulose, starch, and pectin, as

natural biopolymers in barrier films, have been discussed. A focus has been placed on the barrier qualities of synthetic biopolymers such polyhydroxybutyrate (PHB), poly (3-hydroxybutyrate-co-3-hydroxyvalerate), polyvinyl alcohol (PVA), and polylactic acid (PLA). This chapter also provides a broad overview of how these biopolymers work with other substances to produce balanced qualities suitable for barrier packaging.

Keywords

Gas barrier · Biopolymer · Packaging · Permeability

Introduction

The primary goal of a package especially food package is to safeguard the goods from the environment while also fulfilling this objective over the long haul. Food taste, quality, shelf life, and marketability can all be significantly influenced by food packaging. The usage of high-quality packaging, which limits transmission of oxygen and moisture between objects and the environment, is thought to have a key role in preventing food spoiling. A significant factor in food deterioration is the loss or gain of oxygen and water. Making airtight seals and using superior barrier materials are two methods for enhancing packaging in order to extend the shelf life of items. To assist increasing the food's ability to be stored, especially if it is likely to go rancid, some packages contain desiccants, oxygen absorbers, or scavengers. New developments in this field include the use of gas barrier films to control gas permeation.

Gas barrier films for the packaging of food, drugs, and electronics utilize petroleum-derived synthetic polymers. Since almost everything one buys, comes in a package, globalization has caused packaging to have an impact on every part of the industry. The majority of plastic packing films are used once, then burned or dumped in landfills. Due to the fact that these synthetic polymers are neither carbon neutral nor biodegradable, this results in environmental issues. Alternatives made of biopolymers to petroleum-based materials have the potential to cut carbon dioxide emissions by 30–70%, hence lowering the global carbon footprint (Greene 2014).

Biodegradable barrier materials should be used more heavily in packaging materials, which currently make up 60% of plastic items, to reduce the environmental risks. But still a number of issues are being faced by biobased barriers, such as its relatively increased cost, low resistance to heat, water, gases, and mechanical strain, which severely restrict the use of conventional biodegradable polymers for food packaging. This chapter discusses the gas barrier properties of biopolymers under two classes. Starch-, cellulose-, and pectin-based barrier films have been discussed under natural biopolymers. Polyhydroxybutyrates (PHB), Polylactic acid (PLA), and Polyvinyl alcohol (PVA) based barriers are discussed under synthetic biopolymers.

Gas Barrier Property in Polymers

Gas barriers are devices that can impede or stop the flow of gases and vapors. What is kept behind the barrier is usually protected by restricting gas passage. The gas barrier qualities are crucial in polymers used for food packaging because even extremely small amounts of oxygen can cause most products to degrade. Gas barriers are also used in the packaging of commodities like pharmaceutical, electrical, and medical products. No substance is capable of creating an endless barrier to gases.

In polymers, gas permeation is determined by the concentration gradient of the diffusing gas. Gas molecules have a natural tendency to flow across the barrier depending on the concentration gradient. The mechanism is determined by the barrier material and gas' intrinsic physical qualities, as well as the temperature circumstances. For a barrier film, gas permeation includes three steps: (i) gas dissolution into the film, (ii) diffusion through the film, and (iii) desorption from the film. Among this diffusion through the film is the rate-determining step.

Table 1 categorizes the most popular polymers used in packaging applications as barriers based on oxygen and water vapor permeability. From the table, it is clear that oxygen barrier property is opposite to the moisture barrier behavior. This is because good oxygen barriers are always associated with polar bonds or hydrogen bonds within their molecular structure which results in high hydrophilicity (Lagaron et al. 2004). Table 1 gives only rough values since the barrier value of the material will vary depending on the nature, source, grade, and processing methods employed.

Table 1 Classification of polymer films on the basis of oxygen and water vapor permeability^a (Wang et al. 2018)

Grade	Oxygen permeability (cm ³ · μm. m ⁻² day ⁻¹ atm ⁻¹)	Example	WVP (g. μm. m ⁻² day ⁻¹ kPa ⁻¹	Example
Poor	>40,000	HDPE, PP,PS, PHB,LDPE	>3000	Silicone Eastomer
Low	4000–40,000	PVC, BOPP, PHA, PLA	1000–3000	PA 6, PLA
Medium	400–4000	EVOH wet, OPET, PA 6 wet, PET	400–1000	PS, PHA, PLA
High	40–400	PVdC, PA6 dry	40–400	PAN, PVC, PET, LDPE
Very high	<40	EVOH dry	<40	HDPE, PP, PVdC, OPET, BOPP

^aOP values at 23–25 °C without specified RH% and WVP values at 37.8 °C and 90% relative humidity (RH). *BOPP* biaxially oriented polypropylene, *EVOH* ethylene vinyl alcohol, *HDPE* high-density polyethylene, *LDPE* low-density polyethylene, *OPET* oriented polyethylene terephthalate, *PA 6* polyamide 6, *PET* polyethylene terephthalate, *PHA* polyhydroxyalkanoates, *PHB* polyhydroxybutyrate, *PLA* polylactic acid, *PP* polypropylene, *PVC* polyvinyl chloride, *PVdC* polyvinylidene chloride, *PS* polystyrene, and *PAN* polyacrylonitrile

Measuring Barrier Properties

There are various terms to express a material's barrier properties, including transmission rate, permeability, and permeance. The transmission rate is defined as the amount a permeant permeates a film per unit surface area per unit time. Permeance is the transmission rate multiplied by the difference in partial pressure of the permeant. The permeability is equal to the permeance times the thickness. Temperature, pressure, and relative humidity are additional factors that affect a material's barrier capabilities in addition to the characteristics of the material itself. In a controlled setting, equilibrium moisture conditions are typically used to test barrier qualities. A hygroscopic material typically needs one or two days to reach equilibrium. Precision in the controlling test conditions and constancy in sample preparation determine accuracy and reproducibility. The relative humidity across the test film, the partial pressure of the permeant, and the thickness of the film all affect the transmission rate and permeance. Even if it is standardized to thickness, a material's permeability may differ if measured at two distinct thicknesses. At a particular temperature and relative humidity, the property is measured at 1 atm in most cases. Even if a publication only lists one of the parameters, these can be transformed into each other using test conditions and known film thickness.

Barrier performance of a packaging material can be expressed in terms of *Permeability*. SI unit of permeability is $\text{mol m}^{-1} \text{s}^{-1} \text{Pa}^{-1}$, or $\text{g m}^{-1} \text{s}^{-1} \text{Pa}^{-1}$. Barrer is a non-SI unit of gas permeability (Eq. 1).

$$1 \text{ barrer} = 10^{-10} \frac{\text{cm}_{\text{STP}}^3 \cdot \text{cm}}{\text{cm}^2 \cdot \text{s} \cdot \text{cm Hg}} \quad (1)$$

where ' cm_{STP}^3 ' represents the amount of gas (moles or molecules) that occupies one cc at STP, "cm" represents the thickness of the test material, $\text{cm}_{\text{STP}}^3 \text{cm}^{-2} \text{s}^{-1}$ represents the flux of gas that flows through the material, and "cmHg" stands for the pressure drop across the material.

Gas transmission, such as oxygen, liquid and vapor transmission, and oil transmission are the most typical barrier measurements. The characteristics of the penetrating molecule, those of the film material, and the environment all affect the barrier attributes. Feeding the gas into one side of the sample cell and using a sweep gas to convey the penetrated gas to the detector is one method of measuring gas permeation. The parameters of the measurement significantly affect the result. It is necessary to measure, monitor, and record the difference in temperature and humidity across the sample. Comparison of two results would be useless if the measurement conditions were unknown.

Some of the common types of barrier parameters are given below.

Water vapor permeability can be expressed either in terms of **water vapor transmission rate (WVTR)** or **water vapor permeability (WVP)**. WVTR is defined as the mass of water vapor or moisture that permeates per surface area of the barrier film for a definite time period, temperature, and pressure gradient (Rastogi and Samyn 2015).

The standard ASTM E96M-16 is typically used to measure WVTR and WVP (Abdullah et al. 2019). The procedure makes use of a borosilicate glass bottle with a mouth of 3 cm dia, filled with distilled water, and sealed with the sample. To prevent any contact, keep at least a 20 mm space between the water and the samples. Keep the temperature and relative humidity (RH) steady. For instance, an RH gradient of 100/50% can be achieved by utilizing purified water within the container (i.e., 100% RH) and saturated solution of $\text{Mg}(\text{NO}_3)_2 \cdot 6 \text{H}_2\text{O}$ outside it (i.e., 50% RH). To keep the conditions almost identical, the cups are kept in an air oven. Loss in weight of the cups should be noted every day for 2 weeks. WVTR is calculated using the following equation (Eq. 2)

$$\text{WVTR} = \frac{\text{Weight passed through}}{\text{Area} \times \text{Time}} = \frac{\frac{W}{t}}{A} \quad (2)$$

where W, t, W/t, and A stand for weight loss (g), time (h), the slope of linear regression (g/h), and the film area (i.e., cup mouth area) (m^2), respectively. SI unit of WVTR is $\text{g m}^{-2} \text{day}^{-1}$.

WVP of samples can be calculated according to the following equation (Eq. 3):

$$\text{WVP} = \frac{\text{WVTR} \times \text{thickness}}{\text{Saturated pressure} \times \Delta\% \text{RH}} = \frac{\text{WVTR} \times l}{S \times \Delta \text{RH}} \quad (3)$$

where l is the film thickness in “m,” S is saturated vapor pressure of water in “kPa,” and ΔRH is relative humidity gradient (for example, 100/50% in this case). SI unit of WVP is $\text{g } \mu\text{m m}^{-2} \text{day}^{-1} \text{ kPa}^{-1}$.

Since oxygen is the most reactive gas in the atmosphere, it is crucial to shield food material from it in order to ensure a long shelf life. Oxygen transmission can be measured in a number of methods. As per ASTM D3985-17 (2017) standard, the most conventional oxygen transfer rate (OTR) measurement uses the MOCON instrument. OTR is the amount of oxygen that travels through a barrier sample in a specific amount of time under steady-state conditions (Eq. 4).

$$\text{OTR} = \frac{\text{Volume passed through}}{\text{Area} \times \text{time}} = \frac{\frac{V}{t}}{A} \quad (4)$$

SI unit of OTR is $\text{cm}^3 \text{m}^{-2} \text{day}^{-1}$.

The barrier material is positioned between two chambers in this technique under dry conditions (RH 1%) and at standard atmospheric pressure. Both oxygen and nitrogen gas are stored in separate chambers. A coulometric detector detects the penetrated oxygen (Siracusa et al. 2008).

In a conventional gas permeability tester, the preconditioned sample film was placed between two teflon rings in a permeation chamber (temperature and relative humidity should be kept constant and monitored). N_2 gas was used as a carrier gas in one chamber of the permeation cell while O_2 /air was circulated at a controlled flow rate to maintain the pressure gradient of equal to 80 kPa in the other chamber.

The gas mixture was directly injected into a gas chromatograph that was connected to a thermal conductivity detector for examination after a delay of around 1 h. The column temperature was kept at 50 °C, and the used helium flow rate was set at 25 ml/min. O₂/air and N₂ peaks were used to calculate the final test gas content.

Oxygen permeability (OP) is calculated as per the equation below (Eq. 5).

$$OP = \frac{OTR \times \text{Film thickness}}{\text{Oxygen partial pressure difference}} \quad (5)$$

SI unit of OP is cm³ μm m⁻² day⁻¹ atm⁻¹.

Transmission rate of other gases can be calculated once that of oxygen is done using their relationship. Nitrogen has a transmission rate one-third that of oxygen, whereas carbon dioxide has a transmission rate six times that of oxygen. The *carbon dioxide transmission rate* (CO₂TR) is the measure of the amount of CO₂ gas that flows across a substance in a specific amount of time, and it is measured in cc m⁻² s⁻¹. CO₂TR, like WVTR and OTR, plays an important role in food packaging (Siracusa et al. 2008).

Natural Biopolymers

In-depth research is being done on the use of polysaccharides as food-packaging films, including starches, cellulose, chitosan, and pectin. Unfortunately, the poor mechanical properties, high WVP, and moisture sensitivity of polysaccharide derivatives prevent them from being used in industrial applications (Zhang et al. 2014). Some of the recent studies which make use of polysaccharides such as starch, cellulose, and pectin in film applications are discussed below.

Starch

One of the natural resources that is easily obtainable from a variety of renewable sources and may thus be generated in big amounts is starch. At the end of its life cycle, it is fully biodegradable and also quite affordable. It is composed of the same 1, 4-α-D-glucopyranosyl units that make up amylose and amylopectin. Amylose is linear with repeating units connected through α (1–4) connections, whereas amylopectin has a backbone that is α (1–4) linked and contains around 5% α (1–6) linked branches. The relative proportions of these two vary depending on the plant origin and determine the functional properties of starch. Starches with a high amylose percentage can create films that are fracture-resistant (Mali et al. 2004). Aside from carbohydrates, starch granules also include trace amounts of lipids, proteins, and minerals (Rindlav-Westling et al. 1998).

The starch granules are insoluble in cold water in their natural form, hence the majority of uses need for a heating process with an abundance of water. Granules of starch enlarge significantly after absorbing water, below a certain temperature, or the

so-called gelatinization temperature, of roughly 60 °C. The diffusion of amylose outside the granule is responsible for this process. If the temperature goes up to this limit, the inflated starch granules may break apart into smaller aggregates or particles, which will produce gelatinized starch. Thermoplastic starch, also known as plasticized starch, is made when native starch is fragmented and plasticized using water and another plasticizer such as glycerol (Fringant et al. 1996; Majdzadeh-Ardakani et al. 2010). But in native form, its application is constrained by its hydrophilic nature, and poor mechanical and barrier performance.

Chemically Modified Starch Films

A typical method for enhancing the properties of starch films is chemically altering the starch to add new functional moieties that can reduce solubility and WVP. This can also result in improved mechanical properties. By adding varied amounts of glycerol, Cyras et al. (2006) studied the characteristics of gelatinized potato starch and discovered that the glycerol content of the films influences the material's behavior at room temperature.

His research showed that the strong hydrogen bonding between chains of starch and glycerol causes some loss in the crystallinity of the films on glycerol addition. Additionally, the researchers included several chemical alterations in their investigation, including acetylation (using acetic acid and anhydride) and maleation (using maleic anhydride). Due to the decreased contact between the starch chains with reduced -OH groups following alteration, these modifications significantly decreased crystallinity. Esterification of starch reduces water sorption in contrast to that of neat starch because acetylated and maleated starch has a less hydrophilic character than native starch.

According to Zamudio-Flores et al. (2006), oxidized banana starch can be utilized to produce films with better barrier properties. In their study, glycerol and oxidized banana starch were used to create the films. Oxidized banana starch was made at three different oxidation levels (active chlorine concentrations of 0.5, 1.0, and 1.5%). The use of thermal gelatinization and casting was done to prepare the film. Tensile properties, XRD pattern, and water vapor transmission rates of these materials were examined. The films' tensile strength increased together with the degree of oxidation of the banana starch. The peak crystallinity of the films grew together with the starch's level of oxidation. The mechanical strength of the films was improved by the stronger bonds between polymer chains and between polymer and glycerol molecules. The films maintained for 30–60 days did not exhibit any statistically significant variations in their water vapor permeability (WVPc). The highest WVP were found in the films made from oxidized banana starch, and these values improved as the starch's level of oxidation increased.

According to López et al. (2008), acetylated maize starch had the best properties for creating films, was more transparent, and was easier to deal with. Four treatments of modified corn starch viz. acetylated, interwoven/acetylated, interwoven/hydroxypropylated, and acid hydrolysis were used in this study. WVP was decreased in all of the corn starch films in addition of functional groups.

Fig. 1 Photographs of oxidized potato starch films in acidic condition: (a) before test; (b) 1 day; and (c) 60 days

Using oxidized potato starch (OPS) and glycerol as a plasticizer at various concentrations, Hu et al. (2009) made starch films. The OPS films were pliable and transparent. The film with 19.4% glycerol appeared to have desirable mechanical qualities, and the crystallinity of OPS films decreased as glycerol content increased. The film's resistance to crosslinking, resistance to leaking, and stability in acidic or basic conditions were also studied. The results revealed that the OPS films exhibited excellent antileakage properties for vegetable oil, good anti-crosslinking properties in saturated formaldehyde vapor, and high stability in acidic aqueous medium, but low stability in alkali aqueous medium (Fig. 1).

Starch-Based Moisture-Proof Films

When using starch films to wrap meals with high moisture content or those are stored under highly humid conditions, the ability of the film to withstand moisture is a very important film quality. To effectively transmit moisture from wrapped foods to the film matrix, stretchy films must strongly adhere to the food surface. Therefore, the real use of stretchable starch films in the food business depends greatly on their moisture-proofing ability. Starch film's effective moisture-proofing ability preserved the intended texture of the food product by preventing water interaction with the environment, when it was used to wrap dry meals (Yang and Paulson 2000). The moisture-proof property of the film is crucial for preserving the anticipated film performance when it comes to wrapping fresh goods with high moisture content (Petersen et al. 1999).

Using equally mixed octenylsuccinated/native starches (OSS/NS), Li et al. (2015) were successful in creating stretchable sweet potato starch films with better moisture-proof properties. The OSS/NS blend films greatly outperformed the control film with respect to moisture resistance, as evidenced by decreased water solubility and WVP and increased contact angle and oil permeability. The water solubility and WVP of OSS/NS mix films decreased by 23.7% and 20.8%, respectively, at a degree of substitution (DS) of 0.0425. Elongation at break improved by 84.5%, and contact angle and oil permeability improved by 181.1% and 43.6%, respectively. The amplitudes of these gains changed as OSS substitution levels (DS) increased. The OSS/NS blend films' stretchability, elongation at break, and transparency were all

high and enhanced as the DS of OSS increased. OSS/NS mix films displayed less crystallinity than the control film, as evident from XRD measurements. The hydrophobicity of OSS and the plasticization of octenyl groups during film production were essentially responsible for these discrepancies.

Starch Blends in Barrier Applications

Other methods include adding nanoparticles, blending starch with other macromolecules or polymers (such as pectin, cellulose fibers, or proteins), or both. Nanoclays were found to improve the mechanical properties and reduce WVP of cassava starch films as reported by Souza et al. (2012). Using polylactic-acid, Sanyang et al. (2016) attempted to enhance the functional qualities of sugar palm starch (SPS)-based films (PLA). The inclusion of PLA boosts tensile strength and tensile modulus while reducing water uptake. Overall, adding a PLA layer to SPS films makes them stronger mechanically and more water-resistant, which increases their suitability for food packaging.

Ryberg et al. (2011) created renewable barrier films from a wood hydrolysate. By including a co-component, such as CMC or chitosan, the interactions among the constituent molecules are tailored to achieve the right balance. The barriers, which were coated on a PET substrate, displayed extremely low OP at relative humidity levels of 50 and 80% and showed worse results than coatings manufactured from O-acetyl galactoglucomannan, a highly purified form of spruce hemicellulose (AcGGM). They claim that a wood hydrolysate/CMC coating is the optimal composition since it lowers the OP of PET from $14.6 \text{ cm}^3 \mu\text{m}^{-2} \text{ day}^{-1} \text{ kPa}^{-1}$ to as low as $1.6 \text{ cm}^3 \mu\text{m}^{-2} \text{ day}^{-1} \text{ kPa}^{-1}$.

Cellulose

Anselme Payen, a French scientist, discovered cellulose in 1838, and Hermann Staudinger described its polymer structure in 1920. As a polysaccharide, cellulose has the formula $(\text{C}_6\text{H}_{10}\text{O}_5)_n$. The hierarchical structure of cellulose is given in Fig. 1. Cellulose is made up of glucose monomer units. It is a linear chain made up of $\beta(1-4)$ glycosidic connections connecting D-anhydroglucopyranose units (Markovic and Visakh 2017). The noncellulosic materials usually found along with cellulose include lignin, pectin, hemicelluloses, proteins, fats, etc. Cellulose comes in four different crystalline forms, including cellulose I, II, III, and IV. Typically, cellulose I and cellulose II are found in plants (Habibi et al. 2010) in which thermodynamically most stable structure is cellulose II. A noncrystalline form of cellulose also exists, which is known as nematic ordered cellulose.

The polymer chains in cellulose are linear which gives them rigidity and rod-like nature. Intra and intermolecular hydrogen bonding in these chains gives them highly ordered crystalline nature. Due to high crystallinity, these fibers have good strength and are insoluble in solvents. Cellulose swells by absorbing water, but it does not dissolve in water.

Diffusing molecules typically have a hard time penetrating the crystalline portions of cellulose fibrils. Due to its relatively high crystallinity and the ability of the nanofibers to organize into a dense network that is held together by strong interfibrillar connections, it has been suggested that cellulose may serve as a barrier material. Since different cellulose and hemicellulose films offer strong resistance to oxygen absorption, they have been investigated as biobased oxygen barrier materials. For instance, Syverud and Stenius (2009) reported an oxygen transmission value for 21 μm -thick microfibrillated cellulose (MFC) films measured at 23 °C and 0% RH of $17.75 \pm 0.75 \text{ ml m}^{-2} \text{ day}^{-1}$.

When an MFC layer was applied to the PLA surface, observed that the oxygen permeability of polylactide (PLA) film decreased by a factor of more than 700. It is assumed that MFC has a tendency to absorb a substantial amount of moisture since it is very hydrophilic. The mesostructure of the films and the cellulose molecule structure are thought to regulate the intricate phenomena of MFC swelling and water absorption (Aulin et al. 2009).

Transparent, flexible regenerated cellulose films using aqueous alkali (NaOH or LiOH)/urea (AU) solutions were made by Yang et al. (2011). These films had higher oxygen barrier qualities than traditional cellophane, poly (vinylidene chloride), and poly (vinyl alcohol). From various cellulose sources, a series of AU cellulose films were created for various dissolution and regeneration environments. Depending on the conditions under which the films were made, the OP values of these films varied from 0.003 to 0.03 $\text{mL } \mu\text{m m}^{-2} \text{ day}^{-1} \text{ kPa}^{-1}$ at 0% RH. The AU film made from a 6 wt% cellulose solution and regenerated with acetone at 0 °C had the lowest oxygen permeability. It was discovered that the AU films produced by regeneration in a solvent at low temperatures from solutions with high cellulose content typically exhibited low oxygen permeabilities.

Table 2 details the characteristics and oxygen permeabilities (at 0% R.H.) of the cellulose films that were regenerated from aqueous AU solutions. The cellulose samples included filter paper pulp (FP), Whatman CF11 microcrystalline cellulose powder, another cotton linters pulp (CP), and softwood bleached kraft pulp (SBKP).

From Table 2, it is clear that OP value of the AU cellulose film is dependent on the nature of solvent used and regeneration procedure. The lowest value of oxygen permeability reported in this study was $0.003 \text{ mL } \mu\text{m m}^{-2} \text{ day}^{-1} \text{ kPa}^{-1}$ for the film from a 6 wt % cellulose solution in LiOH/urea/H₂O by regeneration with acetone at 0 °C. According to the study, no plastic film has ever been known to have an oxygen permeability as high as this AU cellulose film. For instance, the oxygen permeabilities of nylon-6, PVC, HDPE, PET, and PVA are, respectively, 6, 0.4, 500, 8, and $0.04 \text{ mL } \mu\text{mm}^{-2} \text{ day}^{-1} \text{ kPa}^{-1}$ at 0% R.H. The AU cellulose films also offer good bendability, strong mechanical strengths, and great optical transparency.

Figure 2 shows how OP values and densities of cellulose films made from the solutions by regeneration with 5 wt% H₂SO₄/5 wt % Na₂SO₄ are affected by the concentration of FP cellulose in LiOH/urea/H₂O solutions. The regeneration temperature in this instance was set at 20 °C. The OP of the films decreased from 0.03 to $0.012 \text{ mL } \mu\text{m m}^{-2} \text{ day}^{-1} \text{ kPa}^{-1}$ when the cellulose content was raised from 3 to 6 wt %. In consequence, the AU cellulose sheets' density rose from 1.39 to 1.45 g cm^{-3} .

Table 2 Preparation conditions of AU cellulose solutions and characteristics of regenerated AU cellulose films prepared from them. (Adapted with permission from reference (Yang et al. 2011))

Solvent	Cellulose source	C (wt %)	Regeneration bath	T (°C)	Density (gcm ⁻³)	Oxygen permeability (mL μm m ⁻² day ⁻¹ kPa ⁻¹)

Because they are biodegradable and environmentally friendly, these transparent, flexible, high oxygen barrier cellulose materials show promise as high-performance packaging materials.

Hartman et al. (2006) examined the film-forming capacity of hemicellulose *O*-acetyl-galactoglucomannan (AcGGM) and assessed the material's potential as a barrier. From industrial process water obtained from mechanically pulping wood, the AcGGM was separated and films were made by solution casting. The effects of plasticizers such glycerol, sorbitol, and xylitol were compared in order to prevent brittleness. These additions did, however, increase susceptibility to moisture, which might not be as advantageous for other applications. Interesting mechanical strength and oxygen barrier qualities were attained in a film made from a physical mixture of carboxymethylcellulose or alginate, both of which have a significantly larger molecular weight than AcGGM. Due to the abundance of hydroxyl functionalities in the materials used, no phase separation was noticed. AcGGM-based film with optimum properties was made on the addition of a plasticizer with lower permeability for sorbitol compared to other plasticizers like glycerol and xylitol.

A wood hydrolysate formed from the wastewater following the hydrothermal treatment of spruce wood was successfully used to prepare thin films and coatings, in another study (Edlund et al. 2010). This was improved using ultrafiltration to produce a noncellulosic fraction that was rich in oligo- and polysaccharides and contained 10% lignin relative to dry mass. Wood hydrolysate and CMC or chitosan mixes were used to make coatings for PET film and free-standing films by solution casting. Both kinds of combinations provide clear, glossy films and coatings with

good mechanical qualities and extremely low oxygen permeabilities which make them promising for packing.

Pectin

Pectin is the methylated ester of polygalacturonic acid with different degrees of methylation. It is a branched chain hetero-polysaccharide constituent of the plant cell walls in plants. Other polysaccharides have a known molecular weight, while pectin does not. With celluloses and hemicelluloses, it contributes to the construction of the cell. Commercially available pectin films have degrees of esterification between 15% and 25%. The degree of esterification affects the mechanical properties of pectin films. Samples with a higher esterification degree are more fragile (Penhasi and Median 2014).

Pectin is widely used in food and beverage industry as an additive (Willats et al. 2006). It is a food ingredient that is used in many different products as a thickening or colloidal stabilizer (Wang et al. 2021a). Pectin and its derived compounds are used as a conventional ingredient in functional foods. The degrees of methyl esterification of polysaccharide chain in pectin determine its gelling and film-forming properties. Thus the extent of methyl esterification is the deciding factor about its industrial applicability (Šešlija et al. 2018). Its peculiarity is its cytocompatibility, wound dressing, tissue engineering (Pereira et al. 2018), drug delivery (Almeida et al. 2017) etc., which are the different areas where pectin is exploited in the biomedical field (Kocaaga et al. 2019). Pectin is special because of its biocompatibility, edibility, biodegradability, ability to gel, and ability to form films, among other qualities. As a result, it is an excellent choice for creating food-packaging films (Vanitha and Khan 2019).

Different biodegradable packaging materials use pectin and its derivatives to act as a barrier for the packaged goods. Flexibility is the suitability of this material for considering it as a biodegradable packaging material. Pectin can be treated as the omnivorous diet and can be metabolized. This edible coating simultaneously preserves the nutritional value of packaged food products and shields them from enzymatic deterioration, flavor loss, lipid migration, and pathogenic attack control. Pectin film can be prepared very easily by spray coating, solvent casting, and knife coating. Still, pectin films have two disadvantages, poor thermophysical properties and inadequate mechanical performances, which restrict its applications in food-packaging industries (Espitia et al. 2014).

Low methoxyl (LM) pectin can create hard gels by cross-linking with calcium ions when the pH is low. LM pectin films are employed as edible coatings because these gels are exceptionally stable and capable of acting as water barriers. The capacity of edible films to incorporate a range of substances, including antioxidants, flavors, antibrowning agents, and antimicrobials, is one of its key features (Falguera et al. 2011). Mendes et al. investigated the barrier qualities of the composite made by integrating cocoa butter (CB) in a pectin matrix (PEC) (Mendes et al. 2020). According to a modified version of ASTM E96–16, these composite films' water

vapor barriers were examined. The water vapor transmission rate (WVTR) values were calculated. The force that propels water vapor through the film is the difference in relative humidity (RH). The fact that water vapor migrates through the hydrophilic portion of a film may have led to the prediction that adding hydrophobic substances (like CB) would diminish WVP, and the experimental results are consistent with the prediction. The WVPTR readings dropped from 2.0 to 0.7 g mm kPa⁻¹ h⁻¹ m⁻² as CB concentration rose. The kind, structure, and quantity of the added lipids will determine how successfully the water barrier qualities are improved (Helland et al. 2002). WVPTR may be decreased by the hydrophobic to hydrophilic fraction ratio in the composite film. Due to the hydrophobic nature of cocoa butter and uniform dispersion throughout the pectin matrix, water diffusion rates were decreased. In light of good WVPTR values, the PEC/CB films are suitable for use as moisture-resistant films in food packaging (Otoni et al. 2016).

It was discovered that avocados kept at 10 °C with edible pectin coatings on them had a lower oxygen transmission rate, which delayed fruit decay (Maftoonazad and Ramaswamy 2008). Moalemiyan et al. successfully prepared a coating film using pectin, sorbitol, and bee wax to preserve chopped mangoes in their natural state for more than 15 days (Moalemiyan et al. 2012).

Synthetic Biopolymers

The synthesis of high molecular weight of biopolymers is a tedious process. There can be further challenges. Because of the specific spatial arrangement of the natural biopolymers, synthesis of the copy of a natural polymer is not at all easy. But it is desirable to surpass these issues to overcome the low abundance of the natural biopolymers.

Poly Hydroxybutyrate (PHB)

One widely used biopolymer packaging material in industry is PLA. Among polyhydroxy alkanates (PHA), polyhydroxybutyrates (PHB) are considered a good candidate especially when incorporated with nanofillers (Keskin et al. 2017). PHB has mesophoric regions which is semicrystalline in nature. These regions are somewhat permeable to oxygen and water vapor and may result in deterioration of packaged food items. Thus, an ideal packaging material should be impervious to the atmosphere (Manikandan et al. 2020). Manikandan et al. studied the barrier properties of PHB-based graphene nanocomposite films and evaluated the role of graphene in preventing the transportation of oxygen and water vapor. In their research, adding hard graphene sheets (Gr-NP) to the polymer matrix improved the PHB's barrier qualities (PHB). The Gr-NP in the PHB matrix made the composite film impervious by converting the gas passage track in the composite more and more tortuous. This phenomenon is persisted only up to certain limit, higher concentration of Gr-NP resulted in agglomeration, and the tortuosity in the gas

transmission pathways may be lost. Oxygen (OP) and water vapor permeability (WVP) values of the neat PHB are $1.53 \text{ cm}^3 \text{ mm m}^{-2} \text{ d}^{-2} \text{ atm}^{-1}$ and $9.26 \text{ g m}^{-2} \text{ d}^{-2} \text{ atm}^{-1}$, respectively. On addition of 0.7 wt% of Gr-NPs, OP and WVP values of the PHB/Gr-NP composites were reduced to $0.4 \text{ cm}^3 \text{ mm m}^{-2} \text{ d}^{-2} \text{ atm}^{-1}$ and $4 \text{ g mm m}^{-2} \text{ d}^{-2} \text{ atm}^{-1}$, respectively and they found that it was the optimum filler loading. Further increase in Gr-NP resulted in filler agglomeration.

The OP and WVP values achieved at an ideal Gr-NP concentration in the composite were comparable to and, in some cases, better than those from related research that are referenced in the literature. The OP values of the composite films made of graphene oxide and the polymers such as amylopectin, polythene terephthalate, amylose, and PLA were 1.4, 1.3, 0.7 and $0.6 \text{ cm}^3 \text{ mm m}^{-2} \text{ d}^{-2} \text{ atm}^{-1}$, respectively (Goh et al. 2016). All these results are higher than the OP value ($0.4 \text{ cm}^3 \text{ mm m}^{-2} \text{ d}^{-2} \text{ atm}^{-1}$) obtained by Manikandan and coworkers in their study. The desired limit of OP value is $1.0 \text{ cm}^3 \text{ mm m}^{-2} \text{ d}^{-2} \text{ atm}^{-1}$ (Xu et al. 2020). WVP values showed similar trend in barrier properties compared to OP values.

Poly (3-Hydroxybutyrate-Co-3-Hydroxyvalerate) PHBV

The oxygen barrier characteristics of the PHBV/cellulose nanocrystal (CNC) composite were found to be improved by Malmir et al. Cellulose nanocrystals reduce the oxygen permeability of PHBV to a great extent. It happens as a result of CNC's favorable impact on nanoparticles' crystalline nature and the development of a more tortuous path for gas molecules in their morphology. They examined the nucleating effect of CNC on the crystallization of the PHBV matrix and demonstrated that good dispersion could be obtained up to 4 wt. % of CNC (Malmir et al. 2017).

Keratin/PHBV composites' barrier characteristics were researched by Pardo-Ibáñez et al. Melt blending was used to create composites with various keratin contents. The PHBV composite with the lowest oxygen permeability value contains 1% keratin. In comparison to pristine PHBV film, it dropped from 3×10^{-18} to $1 \times 10^{-18} \text{ m}^3 \text{ m m}^{-2} \text{ s}^{-1} \text{ Pa}^{-1}$ for 1% keratin loading. Higher loadings have caused adverse effect on permeability. Homogeneity of the filler dispersion and hence the tortuosity is the reason for improved barrier property of the composite film. Depending on the size and shape of filler particles, the ideal content can fluctuate. Reduced crystallinity and agglomeration were the results of keratin loadings of more than 3% (Pardo-Ibáñez et al. 2014).

The impact of lignin in PHBV on the barrier qualities of carbon dioxide and oxygen was investigated by Kovalcik et al. The gas permeability was considerably decreased by incorporating 1 wt.% lignin with PHBV such as oxygen and carbon dioxide permeability has got reduced by 77% and by 91%, respectively, in comparison with the neat PHBV. The permeability coefficient for carbon dioxide is higher than that of oxygen in the case of PHBV composite, which is in accordance with gas permeability behavior of many polymers (Huglin and Zakaria 1983). The improved performance in the barrier property of the composite film is due to homogeneous dispersion of lignin in the matrix (Kovalcik et al. 2015).

Martinez-Sanz et al. examined and described nanocomposites constructed of PHBV and bacterial cellulose nanowhiskers (BCNW) with various BNCW concentrations (Martinez-Sanz et al. 2014). Barrier properties were improved with the incorporation of 1 wt. % BCNW. A very small quantity of the nanofillers, 1 wt. % BCNW, produce water permeability drop of 28%. They examined the oxygen and water vapor permeability behavior of PHBV samples which contained low [7.3 mol%, (PHBV7)] and high [40 mol %, (PHBV40)] valerate and discovered that the PHBV films' oxygen and water vapor barrier qualities drastically declined as valerate content rose. The oxygen permeability decreased from 8.16×10^{-19} to $5.24 \times 10^{-19} \text{ m}^3 \text{ m}^{-2} \text{ s}^{-1} \text{ Pa}^{-1}$ for PHBV7 with 1% BCNW and from 10.76×10^{-19} to $9.45 \times 10^{-19} \text{ m}^3 \text{ m}^{-2} \text{ s}^{-1} \text{ Pa}^{-1}$ for PHBV40 and 1% BCNW composites.

Jost and Langowski looked into how different plasticizers affected the mechanical and barrier qualities of PHBV blends. Plasticizers made PHBV more crystalline and had a negative impact on mechanical qualities, although they improved barrier properties. Plasticizers containing ether and ketone groups found suitable for the preparation of PHBV nanocomposite films. Glycerol was shown to be the best plasticizer for the synthetic biopolymer PHBV in terms of oxygen and water vapor permeability (at 5 wt. %) (Jost and Langowski 2015).

The mechanical characteristics of PLA/PHBV blend films and their gas barrier features are being studied by Boufarguine et al. Compared to PLA, PHBV is superior in gas barrier properties. The composite is produced by multilayer coextrusion technique. When they evaluated the blends' helium permeability, they discovered that the presence of PHBV layers reduced it relative to neat PLA (Boufarguine et al. 2013). There are many benefits to helium permeability measurement. Since helium molecules are smaller than those of oxygen, conducting gas permeability studies now takes only less than an hour. As a neutral gas, helium has no interaction with the matrix of polymers. Zembouai et al. concluded from their research on the PLA/PHBV blend that the main cause of the enhancement of barrier characteristics is the crystalline nature of PHBV. As the PHBV ratio in the prepared mixtures increased, the barrier characteristics of the blends improved. This showed that PHBV is a good candidate to improve the barrier performance of PLA even at minimal proportions (Zembouai et al. 2013). Ambrosio-Martin et al. studied the mass transport behavior of PHBV-functionalized graphene sheets (FGS) composites produced by compression molding in a hot press. The oxygen permeability was analyzed. With FGS added, a decrease in oxygen permeability was observed. The PHBV/FGS composite with 3 wt. % FGS exhibited a decrease in permeability of 41.2% (Ambrosio-Martin et al. 2015).

Arturo Rodriguez et al. studied the oxygen permeability on biobased poly (butylene succinate)-PHBV/talc-starch composites (Rodriguez-Urbe et al. 2021). Because of the excellent barrier capabilities of PHBV and the hard, impermeable nature of talc, the barrier properties were significantly improved when these materials were used together with BioPBS. Due to better interfacial contact, the addition of a coupling agent (maleic anhydride grafted BioPBS/PHBV) substantially strengthened the oxygen barrier property. The hydrophilicity of the maleic anhydride groups in the compatibilizer is the main reason for the reduced water vapor barrier

property. The oxygen and water vapor penetration rate of the BioPBS in its neat form was significant, but it was reduced by around 68% in both cases, when 20 wt. % talc was added (oxygen and water permeability). This is due to the presence of stacked layers (platelets) of hydrated silicates ($\text{Mg}_3\text{Si}_4\text{O}_{10}(\text{OH})_2$) inside talc which are impermeable to oxygen and water (Buzarovska et al. 2016). The lowest oxygen permeability and water vapor permeation rate were attained with 24% PHBV, 20% talc, and 1% MA-g-BioPBS/PHBV (80/20) in BioPBS, respectively. Because of its limited dispersion and hydrophilic nature, starch has a little impact on the oxygen and water vapor barrier characteristics.

Pal et al. evaluated the oxygen permeability and water vapor permeability of the compression-molded and cast-extruded PHBV/PBAT films according to the ASTM F3985 and ASTM F1249, respectively (Pal et al. 2020). The effect of nanoclay on the transfer rate of oxygen permeability of PHBV-/PBAT-based nanocomposite films were analyzed. For compression-molded film, oxygen permeability of PHBV/PBAT blend was $546.99 \text{ cm}^3 \text{ m}^{-2} \text{ day}^{-1} \text{ atm}^{-1}$, and reduction in permeability was improved by 54% after the addition of 1.2 wt. % nanoclay. The interface of PHBV and PBAT and the well-dispersed nanoclay helped the composite in reducing its oxygen permeability. The PHBV/PBAT/nanoclay nanocomposite films, prepared by film extrusion technique, showed 78.9% improvement in oxygen barrier property after the addition of 1.2 wt% nanoclay, which indicates that film extrusion technique is superior to compression molding for the preparation of gas barrier films. The reason for the composite film's improved oxygen barrier qualities may be due to the nanoclay's appropriate size, shape, and uniform dispersion in the matrix. Higher loading of nanoclay in the matrix resulted in agglomeration of the filler and hence the oxygen barrier properties get reduced.

The forced parallel orientation of films caused by the machine-directed arrangement of the polymer chains enhances the dispersion of nanoclay and, as a result, increases the crystallinity of the polymer composites. Compared to the compression-molding technique, the barrier qualities are improved with cast film extrusion. A similar pattern was seen in water vapor permeability also. Due to filler agglomeration, the addition of 1.8 wt% nanoclay to the PHBV/PBAT blend occasionally produced results that were lower and occasionally only slightly higher than the matrix. Mondal et al., on the other hand, improved the water vapor transmission rate for PBAT-montmorillonite clay composite films by a significant amount (25.21%), and they attributed this increase to the uniform dispersion of the filler (Mondal et al. 2014)

Poly Vinyl Alcohol (PVA)

Satyajit Gupta et al. evaluated the average transmission rates for different time intervals for PVA/ZnO composites. They created reactive barrier films using nano-scale zinc oxide and polyvinyl alcohol (PVA) as the base polymer matrix. They used thermal deposition of calcium on the surface of composite films, and its degradation for studying the barrier properties (Gupta et al. 2012). According to these

investigations, the calcium layer entirely degraded after 3300 sec for PV4, 200 sec for PV1, and 90 sec for PV0 (PV4, PV1 and PV0 are composites containing 4 wt. %, 1 wt. %, and 0 wt. % ZnO, respectively). The removal of calcium layer can be considered as the measure of gas permeability. The time required for the removal of calcium coating increases with ZnO content in the matrix. The longer amount of time needed to degrade the calcium layer demonstrated how the presence of ZnO in the matrix enhanced the composite's barrier properties. The water vapor permeability values of the composites PV0 to PV1 to PV4 decreased gradually. These results confirmed that the relative reduction in the WVTR is due to increase in ZnO loading.

Commendable improvement in barrier properties of PVA/ graphene oxide (GO) composites were achieved through GO's homogeneous dispersion and effective interfacial contact with the PVA matrix (Kim and Macosko 2008). This investigation shows that GO is a useful nanofiller for creating nanocomposite materials with high barrier characteristics that significantly lower gas permeability. By combining highly orientated and aggregated nanoplatelets with polymer matrix, a gas barrier layer can be created that significantly improves the gas barrier properties of polymer films (Guo et al. 2012).

Ren Peng-Gang and colleagues created a PVA-based nanocomposite film with excellent gas barrier characteristics. Magnetic ferro-ferri oxide nanoparticles ($\text{Fe}_3\text{O}_4@\text{GO}$) were placed on GO sheets to prevent them from moving in a direction perpendicular to the film. The significance of magnetic nanofillers in the matrix is that, by applying magnetic field, gas barrier layer should arrange in the form of congregated network. Then, it was examined how the $\text{Fe}_3\text{O}_4@\text{GO}$ sheets in the PVA matrix affected the oxygen permeability. Oxygen permeability of congregated and oriented PVA/ $\text{Fe}_3\text{O}_4@\text{GO}$ composite films at GO loadings of 0.072 vol % and 0.290 vol % were 0.2126×10^{-15} and $0.1757 \times 10^{-15} \text{ cm}^3 \text{ cm cm}^{-2} \text{ s}^{-1} \text{ Pa}^{-1}$, respectively. In comparison to the neat PVA film, they were 99.0% and 99.2% lower. This work offers a quick and adaptable technique for producing high-barrier polymer nanocomposite films (Ren et al. 2017).

Benoit Van der Schueren et al. investigated the gas barrier properties of composite films containing few layer graphene (FLG) in PVA (Van der Schueren et al. 2020). The barrier properties were in agreement with the nonhomogeneous distribution of and specific arrangement of FLG into connected macroscopic network, with the oxygen transmission decreasing up to 60%, from 10.7 for pure PVA to $4.3 \text{ cc m}^{-2} \text{ day}^{-1}$ for series I-0.5% FLG, and close to this, to 4.5 and $4.7 \text{ cc m}^{-2} \text{ day}^{-1}$ for series II-0.3% FLG and series I-0.5% FLG. The composites exhibited slightly greater transmission at increasing FLG concentrations ($4.9\text{--}6.1 \text{ cc m}^{-2} \text{ day}^{-1}$), which also suggested that the network can expand in the plane rather than in the z direction as more FLG are added.

Poly Lactic Acid (PLA)

Goh et al. prepared sandwich – architected PLA-Graphene composite films and barrier properties were evaluated. The PLA-Graphene composite film was bound

with PVP solution. The PLA film has demonstrated good mechanical and physical qualities, but its water and gas molecule barrier properties are limited (Auras et al. 2003; Li et al. 2014). They used pressure-assisted filtration as a pretreatment technique since the produced rGO core barrier, which had a thickness of less than 5 nm, could not withstand surface abrasion. Polyvinylpyrrolidone (PVP), the binder utilized, is safe for human consumption. The synergistic sandwiched architecture provides good barrier properties and imparts mechanical strength to the composite film. The rGO film improves the barrier property, while the PLA films provide the necessary mechanical support. A 55–65 weight percent PVP binder is necessary for strong PLA–rGO adhesion that is free of delamination. To preserve the integrity of the rGO core barrier throughout the fabrication process, they optimized the concentration of the PVP binder to be at 65 weight percentage (Goh et al. 2016).

Anna J. Svagan et al. studied the Oxygen and Water Vapor Permeability through PLA-Montmorillonite/chitosan bilayer composite films (Svagan et al. 2012). OTR and WVTR were measured according to ASTM standard F2622–08 and E398–03, respectively. Examining the PLA films' multilayer coatings' oxygen barrier qualities, it was found that the OP significantly decreased as the number of bilayers increased. To avoid condensation, the relative humidity (RH) was set at 98% in the wet chamber and 10% in the dry chamber. Between 10 and 70, bilayers were present. The average OP value at 70 bilayers and 20% RH was only $0.255 \times 10^{-2} \text{ mL mm m}^{-2} \text{ day}^{-1} \text{ kPa}^{-1}$, which is significantly less than the value for the plain PLA film ($17.68 \times 10^{-2} \text{ mL mm m}^{-2} \text{ day}^{-1} \text{ kPa}^{-1}$). According to Anna J. Svagan et al., these are the lowest OP values for a PLA-/clay-based film that have ever been recorded. These are the lowest OP values for a PLA-/clay-based film. For comparison with clay loadings ranging from 0 to 10 wt%, Jin-Hae Chang et al. investigated the oxygen permeability tests of PLA-organic clay composite films (Chang et al. 2003). They discovered that with C16-MMT, DTA-MMT, and Cloisite 25A, the O_2 permeabilities dropped from 777 to $327 \text{ cc m}^{-2} \text{ day}^{-1}$, $330 \text{ cc m}^{-2} \text{ day}^{-1}$, and $340 \text{ cc m}^{-2} \text{ day}^{-1}$, respectively. All of the hybrids had oxygen permeability values that were less than half of those of the equivalent neat PLA. Higher clay content films appeared to be much more stiff, which reduced the films' ability to transmit gas.

Traditional PLA/clay nanocomposites typically exhibit a maximum 60% reduction in OP at clay addition levels of 5–10 wt% (0% RH, 23–25 °C) (Chowdhury 2008). A 95 and 90% reduction in OP at 20 and 50% RH, respectively, were accomplished by (Svagan et al. 2012) with PLA films coated with 40 bilayers of MMT/chitosan, which had a total clay content that was substantially lower than that needed for PLA/clay nanocomposites that had been prepared traditionally. These multilayer coated films have adequate oxygen barrier characteristics, making them interesting materials. The layer by layer (lbl) approach enables precise nanometer-scale customization of multilayer coatings.

Chitosan, an antibacterial and nontoxic substitute for the cationic polyelectrolytes, was used in the lbl process to create new multilayer-coated PLA films (Claesson and Ninham 1992). Due to a brick-wall structure of clay platelets and the compact layer structure of the adsorbed chitosan, the oxygen barrier qualities

have been successful. The robust molecular connection between MMT and chitosan is mediated by electrostatic forces and hydrogen bonds (Paluszkiwicz et al. 2011), because it binds the clay to the neighboring polymer and prevents oxygen from penetrating the interfacial polymer layers (Hedenqvist et al. 2006).

Christian Aulin et al. studied the Oxygen and Water Vapor Permeability of PLA/nanocellulose films (Aulin et al. 2013). According to ASTM D 3985–06, the oxygen transfer rate (OTR) of the PLA substrates coated by lbl technique was measured. The uncoated PLA film had an oxygen permeability of $151.5 \text{ cm}^3 \text{ m}^{-2} \text{ day}^{-1} \text{ atm}^{-1}$, while the PLA coated with 20 bilayers of polyethylenimine/nano-fibrillated cellulose (PEI/NFC) had an oxygen permeability of $49.3 \text{ cm}^3 \text{ m}^{-2} \text{ day}^{-1} \text{ atm}^{-1}$. When there were 50 deposited layers, oxygen permeability dropped even further, to $9.0 \text{ cm}^3 \text{ m}^{-2} \text{ day}^{-1} \text{ atm}^{-1}$. PLA, which has a water vapor permeability of $4.8 \text{ g m}^{-2} \text{ day}^{-1} \text{ atm}^{-1}$, improved its water vapor permeability by 30% when a 20 bilayer PEI/NFC coating was applied to it. By contrast, a 50-bilayer coating reduced water vapor permeability by around 50%.

Ningning Wang et al. studied the effect of lignin (LG) with and without bonding agent on the gas barrier properties of PLA films (Wang et al. 2021b). The oxygen permeability of the PLA/LG composite films, with or without the compatibilizer, was used to evaluate the barrier qualities of the composite films. The addition of LG limited the oxygen permeability (PO_2) of the neat PLA sheet. By adding 1 phr LG, the PO_2 was reduced by around 50%. The PLA/LG composites used two different compatibilizers – polylactide-graft-glycidyl methacrylate (PLA-g-GMA) and polylactide-graft-poly (ethylene glycol) methyl ether methacrylate (PLA-g-PEGMA), and they each had a different impact on the oxygen barrier properties. The LG content ranged from 1 to 5 phr. In comparison to PLA-g-GMA, PLA-g-PEGMA can improve the gas barrier performance of PLA and LG composites. Comparing both sets of composites with comparable LG content revealed that PLA/PLA-g-PEGMA/LG composites had improved barrier performance.

During the creation of the films, the LG particles served as nucleating agents to create tiny PLA crystals. These crystals enhanced the barrier properties of PLA/LG composite films because of their impermeable nature, which functioned as a barrier to gas diffusion. To date, most reports on how nanoparticles affect polymer crystallinity have focused on spherical particles (Niyom et al. 2019). The impact of the dispersed particles on nanocomposite gas transport properties was studied by Weigelt et al., and Sadhegi et al. (Weigelt et al. 2018; Sadeghi et al. 2018). Since PLA-g-PEGMA crystallizes more readily than PLA-g-GMA, composite films comprising the former demonstrated superior gas barrier characteristics. The amount of crystallinity in PLA/LG composites affects barrier characteristics more than other factors because the crystalline areas operate as hard regions that prevent gas molecules from penetrating and provide a tortuosity effect. PLA-g-PEGMA serves as both a nucleating agent and a compatibilizer between PLA and LG. Thus, in the presence of PLA-g-PEGMA, newly generated PLA crystals can fill the gaps between LG and act as continuous barrier layers.

PLA/LG composite films were prepared by melt-mixing process. The gas barrier properties of PLA/PLA-g-PEGMA/3LG showed superior gas barrier properties

compared to PLA/graphene oxide (Huang et al. 2014; Pinto et al. 2013) and PLA/montmorillonite composite films (Koh et al. 2008). The factors affecting gas transport performance of composite films are molecular structure and film formation conditions. The film formation process includes preparation method, solvent type in the casting and drying stages (Li et al. 2019).

Abstract

Biopolymers are polymeric materials which are derived from natural or biological resources. They are the upcoming opponent of synthetic polymers. They are diverse and versatile class of materials and have a wide range of applications in various fields. They have great interest in the scientific community due to their excellent properties such as ease of handling, reliability, biodegradability, etc. They can be used as adsorbents, lubricants, cosmetics, drug delivery, adhesives, etc. There are several widely used natural biopolymers, such as collagen, cellulose, starch, chitosan, chitin, etc., which are covered in this chapter, highlighting the studies on incorporation of nanomaterials, tissue regeneration, biocompatibility, and biodegradation. Additionally, this chapter discusses artificial biopolymer-based nanocomposites including poly(lactic acid)-, polyglycolic acid (PGA)-, and polycaprolactone (PCL)-based nanocomposites. In this regard, there are different types of fillers that have been used for the fabrication of the

resulting nanocomposites with natural or synthetic polymer matrix. These fillers include titanium dioxide (TiO₂), hydroxyapatite, zinc oxide (ZnO), silver nanoparticles, etc. depending upon the applications. In this chapter, we talk about the structural, morphological, and textural characteristics of these biopolymer-based systems using common characterization methods like scanning electron microscopy (SEM), Fourier transform infrared spectroscopy (FTIR), and X-ray diffraction and transmission electron microscopy (TEM), among others. In terms of biopolymer research and applications, the evolution of extremely sophisticated and integrated processes has endless promise.

Biopolymers · Chitosan · Cellulose · Polyglycolide · Polylactic acid · Biodegradability · Morphological

Introduction

Biopolymers are simple macromolecules which are usually obtained from naturally occurring organisms. These polymers are also formed by different chemical, physical, and biodegradable processes. Biopolymers can be categorized as natural or synthetic depending on their source (Hassan et al. 2019; Varma and Gopi 2021). Even though there are several advantages of using these biopolymers for various applications, the main interest towards these biopolymers is due to its biodegradability and increased environmental compatibility. In addition, the use of renewable resources offers an incentive to expand nonrenewable petrochemical supplies.

Natural biopolymers are generated from natural renewable resources and contain repetitive units like polysaccharides, proteins, and so on. They have outstanding characteristics like biocompatibility, nontoxicity, antimicrobial activity, biodegradability, renewability, low cost, light weight, and adsorption properties. Synthetic biopolymers are defined as polymers that are chemically generated from synthetic monomers or altered from natural polymers. The three main synthetic biopolymers are Poly(caprolactone), poly(glycolic acid), and poly(lactic acid). It undergoes natural degradation without remaining any residues which are harmful to the natural environments. In contrast, natural biopolymers are preferred over synthetic polymers because of their more biodegradable property.

Synthetic biopolymers have great attention over the last few years, due to their distinct features over natural biopolymers in terms of stability and flexibility suitable for a wide variety of applications. These biopolymers found significant applications in the medical field, because of their exclusive properties like controlled release, nonimmunogenicity, stability, and clearance from the body, which are suitable for their application in human body. They are now preferred as a source for medical devices and supplies, due to their high stability compared to natural polymers during transport, formulation, and use. Owing to these advantages, these biopolymers are broadly used in gene therapy, implanted devices, regenerative medicine, tissue

engineering, novel drug delivery systems, and in many other products (Thomson et al. 1995; Engelberg and Kohn 1991; Nair and Laurencin 2006).

Proteins are large macromolecules which are made up of a combination of amino acids. They are amphiphilic biopolymers. It can be classified on the basis of plant proteins and animal proteins. They are nontoxic and biocompatible and also have strong affinity to bioactive compounds through various molecular interactions such as hydrogen bonds, hydrophobic interactions, and π - π interactions (Park et al. 2017). Monomeric units of monosaccharides are repeated to form polymeric carbohydrates known as polysaccharides. Through glucosidic linkage, they are covalently joined (Liu et al. 2018). Mainly, there are two categories of polysaccharides: those of a plant or animal origin. Starch, cellulose, etc. are of plant origin, and chitin and chitosan are of animal origin, respectively. Polysaccharides act on membranes and intracellular communication, as adhesives, as emulsifiers, as capsular layers, or as protective barriers around cells (Kaplan 1998).

This chapter discusses the structural, morphological, and textural properties of some important biopolymers. For the structural and morphological investigations of biopolymers, a variety of analytical methods like Fourier transform infrared spectroscopy (FTIR), transmission electron microscopy (TEM), scanning electron microscopy (SEM), etc. are used. These extremely advanced methods ensure success in the study of biopolymers as well as in a variety of applications. Therefore, this chapter deals with some of the representative examples of the surface and structural properties of biopolymers which are categorized as natural and synthetic biopolymers.

Natural Biopolymers

Natural biopolymers are materials that are usually found in nature. They may be also defined as biological macromolecules, produced by living organisms. They have a lot of benefits like bioactivity, nature remodeling, and the capability to introduce receptor-binding ligands to cells. The main applications of natural biopolymers are in different fields such as in ophthalmology, dentistry, cardiovascular tissue regenerations, orthopedics, etc.

Collagen

Collagen is the primary building block of vertebrates making up about 20–30% of the total body protein of mammals. It is a fibrous protein, and the individual molecules were threadlike structure. They were arranged together to form a continuous framework all through the body (Harkness 1961). It is a rod-shaped molecule with an approximate molecular weight of 300 kDa, with a length and width of about 3000 and 15 Å [6] (Lee et al. 2001). Collagen appeared in the early stages of development in ancient animals like corals, jellyfish, and sea anemones. By using fibroblasts, collagen is synthesized, which generally arises from reticulum cells or

Fig. 1 Chemical structure of collagen

pluripotent adventitial cells. The collagen molecule has a distinctive size, structure, and amino acid sequence. It is made up of three polypeptide chains entwined to form a three-stranded rope (Fig. 1; Teruo and Taira 1992; Rao 1995). There is an individual twist in opposite directions in every chain. The accumulation of amino acid residues and glycine interfered with the development of helical strands. Covalent bonds and hydrogen bonding between adjacent -CO and -NH groups held these strands together. It can be refined into various forms such as gels, sheets, and sponge, and it can be cross-linked with chemicals or undergo physical treatments to change its degradation rate and to strengthen it. The most common structural characteristics of collagens are the presence of a triple-helical structure with a length of 300 nm. The triple helix structure comprises a rodlike structure, which is significant for fibril formation and structural integrity. It also interacts with a broad range of molecules essential in extracellular matrix organization and function (Brodsky and Ramshaw 1997). There are 29 different kinds of collagen in the human body. The range of collagen types is type I through type IV. The protein that is most prevalent in mammals is type I collagen. Three polypeptide subunits of type I collagen exhibited comparable amino acid contents. All polypeptide units had roughly 1050 amino acids, with a proline-, glycine-, and hydroxyproline-to-lysine ratio of about 25%, 33%, and 25%, respectively. Collagen fibrils of types I and V contribute to the structural framework of the bone, whereas those of types II and XI are mostly found in the fibrillar matrix of articular cartilage (David et al. 1988; Richard Mayne 1989; Mark et al. 1984). Mainly two major groups of collagens are present: fibrillar collagen and non-fibrillar collagen. It is classified based on the variations in structure, location, and properties (Ricard-blum 2011; Sorushanova et al. 2018). Fibrillar collagen forms fibrils which constitute around 90% of all collagen presented in the human body. Non-fibrillar collagen is very much different based on structure, properties, and location. Even though it contains only 10% of the collagen in the human body, it is an important part of many organs (Gelse et al. 2003; Mienaltowski and Birk 2014; Holmes et al. 2018). Collagen fibers were connected to form a macrostructure at the nanoscale, as seen in Fig. 2's cartoon representation of the

Fig. 2 Cartoon structure of collagen showing the packing (Francis et al. 2014)

collagen fiber structure. Single strands combine to form triple helices, which are then strung together to form fibers and bundles.

According to Astbury and Bell's 1940 theory, the collagen molecule is made up of a single prolonged polypeptide chain with amide groups in the *cis* transformation (Astbury and Bell 1940). They made important progress into the structure of the beta-helix and beta-sheet, while Polling and Cory simultaneously presented a structure for collagen (Linus Pauling 1951). Three polypeptide strands are kept together in a helical conformation by hydrogen bonds in that structure. Two of the three peptide bonds and four of the six main chain heteroatoms involved in the hydrogen bond for each amino acid tripod are required for the development of the structure. Using X-ray diffraction, Ramachandran and Kartha conducted a thorough investigation of the structure of collagen fibers in 1954 (Ramachandran and Kartha 1954, 1955). The size, function, and tissue distribution of various kinds of collagen vary significantly (Gelse et al. 2003).

Collagen-based materials have gained much interest in repairing and replacement of body tissue like heart valves, bones, skin, dentals, vascular grafts, and tendons. There are some general properties that make collagen an interesting biomaterial, such as biocompatibility, hydrophilicity, low antigenicity, its suitability as a substrate for cell growth, high mechanical strength of the fibers, and tunable stability by chemical or physical cross-linking. But it also suffers from some poor physicochemical properties such as mechanical strength, thermostability, and resistance to enzymes. As compared to other biopolymers, collagen is the most important constitutive protein that plays a vital role in the formation of the fundamental building block of connective tissues, and its metabolism correlated with many physiological processes of biological adaptations and tissue regeneration.

There are several works reported based on collagen, like hydrogels, composites, films, etc. Here, Ficaí and his colleagues used a self-assembly approach to create a collagen/hydroxyapatite composite material. The starting components for the *in vitro* mineralization process are collagen and hydroxyapatite precursors. It was shown that by utilizing this method, it was possible to produce composite materials with

Fig. 3 FTIR spectrum of COLL/HA composite material. (Reproduced with permission from (Ficai et al. 2010))

different morphologies and compositions. The collagen fibers that were produced do not exhibit any orientation (Ficai et al. 2010). The main constituents of the bone tissue are hydroxyapatite and collagen (Sukhodub et al. 2004). The bones acquire their unique mechanical, physical, and chemical properties through the self-assembling process of the organic phase, particularly collagen, the mineral phase hydroxyapatite, and water (Wahl and Czernuszka 2006). The production of these composite materials, which provide structural and chemical similarities to the bone, was the work's primary point of distinction.

FTIR spectrum of COLL/HA composite materials was shown in Fig. 3. The interferogram shows the characteristic peaks of collagen and hydroxyapatite. The characteristic peaks of collagen are obtained in the regions as follows: 1650 cm^{-1} corresponds to amide I, CO , 1550 cm^{-1} which corresponds to NH stretching and C-N bending (amide II); C-N band appears at 1417 cm^{-1} ; and amide III (C-N bending and N-H stretching) vibrations are obtained at 1241 cm^{-1} . The peaks at 2859 cm^{-1} , 2927 cm^{-1} , and 2957 cm^{-1} represent the asymmetric and symmetric stretching vibrations of CH_2 and CH_3 , respectively. The OH stretching vibration is obtained at $3000\text{--}3500\text{ cm}^{-1}$. The main peaks of hydroxyapatite are also shown. There is a peak at 957 cm^{-1} , 565 cm^{-1} , 605 cm^{-1} , and 641 cm^{-1} which corresponds to P-O stretching, O-P-O bend, and triple degenerate. The existence of carbonate group in the composite materials was confirmed by the absorption bands obtained in the region at 1336 cm^{-1} and 872 cm^{-1} corresponding to $(\text{v}_3\text{CO}_3^{2-})$ and $\text{v}_2\text{CO}_3^{2-}$.

Fig. 4 SEM pictures of collagen/hydroxyapatite composite materials, captured at various magnifications including (a) parallel view with the fibers, (b–c) perpendicular view with the fibers, (d) high-resolution SEM at 80,000 \times magnification. (Reproduced with permission from (Ficai et al. 2010))

SEM images were shown in the figure at different magnifications. Fig. 4 shows a homogeneous arrangement of the fibers. A highly oriented fibers and fiber bundles were observed in the figure. Figure 4b, c images are recorded in fiber's parallel profile. There is a homogeneous arrangement observed in the fiber's parallel profile. While viewing the rupture profile, a shift was observed between the rupture points as compared with the neighboring adjacent layers. Figure 4c clearly depicts the mineral deposition, and the image was viewed at a higher magnification. It is evident that the HA density is higher at the end of the collagen fiber. The heavily mineralized zone of the interfibrillar gap, which is present at the ends of two subsequent fibers, looks to be followed by the rupture profile. When looking at a higher magnification, HA crystals are produced which are in the nanometric range (4–40 nm) and have an enlarged shape.

It should be noted that collagen fibers are destroyed as the sample is prepared, and TEM can only visualize collagen molecules and fibrils (Fig. 5). The collagen molecules and fibrils are attached to hydroxyapatite nanoparticle in an elongated form.

Another major work based on hybrid collagen scaffolds was reported by Kalirajan et al. (2022). They synthesized a novel hybrid collagen scaffold, which

Fig. 5 TEM image of mineralized COLL/HA composite material. (Reproduced with permission from (Ficai et al. 2010))

is prepared by using oxidized inulin (OI) and zirconium dioxide (ZrO_2) nanoparticles. Hybrid biomaterials with metal nanoparticles and active ingredients are becoming more interesting due to their increased wound healing capacity. Here, they hypothesize that oxidized inulin acts as biocompatible cross-linker by interacting with amino groups of collagen molecules. The strength of synthesized collagen scaffolds was increased after the incorporation of ZrO_2 nanoparticles which was used in skin and bone tissue engineering applications. The pore size of the collagen scaffolds is smaller, whereas the hybrid collagen scaffolds show a bigger size, which was confirmed from morphological studies. This is due to the combined effect of the collagen solution's enhanced viscosity following its interaction with oxidized inulin and the presence of ZrO_2 nanoparticles. There is no alteration in the amide I band which is clear from the FTIR spectra. It also reveals that the interaction of ZrO_2 nanoparticles and oxidized inulin did not affect the triple-helical structure of the collagen. This result confirmed that the hybrid scaffolds were obtained with unaltered secondary structure of the collagen.

Collagen-based hydrogels have gained popularity as biomaterials in biomedical engineering over the past few decades as cell or drug transporters, medical implants, and three-dimensional (3D) scaffolds (Mei et al. 2019; Branco et al. 2014; Sun et al. 2017). Zhang and his co-workers described a straightforward method to create a multifunctional hydrogel out of collagen, poly(N-isopropylacrylamide), guar gum, borax, and graphene oxide (GO), by expanding both the reversible and permanent networks (Zhang et al. 2021). The obtained hydrogels (COL-GG-PNIPAMs) display desirable properties, comprising processability, remoldability, and injectability.

From the SEM images, it was confirmed that the synthesized hydrogels exhibit a 3D interconnected porous network structure without any agglomeration of GO particles. The thermal studies demonstrated that the thermal stability also improved for the collagen-based hydrogels.

Cellulose

Cellulose, a polysaccharide and a linear naturally occurring polymer of β -(1 \rightarrow 4)-d glucopyranose, acquires a significant number of hydroxyl groups on its surface, in order to create inter- and intramolecular hydrogen bonds. It is comprised of repeating glucose units $(C_6H_{10}O_5)_n$ (French 2017). It is a key structural element of the principal cell walls found in plants, oomycetes, and various types of algae. The cellulose is mechanically strengthened by the plant cells' cell walls (Khandelwal and Windle 2013). It is able to maintain the semicrystalline state of aggregation while still in aqueous environment, which is rare for polysaccharides. It is a homopolymer of glucose derivative and also an excellent source of fermentable sugar. It is a water-insoluble polymer and also a semicrystalline material. Based on its origin, pre-treatment, and extraction method, the degree of crystallinity was measured. In the cellulose structure, each glucose residue has three hydroxyl groups. The degree of polymerization ranges from 1000 to 15,000 depending on the glucose units. The link is stabilized by intra-hydrogen bonding between the cellulose molecule's hydroxyl groups and the nearby oxygen group. As a result, cellulose chains took on an unbranched shape (Agoda-Tandjawa et al. 2010). These molecules were found in parallel layers organized as primary fibrils (1.5–3.5 nm in diameter) in the tunicate cell walls of algae, plant cell walls, epidermal cell membranes, and bacteria. Van der Waals forces and/or strong intra- and/or intermolecular hydrogen bonds hold the cellulose chains together, giving them a lateral dimension of 3–5 nm. Each elementary fibril is made up of a cluster of cellulose crystals that alternate with irregular domains along the fibril axis. These basic fibrils bundles contain cellulose microfibrils with a cross-sectional width of 5–20 nm and a length of different micrometers, depending on their origin.

Cellulose exists naturally or separated from different sources by some pre-determined shape and dimension. It can be classified into cellulose filaments, cellulose fibers, cellulose micro/nanofibrils, and cellulose crystals. Every cellulosic particle has a specific size, crystallinity, aspect ratio, morphology, and physicochemical properties (Seddiqi et al. 2021). It is the main component of plant fibers enclosed by hemicellulose and lignin. Cellulose chains are organized into fibrils in plant cell walls forming microfibrils of a few nanometers in diameter. Figure 6 shows the ordered arrangement of microfibrils (Joseph et al. 2020).

Cellulose in nanometer size range (10 nm–50 nm) is known as nanocellulose (NC). They have a wide range of applications because of their distinctive properties like low density, biodegradability, and good mechanical properties. Adil et al. reported the isolation of nanocellulose from flaxseed hull by acid hydrolysis. FTIR spectra of cellulose nanocrystals (CNC) were shown in Fig. 7 (Farooq et al. 2020).

Fig. 6 The hierarchical structure of the cellulose found in plants and trees ranges in size from meters to nanometers, as shown in (a). Reproduced with permission from Multidisciplinary Digital Publishing Institute (MDPI) (Miyashiro et al. 2020)

Fig. 7 FTIR spectra of the CNC. (Reproduced with permission (Farooq et al. 2020))

The spectrum reveals that the nanocrystals exhibit a wide band observed around 3400–3500 cm^{-1} , depicting the OH stretching vibrations of cellulose from adsorbed water (Orasugh et al. 2018). The aliphatic saturated (CH_2) stretching vibrations in cellulose and hemicellulose are shown by the peaks at 2920 cm^{-1} . Due to the presence of lignin, another peak was produced in the region at 1627 cm^{-1} that is associated with the C-C vibration. The peak at 1458 cm^{-1} depicts the C-O stretching vibrations, and in addition there is another peak at 1160 cm^{-1} ascribed to the C-O-C stretching of CNC (Rani et al. 2019).

The surface morphology was measured using scanning electron microscopy (SEM) (Fig. 8). CNC acquires a granular surface morphology where individual particles are attached to one another with some agglomerations. Further research using TEM revealed in Fig. 9 that the flaxseed hull fraction-derived CNC featured a

Fig. 8 SEM micrograph of CNC. (Reproduced with permission (Farooq et al. 2020))

Fig. 9 TEM images of (a) CNC film and (b) granular crystal obtained on CNC films. (Reproduced with permission (Farooq et al. 2020))

film-like surface made up of spherical grains that was visible under magnification. The granules of nanocrystals had an average particle size of 6.28 nm.

The textural and surface morphological evaluations were determined using nitrogen adsorption-desorption isotherms. N_2 adsorption-desorption isotherms were attained and shown in Fig. 10. The figure illustrates that the isotherm is type II b according to the classification by Brunauer and his co-workers. The IUPAC depicts the collection of nonporous granules (Stephen et al. 1940). The pore size distribution of CNC was shown in Fig. 11. The CNC's pores were tiny, and an average pore volume of $0.2 \times 10^{-3} \text{ cm}^3/\text{g}$ was noted.

Natural carbohydrate biopolymers with enough hydrophilic groups include cellulose and compounds generated from it (Sarkar and Singh 2017; Sabzalian et al.

Fig. 10 Nitrogen adsorption-desorption isotherms for the CNC. (Reproduced with permission (Farooq et al. 2020))

Fig. 11 Pore size distribution of CNC. (Reproduced with permission (Farooq et al. 2020))

2014; Jeong et al. 2018). Owing to its excellent properties such as biodegradability, low cost, and abundant sources, these materials were extensively applied for expanding superabsorbent hydrogels (SHs) (Mignon et al. 2019; Fekete et al. 2014). Sodium carboxymethyl cellulose (CMC-Na) is more soluble in water than cellulose and can create a hydrogel when combined with distilled water. Using sodium carboxymethyl cellulose (CMC-Na), acrylic acid (AA), and 2-acrylamido-2-methylpropanesulfonic acid, Guo and colleagues created a superabsorbent hydrogel (AMPS). In locations with drought and salty soil, it is mostly utilized for soil

conditioning applications that need water absorption and salt tolerance. This work presents a novel process that generated cellulose-SH by exchanging AMPS with CMC-Na. FTIR spectroscopy was used to examine the CMC-Na hydrogel's structural characteristics. The characteristic peaks were obtained after the addition of CMC-Na and AA with different ratios. The results demonstrated that the CMC-Na had been attached onto the polymers. From the morphological studies, grafting of CMC-Na onto polymer chains exhibited a porous anatomy. The size and density of the pores were varying and also irregular. The presence of cavities in the hydrogels confirms the water absorbency capacity. The hydrogel's pore structure became more compact and dense as the concentration of CMC-Na rose and the amount of AMPS reduced. The swelling study also confirms that the CMC-Na graft was successfully grafted onto the structure of hydrogels (Guo et al. 2022).

Starch

Starch is a biopolymer of anhydroglucose units which is linked by $\alpha \rightarrow 4$ linkages and is also a special form of carbohydrate. It is one of nature's energy sources, and it is one of the cheapest biodegradable polymers. This is one of the most abundant naturally occurring biopolymers (Shrestha and Halley 2014). The carbohydrate is stored in various plant parts such as in the roots, pollen seeds, fruits, leaves, cereal grains, tubers, and stem piths. It appears as distinct granules and varies in size and shape based on the botanical source. The physical characteristics, organization, and the chemical composition are also basically common of the biological origin of the starch. It is semicrystalline, water-insoluble, and dense in the granule form. It contains only a small amount of water, so a large amount of carbohydrates is stored in small volume. It is largely extracted from wheat, rice, corn, and potatoes. It is made up of generally two polysaccharides especially amylopectin (100–400,000,000) and amylose (molecular weight of up to 2,000,000) (Fig. 12). The D-glucose units that make up these molecules number in hundreds or thousands. They are linked by α -D-(1 \rightarrow 4) and α -D-(1 \rightarrow 6) glucosidic connections to create linear polymer chains (amylose) and branching chains (amylopectin), respectively. Glucose is the basic building block in both molecules. These molecules may be small amounts of proteins, phosphorus, lipids, and some minerals (Tester et al. 2004). Most plants contained between 70 and 85 percent amylopectin and between 15 and 30 percent amylose. The size of both starch granule molecules, however, can be greatly impacted by mutations that influence starch production.

Amylopectin is the highly branched component of starch, whereas amylose is the linear or barely branched component. Amylose is significantly smaller than amylopectin. The amylose and amylopectin molecules are arranged in the starch granules in a well-ordered manner, which gives the granules their crystallinity. Because of the hydroxyl groups on the granule surface, these starch granules exhibit hydrophilic characteristics and a significant intermolecular contact through hydrogen bonding (Johnson et al. 2003).

Fig. 12 Structure of amylose and amylopectin

The morphological characteristics of starches derived from various plant sources vary depending on the genotype and cultural practices. The biological origin of starch granules influences their variety in shape and size. It depends on the physiology of the plant and the biochemistry of the chloroplast. Scanning electron microscope (SEM) was used for characterizing the morphological studies. From SEM analysis, it was observed that the granular structures of various plants such as potato, rice, wheat, and corn illustrate major variations in size and shape. SEM images of the starch granules from different plants were shown in Fig. 13. The typical granule size for little potato starch ranges from 1 to 2 mm and from 20 to 110 mm for large potato starch, according to the SEM image. It has been observed that potato starch granules were irregular and oval or cuboidal in shape. The granule size of rice was in the range from 3 to 5 mm, and it appeared as pentagonal- and angular-shaped. The typical granule size and form of maize starch are angular and range from 1 to 7 mm for tiny granules and from 50 to 20 mm for large granules. Two different forms of starch granules – the large A- and little B-type – were found in wheat starch. A-type granules typically range in size from 10 to 35 mm and have a disclike or lenticular form. In type-B starch granules, the size is ranging from 1 to 10 mm in diameter, and they appeared as roughly spherical or polygonal in shape. According to the SEM study, the surfaces of the granules made of rice, wheat, and corn were smoother than those made of potato starch (Singh et al. 2003).

The production of biodegradable, renewable, and environmentally friendly materials has greatly benefited from the use of starch and its nano-derivatives. Starch nanocrystals (SNC) have been extensively used in different fields because of their biodegradability, biocompatibility, availability, low price, renewability, and good biosafety. The diameter of potato starch nanocrystals was about 40–70 nm, pea SNC was about 30–150 nm, and the waxy corn SNC was 50–100 nm (Chen et al. 2008b; Chen et al. 2008a; Yu et al. 2008). Sai Li and his co-workers synthesized

Fig. 13 SEM images of starches from several sources that have been separated (bar = 10 mm): (a) rice, (b) wheat, (c) potato, and (d) corn. (Reproduced with permission from (Singh et al. 2003))

graphene-SNC nanocomposite films which are made by merging reduced graphene (RGO) and starch nanocrystals (SNC). The microstructure and morphology of the composite film were significantly impacted by SNC, which also had a greater influence. Starch's large number of functional groups can offer the GO strong interaction sites for binding. The composite materials with 10% RGO-SNC (front view) were observed as a plain sheet of RGO with a wrinkled structure on the surface based on morphological analyses. SNC was uniformly dispersed in the matrix. The diameter of SNC particles was altered with a small diameter of about tens of nanometers and a large diameter of about 200 nm. The reason was due to the aggregation of some SNC particles. The cross-sectional morphology of 10% RGO-SNC reveals that a small amount of granules between the layers and also a clear and thick layered structure were observed. From this it is confirmed that the SNC is incorporated between the layers of graphene. Using FTIR studies, the characteristic peaks of SNC were observed at 340 cm^{-1} , depicting the O-H stretching vibration. The starch's C-H stretching vibration, O-H bending vibration, and hydroxyl group stretching vibration are represented by the other significant peaks found at 2942, 1640, and 1022 cm^{-1} , respectively. Another peak at 2942 cm^{-1} ascribed to the CH_2 stretching vibration for 10% GO-SNC confirms the successful combination of GO and SNC. This study showed that the inclusion of SNC didn't

prevent GO decrease and that its incorporation enhanced the electrical and mechanical capabilities of the composite membranes.

Chitosan

Chitin has been partially deacetylated to generate the linear polymer known as chitosan. Additionally, it is a copolymer made up of units of β -(1 \rightarrow 4)-2-acetamido-D-glucose and β -(1 \rightarrow 4)-2-amino-D-glucose. It is a crystalline, cationic, hydrophilic biopolymer with exceptional gelation and film-forming capabilities. The deacetylation process is comparatively severe, and it contains the removal of acetyl groups from the chitin molecular chain and the removal of complete amine groups (NH_2) after prolonged treatment with concentrated NaOH. Chitosan was prepared by mainly four major steps from crustacean shells which are (1) demineralization, (2) deproteinization, (3) decoloration, and (4) deacetylation which is demonstrated in Fig. 14a. Chitin includes 5–8 percent (w/v) N_2 , in the form of primary aliphatic amino groups similar to those found in chitosan, depending on the degree of deacetylation (Dutta et al. 2004). Chitosan has the highest metal coordinating ability of all natural polymers in adsorption because it contains reactive primary, secondary, and amino/acetamido functional groups (Prashanth and Tharanathan 2007; Begum et al. 2021). Chitosan is insoluble in the majority of organic solvents and is only soluble in diluted acids such as hydrochloric acid (HCl), acetic acid, and formic acid (Islam et al. 2017; Younes and Rinaudo 2015).

Due to its superior qualities, chitosan-based materials in various forms, such as nanoparticles, nanocomposites, and hydrogels, have been used in biomedical

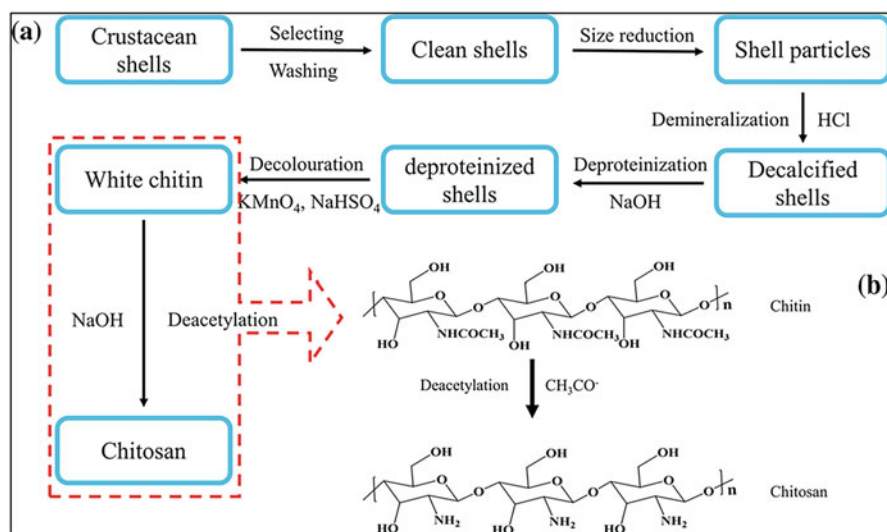

Fig. 14 Schematic for the preparation of chitosan. (Reproduced with permission (Liu et al. 2022))

applications. These attributes include nontoxicity, antifungal, biocompatibility, and anti-tumor activity (Safari et al. 2015; Xue et al. 2015; Ali and Ahmed 2017). It is an outstanding material for medical, cosmetic, and pharmaceutical applications and the preservation of agricultural products (Ibrahim et al. 2020a; Ibrahim et al. 2020b). It is also used in food industry, wastewater treatment, and many other industrial applications (Argu et al. 2006). The major plus point offered by chitosan-based nano-encapsulations is the ability to improve the solubility rate of poorly soluble drugs, thus increasing their bioavailability. This ability relies upon the particle size and specific properties of chitosan, which makes this polymer a suitable drug carrier. One of the major works in the field of composite scaffolds was reported by Olad and his collaborators. The synthesis was carried out using chitosan/gelatin/nano-hydroxyapatite-montmorillonite by means of freeze-drying method for tissue engineering applications. After the mixing of nano-hydroxyapatite and montmorillonite, the swelling behavior of the composite was decreased. The invention of nano-hydroxyapatite and montmorillonite barriers, which controlled the water molecules without allowing them to enter the composite structure, was largely responsible. Additionally, the hydrophilicity of gelatin was reduced by the presence of nano-hydroxyapatite and montmorillonite by joining calcium and phosphate with hydrophilic groups like NH_2 or $-\text{COOH}$ that are present on the gelatin backbone structure (Olad and Azhar 2014).

Menazea et al. reported a new, simple, low-cost, cost-effective antimicrobial composite based on chitosan loaded with different amounts of tigecycline (TIGE) using casting method (Menazea et al. 2020). The US Food and Drug Administration has approved the tetracycline derivative TIGE, which has a low toxicity (FDA) (Bai et al. 2018). They are widely used in antibacterial composites for the treatment of different bacterial infections. The obtained composite materials were characterized by various techniques like FTIR, SEM, etc. FTIR of pure chitosan tigecycline drug and the composite of CS/TIGE in five different ratios were shown in Figs. 15 and 16. A broad peak obtained in the region at 1650 cm^{-1} , 1600 cm^{-1} , and 1640 cm^{-1} corresponds to amide I from chitosan, TIGE, and the composite, respectively. The NH vibration of amide II is obtained at 1560 and 1533 cm^{-1} for CS and TIGE and the composite. The other major peaks of chitosan were at 1405 , 1316 , 1079 and 1038 cm^{-1} depicts the CN stretching, CH_3 (Amide II), C-O-C stretching and CO stretching vibrations. In the composite material, there is a band that disappeared, and other bands were shifted to 1425 , 1086 , and 1018 cm^{-1} in the same arrangement. But the characteristic peak of CS has not been shifted for the composite material. A new peak obtained in the region at 1709 cm^{-1} corresponds to C-O stretching vibrations (Mansour et al. 2017). The reason is because the positively charged amino groups of TIGE and the negatively charged groups of chitosan interact ionically (Faneca et al. 2011).

The morphological studies were carried out using FESEM. SEM images of pure CS, chitosan doped by different concentrations of TIGE such as CS/TIGE1, CS/TIGE3, and CS/TIGE5 samples, was shown in Fig 17 respectively. The pure CS films show a homogeneous nature as already reported in literature (Fig. 17a). In Fig. 17b, at the low doping (CS/TIGE1), the homogeneous film begins to acquire a

Fig. 15 FTIR spectrum of pure chitosan and TIGE. (Reproduced with permission (Menazea et al. 2020))

small amount of white bright TIGE that is dispersed across the sample's surface. These white brights were increased as the concentration of TIGE was increased which is clearly observed in Fig. 17c. But in Fig. 17d, TIGE concentration was increased; some aggregates were observed due to the agglomeration in certain parts in the samples.

The crystallinity studies and the complexation behavior were recorded using XRD analysis. Figure 18 shows the XRD pattern of pure chitosan and tigecycline at 2θ ranging from 5° to 60° . In the XRD pattern of CS, two distinctive broad hump peaks at 9° and 22° were observed (Mohseni-Bandpi et al. 2015; Choo et al. 2016). And the XRD pattern of TIGE also shows peaks at 7° and a broad hump peak at 21° (Ignjatovic et al. 2010). The XRD pattern of CS doped with different concentrations of TIGE showed that the crystallinity was enhanced after the addition of TIGE (Fig. 19). The intensity of the CS peaks was lowered after the incorporation of TIGE content, which shows the interaction between CS and TIGE.

Chitosan-based hydrogels have received a lot of attention recently for use in biomedical applications, but cross-linking them effectively and safely still poses significant difficulties. Chitosan-based hydrogels were created by Dziadek et al. and cross-linked with 2,3,4-trihydroxybenzaldehyde (THBA). Pectin, rosmarinic acid, and bioactive glass were then added (BG). 2,3,4-Trihydroxybenzaldehyde, a

Fig. 16 FTIR spectrum of chitosan doped by different concentrations of TIGE. (Reproduced with permission (Menazea et al. 2020))

phenolic monoaldehyde, was employed for the first time as a cross-linking agent in CS-based hydrogels for potential uses in tissue engineering. THBA acted as a cross-linker, resulting in enhanced mechanical properties, delayed degradation, and high swelling capacity, and it also performed high antioxidant activity and anti-proliferative effect on cancer cells without cytotoxicity for normal cells. The morphological studies reveal that the obtained hydrogels possess irregular highly porous morphology obtained using freeze-drying method. All the materials exhibited sheet- or spongelike structures. As compared to the uncross-linked hydrogels, the pores of cross-linked materials appeared to be smaller. This is due to the lesser amounts of water entrapped between cross-linked CS chains (Dziadek et al. 2022). The hydrogels had pore mostly in the range of 50–150 μm which was confirmed from pore size distribution method and also SEM observations. According to the results, hydrogels are promising multifunctional biomaterials with a wide range of customizable physicochemical and biological properties that have a lot of potential for usage in a variety of tissue engineering fields.

Chitin

Chitin is a natural polysaccharide. It is an abundant biopolymer found in the exoskeleton of crustacean, algae, insect's cuticle, and in the cell wall of fungi. It is

Fig. 20 Structure of chitin

the deacetylated form of chitosan. It is made up of $\beta(1\text{--}4)$ -linked with acetamido-2-deoxy- β -D-glucose. Chitin is nearly identical to cellulose because it has acetamide groups at the (--NHCOCH_3) C-2 locations. The structure of chitin is shown in Fig. 20. The main commercial sources of chitin are shrimp, crab, krill, and lobster. Crustacean chitin is highly connected with minerals, lipids, pigments, and proteins. Industrially chitin extraction involves three steps: (i) deproteinization to remove proteins using aqueous solutions of carbonate, sodium hydroxide, sulfide, sulfite, hydrogen sulfite, potassium hydroxide, carbonate, and calcium hydroxide; (ii) demineralization to remove calcium carbonate using HCl and other acids such as acetic, nitric, sulfuric, and formic acid (No and Hur 1998; Younes and Rinaudo 2015; Percot et al. 2003); and (iii) decolorization to remove pigments with acetone, ethanol, bleaching hydrogen peroxide, etc. (Laurienzo 2010).

Due to its biocompatible, biodegradable, nontoxic, and mucoadhesive qualities, it has been assessed for many applications in the medical, food, chemical, pharmaceutical, and agricultural industries. It is one of the strongest materials for future applications, in competition with petroleum-based polymers. Chitin-based materials have a wide range of applications in various fields. Chitin and its derivatives can be safely applied to both animals and humans. For medical applications, a wide variety of chitin-based products are available, such as porous beads, nonwoven fabrics, finely divided powder, lyophilized soft fleeces or gels, transparent films, laminated sheets, and porous beads (Yang 2011). Kumar and his co-workers synthesized and characterized β -chitin/nanosilver composite scaffolds by using β -chitin hydrogel and silver nanoparticles which are used for wound healing applications. These nano-silver/chitin composite scaffolds have been shown to have antibacterial characteristics after being exposed to *S. aureus* and *E. coli* (Kumar et al. 2010).

Silver molybdate nanoparticles were created in situ in the chitin matrix's microporous structure, which served as a reaction chamber for the creation of $\text{Ag}_2\text{Mo}_2\text{O}_7$ nanoparticles, according to Tang et al. (Tang et al. 2013). CGM networks were made by dissolving chitin in a NaOH/urea aqueous system at -30°C and then cross-linking it with epichlorohydrin. Utilizing a number of different techniques, the produced composite materials were characterized. SEM was used to examine the morphology of the resultant composite materials. Figure 21 shows the SEM image of the $\text{Ag}_2\text{Mo}_2\text{O}_7$ /chitin composite membranes. The CGM displays three-dimensional, porous, stiff, and linked structures. The obtained CGM films had pores with an average size of about 41 nm, which suggests that they had a microporous structure. To form the large pore structure of CGM, the semi-stiff molecular chitin chain significantly contributes to strengthening the pore wall in the gel membrane. In other words, the chitin chains' rigidity supported the hole's wall, allowing it to

Fig. 21 SEM images of the CGM (a), Ag001 (b), Ag005 (c), Ag01 (d), Ag02 (e), and EDS spectrum (f) from SEM. (Reproduced with permission (Tang et al. 2013))

absorb more water and produce huge pores. As the CGM dried, the size of the pores in the gels rapidly shrank as the heavy water was expelled from the pores (Liu and Zhang 2009). As a result, it is simple to create and immobilize $\text{Ag}_2\text{Mo}_2\text{O}_7$ nanoparticles in chitin matrices. The micropores found in the chitin membrane were regular and had a thin wall, as shown in Fig. 21a. $\text{Ag}_2\text{Mo}_2\text{O}_7$ nanoparticles were filled in the pores of chitin matrices, for the composite membranes (Fig. 21b–e). As the concentration of AgNO_3 increases from 0.001 to 0.02 mol L⁻¹, more $\text{Ag}_2\text{Mo}_2\text{O}_7$ nanoparticles were synthesized, and the $\text{Ag}_2\text{Mo}_2\text{O}_7$ was formed as thicker nanofibers (Kato 2010).

EDS was an analytical method for determining the chemical composition of solid materials. EDS spectrum (Fig. 21f) of the composite membranes was obtained via FESEM. It demonstrated the coexistence of C, O, Ag, and Mo components in the composite membrane, confirming the existence of $\text{Ag}_2\text{Mo}_2\text{O}_7$. As a result, the porous chitin matrix was used as a platform for the in situ synthesis of the nanocomposite membranes.

FTIR spectrum of the CGM and AgO_2 composite membranes were demonstrated in Fig. 22. Chitin's major peaks can be seen at 3430 cm⁻¹, 3270 cm⁻¹, 1660 cm⁻¹, 1623 cm⁻¹, and 1557 cm⁻¹, which correspond to N-H bending vibrations, O-H stretching vibrations, and N-H stretching vibrations (amide I, amide II) (Dong and Ozaki 1997). The hydroxyl and acetyl groups in the AgO_2 composite membrane change typically, from 3430 and 1660 cm⁻¹ to 3420 and 1650 cm⁻¹, respectively. The stretching vibration of the -NH group, which is represented by a minor peak at 3270 cm⁻¹, is lost in the spectrum of AgO_2 due to the strong interaction between the

Fig. 22 FTIR spectra of CGM (a) and AgO_2 composite membrane (b). (Reproduced with permission (Tang et al. 2013))

-OH groups and the acetyl groups of chitin in $\text{Ag}_2\text{Mo}_2\text{O}_7$. The chitin backbone's CH stretching vibration is represented by a band at 2890 cm^{-1} , which shifts from 2890 to 2920 cm^{-1} in a significant way. This is another evidence for interactions between chitin and $\text{Ag}_2\text{Mo}_2\text{O}_7$ nanoparticles through hydrogen bonding.

Chitin nanowhiskers (ChWs) Along with other different nanoscale natural filler materials, chitin nanowhiskers (ChWs) have been of tremendous interest for materials applications. Peng et al. successfully fabricated a highly porous, biodegradable, and elastic PVA/ChW hydrogels by physical and chemical cross-linking using glutaraldehyde (GA) for controlled release. The usual peaks of ChWs and PVA are clearly visible in the created composite films' FTIR spectra. No peaks or no changes appeared suggesting that, during the formation of gels, chitin nanowhiskers were physically blended with PVA. Both the materials maintained their own unique chemical structure. SEM micrographs of the hydrogels were carried out. The hydrogel was made using various ChW concentrations. The range of the pore size is from 10 to 100 nm . The pore size was large due to the low ChW concentration. When ChW concentration was increased, an improved microstructure with filamentous structures and smaller pores were observed. As the weight content of ChWs was around 40% , a uniform network structure was examined (Peng et al. 2019).

Synthetic Biopolymers

Synthetic biopolymers are either altered from natural polymers or completely synthesized from synthetic monomers. The superior biodegradability and environmental safety of synthetic biopolymers, on the other hand, make them the preferred choice over synthetic polymers.

Poly(Glycolide) PGA or Poly(Glycolic Acid)

Poly(glycolic acid) PGA or poly(glycolide) (Fig. 23) is the simplest and linear aliphatic polyester. It is one of the important synthetic biodegradable polyesters. It has a high melting point (220 – $225\text{ }^\circ\text{C}$) and also shows a higher crystalline behavior. Due to its increased crystallinity, it is soluble in hexafluoroisopropanol (HFIP), up to a molar mass of $45,000\text{ g/mol}$, but insoluble in other solvents (Middleton and Tipton 2000). Its glass-transition temperature (T_g) is in the range of 35 – $40\text{ }^\circ\text{C}$. Since the 1960s, Davis and Geck have used PGA to create the first totally synthetic absorbent suture, known as Dexon (Frazza and Schmitt 1971). Due to PGA's unstable and

Fig. 23 Chemical structure of PGA

easily degradable nature, its industrial manufacturing has proven to be quite difficult, especially when it comes to achieving larger molecular weights (Lu et al. 2014). Although general processing techniques like injection, extrusion, and compression molding can be used to produce PGA in several forms, its high sensitivity to hydrolytic degradations needs a careful control of processing conditions. The monomers used for the PGA synthesis are glycolic acid and glycolide. Ring-opening polymerization of glycolide, polycondensation of glycolic acid, and solid-state polycondensation of halogenoacetates are the three processes used to make PGA. The high molecular weight of PGA is produced by ring-opening polymerization of glycolide (cyclic dimer form of glycolic acid), while the low molecular weight PGA was produced using polycondensation techniques (Dobrzyński et al. 1999; Nieuwenhuis 1992). For industrial applications, it has been synthesized via ring-opening polymerization of glycolide. To initiate the polymerization, Tin octanoate/benzyl alcohol is used as the catalyst system. It can be achieved cationically from glycolide. At room temperature, triflic acid (Lewis acid catalyst) initiates the polymerization reaction (Chamberlain et al. 2000).

In addition to having increased strength and modulus, PGA-derived fibers are also too stiff to be employed as sutures and instead act as tangled material. PGA sutures lose 50% of their strength after two weeks and 100% after four weeks and are entirely dissolved after four to six months. The glycolide monomer was copolymerized with additional monomers to minimize the stiffness attribute.

Zhang et al. synthesized poly(glycolic acid) grafted with chitosan films to enhance the degradable properties of chitosan. The reaction was carried out without using a catalyst. The obtained grafted films were characterized by using various techniques. The variation in glucosamine unit-to-glycolic acid feeding ratios was changed from 1/1 to 1/10. In Fig. 24, IR spectra of chitosan and films with polyglycolic acid-grafted chitosan copolymer that were extracted using methanol were displayed. The largest peaks of chitosan are seen at 1595 cm^{-1} and 1658 cm^{-1} , which correspond to the secondary amide's amide I band and the non-acylated NH_2 group's N-H bending vibrations, respectively. The NH_2 groups of chitosan units are acylated by glycolic acid, and a new peak was identified at 1639 cm^{-1} and 1087 cm^{-1} with regard to the carbonyl stretching of amide and the C-O stretching of glycolic acid $\text{CH}_2\text{-OH}$, respectively, for the PGA chitosan films. The glucosamine-to-glycolic acid molar ratios were raised to 1/5 and 1/10, and a new peak was found at 1749 cm^{-1} and 1184 cm^{-1} that shows ester C=O stretching and oligo(glycolic acid) C-O stretching, respectively. This showed the formation of oligo (glycolic acid) related to chitosan. Moreover, in the spectrum of PGA chitosan, there is no ether peaks between hydroxyl groups depicted, indicating the successful synthesis of poly(glycolic acid)-grafted chitosan.

The morphology of poly(glycolic acid)-grafted chitosan after 4 weeks of degradation was performed using SEM (Fig. 25). Before degradation, the surface of grafted chitosan films and chitosan was found to be smooth. Chitosan film degraded in PBS containing lysozyme and PGA-CS film under the same conditions also showed a rough surface. These findings indicate that PGA-CS film degrades more

Fig. 24 The feeding molar ratio of glucosamine unit (CS) to glycolic acid is shown in the FTIR spectra of chitosan (a) and the poly(glycolic acid)-grafted chitosan (b, CS/GA = 1:1; c, CS/GA = 1:5; d, CS/GA = 1:10). (Reproduced with permission (Zhang et al. 2013))

quickly than chitosan film, which is consistent with the average weight loss of chitosan that has been grafted with poly(glycolic acid).

The grafted poly(glycolic acid) chitosan film degraded noticeably more quickly than the chitosan film. The breakdown rate of PGA-CS films gradually increased as the molar ratio of glycolic acid to chitosan increased. These findings suggested that chitosan with poly(glycolic acid) grafts might be an excellent biocompatible and biodegradable material.

Poly(Lactic Acid) (PLA)

Poly(lactic acid) (PLA) is both a thermoplastic and a biodegradable polymer. Lactic acid monomers or cyclic dimers are polymerized to make it synthetically. The chemical structure of PLA is shown in Fig. 26. It is created through the fermentation of natural carbohydrates, such as waste from the food or agricultural industries or grains like wheat or maize. It has numerous uses in the delivery of drugs, sutures, stents, and dialysis medium. The cyclic dimer of lactic acid is lactide. Two optical

Fig. 25 Chitosan and poly(glycolic acid)-grafted chitosan films were photographed using a scanning electron microscope (SEM) before and after 4 weeks of degradation (**a**, chitosan; **b**, poly(glycolic acid)-grafted chitosan; **c**, chitosan). The glucosamine unit-to-glycolic acid molar ratio in chitosan-g-poly(glycolic acid) is 1:10. (Reproduced with permission (Zhang et al. 2013))

Fig. 26 Structure of polylactic acid (PLA)

isomers, such as D-lactide and L-lactide, are present. The isomer that occurs naturally is called L-lactide. To create DL-Lactide, D-lactide and L-lactide are synthetically combined. The polymerization procedure is similar to glycolide. PLA has a glass-transition temperature of 60–65 °C and a melting point of 175–178 °C and also 37% crystalline (Daniels et al. 1990). PLA was certified by the US Food and Drug Administration as early as the 1970s, and it has been broadly used in clips, plates, screws, sutures, and drug delivery and food packaging applications. The environment to which PLA is exposed determines how biodegradable it is. According to theory, PLA is first hydrolyzed into a polymer, which is then broken down, and the resulting soluble oligomers are then broken down by cells. When removed from the environment, it hydrolyzes into low molecular weight oligomers and mineralizes the microorganisms contained in the environment in CO₂ and H₂O.

PLA has some drawbacks for food packaging applications because of its weak thermal stability, low toughness, ductility, high rigidity, low gas, and water vapor barrier properties (Harada et al. 2007). In order to improve film qualities with additional functional properties like UV-light screening and antibacterial capabilities, PLA is combined with nanofillers such as nanocellulose, nanoclay, and nanometals to overcome these shortcomings (Therias et al. 2012). Along with metal oxide nanofillers, zinc oxide nanoparticles (ZnO NPs) are very remarkable because they achieve many significant properties such as low cost, availability, nontoxicity, stability, strong antimicrobial activity, and high ultraviolet absorption capacity (Shankar et al. 2015). Shankar et al. developed PLA/ZnO NP composite films synthesized by solution casting method. On structural, thermal water barrier, and antibacterial properties, the impact of ZnO NP concentration was investigated. The morphological studies were carried out using SEM. SEM image of ZnO nanoparticles were shown in Fig. 27. It proved that the particles were cubic in shape and ranged in size from 50 to 100 nm. Using ImageJ software, the average diameter of the NPs was determined to be 56.1 ± 18.6 nm. The resulting films had a flat surface and were uniform, transparent, and flexible. Figure 28 shows the FESEM images of PLA and PLA/ZnO NP composite films. While PLA/ZnO NP films reveal a slightly rough surface with nanoparticles scattered in the polymer matrix, neat PLA showed a smooth and compact surface. With higher ZnO NP concentrations, the produced films were more uneven. ZnO NPs developed on the surface of the film when the ZnO NPs were distributed in the chloroform solution in which PLA was dissolved without any surface treatment, as seen by the high concentrations of ZnO NPs.

Fig. 27 SEM image of ZnO NPs. (Reproduced with permission (Shankar et al. 2018))

Fig. 28 SEM pictures of PLA and PLA/ZnO NP composite films. (Reproduced with permission (Shankar et al. 2018))

The FTIR analysis was carried out to check the interactions between PLA and ZnO NPs, and the spectrum was presented in Fig. 29. The main PLA peaks, which were obtained at 3658 cm^{-1} , 2931 cm^{-1} , and 1750 cm^{-1} , respectively, show vibrations of the O-H stretching, CH_3 stretching of saturated hydrocarbons, and ester $\text{C}=\text{O}$ stretching in the PLA molecules. The asymmetric and symmetric CH_3 deformation vibration is shown by the peaks observed between 1456 and 1365 cm^{-1} . The PLA's amorphous phase and crystal phase are represented by the other peaks at 871 cm^{-1} and 756 cm^{-1} , respectively. None of the peaks from PLA changed except for an increase in the intensity of the peaks at 3654 cm^{-1} after the addition of ZnO NPs. This finding indicates that the only primary forces present were weak hydrogen bonds between the PLA matrix and the ZnO NPs.

Figure 30 shows the XRD patterns of the PLA-based films. No specific diffraction peak is observed in the range of $30\text{--}80^\circ$ for neat PLA. Clear diffraction peaks were seen in PLA/ZnO NP composite films in the $30^\circ\text{--}40^\circ$ range, which matches with the typical peaks of ZnO NPs (100), (002), and (101). Additionally, Virovska and his colleagues discovered that when nano ZnO was added to the PLA, the distinctive peaks of ZnO were identified at 31.8° , 34.5° , and 36.4° , which correspond to crystal planes 100), (002), and (101) (Virovska et al. 2016). The findings showed that, owing to their antibacterial and UV-light barrier capabilities, the produced PLA/ZnO

Fig. 29 FTIR of PLA and PLA/ZnO NP composite films. (Reproduced with permission(Shankar et al. 2018))

NP composite films have a significant potential for usage as functional active food packaging and biomedical applications.

Polycaprolactone (PCL)

Polycaprolactone (PCL) is a biodegradable aliphatic polyester. It is a semicrystalline polymer with a glass-transition temperature of -60°C and a melting temperature between 59 and 64°C . Therefore, due to its high toughness and excellent mechanical qualities including elasticity due to its high molecular weight and strength, semicrystalline PCL transforms into a rubbery state at physiological temperature (Bez-wada et al. 1995). It has been of great interest in various scientific and industrial fields since the 1970–1980s. This polyester is unique by its excellent biodegradability, biocompatibility, and mechanical and physicochemical properties. It can be produced through ring-opening and polycondensation polymerization techniques. PCL moiety is hydrophobic, and it is able to form aggregates by its self-assembly behavior after merging with a hydrophilic entity. These aggregates can create sophisticated architectures of extensive biomedical applications. It is widely utilized as scaffolds and resorbable sutures in regenerative medicine and in drug delivery

Fig. 30 XRD spectra of PLA and PLA/ZnO NP composite films. (Reproduced with permission (Shankar et al. 2018))

since it is tissue-friendly and nontoxic. PCL degrades more slowly (2–3 years) and is hydrolyzed by either microbes or its aliphatic ester linkage. It is soluble in various solvents like chloroform, tetrahydrofuran, dichloromethane, toluene, cyclohexanone, benzene, carbon tetrachloride, etc. It is less soluble in ethyl acetate, acetonitrile, dimethylformamide, and acetone and insoluble in alcohol and ether (Hedrick et al. 2006). By blending and copolymerization, the physical, chemical, and mechanical properties of PCL can be effectively changed (Azimi et al. 2014). It has been found that after blending, physical and mechanical properties were altered along with biodegradation. For example, mixing of PCL with PLA reduces the Young's modulus and tensile strength; but in the case of PCL/cellulose composites, the crystallinity was increased. Moreover, the copolymerization alters chemical properties, which indirectly affect other properties like crystallinity, degradation, and solubility.

The impact of blending with PLA/PCL and the presence of TiO₂ nanoparticles in the polymers were both examined by Mofokeng et al. While PLA blends with PCL, the overall thermal stability was reduced. By adding TiO₂ nanoparticles, thermal stability was increased. As a result of the incompatibility of PLA domains with weak mechanical properties with PCL, several studies based on the blending of the two

Fig. 31 TEM images of 30/70/5 w/w PLA/PCL/TiO₂ at (a) 1950 \times and (b) 13,500 \times magnification and (c) 70/30/5 w/w PLA/PCL/TiO₂ at 13500 \times magnification. (Reproduced with permission (Mofokeng and Luyt 2015))

materials have been described (Laredo et al. 2010; Jain et al. 2010; Eng et al. 2013; Xu et al. 2011). The prepared blends and nanocomposite morphological studies were carried out using TEM. TEM images of PLA/PCL blends with 5 wt% TiO₂ nanoparticles are shown in Fig. 31 in two distinct compositions. PCL was visible in the figure as the black phase that could be distinguished from the TiO₂ polymer phases. The majority of the nanoparticles was distributed in the PLA phase, and some small and large aggregates could be seen clearly in the pictures. However, there isn't a noticeable concentration of nanoparticles at the PCL and PLA interfaces.

The degradation products of neat PLA and 97/3 w/w PLA/TiO₂ are represented by their FTIR spectra in Fig. 32. It is evident that CO₂ intensity is higher between 2300 and 2400 cm⁻¹, at 1792 cm⁻¹, and at 325 °C for the C-O-C bands in the spectrum. The same bands have considerably lower intensities, at about 350 °C. At the same time, the other peaks such as at 2998 cm⁻¹, 2819 cm⁻¹, 2732 cm⁻¹, 2170 cm⁻¹, 2108 cm⁻¹, and 1371 cm⁻¹ completely disappeared. When TiO₂ nanoparticles were included, the carbonyl band shifted from 1792 to 1764 cm⁻¹ at around the same temperatures and lost intensity compared to pure PLA; the intensities were higher at higher temperatures. Strong evidence that the PLA interacted with nanoparticles and prevented their diffusion from the liquid polymer was obtained from these observations.

Fig. 32 FTIR spectra of (a) neat PLA and (b) 97/3 w/w PLA/TiO₂ degradation products. (Reproduced with permission (Mofokeng and Luyt 2015))

The degradation products of neat PCL and 97/3 w/w PCL/TiO₂ are depicted in FTIR spectra (Fig. 33). The hydroxyl (-OH) band is shown at around 3577 cm⁻¹. The carbonyl peaks obtained at (C=O) 1756 cm⁻¹ and the peak obtained between 2400 and 2300 cm⁻¹ correspond to carbon dioxide (CO₂). In contrast to the high intensities of pure PCL at higher temperatures, the overlap of the C-O-C, C-O, CH, and CH₂ bands between 1400 and 1100 cm⁻¹ is less than that of TiO₂ containing PCL at high temperatures.

The degradation volatiles of the mix and nanocomposites are shown in Fig. 34 as their spectra at 344 °C (the PLA degradation stage) and 396 °C, respectively (degradation stage of PCL). The previously described degradation products of PLA are represented by the peaks in the image that are characterized by lactide molecules, acetaldehydes with carbon monoxide, and oligomeric rings. The wavenumbers of the carbonyl peaks displayed in the degradation products from PCL and PLA correlate to the wavenumbers of the C-O peak's two peaks (1794 and 1758 cm⁻¹), which separate into two peaks. Two different wavenumbers were used to observe the CO₂ band (2375 and 2309 cm⁻¹). The spectra show different carbonyl and CO₂ bands corresponding to the breakdown products from each of the two polymers because PCL's degradation has been initiated and PLA's degradation is still underway.

Polycaprolactone shows excellent biocompatibility, biodegradability, and tensile strength. Due to its excellent resistance to slip, dislocation, and fatigue, it also shows significant potential in biomedical applications. Being able to overcome the limitations of ceramics, it can fulfil the critical need for medical materials (Abrisham et al. 2020). Kotcharat and his colleagues reported on the fabrication of aloe vera-loaded bacterial cellulose (BC) and polycaprolactone-based composites for wound dressing applications (Kotcharat et al. 2022). The composite material appeared as flat sheet and whitish in color. The structural confirmation was carried out using FTIR. Asymmetric and symmetric C-H stretching peaks are shown by the primary characteristic peaks of PCL at 2864 cm⁻¹ and 2949 cm⁻¹, respectively. Peaks at 1726 cm and 1296 cm⁻¹ are attributed, respectively, to carbonyl stretching and C-O and C-C stretching in the crystalline phase's backbone. The findings show that PCL was a significant portion of the composite's matrix phase. Increasing the aloe vera content revealed a striking increase in transmittance. From the morphological studies, the microstructure displays microcracks and porosity as the aloe vera was incorporated into the composite. The presence of voids was also observed, which is due to evaporation of solvent during the composite preparation. The characteristic peaks at 2θ values of 21°, 22°, and 24° matched with diffraction planes of (110), (111), and

Fig. 34 FTIR spectra of the degradation products PLA and PCL in 50/50 w/w PLA/PCL and its nanocomposites with 3 wt%. (Reproduced with permission (Mofokeng and Luyt 2015))

(200), respectively, according to X-ray diffraction studies. No noticeable peaks were seen when the aloe vera was loaded into BC and PCL, most likely as a result of the reduced aloe vera concentration. Aloe vera, on the other hand, was incorporated into the composite's subsequent cellular foam, which reduced the crystallinity of the material. Aloe vera's amorphous phase hindered PCL's crystalline phase and had an impact on the composite film's tensile strength.

Conclusion

Due to its environmental benefits and the search for alternatives to petroleum-based resources, biopolymer-based research has significantly increased during the last few years. They are superior to other polymers due to their nontoxic nature, biodegradability, and biocompatibility and have a wide range of uses. In this chapter, we are highlighting the structural, morphological, and textural properties of some important biopolymers. A greater knowledge on biopolymers has resulted from the extensive study on structural and morphological investigation utilizing various microscopic techniques. Here, we are discussing some important biopolymer-based hydrogels, nanocomposites, and membranes using different methods. All the mentioned works

were focused on biomedical applications. The incorporation of biopolymers results in enhanced properties. Therefore, understanding the structural and surface properties of the biopolymers through these microscopic techniques and others will take great promises in all fields.

Abstract

Biopolymers gained increasing attention in various fields due to their versatile properties such as renewability, biodegradability, sustainability, eco-friendly, and because they possess good mechanical properties. However, some of the intrinsic properties of biopolymer such as wettability limit their industrial application. Modification (physical/chemical) of biopolymers is an accepted technique to tune their surface properties and consequently increase the potential application. This chapter summarizes some of the recent advances in various surface modification techniques, modifying agents, and functionalization of biopolymers (natural and synthetic) as well as their physicochemical properties before and after modification.

Keywords

Biopolymers · Surface modification · Functionalization · Physio-chemical properties

Introduction

The growing environmental awareness has become an important factor in recent decades and resulted in increased attention to the development and application of biopolymers. The term “biopolymer” applies to various thermoplastic and thermoset polymers derived from renewable resources or fossil fuels. It is also applied to biodegradable polymers. Biopolymers are classified into two major groups: natural biopolymers (polysaccharides, proteins, polypeptides, etc.) and synthetic biopolymers (polylactic acid, poly hydroxybutyrate, polybutylene succinate, etc.). Biopolymers can either be hydrophilic or hydrophobic by their chemical structure but most of them are hydrophilic due to the presence of surface hydroxyl groups especially plant fibers. But this intrinsic character sometimes could turn into a challenging factor especially in the application stage, for example, in the preparation of composites with hydrophobic matrix, there occurs a decrease in the interfacial adhesion. Hence the need of tuning the surface properties is an essential criteria as per the need.

The different types of surface modification of the biopolymers with appropriate modifying agents can induce hydrophobic or hydrophilic properties. The reactive functional groups in the chemical structure of these biopolymers serve this purpose. The modifying agents can simply be a biopolymer with the desired property or biological enzymes or the agents should contain a reactive site with either a long chain hydrocarbon or a simple hydrocarbon to induce hydrophobicity and hydrophilicity or simple oxidation as per the application. The selection of an appropriate modifying agent is challenging because even though the tuning of wettability property is the main factor, we should also consider other factors like thermal degradability, mechanical properties, cost-effectiveness, cytotoxicity, etc. in different disciplines of application. Hence, this could turn out to be a challenging brainstorming matter. The selection of the modifying technique is also equally challenging. There are different chemical, physical, and environmentally friendly green modifying agents and techniques reported.

Researchers are in constant search to optimize the best agents to serve different purposes with cost-effective procedures because the effectiveness of these agents in one dimension could be a disadvantage in the other dimension. This chapter briefly explains the sources, production or synthetic technique, and physio-chemical properties of natural and synthetic biopolymers and discusses the different types of modifying agents and the techniques used.

Natural Polymers

The term “natural polymers” is an accepted definition for the polymers found in plants, animals, and microorganisms, and composed of either inorganic or organic subunits. The following section describes the most abundant and common natural polymers from three major groups of polysaccharides, proteins, and polyphenols.

Scheme 1 Chemical structure of cellulose

Cellulose

Cellulose is the most abundant polysaccharide on Earth. It exists in plants, animals, and some bacteria. It is a linear semicrystalline polymer, made of the repeat unit of anhydro-D-glucopyranose connected by $\beta(1 \rightarrow 4)$ -glycosidic bonds (Scheme 1). Cellulose has a very organized structure in wood fiber due to its linear structure and intermolecular hydrogen bonding. Cellulose fibrils consist of alternating less ordered amorphous and high ordered crystalline phases. The amorphous part is more reactive than the crystalline part due to the low amount of intermolecular interactions which ease the accessibility of the reagents. The degree of polymerization of cellulose is in the range of 10,000 to 15,000 depending on the source. Cellulose crystallite exists in four major polymorphic forms, I, II, III, and IV. Native cellulose I exists in the crystalline form of I_α containing a triclinic one chain unit cell and I_β containing a monoclinic two chain unit cell. The other three crystalline allomorphs are attributed to modified cellulose. For example, cellulose II can be obtained via alkali treatment.

Due to its high crystalline structure, cellulose is insoluble in water and some high polarized solvents. However, the presence of hydroxyl groups on its polymer chain makes it highly hydrophilic. Various chemical and physical modification techniques have been used to modify the hydrophilicity of cellulose and its functionalization. The hierarchical architecture of natural cellulose consisting of nanoscale fibrils and crystallites allows the extraction of the nanocomponents via mechanical and chemical methods or through a combination of both of these techniques. Cellulose nanocrystal and cellulose nanofibers with different geometry and properties can be extracted from different sources of cellulose. They have gained extensive attention in the past decades due to their renewability, biodegradability, nontoxicity, low weight, and high mechanical properties. These two new classes of nanomaterials are used in a wide range of high-performance products such as food, medicine, clothes, cosmetics, papers, composites, and packaging (Kargarzadeh et al. 2017, 2018).

Hemicellulose

Hemicellulose is a heteropolysaccharide with a branched structure present in the primary and secondary cell walls of wood and annual plants. Hemicellulose has an amorphous structure with low molecular weight which makes it soluble or partially soluble in water. Unlike cellulose in which the monomer units are chemically

Scheme 2 The main monosaccharides of hemicellulose

homogeneous, hemicellulose consisted of mixed monomers of sugars such as glucose, xylose, mannose, galactose, arabinose, fucose-glucuronic acid, and galacturonic acid. The hemicellulose composition, chemical structure, and abundance vary widely between different species and cell types. For example, the prominent hemicellulose in softwood, plant seed, and fruits are arabinose, galactose, and mannose, whereas the main hemicellulose monosaccharide in hardwood and grasses is xylose (Scheller and Ulvskov 2010; Zhang et al. 2021). The chemical structure of main hemicellulose monosaccharides is shown in Scheme 2.

Hemicellulose can be extracted from lignocellulosic biomass via several techniques such as hydrothermal extraction, alkaline treatment, dilute acid hydrolysis, auto-hydrolysis, and steam explosion. Among them dilute acid hydrolysis is the most common technique that produces a high quantity of monomeric sugars. Auto-hydrolysis and steam explosion produce oligomer form of hemicellulose while alkaline treatment extracts hemicellulose in polymeric form. Hemicellulose is highly hydrophilic due to a large number of hydroxyl groups on its backbone and side chains. Esterification, etherification, graft copolymerization, and other reactions can be conducted to chemically modify these hydroxyl groups. The chemical modifications convert the free hydroxyl group to other functional groups which tune various properties such as hydrophobicity, thermal stability, and solubility in different solvents. The modified hemicellulose can find applications in various fields such as composites, food packaging, coating, filtration and adsorbent.

Starch

Starch is a semi-crystalline plant-driven polysaccharide. It serves as an energy reserve in a variety of plants such as fruits, grain seeds, tubers, and roots. It is a copolymer with a complex structure consisting of 20–30% of amylose, which is a linear polysaccharide of α -D-glucose units linked α -(1 \rightarrow 4) with a molecular weight of 10^3 – 10^6 Da, and amylopectin which is a high molecular weight 10^7 – 10^9 Da branched polymer. Amylopectin is the main composition of starch and consists of α -D-(1 \rightarrow 4)-glucose units and α -D-(1 \rightarrow 6)-glucose units in the branched point

Scheme 3 Chemical structure of starch with amylose and amylopectin components

(Scheme 3). The starch granule size, shape, structure, and ratio of amylose and amylopectin, and the degree of crystallinity depend on the origin of starch (Smith 2001). Amylopectin is the main crystalline component of starch with a degree of polymerization around 10–20 which is insoluble in water and produces soft gel and weak film when disperse in water, whereas amylose is the amorphous component that produces tough gel and strong film with the tendency to retrograde. The structure of starch granules is well described by Bertoft (2017). Due to its gelling and film-forming properties as well as its biodegradability and biocompatibility, it has been widely used in various applications such as food, packaging, cosmetics, and drug delivery (Rodrigues and Emeje 2012; Yazid et al. 2018; Qamruzzaman et al. 2021). However, native starch is unable to attain specific industrial requirements which restricted its application. The chemical or physical modification is therefore proposed to improve the properties of starch. Crosslinking, acetylation, esterification, oxidation, and acid hydrolysis, ultrasonication, heat moisture treatment, dry heat treatment, pulsed electric field, and plasma are some examples of starch modification which is comprehensively discussed in the following publication (Chen et al. 2015; Zhu 2017; Zia-ud-Din and Fei 2017; Yazid et al. 2018; Amaraweera et al. 2021; Maniglia et al. 2021).

Chitin and Chitosan

Chitin is the second most abundant polysaccharide after cellulose. It is nontoxic, nonallergic, antimicrobial, and biodegradable. It is the primary component of the exoskeleton of arthropods such as crustaceans, cell walls in fungi, and insects. It is an amide derivative of glucose with a linear structure composed of β-(1–4)-linked *N*-acetyl-D-glucosamine units (Scheme 4). Chitin is hydrophobic and insoluble in water and organic solvents (Rinaudo 2006). Its average molecular weight is $1\text{--}2.5 \times 10^6$ Da with a degree of polymerization of approximately 500–10,000 and a degree of acetylation of more than 90% (Mourya and Inamdar 2008). The crystallinity and thermal

Scheme 4 Chemical structure of chitin and chitosan

properties of chitin are determining factors for its various potential applications (Villette et al. 2002; Rihaudo 2006). The high crystallinity and mechanical properties of chitin and its nanoparticles make them also suitable candidates for reinforcement in polymer composites. However, its insolubility limits its application. If the degree of deacetylation (DA) of chitin reaches about 50%, it becomes soluble in aqueous media and is called chitosan (Rihaudo 2006). Chitosan can be prepared in different forms such as film, powder, gel, paste, fiber, and nanoparticles (Ahmed and Ikram 2016). Its solubilization occurs by protonation of the basic amino group on the C-2 position of the D-glucosamine. Chitosan is a linear semicrystalline polysaccharide and can be prepared with different molecular weights and DA from chitin. The average MW of chitosan is about 100–500 kDa which is lower than the MW of chitin. The chitosan chemical structure is composed of β -(1–4)-linked glucosamine and *N*-acetyl glucosamine units. Similar to chitin, it is almost insoluble in water (except in acidic pH) and highly crystalline which limits its application to some extent. Therefore, many techniques are applied to improve the solubility of chitosan such as chemical and enzyme modification (Kaczmarek et al. 2019; Wang et al. 2020). Both hydroxyl and amine groups of chitosan are reactive groups that ease the modification and functionalization of chitosan. Effective chemical modifications expand the application of chitosan compared to its natural compound. For example, acetylation and etherification of chitosan enhance its water solubility, biocompatibility, anticoagulability, and blood compatibility which can be used as a carrier or sustained release agent in the pharmaceutical application (Furlani et al. 2019). Alkylation also improves the solubility of chitosan; however, due to its hydrophobicity, the solubility is low depending on the length of the alkyl chain (Burr et al. 2018). More examples of the effect of various chemical modifications on the properties of chitosan and its applications can be found in (Negm et al. 2020; Wang et al. 2020; Saheed et al. 2021). Due to the biodegradability, antimicrobial, non-toxicity, antioxidant activity, and functionality, both chitin and chitosan are investigated in many areas of application such as tissue engineering, drug delivery, stabilizing cosmetic ingredients, packaging, and membrane for removal of metal ions, dyes, and pigments in wastewater (Rinaudo 2006; Khoushab and Yamabhai 2010; Ahmed and Ikram 2016; Wang et al. 2020).

Agar

Agar is a natural polysaccharide with strong gelling properties. It is occurring in the cell wall of various red seaweeds where they promote flexibility and mobility to the plant for easy adaption to different marine environments (Matsushashi 1990). Agar

Scheme 5 Chemical structure of agarabios, repeating unit of agar

consists of two different polysaccharides, agarose, and agaropectin. Agarose which is the gelling fraction of agar is a linear polysaccharide consisting of alternate D-galactose and 3, 6 anhydro-L-galactose (Scheme 5). It has a high molecular weight ($>100,000$ Da) and low sulfate content ($<0.15\%$), whereas agaropectin has a lower molecular weight ($<20,000$ Da) and higher sulfates content (5–8%). The agarose backbone may contain sulfate, urinate, pyruvates, or methoxy groups (Lee et al. 2017). The typical ratio of agarose and agaropectin is 70:30 (Zeece 2020). However, the ratio of agarose and agaropectin is varied from one species to another and depends on the species, the season, the environment it grows in, the extraction method, etc. The higher ratio of agarose to agaropectin results in higher gel strength (Padmesh and Singh 2021).

Agar is water-soluble. A small amount of 1% agar in water is good enough to form a rigid gel suitable for most applications. Agar is a physical gel and translucent, which does not require any other substances to gel. Unlike the chemical gels with the covalent bond, the agar gelation process is thermally reversible and occurs exclusively by hydrogen bonds. Due to this unique gelling property, it holds a great amount of water in the interior network which can freely move through the macroreticulum (Matsushashi 1990; Armisen et al. 2009). The gelling properties and gelling condition of agar depend on the functional groups on its backbone, for example, the gel setting temperature of agar depends on the level of methoxy content, and the low methoxy contents give the lower gel setting temperature and vice versa. Alkali pretreatment increases the anhydrous bridges within the agar molecules, consequently increasing gel strength, gelling, melting temperature, and viscosity (Yarnpakdee et al. 2015). Agar has wide application mainly in food industry for production of puddings, custards, soft candies, etc. It is also added to baked goods to inhibit staling and improves the texture of processed cheese and frozen desserts. Agar has similar properties to gelatin which makes it a potential substitute for animal-based gelatin in vegetarian food (Lestari et al. 2019). Packaging (Wang and Rhim 2015) and tissue engineering (Salati et al. 2020) are other applications of agar.

Carrageenan

Carrageenan is a linear sulfated polysaccharide and originated from red seaweed. The chemical structure of carrageenan consists of 3-linked β -D-galactopyranose and 4-linked α -D-galactopyranose or 4-linked 3,6-anhydro- α -D-galactopyranose unites (Scheme 6). Based on the chemical structure and position of sulfate ester and the presence of anhydro group, carrageenan is classified into six types, kappa, iota,

Scheme 6 Chemical structure of the repeating units of carrageenan

lambda, mu, nu, and theta. The molecular weight of carrageenan is in the range of 100 to 1000 kDa. It is soluble in hot water, partially soluble in cold water, and insoluble in organic solvents, oil, and fats. The water solubility of carrageenan depends on the level of hydrophilic sulfate groups and their associated cations. Among all types of carrageenan, kappa and iota possess strong gel properties, whereas, lambda-carrageenan is characterized as a thickener agent. Similar to agar, the gelation behavior of carrageenan in aqueous solution is thermally reversible and depends on the temperature, concentration of carrageenan, and species of cations, typically potassium or calcium which are essential agents for gelation to proceed. Gelling mechanism of carrageenan is described in Campo et al. (Campo et al. 2009). Potential applications of carrageenan in biomedical (Deng et al. 2018), electrode devices (Sangeetha et al. 2020), composites, and food industry (Hotchkiss et al. 2016) were reported.

Dextran

Dextran is a bacterial polysaccharide produced by lactic acid bacteria, mainly by *Leuconostoc mesenterioide*. It is branched and its main chain consists of α -(1 \rightarrow 6) linked D-glucose units in which α -(1 \rightarrow 6) linkage varies from 50 to 97% of the total glycosidic bonds. The branches mainly take place in the position α -(1 \rightarrow 2), α -(1 \rightarrow 3),

Scheme 7 Chemical structure of dextran repeating units

Scheme 8 Chemical structure of pullulan

and/or α -(1 \rightarrow 4) (Scheme 7). The differences in the size and chemical structure of dextran as well as its molecular weight (from 3000 to 2,000,000 Da) depend on the dextranase produced by the bacterial strain (Varshosaz 2012; Wang et al. 2017). Dextran is hydrophilic and water-soluble; however, the branch linkages pattern of dextran determines its solubility. The presence of >43% branching via 1,3- α linkage leads to enhance the water insolubility of dextran, while the presence of 95% linear linkage makes dextran water-soluble (Purama et al. 2009). The presence of reactive hydroxyl groups on the chemical structure of dextran eases its chemical and physical functionalization. The properties of dextran are changed, depending on the degree of substitution of functional groups. For example the high degree of substitution of hydrophobic functional groups makes the dextran water insoluble and nondegradable by the enzyme (Aumelas et al. 2007; Wang et al. 2016). The water-solubility and its functionability, biodegradability, biocompatibility, and nontoxicity make dextran in both nano and micro size a suitable material in drug delivery application (Huang and Huang 2018; Elalmis et al. 2022), food industry (Kothari et al. 2014; Lazić et al. 2020; Wang et al. 2021), and cosmetics (Baptista and Freitas 2021).

Pullulan

Pullulan is a linear microbial polysaccharide produced by a yeast-like fungus, *Aureobasidium pullulans*, in a fermentation medium. It consists of α -(1 \rightarrow 6)-repeated maltotriose units linked α -(1 \rightarrow 4) glycosidic bond (Scheme 8). Its chemical structure and molecular weight depend on pH, carbon source, producing

microorganism, and fermentation condition (Singh et al. 2015). The polydispersity of pullulan is between 2.1 and 4.1 (Wiley et al. 1993) which is significantly lower than the polydispersity of dextran and amylose which is due to the different cell morphology-regulated mechanism or the biosynthesis pathway of pullulan formation (Shingel 2004). Pullulan is soluble in water and dilute alkali and insoluble in alcohol and other organic solvents except dimethylsulfoxide and formamide (Prajapati et al. 2013). However, its solubility limits the application of pullulan. The solubility of pullulan can be decreased by chemical modification, polymer grafting, and blending with other polymers (Shingel 2004; Babu et al. 2013). Pullulan is a nonionic polysaccharide, colorless, tasteless, non-toxic, edible, non-mutagenic, non-carcinogenic with good film and fiber formability. These unique properties make it a suitable material for food coating and packaging, cosmetic, biomedicine and drug delivery, and water purification (Ghosh et al. 2022). Due to the unique structure of pullulan, its nanoparticle consists of both hydrophobic and hydrophilic characteristics which increase its utility in the field of pharmaceuticals (Singh et al. 2015).

Collagen and Gelatin

Collagen is the most abundant protein found in the tissues of animals. The main natural sources of collagen are pig skin, pork and cattle bones, and bovine hide while it can be also obtained from nonmammalian species (Gómez-Guillén et al. 2011). Collagen is made up of amino acids, such as glycine, proline, arginine, hydroxyproline, lysine, alanine, aspartic, glutamic, and hydroxylysine, of which glycine is the main amino acid. Collagen is classified into two main groups, fibrillary and non-fibrillar consisting of 29 different types based on the differences in structure, location, and properties (Owczarzy et al. 2020). Collagen with a molecular weight of 300,000 is insoluble in water. Its solubility can be improved by enzyme, acid, or alkali treatment. Native collagen possesses high mechanical properties, which are lost when it became water soluble (Figueiró et al. 2004).

Gelatin is hydrolyzed collagen with a lower molecular weight than collagen, and the amino acid structure. It is soluble in hot water, but if the gelatin solution boils for a long time, it changes its properties due to decomposition and would not be reformed after cooling. While at a temperature below 35 °C to 40 °C it is gelatinous (Williams and Phillips 2003; Raja Nhari et al. 2011). Gelatin has excellent physical properties such as high dispersibility and dispersion stability, low viscosity, and high water retention as well as high toughness. It is an important material in food industries where it is used as a thickener and foaming agent, emulsifiers, clarifiers, and dispersants. Both collagen and gelatin can be modified chemically and physically, blend with other polymers, or cross-linked to obtain desired properties (Erikson et al. 2008; Zhang et al. 2010; Sionkowska 2021). Both collagen and gelatin have a large range of applications in biomedical, drug delivery, and food and beverage industries (Hashim et al. 2015; Ghomi et al. 2021; He et al. 2021; Luo et al. 2022).

Lignin

Among natural polyphenols, lignin is the most abundant polymer on Earth. It is the third major wood cell wall component and is covalently bonded to polysaccharides. Lignin serves as a block of cement between wood fibers, as a stiffening agent within the fibers, and as a barrier to the enzymatic degradation of the cell wall (Goldstein 2004). It is an amorphous complex polymer with a three-dimensional cross-linked network of phenylpropane units with high molecular weight. Lignin is relatively hydrophobic and its chemical structure consists of three monolignols – p-coumaryl alcohol, coniferyl alcohol, and sinapyl alcohol, and also consists of three types of phenylpropanoid – p-hydroxyphenyl, guaiacyl, and syringyl (Scheme 9). These reactive components are attached by a series of characteristic linkages, such as α -O-4, β -O-4, β -5, and β - β' . Similar to polysaccharides, the chemical structure of lignin and the ratio of monolignol and intermolecular linkages depend on its source (Duval and Lawoko 2014; Spiridon 2020). For instance, hardwood lignin mainly consists of coniferyl alcohol and sinapyl alcohol, while the major monolignols component in softwood lignin is coniferyl alcohol and grass lignin has three types of monolignols (Gellerstedt and Henriksson 2008). In addition, softwood and hardwood lignins differ in methoxyl content and in the degree of crosslinking. Hardwood lignins have more methoxyls, which reduce the degree of crosslinking and block potential reactive sites (Goldstein 2004). The molecular weight of lignin depends on the extraction method. Klason lignin has MW from 260 to 50 million and Bjorkman lignin has MW of 11,000 (Rowell et al. 2012). Lignin is obtained as a by-product of the paper and lignocellulosic industries. Based on the production process, lignin is classified into Kraft lignin, Soda lignin, Lignosulphonates, Organosolv lignin, steam explosion lignin, and enzymatic hydrolysis lignin (Vishtal and Kraslawski 2011). Each of the lignin classes possesses different chemical functionality and properties. However, all classes of lignin have many unique properties such as UV absorbance, antioxidation, and antimicrobial activity which is attributed to the presence of phenolic, ketone, conjugated double bonds, and other

Scheme 9 Chemical structure of monolignols and their corresponding phenylpropanoid

chromophore groups (Espinoza-Acosta et al. 2016; Lin et al. 2021; Zhang and Naebe 2021). Lignin has potential applications in polymer industries. However, its application is limited due to its thermal degradation and mechanical properties. Different modification techniques have been proposed to improve the chemical reactivity and properties of lignin. For instance, oxidative pre-treatment of lignin increases its thermal stability (Brodin et al. 2010). The sulfonation treatment increases the water solubility of kraft lignin (Konduri and Fatehi 2015). Alkylation treatment improves the compatibility of lignin with hydrophobic polymers like polypropylene (Barkoula et al. 2008). Other lignin modification techniques such as methylation, esterification, carboxymethylation, and polymer grafting have been also reported in the literature (Jardim et al. 2020). Lignin in both micro and nanoscale can be used as reinforcement in polymer composites (Kargarzadeh et al. 2020) or as surfactant, emulsifier, and plasticizer (Österberg et al. 2020). It has a good capacity to adsorb heavy metal ions and thus possesses potential application for water purification application (Thakur et al. 2017). Lignin also shows potential applications in food, cosmetic, and pharmaceutical industries as an antioxidant agent instead of synthetic additives (Widsten et al. 2020; Chaubey et al. 2021).

Synthetic Biopolymers

The term “synthetic polymer” refers to chemically created polymers that are either manufactured from renewable sources or selectively subjected to different types of degradation, such as heat, photo, and corrosion degradation. Therefore, the degradation characteristics of the polymers are crucial in understanding the term “synthetic biopolymer,” notwithstanding variations in the sources of the monomers used. For instance, poly- ϵ -caprolactone (PCL), a biopolymer derived from petroleum, can undergo total degradation. On the other side, there is a non-degradable biopolymer made from bio-based materials, like bio-polyethylene (bio-PE). Therefore, these variables must be considered when discussing biopolymers. Figure 1 provides a more precise illustration of the categorization of synthetic biopolymers. Polylactic acid (PLA), polyhydroxybutyrate (PHB), polyglycolic acid (PGA), polycaprolactone (PCL), poly(butylene succinate) (PBS), poly(butylene-adipate-co-terephthalate) (PBAT), and poly(hydroxyalkanoates) (PHAs) are the main synthetic biopolymers. Each of these is covered in detail in the following sections.

Polylactic Acid

Over the past few decades, researchers have focused the most on PLA, a thermoplastic polyester (Ray and Okamoto 2003; Tang et al. 2012). It is made up of repeating lactic acid units, as in Scheme 10. This lactic acid is typically produced by converting sugar or starch from plant sources like corn, wheat, or rice via bacterial fermentation or petrochemical methods.

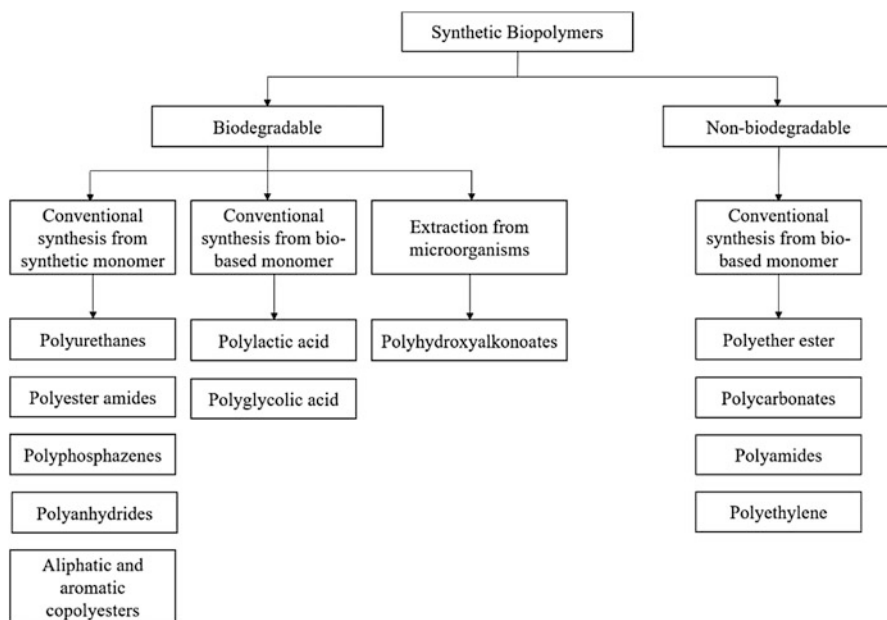

Fig. 1 Synthetic biopolymer classification based on biodegradability. (Reprint with permission from (George et al. 2020))

Scheme 10 Repeating unit of PLA

Compared to other biopolymers like PHA, PEG, PCL, etc., PLA has more excellent heat processing and energy savings (Vink et al. 2003). Its elastic modulus and tensile strength are equivalent to poly(ethylene terephthalate) (PET). It is a biopolymer that is environmentally friendly and has outstanding biocompatibility, but it also has several drawbacks that restrict where it may be applied. PLA is a highly fragile polymer, breaking with less than 10% elongation. PLA's hydrolytic degradation rate is generally slow and greatly influenced by the substance's crystallinity, molecular weight, morphology, and water permeability (Rosli et al. 2021). The hydrophobic characteristic of PLA, which exhibits a static water contact angle of around 80 °C, accounts for its slow degradation rate. Furthermore, because of its less reactive side-chain group, PLA is chemically inert, making bulk modification a difficult procedure.

Numerous techniques, including copolymerization and blending, are used to boost the usage of PLA in various applications to enhance its toughness capabilities

(Chang et al. 2015; Kong et al. 2018). PLA is blended with various thermoplastics and elastomers (Bitinis et al. 2011; Armentano et al. 2015), and as a result, its toughness increases in addition to its degradation rate (Rosli et al. 2018). The polymerization of PLA with various monomers was also performed to increase the toughness and degradation rate of PLA. For instance, due to the hydrophilic and biocompatible properties of PEG, the copolymerization of PLA with PEG is widely reported. Consequently, PLA's toughness and degradation rate successfully improved through PEG's copolymerization (Han et al. 2016).

In addition to bulk modification, PLA surfaces may be modified; these modifications are classified as permanent (covalent bonding) and non-permanent. Entrapment, coatings, migratory additives, and plasma treatment are a few examples of non-permanent alterations to PLA surfaces. Meanwhile, photografting and wet chemistry are used in the chemical conjugation process to modify PLA's surface permanently. All of these methods effectively increase the hydrophilic properties of PLA (Mann et al. 2019; Varga et al. 2019; Wu et al. 2022).

Poly Hydroxybutyrate (PHB)

Poly (hydroxybutyrate) (PHB) is a biologically formed product and is the largest class of PHAs. PHBs are natural polymers in some bacteria and algae as intracellular storage materials. They are extracted from the corresponding cell biomass utilizing the proper downstream processing processes (Raza et al. 2020). If the alkyl (R) group in PHAs is methyl, it will produce the structure of PHB as shown in Scheme 11. PHB displayed above 50% ordered crystallinity and a melting point of 180 °C. Due to this, PHB displays high brittle properties much as PLA. PHB's hydrophobic characteristics also cause it to degrade slowly (Abid et al. 2016).

Based on the desired properties, bulk modification of PHB is done through blending techniques with synthetic or natural polymers. The mechanical and physicochemical characteristics of PHB are often successfully enhanced after blending (Parra et al. 2006). PHB's surface may be modified in two ways: by modifying the functional group physically or chemically and via coating (Bu et al. 2019). PHB can have its surface chemically modified by aminolysis, hydroxylation, methylation, or chlorination (Raza et al. 2018; Yeo et al. 2018). Chemical treatments on the surface of PHBs provide new active functional groups that can enhance the interaction of PHBs with other molecules (Wei et al. 2015; Kai et al. 2019).

Scheme 11 Repeating unit of PHB

Polyglycolic Acid/Polyglycolide (PGA)

Poly(glycolic acid) (PGA), a valuable biopolymer due to its high cost and lack of a technique for cost-effective big-scale manufacturing, is a member of the poly(α -hydroxy acids). Due to its high crystallinity (45–55%), PGA is insoluble in many solvents (Budak et al. 2020). Compared to PLA, it degrades more quickly and has stronger mechanical properties. In addition, when compared to other polyesters, PGA is the most hydrophilic. Glycolic acid and glycolide are employed as monomers to manufacture PGA (Scheme 12).

Although the hydrophilic properties of PGA are among the highest compared to other polyesters, however, synthetic aliphatic polyesters are often not chemically modifiable and are pretty hydrophobic. Chemical modification, such as grafting, which involves adding various new functional groups to the PGA backbone, is one of the modification techniques that can be used (Zhang et al. 2013). Another approach to modifying the hydrophobic properties of PGA is through the simple coating and covalent bonding of ligands on the surface of PGA (Fu and Zhang 2020).

Poly- ϵ -caprolactone (PCL)

An aliphatic polyester made of hexanoate repeating units is called poly(ϵ -caprolactone) (PCL), as depicted in Scheme 13. Most PCL's properties rely on the degree of crystallinity and molecular weight. It is naturally hydrophobic and highly flexible, with an elongation at break of 1100% (Matzinos et al. 2002). PCL is a unique biopolymer since it frequently forms miscible and compatible blends when combined with other polymers (Labet and Thielemans 2009). However, PCL's poor solubility, mechanical strength, and stability limit its usage in various applications (Dash and Konkimalla 2012).

PCL can be modified physically (blend and composite) and chemically (copolymerization and grafting) to improve or add specific properties to PCL. Physical modifications are usually performed to improve the mechanical properties of PCL without altering the backbone of the polymeric chain (Olgun et al. 2011). Contrarily, chemical modification involves changing the PCL backbone by introducing different

Scheme 12 Repeating unit of PGA

Scheme 13 Repeating unit of PCL

functional groups. Typically, hydrophobic PCL is changed chemically to add hydrophilic properties; consequently, the modified PCL has amphiphilic properties (Hu et al. 2012).

Poly(Butylene Succinate) (PBS)

Poly (butylene succinate), an aliphatic polyester formed from succinate, is not considered bio-based because it is made from traditional fossil fuels. However, it can also be made utilizing monomers from renewable sources (Jansen and van Gulik 2014). PBS is often made by reacting a diacid or acid anhydride with diols, and Scheme 14 illustrates the recurring molecules of PBS.

PBS demonstrates good biodegradability, mechanical properties, thermal stability, and heat deflection. PBS is typically combined with other polymers or fibers to address some drawbacks, including excessive softness, poor gas-barrier properties, and low viscosity (de Matos Costa et al. 2020). The hydrophobic characteristics of PBS can also be modified via photografting and plasma methods, which involve introducing hydrophilic substances into the molecular structure of PBS (Mizuno et al. 2015).

Poly (Butylene-Adipate-co-Terephthalate) (PBAT)

Poly (butylene-adipate-co-terephthalate) (PBAT) is a completely biodegradable synthetic biopolymer. PBAT is produced by poly-condensation of butanediol, adipic acid, and terephthalic acid from fossil fuel sources. The repeating unit of PBAT is shown in Scheme 15.

Along with being biocompatible, PBAT has excellent processing capabilities and flexibility. However, modifications are typically made to enhance its low strength and thermal stability. Contrary to other synthetic biopolymers, PBAT's flaws are significantly strengthened by introducing fibers, which boost their stiffness and thermal stability (Ferreira et al. 2019). However, using the centrifugal melt spinning

Scheme 14 Repeating unit of PBS

Scheme 15 Repeating unit of PBAT

Scheme 16 Repeating unit of PHAs

technique, the hydrophobic characteristics of PBAT may be modified to hydrophilic PBAT fibers (Li et al. 2021).

Poly(Hydroxyalkanoates) (PHAs)

Natural polyesters called polyhydroxyalkanoates (PHAs) are produced by various bacteria that use them as a source of carbon or energy. Several PHAs kinds have been reported with different monomers (repeating units) (Koller and Mukherjee 2022), as indicated in Scheme 16.

PHAs are entirely biodegradable and biocompatible. However, the thermo-mechanical characteristics of PHAs are significantly influenced by the chemical structure, co-monomeric composition, unit-comonomer composition distribution, molecular weight distribution, and average molecular weight due to the variability of its repeating units. Compared to other synthetic biopolymers, the main problem faced by PHAs is their high cost. Therefore, in addition to lowering PHAs' costs, PHA modification is also necessary to increase their functionality. The functionality of PHAs can be enhanced through various modifications, including chemical, curing, and surface modification. Chemical modification of PHAs such as chlorination, carboxylation, hydroxylation, and epoxidation successfully enhance the functionality of PHAs through the introduction of new reactive functional groups in polymer chains (Sharma et al. 2021). However, PHAs that have undergone chemical modification frequently yield materials with poor mechanical properties. Through curing techniques, either utilizing natural, chemical, or physical crosslinking processes, PHAs with good mechanical characteristics can be created (Jo et al. 2021). The hydrophilic characteristics of PHAs are improved through plasma surface modification, photografting, and surface polarization, particularly in biomedical applications.

Physical Modifications of Biopolymers

Plasma Treatment

In plasma treatment, the biopolymer is subjected to thermal treatment in an inert atmosphere that is enriched with reactive atomic, molecular, radical, or ionic species. The inert atmosphere can be gases like air, nitrogen, argon, oxygen, nitrous oxide,

carbon dioxide, water vapor, helium, ammonia, or methane. Plasma, “the fourth state of matter,” is a gaseous environment comprised of inert or reactive gaseous radicals, ions, polymers, monomers, etc. with an overall charge density of zero. Plasma produced between high voltage electrodes contains high energetic accelerated electrons. This high energetic plasma containing electrons or reactive ions hits the polymeric surface causing the hydrogen radical abstraction or covalent bond breaking leading to the further functionalization with the radical present in the reactive plasma atmosphere (Kale and Desai 2011). The collision of electrons with air particles might cause oxidation of the substrate surface. The reactive plasma atmosphere could act in two ways:

- (i) Bombard the surface causing a chain scission on the surface for etching or activation by non-polymerizing gases like Helium, Oxygen, Nitrogen, or Air.
- (ii) Plasma-induced grafting or polymerization involving polymerizing gases containing reactive precursors like hydrocarbons, silicon monomers, etc.

Plasma treatments cause surface modification rather than bulk modifications. The surface functionalization of the biopolymers depends on the nature of the polymer surface, pressure, gaseous atmosphere, etc. For example, the H_2O atmosphere causes the hydroxyl functionalization of the polymeric surfaces. The monomers for the surface functionalization can be of a reactive intermediate or any ring structures with some degree of unsaturation.

Plasma treatment of nanocellulose in air induced hydrophobicity whereas N_2/NH_3 induced hydrophilicity attributed to the surface functionalization by polar groups (Flynn et al. 2013). Contradictory to this, bacterial nanocellulose did not show any effect by air plasma treatment (Pertile et al. 2010). The effect of ozone and low-temperature plasma treatment and acetylation modification on cellulose in biocomposites has been discussed by Lenfeld et al. (2020). Chitosan can also be surface-modified hydrophilic using oxygen plasma treatment and UV/ozone treatment. Both the treatments produced the oxidized carbonyl group keeping the amino group and the hydroxyl group of chitosan intact (Matienzo and Winnacker 2002). Also, chitosan is made adhered over the cotton and polyethylene terephthalate (PET) fabrics via low-temperature air plasma treatment surface modification of cotton and PET. The formation of carboxyl groups increased the adherence of chitosan on those fabrics (Shin et al. 1998). Starch biopolymer has also shown an increase in hydrophilicity by plasma treatment with a contact angle between 5° and 14° (Wiacek 2015). PLA has also shown increased hydrophilicity using medium pressure plasma treatment (Jacobs et al. 2012) and the surface modification of PLA by air atmospheric plasma treatment has been discussed in a review by Vilaplana et al. (2014). Depending on the nature of the substrate, the plasma treatment can lead to cross-linking, ablation, pre-deposition, or surface activation by forming free radicals on the substrate surface itself. Plasma oxidation, amination, and nitration will increase the hydrophilicity of the biopolymer.

Plasma treatment can be performed in low temperature, low pressure, or as atmospheric pressure plasma jet (APPJ) or atmospheric glow discharge (AGD). AGD uses high-voltage high-frequency radio waves whereas APPJ developed by

Fig. 2 Plasma treatment for surface functionalization. (Reprinted with permission from (Bazaka et al. 2011))

Jeong et al. (1998) uses atmospheric pressure plasma with temperature between 100 °C and 275 °C to treat a specific part of the biopolymer and also for three-dimensional structures and temperature-sensitive biological materials (Kalia et al. 2013). Low-pressure plasma uses atmospheric pressure or vacuum condition using low power output of about 60-100 W, thereby mitigating thermal damage to plant fibers and maintaining a uniform, high concentration of reacting species (Yuan et al. 2004). Plasma treatment is a clean, dry, and economically and environmentally benign technique with no emission of pollutants. It does not require any type of water or chemicals. It changes the hydrophilic and oleophilic properties of a biopolymer, wettability, and physical and electrical properties through surface modifications (Morent et al. 2008). Also, the plasma-treated biopolymers can be a platform for further surface modifications for the incorporation of different functionalities as per the need for application (Fig. 2) (Bazaka et al. 2011).

Plasma treatment might also pose some challenges like fragmentation due to the temperature conditions. Hence, a method of pulse plasma technique is now being used to give a fine control over the surface functionalization with good stability.

Bacterial Nanocellulose Coating

Coating with bacterial nanocellulose is a type of noncovalent modification. Non-covalent adhesion aids in physical adhesion or self-assembly of the macromolecules, polymers, nanoparticles, or any other modifying agents over the biopolymer surface. The method is very simple and sometimes later cured for stability (Choudhury et al. 2018). Bacterial nanocellulose stands different from other types of cellulose in terms of its high purity, water holding capacity, greater strength, and mold ability. The biopolymer plant fibers can be modified to increase the interfacial adhesion between the biopolymer and the matrix by just coating the fibers with bacterial nanocellulose.

The bacterial nanocellulose can be coated in situ by culturing the fibers in presence of bacterium like *A. xylinum* in an appropriate culture medium (Kalia et al. 2013).

Adsorption of Macromolecules

Macromolecules such as surfactants, copolymers, polyelectrolytes, or oligomers can be made adsorbed onto the surface of biopolymers via noncovalent interactions which tune the biopolymer for the hydrophobic properties. The adsorption on the biopolymer surface occurs via hydrogen bonding or intermolecular interaction or van der Waals forces (Habibi 2014). The surfactant molecules form a thin coating over the biopolymer which is evident from the small angle neutron scattering experiment studied on nanocellulose. Especially cationic surfactants like dodecyl trimethyl ammonium chloride possibly get easily adhered to the negatively charged surfaces of the biopolymer (Ansari et al. 2015). Uncharged macromolecules also adhere to the biopolymer surface. Thus the adsorption mechanism could tune the hydrophilic and hydrophobic properties and increase its dispersibility in a nonpolar medium (Kargarzadeh et al. 2018). The surfactant to biopolymer ratio greatly influences the hydrophobicity of the modified biopolymers. This type of interaction is not strong as the other covalent interactions and can easily be broken by vigorous stirring in excess water (Dhali et al. 2021).

Radiation

High energy gamma radiations, UV radiation, and even microwave radiations have also been applied for the surface modifications of biopolymers. The gamma radiations ionize the surface of the biopolymers creating the surface radicals or reactive ions which paves the way for further surface modifications like polymer grafting, crosslinking, oxidation, etc. for the tuning of hydrophilic or hydrophobic properties. Khan et al. reported the effect of gamma radiation on the water vapor permeability (WVP) of nanocellulose/methylcellulose composite film wherein WVP decreased from 41% to 28.8% (Salmieri et al. 2014; Kargarzadeh et al. 2018).

UV light has also been used for surface modification as a photochemical radical initiator for further surface modifications (Coulibaly et al. 2014). Microwave radiation creates an internal heat transfer within the biopolymer molecules which helps in further acetylation and hydrolysis which is reported with nanocellulose biopolymer (Kargarzadeh et al. 2018).

Chemical Modifications of Biopolymers

Mercerization

Mercerization is a technique used in the study of nanocellulose. It involves the use of concentrated NaOH solutions. Even though this is not a surface modification method, it involves a transition from cellulose I polymorph to cellulose II polymorph

which differs by the degree of crystallinity. Cellulose II is less crystalline than cellulose I and this difference will also be reflected in the hydrophobic and hydrophilic properties of cellulose. The transition of cellulose chains from parallel arrangement in Cellulose I to antiparallel arrangement in Cellulose II greatly affects the properties. This transition can be the effect of two reasons during this NaOH treatment: (a) disruption of the hydrogen bond network in the cellulose chain (Simon et al. 1988) and (b) the random presence of the anti-parallel and parallel chains in the junction of crystalline and the amorphous phase. Some papers report the combination of the two polymorphs in cellulose nanocrystals (Kobayashi et al. 2011; Kargarzadeh et al. 2018).

Esterification

Esterification reaction is a covalent modification involving the formation of ester bonds (-OCOR) to link modifying agents with biopolymers. Esterification occurs between hydroxyl group and acid or acid derivatives in acidic medium by the elimination of water. Many long-chain carboxylic acids or alcohols are reported to be reacted with the biopolymers to yield hydrophobicity in biopolymers. The biopolymer utilizes its hydroxyl group or modified carboxylic group to undergo this reaction.

For example, cellulose is converted to cellulose acetate via acetylation reaction with acetic anhydride. Catalysts like imidazole, trimethylamine, and lipase have been used to functionalize cellulose surface by the ester bond formation. Acid chlorides like dodecanoyl chloride and lauroyl chloride react with cellulose primary hydroxyl groups forming ester bonds by the elimination of HCl (Pasquini et al. 2008; Cunha et al. 2014). The long aliphatic chains thus incorporated can stabilize oil/water/oil interfaces (Kargarzadeh et al. 2018). Surface modification using anhydrides like succinic anhydride and maleic anhydride via simple coupling reaction with the surface hydroxyl groups of MFC is reported to produce negatively charged hydrophilic surface (Stenstad et al. 2007). The hydrophilic cellulose nanocrystals are made hydrophobic by a covalent interaction with octenyl succinic anhydride (OSA) for the application as a Pickering high-internal-phase emulsion (Chen et al. 2018).

Citric acid is used to tune hydrophilicity of lignocellulose via simple, cost-effective esterification, or etherification reactions. Cellulose undergoes esterification reaction whereas lignin undergoes etherification reactions (Fig. 3) (He et al. 2018). A simple solvent-free one-pot acid-catalyzed hydrolysis reaction and Fischer esterification reactions using natural di- and tri-carboxylic acids like citric acid, malonic acid, and malic acid are reported (Spinella et al. 2016).

Etherification

Etherification involves the formation of ether bonds (ROR) on the surface of biopolymers. The hydroxyl groups in the surface of biopolymers react with the modifying agent containing any best leaving group resulting in the formation of ether

Fig. 3 Citric acid modification of cellulose and lignin. (Reprinted with permission from (He et al. 2018))

bond in an appropriate reaction medium. The long chain modifying agents undergo this type of reaction to increase the compatibility with a hydrophobic matrix. The application of this reaction comes mostly with nanocellulosic biopolymers. Long-chain octyl bromide or dodecyl bromide reacts with the cellulose to form hydrophobic nanocellulose derivative via ether bond formation. The bromide ion gets eliminated during etherification (Bae and Kim 2015). Hydrophobic anthraquinone derivative is also made to undergo the etherification reaction for the generation of hydrophobic nanocellulose material (Gorgieva et al. 2015). Also, hydrophilic cationic nanocellulose can be prepared by the etherification reaction between the hydroxyl groups of nanocellulose and the epoxy group of (2, 3-epoxypropyl)-trimethylammonium chloride (Hasani et al. 2008; Kargarzadeh et al. 2018).

Silylation

Silylation reaction is a type of covalent modification involving the reaction between the silane coupling agents and the nucleophilic surface groups like alcoholic, carboxylic, or amine groups of the biopolymer. A vast number of investigations have been reported with nanocellulose to produce the hydrophobic material with a decrease in the interfacial tension between the polymer and a hydrophobic matrix or organic solvents. Cellulose could be modified using organofunctional silanes to form Si-O-cellulose and Si-O-Si bonds to induce hydrophobicity via condensation reaction (Abdelmouleh et al. 2004). Organofunctional silanes like triethoxyvinylsilane, n-butyldimethylchlorosilane, n-dodecyldimethylchlorosilane, octyldimethylchlorosilane, 3-aminopropyltriethoxysilane, isopropyldimethylchlorosilane, and hexamethyldisilazane have been used for the silylation of nanocellulose (Dhali et al. 2021). If the degree of silylation is not properly controlled, the crystallinity of the biopolymer will be lost, hence proper control of reaction needs much attention. Photolithography can also be used to deposit hydrophobic alkylsilane layer over CNC via chemisorption. Photolithography can also be used to deposit hydrophobic alkylsilane layer over CNC

via chemisorption (Kargarzadeh et al. 2018). The Kenaf nanocellulose fiber-carrageenan macroalgae biopolymer film is made hydrophobic by modification with trimethoxysilane in methanol (Oyekanmi et al. 2021).

Silanetriols in neutral aqueous solution had been demonstrated as a silane modifying agent by Spirk et al., generating a hydrophobic material. This exploited the surface hydroxyl groups of the biopolymers essentially polysaccharides. Later, the oxidation of these hydrophobic surfaces using ozone/UV could generate hydrophilic compartments on these biopolymer substrates. Hence, a combination of these two techniques could finely tune the surface properties of a biopolymer (Spirk et al. 2010).

Silane coupling agents like 3-glycidoxypolytrimethoxysilane, 3-aminopropyltriethoxysilane, and a Titanate coupling agent are used to fabricate a hydrophilic microfibrillated cellulose (Lu et al. 2008).

Polymer Grafting

Polymer grafting involves the covalent bond formation between long-chain aliphatic polymers and reactive sites in the surface of the biopolymers to improve its hydrophobic properties. The polymer grafting can be a successor of the other modifying techniques like esterification, etherification, silylation, acetylation, plasma, or radiation so as to generate reactive sites on the surface of the biopolymers. There are two grafting techniques involved in polymer grafting: “Grafting from” and “Grafting to” approach. “Grafting from” approach involves the growth of the polymer right from the reactive sites present in the biopolymer whereas the “Grafting to” approach is the technique of grafting the already designed polymer chain onto the surface of the biopolymer via any covalent reactions. “Grafting from” approach can result in the design of the higher density polymer grafted biopolymers due to less steric hindrance whereas the “Grafting to” approach results in low-density polymer grafts due to more steric hindrance of the already grafted polymer. “Grafting from” approach employs atom transfer radical polymerization or ring opening polymerization and “Grafting to” employs click chemistry approach or epoxy groups or nucleophilic addition (Kargarzadeh et al. 2018; Dhali et al. 2021). Other grafting techniques involve chemical vapor deposition (CVD), plasma enzymatic, etc. (Choudhury et al. 2018).

TEMPO-Oxidation

TEMPO (2,2,6,6-tetramethylpiperidine-1-oxyl) radical oxidation of biopolymers involves the hydrophilic modification of the biopolymers by the oxidation of primary hydroxyl to carboxylic acid groups. The dense polar carboxylic acid groups increase the dispersibility of the biopolymer in aqueous media. The negative surface charge density on the surface of the biopolymer increases its hydrophilicity. Also, these carboxylic acid groups can be a gateway for the other modifications for the biopolymers. In the case of cellulose, primary hydroxyl groups at C6 carbon atom undergo TEMPO oxidation (Kargarzadeh et al. 2018; Dhali et al. 2021).

Acetylation

Acetylation reaction aids in increasing the hydrophobicity of the biopolymer by the treatment with a high concentration of acetic anhydride in presence of a catalyst via a simple, cost-effective procedure. The acetate ester groups at the surface groups of biopolymer increase the dispersion of the biopolymer in nonpolar hydrophobic matrices. Acetylation also acts on buried hydroxyl groups of cellulose nanocrystals in addition to the surface hydroxyl groups. Single route to the acetylation procedure has been reported by Cetin et al. via trans-esterification reaction with vinyl acetate (Çetin et al. 2009).

Sulfonation

Sulfonation helps in the production of biopolymers with enhanced hydrophilicity and good dispersion in aqueous media. The presence of surface hydroxyl groups in the biopolymer undergoes hydrolysis with sulfuric acid to form sulfate half ester moieties. These half-ester moieties are negatively charged which enhances its dispersion in an aqueous medium by inter-anionic repulsion between the biopolymer particles. But sulfonation alone could not produce high density of sulfate ester moieties; hence an oxidation step must also be needed after sulfonation step. Chlorosulfonic acid has been used to modify nanocellulose by sulfonation reaction which showed a large negative surface charge density (Luo et al. 2018; Dhali et al. 2021).

Epoxidation

Another modifying technique includes epoxidation. Stenstad et al. reported the epoxidation of microfibrillated cellulose via oxidation with Cerium (IV) generating free radicals followed by grafting by Glycidyl methacrylate (Stenstad et al. 2007).

Other Covalent Modifications

Amidation

Grafting of hexamethylene diisocyanate followed by amination introduces positive charge on the surface of MFC. The grafting of hexamethylene diisocyanate gives hydrophobic nature but the excess isocyanate introduces allophanate groups with free amino groups which makes the surface hydrophilic (Stenstad et al. 2007).

Modification with Natural Polyphenols

The hydrophobic nanocrystalline cellulose is fabricated from micro-crystalline via oxidation-citric acid esterification-octadecylamine amidation (Majdoub et al. 2021).

Fig. 4 Covalent Mannich modification of cellulose nanocrystals with tannic acid and decylamine. (Reprinted with permission from (Hu et al. 2017))

The nanocellulose can be covalently modified with decylamine via a Mannich reaction forming a hydrophobic tail part over the nanocellulose nanocrystals with the involvement of tannic acid as a primer for the modifications in water media (Fig. 4) (Hu et al. 2017).

Modifications by Enzymes and Amino Acids

Starch is reported to be modified with lysosome solution which increased the hydrophilicity and antibacterial property (Wiacek 2015). Further, polyamide was surface modified with 3-(3,4-dihydroxyphenyl)-L-alanine (L-DOPA) for anti-fouling property by enhancing the acid-base interaction between the fouling agent and the polyamide reverse osmosis membrane (Azari et al. 2014).

Modification with Chitosan

Chitosan is deacetylated derivative of chitin, the natural polycationic linear biopolymer derived from the exoskeleton of insects, crustaceans, and cell wall of fungi. The structure of chitosan consists of randomly arranged β -(1–4)-linked D-glucosamine and N-acetyl-D-glucosamine randomly distributed within the polymer. Chitosan modifies the other biopolymers to become more hydrophobic like it modifies the PVA, a synthetic biopolymer imparting them with enhanced hydrophobicity (Jayasekara et al. 2004). Starch is also reported to be modified with chitosan solution and the contact angle measurement showed an increase in the hydrophobicity of the biopolymer and antimicrobial property (Wiacek 2015). Chitosan is reported to be linked with natural clay mineral, Halloysite exploiting the amino and hydroxyl functional groups of chitosan and the hydroxyl groups of the mineral, thereby tuning the hydrophobicity of the hybrid material (Tan et al. 2016).

Triazine Modification

Triazine chemistry for the modification of nanocellulose was carried out using octadecyl, benzyl, propargyl, and monoallyl-PEG triazinyl derivatives via aromatic nucleophilic substitution in presence of a base. The surface-modified nanocellulose showed hydrophobic or hydrophilic nature as per the modifying Triazine (Fatona et al. 2018).

Conclusion

Biopolymers are a class of polymers that are either biodegradable or derived from natural resources or both. Biopolymers are attracting marked attention due to environmental concerns and the growing need to decrease dependence on fossil and petroleum resources. Biopolymers possess many unique properties which make them potential alternatives to petroleum-based polymers, such as renewability, biodegradability, nontoxicity, biocompatibility, being environmentally friendly, etc. They also have mechanical properties comparable to conventional polymers. Due to the presence of reactive groups, biopolymers exhibit a wide degree of functionalities that allow physical and chemical properties to be modulated for intended applications. Surface modification of biopolymers is a well-known technique of functionalizing biopolymers to new materials with superior properties and applications. The physio-chemical properties of biopolymers such as hydrophilicity/hydrophobicity, water or organic solvent solubility/dissolubility, mechanical, thermal, and rheological, properties, etc. can be modified via chemical or physical surface treatments. When selecting a chemical modification, it is important to consider the simplicity of the chemical modification process. The complex modification process may hinder production scale-up. The selection of an appropriate modifying agent, and modifying technique must be done carefully in order not to weaken other intrinsic properties of the biopolymer such as its biodegradability. While some of the modification processes have been successfully implemented on a large scale, there is a growing concern about the environmental impact of these processes, increasing the need for the eco-friendly modification techniques and green modifying agents.

Abstract

The indispensable nature of plastic-based materials in packaging processes and their widespread global dependency marks an era of a “plastic crisis” with toxicological and environmental consequences to all living entities in our ecosystem. The potential biohazards associated with plastic manufacturing industries resulting from the chemical breakdown to toxic components present a challenging technological issue. While the petroleum-based plastic market is predicted to shrink marked by a notable effort toward an emerging bioplastic market bearing a low environmental load, the shift is expected to abolish the dependency on plastic

use in a plastic-free society. The bioplastic growth trajectory is discretely rising, but advancements have been dampened by price economics and the underperformance of biobased plastics due to material properties in comparison to their counterparts. Polymer blending is considered an important route in the design of new materials' properties to incorporate adhesive and interfacial features to impart biodegradable characteristics in the form of bioplastics. This chapter aims to present various approaches to blending strategies and to discuss the physical and chemical limitations of polymer blending, and structure-property relationships can yield bioplastics as viable materials.

Keywords

Bioplastics · Polymer blends · Copolymerization · Biodegradability · Biopolymers · Microbial degradation

Introduction

Polymers are the most abundant commercially used materials. Consumer-driven use of plastic use has exponentially increased. Alarming statistics reveal that one million plastic bottles reach consumers every minute and five trillion plastic bags are in circulatory use each year (United Nations, Environment Programme 2022) – a situation that promises to worsen with devastating consequences with the rise of industries (Mecking 2021). Plastic materials by their compositional nature are “single use products” and can show considerable resistance to degradation under ambient conditions making them heat, force (e.g., mechanical) and chemically, moisture, biologically, and weather resistant. This resistance can span decades of slow toxic release of plastic constituent materials into the environment. The consequential ripple effect of nondegradable plastics is driven by the dynamics of mother nature in the form of high velocity winds and ocean currents from local to global scales spreading to oceans (Jenna Jambeck et al. 2015) resulting in their accumulation (Lebreton et al. 2018) in ecosystems as far as the Arctic polar regions on the planet (Bergmann et al. 2022). The disintegration of plastics into secondary products in the form of microplastics (Zhang et al. 2021) from their bulk counterparts which exist on the millimeter scale or smaller is environmentally catastrophic to marine, land, and human life and results from the lack of reliable methods to detect and remove small-scale contaminants particularly if embedded within animals that enter the human food chain. Consideration is now being given to the fate of nanoplastics that find their way into reproductive organs of organisms which can be inherited by their offspring (Zhao et al. 2017). Plastic waste has now reached catastrophic proportions threatening the existence of life incubated by an exponentially increasing microtoxic environment.

The purpose-built nature of plastics as long durable polymer chains is resistant to environmental stress and strain, chemical attack, and physical absorption which are variable features of different plastic compositions. Such characteristics define material toughness, stiffness, mechanical properties, moisture and gaseous absorption (vapor diffusion), hydrolysis, compressibility (mechanical load) and creep, and UV

Fig. 1 Comparison of plastic degradation rates of Landfill (L), Soil (S), Marine (M), Biological (B), and Sunlight (S). (Reprinted from (Chamas et al. 2020). This work is licensed under a Creative Commons Attribution 4.0 International (CC BY 4.0))

resistance. Questions that are universal to understanding the physical and chemical resistance of plastics and many pertinent issues related to plastic degradation remain elusive (Chamas et al. 2020). The variability in degradation rates of commonly categorized plastics summarized in Fig. 1 provides insightful clues of the persistence of polymers in the environment, and their degradation profiles can be highly multiphasic as the disintegration of the materials depend on their dimensional occurrence, polymer type and complexity, filler content, and susceptibility to degradation and the surroundings. Such factors decidedly determine the fate of degradation that may be mediated by chemical, physical, or biological means.

Reducing plastic waste consumption through the utilization of alternative material packing and increasing efforts to recycle plastics can certainly slow down the impact of plastics and their derivatives. However, the huge global dependency on plastics from food containment to pharmaceutical packaging inevitably means that the demand for cheap plastics will continue to contribute to this growing crisis. Hence, there are growing concerns that recyclability which applies to only 10–25% of waste plastics will not be able to sustain and accelerate growth to a plastic-free environment. To overcome this limitation, it is essential to ensure that plastic utilization is aimed to be entirely recyclable or to undergo some process to reinvent waste plastic into a reusable form. Solutions to resolving the sustainability of environmentally friendly and degradable plastics have become an urgent matter of formulating polymer chemistry through engineering of molecular building blocks and bond accessibility for safe degradation using a multidisciplinary approach involving aspects of polymer chemistry, materials engineering, and biological science (Fig. 2). This reflects that the future of plastic formulation has evolved into a multifaceted cross-disciplinary area (Belontz et al. 2019). This will likely involve engineering new functionalities into plastics for the facile disassembly of persistently long-chain lengths into smaller components which are not toxic (Yun 2011).

Fig. 2 Multidisciplinary overlap to engineering plastics

Breaking of C-C and C-H bonds via oxidative bond cleavage resulting in the fragmentation of the carbon framework into removable or nontoxic components on a timescale that can process tonnes of quantities of plastic on a daily basis is currently unachievable. A key goal is to deliver a rational technology to modify the polymer skeleton of plastics by weakening bonded structures and making available new entities for transformations into precursors for manufacturing of industrially important constituents (Vollmer et al. 2020). Ceasing such opportunities for the conversion of degraded synthetic by-products into commercially useful avenues can visibly have a positive impact on the environment.

Mechanisms that involve bioremediated destruction of polymers by microorganisms are inspirational by design provided by nature itself. Bioplastics from a cost perspective are considered expensive, but their interest has slowly but steadily increased over the last decade. A hallmark of biodegradation is often signified by metabolic products – carbon dioxide, water, and methane – driven by electron transfer processes that utilize oxygen, hydrogen, and metals and thus facilitating bond cleavage for energetically demanding bond conversions.

A promising route that has steadily gained considerable interest over the last few decades is the concept of polymer blending. Principally, polymer blending is based on the rationale of tuning the physical and chemical characteristics of polymers which when combined into a single polymer, certain properties can be suppressed or enhanced, or more probable is the introduction of new characteristics acquired by the resulting blend. Polymer blending has the potential to deliver renewable plastics as new materials from existing sources through mixing and processability by overcoming barriers to their formation that may be chemically demanding. There is an unmet need that combines the economics of material production with selected engineered properties that falls within the periphery of stable plastics for the purpose they are

made but adequately unstable for less costly degradation strategies. These limitations can be overpowered by the design of blended polymers which can structure and shape materials for one of the most sought after functionality of materials today – controlled degradability of by-products.

This chapter brings a recent perspective on polymer blending strategies to introduce new material capabilities as viable solutions to ultimately reduce the environmental burden from the overload of plastic released into the far-reaching habitats of our ecosystem and beyond through ocean waste (Suaria et al. 2016; Jambeck et al. 2015). We also discuss the limitations of polymer blends with a view to explore some of the key reasons that must be addressed in order to secure the future from the growing threat of plastic intoxication.

Nonbiodegradable Degradation of Plastics (Abiotic)

The chemical degradation of polymers that do not involve the action of microbial components in their breakdown to liberate polymer fragments is termed as abiotic. Early investigations on biopolymers, namely, starch, show that they ordinarily degrade assisted by the presence of prooxidant (Koutny et al. 2006) which under abiotic conditions driven by thermal aging degenerates to monomer products released as ketones, aldehydes, alcohols, lactones, and carboxylic acids (Albertsson et al. 1994). Polymers receptive to photooxidation also represent important abiotic pathways (Fig. 3) through which common plastics can absorb external light energy to excited chemical states and photo-degenerate to smaller stable products (El-hiti et al. 2022). Under changing weathering conditions, synthetic plastic/polymer degradation is unfeasibly slow spanning decades with very limited depolymerized fragmented product evolution. Evidence has recently surfaced which points to the abiotic chemical destruction of potent chlorinated tetrachloroethene (PCE) and trichloroethene (TCE) using abiotic processes. An abiotic route for the accelerated breakdown of synthetic plastics was shown by the addition of oxo-additives to synthetic plastics PP, namely, oxo-degradable polypropylene (PP-oxo) and high

Fig. 3 Degradation products generated from abiotic products. (Reprinted from (Chamas et al. 2020). This work is licensed under a Creative Commons Attribution 4.0 International (CC BY 4.0))

density polyethylene (HDPE-oxo) under weathering differing conditions (Ángeles-López et al. 2016). The study reveals that it is possible to reduce plastic resistance to disassemble under ambient conditions. Further, the use of Fe(II) at concentrations of 20 mM were effective in the structural degradation of chlorinated polymers resulting in the release of detectable PCE and TCE reduction products (Entwistle et al. 2019).

A recent study attempted to decipher some of the complexities associated with plastic degradation by probing abiotic and biotic activities related to polymer degradability and structure-property data as predictors for screening underlying hierarchical patterns of variable polymer types. Using a key parameter defined by hydrophobicity ($\text{Log}P$) modeling, crystallinity, T_g , number-average molecular weight (M_n), and dispersity (M_w) were screened against 110 polymers exhibiting a wide range of hydrophobicities (Fig. 4b) using a computational predictor tool, modeling (Fig. 4a), and machine learning. The findings provide significant insight of functional group chemistry of carbonates, esters, and amides with low hydrophobicity that assists abiotic hydrolysis and biotic mechanisms. This is in contrast to higher $\text{Log}P$ values correlating to C-H bond the breakdown of which is perturbed by additives. Polyester hydrolysis is largely influenced by positive changes in values of $\text{Log}P$ and crystallinity affecting degradability. Further, the study concludes that biotic mechanisms operate more rapidly compared to abiotic routes (Min et al. 2020).

The Problem with Plastic and the “One-Way” Transition from Recycling to Polymer Blends

The long-chain composition of polymers and the resulting complexity in terms of shape and structure are usually a result of strong bonded networks intricately defined by assembly patterns of repeated units locked into a predetermined configuration. Thus, molecular bond chemistry is at the heart of the “plastic” industry. Decades on, polymer chemists are now working to undo what their predecessors have worked tirelessly to achieve – strong polymer plastics. However, reversing tough polymer bond synthesis is no easy task. While some plastics are easily reversible, others pose a huge environmental burden. The variability in polymeric bond strength, the toxicity of breakdown products, and the recovery of starting materials coupled to the cost and severity of processes pose workable barriers to manage plastic disposal. While it is chemically feasible to drive polymerization reactions from monomeric units, it is energetically demanding to depolymerize some of the more common plastics. For instance, polyolefins composed of polymerized alkenes are an example of some of the most difficult plastics to degrade and are estimated to decompose only up to 0.5% of their original structures over a period of 100 years. Polyolefins such as polypropylene and polyethylene are ubiquitous industrialized plastics used for their high density, low density, and linear low-density characteristics with wide-scale properties highly resistant to oxidation in their hydrophobic states (Koteswara Reddy and Kiran 2019).

Due to bond strength, pyrolysis continues to be a commonly chosen method for breaking polymers into smaller units. With temperature, time, and pressure being key parameters for steering the molecular assembly of polymers, the same parameters are being used to control the release of monomers from their polymeric counterparts as a pyrolysis-based renewable technology for recycling complex plastics on a commercial scale. The technology drives the process to deliver useable monomers from a high carbon feed to a low carbon output by minimizing the oxygen availability of the environment. Mundane degradation caused by weathering conditions in the natural environment typified by low susceptibility to polymer oxidation and hydrolysis' subsequent breakdown is both uncontrolled and impractical for managing plastic pollution. The initial conversion of hard-to-degrade plastics from a state of low-to-high susceptibility for bond cleavage to occur requires (1) processes which can match or exceed the current and future rate of plastic utilization; (2) the

conversion or incorporation of bond types that are accessible to bond fission; and the (3) controlled release and containment of degradation products for safe disposal, particularly microparticles that often find their way into the digestive tracks of animals.

While toughness has been a key attribute to polymer performance, environmental policies are reshaping a new trend in polymer design, and time and cost are an added advantage of bond making and bond breaking. Although high-temperature recycling and polymer blending approaches are conceptually different, both methods border on the same on delivering low-carbon products as precursors for further recycling and commercialization (Fig. 4). However, the primary advantage of using polymer blending to pyrolysis or catalytic processes for disposing chemicals is the suppression of volatile toxic fume release such as chlorine from poly(vinyl chloride) which is often uncontrolled in the latter process. Gaseous by-products like hydrochloride render heat-driven processes unsuitable, and polymer blending using chemical approaches could be a more environmentally acceptable procedure to possibly reduce, divert, or even eliminate poisonous side products during the monomerization of polymer chains (Walker et al. 2020). Using the example of polyolefins as one of the most persistent man-made plastics that exist on our planet, processes which involve oxidative degradation usually via the absorption of thermal energy from natural sunlight result in excessively slow degradation (0.5%) of the polymer that spans decades. The O_2 activation from the sun's energy can directly permit bond scission of the carbon chain and liberate free radical structures with variable energies, and the radicals formed hold the potential to introduce a new array of reactive moieties such as carboxylate and hydroxide anions and hydrocarbon radicals which pacify other radicals to form stable shorter chains and molecules (Fig. 5). The introduction of localized hydrophilic regions within the hydrophobic polymer through high energy absorption of thermal energy from the surroundings forming smaller structures can be further used by microorganisms as a source for carbon. The utilization of carbon units in metabolic product assembly is coupled to CO_2 and H_2O release and underlines processes that essentially support life. This can only occur by the interaction of microbial cells with recognizable structures and their entry into cells. However, most plastics have almost negligible oxodegradation profiles and must be assisted by additional groups that are aligned to nature. Considerable efforts are being applied to engineer nonbiodegradable plastics derived from petrochemicals into biodegradable forms to enable their interaction and uptake by microorganisms for carbon recycling. Polymer blending is one such process to formulate new but more desirable properties by combining existing ones which is inherently different to the intrinsic nature of the separated polymer components. Hence, copolymerization of the blended components offers a cheaper alternative to modify polymer properties using a facile route compared to the polymerization of new monomers or their reformation prior to polymerization.

Polymer blending as an approach to tailor polymer properties as desired for task-specific functions has gained superiority to using base materials for the assembly of different types of plastics with variable characteristics that traditionally depended primarily on synthetic conditions. The distinctive functional features of the new

Fig. 5 Thermocatalytic recycling of complex plastics and polymer blending of synthetic polymers leading to the introduction of engineered properties for facile degradation into useful recyclable precursor products

polymer blend take advantage of the most economical and most versatile approach to access the most diverse property range completely different from its constituent properties. In view of the current accumulation rates of plastic (Geyer et al. 2017) and its effect on the natural environment, the complete recovery of carbon from plastic for renewable use is a leading mandate of the twenty-first century. Degradation strategies are now geared toward biobased plastics composed of compostable and biodegradable polymer frameworks. A central concern to the design of biodegradable plastics is the degree of synergistic interaction and compatibility during coprocessing of the blended components to make the process and the product as feasible as possible. While the properties are different to the source, both the physical and chemical properties are dependent on individual elements that come together in a single phase rather than as a composite in which the components are separated by virtue of their own properties in a multiphase. Structural factors such as complexity, bond type, composition, polymer arrangement, and the degree of crystalline / amorphous morphology and physical properties like solubility, density, and molecular weight and toughness ultimately determine the polymer degradability (Zeenat et al. 2021).

Biodegradable Plastics: Understanding Microbial Interaction

To gain an appreciable understanding of the mechanisms microbes use in their interaction and degradation of plastic, it has become necessary to profile the inherent structural and functional characteristics microbes use to derive carbon from plastics

waste. Modeling microbes versed in polymer chain scission can provide a potential wealth of information in understanding the mechanistic aspects of biodegradation of polymers to useful precursor materials such as hydrocarbons (Pundhir and Gagneja 2016). In the same context, biostability of plastics that show resistance to degradation in biological environments is equally of interest to determine how material persistence is related to functional group chemistry (Padsalgikar 2017). Some earlier observations demonstrated the biodegradable activity of microbes toward synthetic plastics. The parametric of weight loss, polymer elongated shape change, and tensile strength were notable effects of the interaction of lignose microorganisms with heat and UV-treated oxidized polyethylenes under culture conditions (Lee et al. 1991). Microbial degradation of UV-irradiated samples showed superior performance indicating increased susceptibility to the UV-induced oxidized state of the polymer and hence better accessibility to bond cleavage and highlighting the importance of the pro-oxidized weakened state of the extensive carbon skeleton framework. This is suggestive of the notion that a thermo-or UV oxidative pathway is the preferred route by which oxygen can liberate shorter chain lengths from polymers that are elevated to structures of higher energetic order. This can initiate chain scission events along the length of the polymer resulting in radical formation (George Wypych 2015) (Fig. 6). The diverse range of detectable oxidative products that include a wide selection of functional organic structures including alkanes, esters, alcohols, carboxylic acids, aldehydes, ketones, and keto acids, among others, brings into question the multiple mechanisms nature microorganisms employ to access (Hakkarainen and Albertsson 2005).

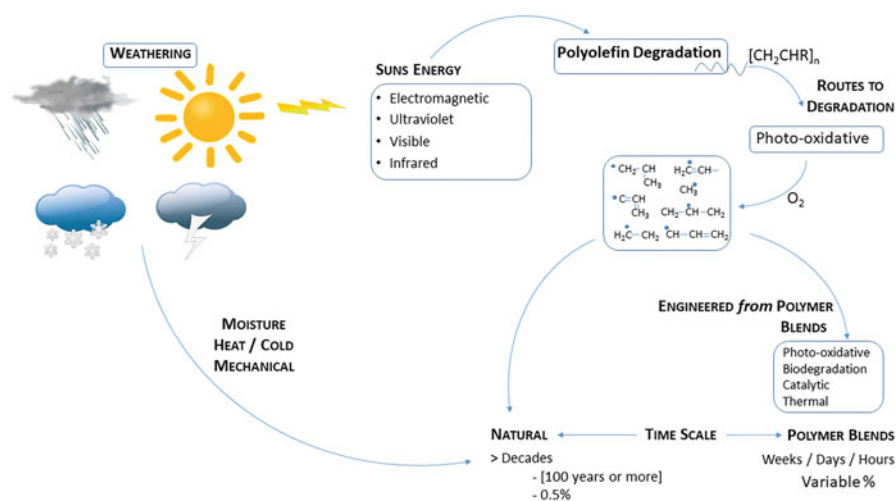

Fig. 6 Slow polyolefin bond degradation under natural weathering conditions can be accelerated by the introduction of engineered polymer blends

Barriers to Biodegradation

Some of the common commercially used plastics are shown in Fig. 7. Most of the polymers targeted for degradation by microbes are naturally occurring polycaprolactone (PCL) and polylactic acid (PLA) and have not evolved to efficiently disassemble unsaturated bonds of the C = O and C-O-C type which are often further stabilized by additives as plasticizers or fillers as supports (Björkner 2000). However, there is considerable debate surrounding the biodegradation of synthetic of plastics by microorganisms (Lear et al. 2022) and their standardization in general to degradation (Chamas et al. 2020). Modest efficiencies typically less than the 20% upper limit which falls far below the expected threshold required to diminish the plastic population to nontoxic levels. Currently, the high molecular weight of macroscale plastics and the addition of fillers, plasticizers, and antioxidants intensified to their general inertness make accessibility to these chemical functional groups extremely difficult as microbial substrates. Other barriers to biodegradation are shown in Fig. 8. Degradability of high resistant plastics notably low density polyethylene (LDPE), high density polyethylene (HDPE), polypropylene(PP), polyvinylchloride (PVC), polyethyleneterephthalate (PET), and polystyrene (PS) is largely attributed to high bond strengths which usually require temperatures

Fig. 7 Structures of some common plastics used in commercial products in a varying proportion

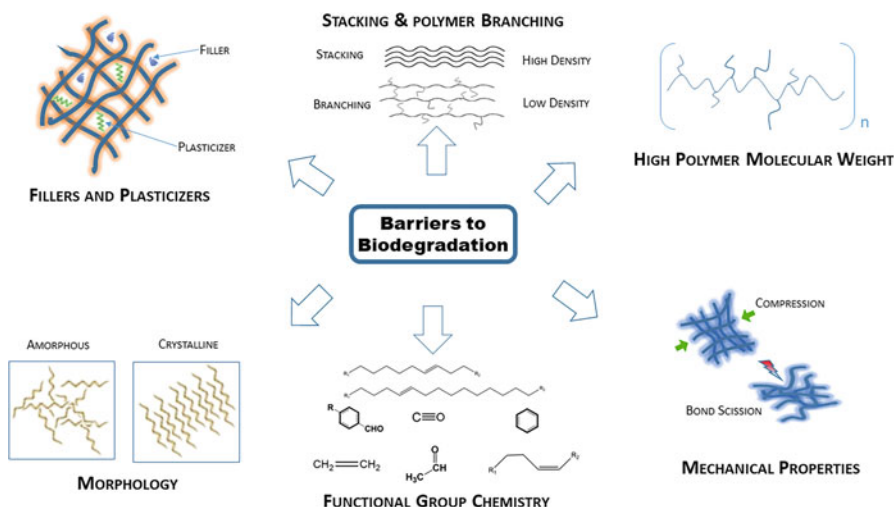

Fig. 8 A summary diagram of the barriers to biodegradation through natural processes

exceeding 100 °C and external mechanical stresses ranging from 10 to 15 MPa to break them. The alignment of the polymer bond is enhanced through the stacking of chains which contrasts the arrangement of branched polymer morphologies forming less densely packed structures which are more accessible to bond scission and enzyme degradation. Unrelated to the stacking or nonstacking nature of the polymer, the morphological state of plastics that reside between the fully crystalline and amorphous state impacts the extent to which it can be biologically degraded (Ronkvist et al. 2009) suggesting that microbial enzymes such as PETase may be better suited to depolymerize plastic materials of semicrystalline character and aromatic polyesters while showing little to no specificity for aliphatic structures. Also functional group chemistry exhibited by plastics becomes important not only for the potential for degradation but also for the utilization of degradation products as a carbon source for energy and metabolic product growth as demonstrated by the assimilated use of poly(ethylene terephthalate) (Yang et al. 2016). Perhaps the biggest barrier to biodegradation is functional group chemistry. Since nonpolar aliphatic C-C bonds are intrinsically inert, their uncreativity renders them demanding to split enthalpically. The exceptional stability of the carbon bonds makes it difficult to excite bond opening to more stable complexes particularly those of the metal type via an insertion mechanism (Jun 2004). However, C-C bond cleavage is ubiquitous in nature, and the high bond inertness necessarily requires access to functionalized groups within the polymer structure that is integral to biological catalysis. As in enzymatic cleavage of C-C bonds, transformation to other forms requires redox reactions which is often not the case with C-N and C-O bonds in the case of cytochrome P450 reactions (Guengerich and Yoshimoto 2018). Hence, bacterial enzymes can target polymer degradation products such as aldehydes and ketones for conversion to alkenes, alcohols, and acids from aromatic

hydrocarbons via carbocation and de-saturated intermediates, electrophilic, decarboxylation, nucleophilic, desaturation, and oxidative cleavage-driven reactions.

Hence, in the same context, it becomes crucial to understand the importance of functionalization of synthetic polymers in plastics in pursuit of their biodegradation. Plastics that use polyvinyl alcohol (PVC) and polyethylene succinate (PES) are able to accommodate more cleavable groups in their structure in the form of hydroxyl and ester moieties, respectively, which are recognizable by a large number of microbial strains. The incorporation of hydroxyl groups in highly resistant polymers can considerably aid polymer breakdown as modeled by polyethylene glycols (PEG) containing terminal hydroxyl groups (Rogers et al. 2019), and the conjugation of PEG-OH can provide added hetro-functionality to biopolymers like chitosan broadening their utility (Wu et al. 2008). Recently, Hadad et al. (2005) found carbonyl residues induced through photo-oxidation had a strong correlation with biodegradation activity of polyethylene via the thermophilic bacterium *Brevibaccillus borstelensis*.

Polystyrene, on the other hand, is strongly hydrophobic, variably thick, and a very durable plastic which makes the polystyrene composition hard to degrade in most landfill and soiled environments. The chemical modification of the polystyrene is required for microorganisms to adapt for the metabolic feed to occur usually oxidative enzymes to make available metabolically utilizable carbon-based substrates. This can occur readily under UV irradiation (Yousif and Haddad 2013) which initiates the production of mobile radicals that recombine following carbon-carbon bond chain scission to form energy precursors (Fig. 8). In the absence of a high energy input, PS degrading bacteria isolated from the gut of superworms have been identified as a serine hydrolase where the enzyme activity is characterized by a shift from hydrophobicity to a hydrophilic environment, and this change is accompanied by an increase in unsaturated carbon-oxygen bonds. Hence, oxidation of the C-C bond to a C-O is the first step to the enzyme-directed depolymerization process (Kim et al. 2020). Depolymerized products obtained from sunlight-treated oxo-biodegradable bags were taken up as metabolic substrates reinforcing the importance of the prooxidant state of the original polymer (Da Luz et al. 2014).

The attachment and growth of microbial colonies leading to the formation of biofilms also has an important place in plastic degradation. Surface hydrophobicity in plastics tend to discourage the colonization of bioentities to microparticles by PVA (Hüsler et al. 2018) and also by resisting non-specific protein adsorption via surface water (Shengfu Chen et al. 2006) which forms both a formidable physical and enthalpic barrier to invading microbes (Shenfu Chen et al. 2010). It has been reported, however, that certain synthetics support growth of bacterial colonies (Sivan et al. 2006). The lack of adhesion is overcome through the secretion of biosurfactants that take the form of lipopeptides and glycolipids from microbes that enable swarm mobility at the surface correlated to surfactant release (Be'er and Harshey 2011). The notion that plastics are not fully eliminated from the environment but persist as microplastics of the size order $\sim 100\text{ }\mu\text{m}$ in effluent waters (Wolff et al. 2019) adds another layer to the plastic problem. In an effort to ascertain how biofilm communities grow and effect polymer surfaces, microplastics derived

from polyethylene [PE], polypropylene [PP], and polystyrene [PS] were incubated with sea water bacterioplanktons. Figure 9 shows that crystallinity, stiffness, and compressibility are affected significantly relative to control samples in water in the absence of microbes. The increased crystallinity of [PE] was notable in comparison to the control sample, and [PP] experienced the most significant loss in stiffness while the other polymers were similar to the control (McGivney et al. 2020). The loss in material property from the structural changes observed in this study and the irreversibility associated with this loss primarily from the breakdown of structure and mechanical properties suggest that degradation of smaller particles through the formation of biofilms is possible resulting in the variable accumulation of different bacterial colonies (Fig. 9). Specific effects are assigned to changes in surface chemistry and provide evidence for the attachment and degradability of polymers with strong dependency on the polymer structure. Hence, biofilm formation is polymer specific (Figs. 10 and 11).

These studies suggest that polymer biodegradation hinges on a number of factors, a single decisive factor rests on the structural and group composition, and the structural compatibility of the polymer-microbe is highly dependent on the nutritional source and energy requirements of microorganisms. Hence, the general limitation of polymer degradability might also be regulated by nutritional and energy requirements and the process may relate to a specific source type of plastic. This

indicates that synthetic polymers are not optimal substrates for secreted enzymes but rather are optimized for biopolymers that undergo rapid biodegradation such as chitin, cellulose, corn, starch alginate, etc. This requires the implementation of strategies and technologies to accelerate polymers that are not biologically designed for depolymerization but synthetically resistant in their makeup. One of the biggest challenges faced in the current era is the mass availability of alternative polymers that can easily replace plastics with sustainable properties that rival the mechanical characteristics and durability of polymerizable “hardcore” plastics. While polymer blending can deliver eco-friendly replaceable plastics, much effort is being directed to fabricate favorable polymers blends formulated with new elements for easy waste disposal with the same utilizable quality of existing plastics. Polymer blending is perhaps the only sustainable alternative to reduce and minimize environmental toxicity while partnering with the mechanics of natural living ecosystems to recycle plastic waste.

Polymer Blends Composed of Synthetics Polymers

Mainstream materials used for “everyday” packaging applications still remain essentially nonbiodegradable, and their replacement or their compatibility through modification is necessary to deliver environmentally safe and sustainable degradable products. Polymerizable monomers that can be environmentally degraded such as biodegradable polymers are extremely attractive to overcome these challenges. While synthetic polymers possess very strong bonding associations across the polymer backbone in traditional material such as polystyrene, biodegradable polymers are generally characterized by weaker bonds that allow them to satisfy their natural role as functionally degradable biomaterials. The replacement of synthetics with existing biodegradable materials is often hindered by inadequate mechanical properties and cost limiting their long-term durability. In response to the plastic crises, interest has intensified in recent years to chemically rationalize polymer with phase properties that favor their breakdown without damaging the marine and soiled

environments. The current approach is looking to overcome issues related to thermodynamic immiscibility which is often subject to thermodynamic aging in the face of nonstable interfaces that change physically with time (Vanhee et al. 2000).

Natural polymers fall into a number of functional group categories identified by their repeating chemical unit which are normally not programmable interconvertible with each other despite the adsorptive ability to interface with other chemicals, to show temperature and mechanical responsive behavior, and at the same time to resist change and retain their original structures which are strongly aligned to their chemical and physical properties. However, conditions are applied outside the stability range of the polymer by creating weak chemical links to liberate stable and reactive high energy radicals for creating new bonds in inert structures.

To address the process-cost factor relationship for achieving material sustainability for alternative polymers applicable in a broad commercial context, polymer blending finds considerable utility that makes use of a number strategies to enhance mechanical properties in particular (Paul 1992). Polymer composite technology is seeking to use base materials that are chemically different in tier properties and hold the potential to modulate both physical and chemical properties when strategically combined as a new biodegradable polymer blend. Man-made polymers that are not natural targets for biodegradation but can be chemically engineered to use biodegradable properties through compatible blending of functional are coming of age as the commercial is forced to move away from synthetics. While biodegradable polymers consist of many of the characteristics synthetic chemists aspire to incorporate into synthetic materials, the cost of making available natural biodegradable polymers is being challenged by tailoring chemistry itself to make synthetics susceptible to degradation via chemical routes using stimuli-responsive cleavable linkages – strategies that are becoming important for drug delivery (Zhang et al. 2012), cosmetics (Adli et al. 2020), and biomedical applications (Ju et al. 2009). Biobased polymers are poised to become the new bioplastics to replace petroleum of fossil-fuel plastics which have limited recyclability and utility after successive rounds of waste processing while decreasing the plastic grade quality. Selecting alternatives to “throw-away” plastics inevitably means choosing easily degradable components with limitless recyclability. To control the surge of petroleum-based plastics and their environmental impact, there has been a conscious shift to produce green plastics to replace their shift in product and food packaging and other sale products including toys and sports equipment. Such strategies open exceptional opportunities for overcoming these limitations with appropriate approaches to overcome barriers to their immiscibility, chemical compatibility, as it applies to performance-related behavior.

From an environmental point of view for the management of plastic degradation in soil, Varyan et al. (Varyan et al. 2021) proposed to use low-density polyethylene (LDPE) with natural rubber. With particular emphasis on low-strength synthetics, this approach makes use of low-strength polyethylene. The selection of the additive fits well with the rationale of weak bonds in LDPE in that the elasticity of the rubber additive reduces the elongation of break of the composite accompanied by increased water adsorption and caters for an efficient route for the biodegradability of PE in the

soil environment. However, soil degradation of natural rubber composites by microbes was reported to be dependent on filler content, filler particle size, and chemical treatment. Figure 12 shows the different types of enzymes that degrade natural rubber. Particularly, lignocellulosic fillers at the microscale played a prominent role in degradation, but chemical treatment significantly delayed microbial degradation of composites. Microvoids (revealed by SEM) indicated that tensile strength and hardness were sharply reduced facilitated through the formation of microvoids which also resulted in weight loss determined over a period of days (Sareena et al. 2014). Figure 13 shows an image of microvoids by scanning electron microscopy (Muniandy et al. 2016).

Natural polymers are prime targets for replacing fossil-based plastics for mainstream applications. Some of the more common pursuits are poly (lactic acid) (PLA), among others, pertinent to industry including polybutylene succinate (PBS), polybutylene succinate adipate (PBSA), polyhydroxy alkanates (PHAs), and polybutylene adipate terephthalate (PBAT), silk wool, Nylon-2-nylon-6, Poly β -hydroxybutyrate-co- β -hydroxy valerate (PHBV), cellulose, cyclodextrin, chitin, alginate, polysaccharides, starch, and rubber. The most recent consensus is that materials like PLA are feasible as replacements for synthetics for artificial bioplastics balanced by a high biocontent exceeding 80% (van den Oever and Molenveld 2017). The performance profile of a substituted biopolymer benchmarked against PS is shown in Fig. 14. The modeling of additives or modifiers in the substituted polymer signifies retainment of a high biocontent between 72% and 85%. This might be indicative of the unchanged biodegradation characteristics between mineralized and nonmineralized polymers, namely, PBS, PHBH, PBSA, and PBAT but marked an increase in the moduli state of the polymer (Ángeles-López et al. 2016).

There has been considerable interest for formulating novel biodegradable materials with the capability of enhancing mechanical properties of biodegradable blends which currently are limited by their fragile mechanical and thermal properties. In this respect, cellulose and chitosan (Nasalapure et al. 2020), their derivatives at the micro/nanoscale, exhibit water properties which may be coupled to their mechanical resistance. Polymer blends with short-life properties are of particular interest for tuning their biodegradability as an intrinsic property of the blend. However, some of the most efficient biodegradability rates are associated with biodegradable polymer blends (PCL-Starch) compared to the individual components (PCL and Starch) (Cho et al. 2011), and the inclusion of synthetics tends to drastically slow down depolymerization. Another ongoing concern with acidic biopolymers is the highly acidic nature of biodegradable products into the environment. While the chemistry of biosynthetic degradable polymers can potentially curb the release of acidity products through strategic polymer design, a congruent structure mimicking the blend lactic acid and glycolic was synthesized to lower the acidity of released products relative to both the natural polymer acids. The requirement for neutralization of biodegradable products of polyphosphazene/poly(alpha-hydroxyester) blend were reported to be significantly lower than those associated with the natural polymer acids (Ambrosio et al. 2002).

Ideally, aligning the plastic properties of the polymer blend to suit its degradability under both biotic and abiotic conditions might be envisaged to broaden its applicability. This serves as an important goal to minimize the persistence of the synthetic component of the blend in diverse aquatic and soil environments that have variable effects on its degradability. For example, natural polymers may degrade differently under the same physical conditions (e.g., temperature) with varying degradation rates and accumulate differently in the environment. Biobased polymers are poised to become the new bioplastics to replace petroleum of fossil-fuel plastics which have limited recyclability and utility after successive rounds of waste processing while decreasing the plastic grade quality. Selecting alternatives to “throw-away” plastics inevitably means choosing easily degradable components with limitless recyclability. To control the surge of petroleum-based plastics and their environmental impact, there has been a conscious shift to produce green plastics to replace their shift in product and food packaging and other sale products including toys and sports equipment.

Controlled biodegradation and the release of nonharmful products from disposal plastics require a better understanding of the chemical and physical factors across all scales. Current and future objectives rest on understanding numerous aspects of polymer blends that relate to the composition type and methods used for blending, influence of blending ratios, and morphology and properties of composite; biodegrading rates and blends could be made smarter using analytical tools. A lack of understanding in the blending of biopolymers with synthetics such as that of starch with LPPE/TPS subjected to multiple cycles of extrusion processes does not often result in significant enhancement of mechanical properties (Peres et al. 2016) as desired. For example, AFM and ToF-SIMS have been used to conclude the distribution of surface energies in PLC and PVC blends and the location of Cl and O ions along the ridges and valleys of the blend (Chan and Weng 2016) (Fig. 15). Also, a leading limitation is in extending the utilization of polymer blends for the biodegradation of synthetics in distinguishing between miscibility, immiscibility, and complex mixed blends in between the extreme phases. In this context, Positron Lifetime Spectroscopy (PLS) and a hydrodynamic approach have been used to determine the level of interfacial adhesion (Ranganathaiah 2015) and to assess the potential for degradability. Such new techniques build upon knowledge relating to the compatibility of polymer blends using more traditional methods (Venkatramanan and Arumugam 2010). The method has been useful in establishing the degree of friction, repulsion, and attraction between biodegradable PCL and PVC components of the blend. For blends comprising a volatile solvent component, information is derived from processing conditions specific to blend ratio and evaporation rates. Computational approach has been insightful in relating such parameters to internal morphological patterns and to characterize emerging morphological types. The method therefore has considerable value in deciphering the mechanics of multistage processing, and often this information remains hidden and unavailable for process

optimization (Pokuri and Ganapathysubramanian 2016). Additional factors driving the use of polymer blend technologies as future plastics not only reduce the carbon footprint of nondegradable plastics but also encourage the derivatization of CO and CO₂ while lowering energy requirements and temperatures, better by-product utilization of waste-degraded products. Efforts in this direction have seen new patented technologies emerging that take these into consideration by making use of polyolefins such as polyethylene (PE) and polypropylene (PP) as ingredients for blends and films with aliphatic polycarbonates (APCs) (Scott and Sanjeev 2013). For polymer blends that require a noninvasive route to their characterization, phase-sensitive acoustic microscopy can uniquely probe elastic subsurface material properties revealing a detailed contour with water as a coupling fluid (Ngwa et al. 2005), imaging difference between atomic force microscopy (AFM) and phase-sensitive acoustic microscopy (PSAM) (Fig. 16).

The advantage of using polymer blends composed of both a synthetic and a biosynthetic component is that the degradation of the biosynthetic counterpart which proceeds more readily necessarily assists in the fragmentation of the synthetic part allowing it to be more easily metabolized and thereby reducing the polymers bioresistivity. Polycarbonate (PC) is an example of one such biodegradable – a semicrystalline polymer that exhibits strong rigidity and mechanical toughness. However, the PC has long been recognized for its industrial importance especially as a modified polymer using polyester to generate compositions for molding with increased modulus and tensile strength, but transesterification between PC and polyester was considered undesirable (Bassett 1991). To improve its

physicochemical properties and cleavable properties under γ -radiation, PC-ethylene-vinyl acetate (EVA) blends, copolymer blends supplemented with abietic acid (Rosin) (20% Rosin/ 80% PC-EVA), were fabricated. Degradation of the copolymer under γ -radiation and the overall degradative properties of the copolymer are attributed to the photoreactive abietic acid moiety as demonstrated by the crosslinking activity of poly(glycidyl methacrylate) (Kim et al. 2005). The resulting photoactive copolymer, comprising a thermally stable low-modulus flexible EVA moiety, can potentially function as a biodegradable plastic modulated by the Rosin content (Nouh et al. 2016). An organic synthetic in the form of castor oil used as a plasticizer with starch derived from pumpkin was applied as a multicomponent composition to chitosan. Enhancement in the tensile strength of the composite was correlated to an increase in chitosan with an optimum starch-to-chitosan ratio of 50: 50, respectively Here, the ease of microbial biodegradability of the composite in the culture medium was correlated to be a function of the glucosidic bond content of the amylose and amylopectin units of starch and was counterbalanced by the Young's modulus which was strongly influenced by the presence of chitosan (Hasan, Rahmayani, and Munandar 2018). The role of starch degradability was supported by the bioplastic performance of a starch / chitosan composite reinforced by polypropylene as the synthetic component. The optimal ratio of starch/chitosan was established as 65/35 and displayed mechanical properties that were well-suited for material degradation under soil burial demonstrating a high percentage (>80%) after 28 days (Fig. 17).

Potential for Smarter Polymer Blends for Controlled Depolymerization

A novel route to degradability of polymers reportedly supports the existence of mechanically gated degradable polymers. The concept relies on combining a stimulated trigger degradation which is further enhanced by a site-specific mechanical force applied on the polymer backbone. In this specific example, cyclobutane (CB) serves as the mechanopore which acts as a “mechanical gate” that modulates an acid-responsive ketal group integrated into the polymer backbone. It has been evidenced that the acid component alone does not elicit the optimum breakup of the polymer in the absence of an ultrasonication step delivering the mechanical trigger (Fig. 18) (Lin et al. 2020b).

The observation also raised a pertinent question whether mechano-triggered bond scission leading to polymer fragmentation was confined to only to single site degradation or whether multiple site depolymerization was also a phenomenon. To shed further light on this area, in a follow-up study, a [4.2.0] bicyclooctene (BCOE) was investigated for properties as a mechanophore. In an exquisite study, Lin et al. (2020a) performed mechanical degradation on the solvent-treated polymer by ultrasonication and reasoned the effect of supplying a mechanical-based trigger for the type of polymer chosen should (a) result in the reduction of the MW, (b) fragmentation will lead to their respective mechanophore products, and finally (c) result in a ring opening of cyclobutane core of BCOE. The increase in sonication expectedly caused an increase in the rate of events (a), (b), and (c) followed by a decrease in rate as result of polymer fragmentation. In fact, it was revealed that the liberation of smaller molecular weight oligomers from stress-induced fragmentation via ultrasonication was operational giving credibility to the existence of mechanophores. The mechanism that was originally thought to be restricted to single-site scission is in fact driven by collective forces over a timescale of 221 h that when delayed, polymer degradation occurs very slowly resulting in multiple scissions across the length of the polymer. Mechanical degradation via this

Fig. 18 Schematic mechanism describing polymer backbone fragmentation by a mechanically gated mechanism. (Reprinted from (Lin et al. 2020b). This work is licensed under a Creative Commons Attribution License (CC BY))

mechanism allows the degradation of polymers, and in this case multiple fragments were identified tenfold smaller than the original polymer. The mechanism is summarized in Fig. 19.

Concluding Comments

Depolluting the earth begins with drastically diminishing nondegradable plastic accumulation. The chemical merger of synthetic and biobased polymers materials in the form of biosynthetic blends to induce artificial and tuneable properties is just being understood. The quality and performance of the resulting polymer depends on selection of the blend, and the shift to biodegradable polymers to replace plastic-based materials derived from fossil derivatives is currently in development. There is tremendous interest in the application of polymer blends particularly toward the biodegradable plastics. The strategic blending of synthetic and biodegradable polymers continues to evolve but at a slower pace solely to their biodegradable counterparts. Material capability depends on deciphering complex factors to develop highly degradable plastics that also have synthetic value that provide the necessary mechanical support and rigidity that biodegradable plastics lack. To make progress, the evolution of analytical tool is also important to understand complex interfaces to optimize both the structural and functional performance of highly degradable blends. In the advancement of this technological pursuit to implement functionally

competent eco-friendly biodegradables, engineering the design of smarter polymer blends should be a prime objective while exploring common and cost-effective synthetic materials.

Abstract

Interpenetrating networks (IPNs), the blend of cross-linked polymers, exhibits unique attributes as these networks can retain the properties of constituent polymers and can offer new features of the polymer blend. IPNs are usually fabricated by sequential or simultaneous method and can produce different types like full IPN, semi-IPN. Based on the constituents and pattern of cross-linking, each IPN shows its own characteristic properties. One of the emerging areas in IPN fabrication is the use of biopolymers like polysaccharides, proteins, or oils in the polymer blend. Among the various biopolymers, many polysaccharides like alginate, chitosan, starch, xanthan gum are extensively used for IPN fabrication. Proteins like fibrin, silk fibroin, and gelatin are also used in many interpenetrating networks. These biopolymer-based IPNs are mainly used in biomedical fields in sustained and targeted drug delivery, tissue engineering, and gene delivery due to its biocompatibility and biodegradability. Nowadays, cellulose-based IPNs are fabricated to develop cost-effective sustainable alternative to plastics in food packaging industry. The benefits of these biopolymer-based IPNs in various fields, especially biomedical field, can be explored in depth with more detailed investigation in this area of polymer chemistry.

Introduction

Polymers are extensively used in many industrial sectors and are considered to be the most widely used chemical product with a growing demand in global market. The versatile properties exhibited by polymers and its various assemblies contribute to its immense industrial applications including biomedical and therapeutic applications. Many polymers are extensively used in biomedical applications as excipients in formulations of capsule and tablet (Kumar and Kumar 2001), as enhancers of blood circulation time (Blume and Cevc 1990) and in targeted drug delivery system (Liechty et al. 2010). Naturally occurring biopolymers, produced by living organisms, have fascinated the scientific world with its ability to design novel polymer-based materials due to its biodegradable, biocompatible, and nontoxic properties. Amidst all these, continuous efforts are going on to improve polymer qualities like biological performance and mechanical strength. This led to the design of new class of polymers by blending various polymer mixtures, either natural or synthetic polymers alone or in combinations, to get cross-linked polymers (Giusti et al. 1996).

Interpenetrating polymer networks (IPNs) are exclusive blend of polymeric substances in which a polymer network is cross-linked to another. IPNs are unique in its properties as it confers the key attributes of one polymer by maintaining the essential attributes of other polymer in the blend. Occasionally, totally newer properties, than any of the two polymers used for blending, are exhibited by the IPNs. Thus, developing interpenetrating polymer networks system using various polymers provides a perfect method to obtain materials with wide range of characteristics to improve existing properties and to overcome the demerits of individual polymer network. The better qualities exhibited by IPNs over the conventional individual polymers have contributed to its high demand for various applications. The superior qualities of IPNs like highly compatible, degradable, and stable nature within biological systems and nontoxic nature point to the intense demand for these materials in the production of new deliverance mechanisms for controlled drug release studies (Lohani et al. 2014). This chapter encompasses an overview about IPNs, its types, design, and characterization of IPNs, biopolymer-based IPNs, and its biomedical and other applications.

Interpenetrating Polymer Networks (IPNs)

An IPN is defined as an arrangement of polymers in such a way that one (or more) polymer is produced in the presence of another to form a network with cross-links (Sperling and Hu 2003). Here, the polymer chains of one system intertwine the network formed by another polymer. The uniqueness of such system is the ability to retain individual properties by both polymers and sometimes synergism is also observed for properties like mechanical strength or toughness (Ignat and Stanciu 2003). An IPN is different from a usual blend of polymer with its capability to swell without suppressing flow or getting dissolved in the solvents (Kudela 1987).

IPNs are different from the complexes or grafts of polymers/copolymers, which have chemical bonds and/or partial cross-linking. Thus, IPNs are considered as “polymer alloys” where blends of polymers are made chemically compatible to achieve the desired phase morphology (Work et al. 2004). IPNs are different from other multiple systems due to its continuous cross-linked structure formed by two polymers of intimate contact without any chemical bonding, which can produce a novel material of improved qualities depending on composition and degree of cross-linking (Fig. 1). Hence, we can consider IPNs as entangled polymer networks holding to each other by stable peripheral interactions. The chemical interactions between polymers make the IPN a stable entanglement that needs breakage of one or more networks to separate them.

Generally, polymers are difficult to mix with each other, resulting in phase separation of blended polymers, and hence, miscibility of the interpenetrating polymers determines the success in fabricating IPNs (Olabisi et al. 1979). Thus, cross-linking plays a pivotal role in enforcing the miscibility of two polymer materials, which are normally immiscible, and many combinations of polymers can be explored by this cross-linking to identify IPNs with unique properties and applications. Fabrication of IPNs using biopolymers from various sources is an area of immense potential due to its sustainability and biocompatibility.

Fig. 1 Schematic representation of various polymer networks like interpenetrating networks, blend and cross-linked copolymer

The idea of interpenetrating polymer network was first introduced by Aylsworth as early as 1914 by fabricating a mixture of natural rubber, sulfur, and partly reacted phenol-formaldehyde resins (Aylsworth 1914). It was only in 1960s that these cross-linked networks were named as interpenetrating polymer network by Miller based on his scientific study about polystyrene networks (Millar 1960). Later on, IPNs have been an area of great interest in the field of material design with new combinations emerging at a fast pace for various applications in different sectors. Now, the field of polymer science is witnessing an ever increasing quest towards devising new IPNs with better properties. IPNs are ideally permanent entangled networks of polymers held together by topological interactions (Sperling et al. 1972). The inter-network entanglements are permanent by virtue of the fact that the two networks are themselves chemically cross-linked and thus cannot be “pulled apart” from each other without fracturing one or both of the networks.

Major Features of IPN

Ideally, when polymers are blended together to form IPN, creep and flow movements are suppressed. When mixed with a solvent, IPNs exhibit swelling and do not dissolve. IPNs mainly form insoluble network with high tensile strength and adhesive property. Most of the IPNs are heterogeneous systems with two phases: rubbery and glassy to get perfect synergism in the blend. The number and nature of cross-links determine the differences between various IPNs. Due to its unique properties, IPNs are suitable for controlled release of compounds like drugs.

Classification of IPNs

Intensive research in polymer technology resulted in the development of different forms of IPN for various applications. A lucid classification of IPNs into different categories is difficult, but it can be broadly classified based on the chemical bonding or pattern of arrangement due to different synthesis methods.

Fig. 2 Schematic representation of types of interpenetrating networks based on chemical bonding

Based on Chemical Bonding

IPNs can be formed by irretrievable chemical links formed by covalent or non-covalent chemical bonds.

The primary goal of these chemical bonding is to ensure proper entrapment of the absorbed water and carrier molecules and its controlled release on stimulation by simple diffusion. The different IPNs based on chemical bonding are described below (Fig. 2).

Covalent Semi-IPN

In this, covalent bonds link two different polymers resulting in one cross-linked polymer network.

Noncovalent Semi-IPN

In this, only one polymer system in the polymer network (comprising of two or more polymer systems) forms cross-links.

Noncovalent Full IPN

Here, all the polymers (usually two polymers) used for IPN fabrication will form cross-links in an independent manner to form a full IPN.

Based on the Pattern of Arrangement

There are different methods for synthesis of IPNs and this contributes to different patterns of arrangements (Fig. 3). Accordingly IPNs can be classified as follows:

Fig. 3 Schematic representation of types of interpenetrating networks based on pattern of arrangement

Simultaneous IPN

In this process, all the components for IPN synthesis are mixed simultaneously. In a single step, all prerequisite materials like the polymers, its cross-linkers, and activators are added under optimal conditions for effective fabrication of IPN mediated by noninterfering concurrent polymerization reaction (Tang et al. 2009).

Sequential IPN

Here, the production of IPN occurs in a sequential manner, that is, the monomers of one polymer polymerize to form the first polymer network and this is followed by the next polymer. This can be achieved by simple blending of materials. The first polymer system will swell in the presence of the monomers of second polymer, and the activators and cross-linkers will in turn form the entangled networks (Patri et al. 2007).

Gradient IPN

In this type, one monomer network undergoes swelling inside second network and the swelling stops before attaining equilibrium. Polymerization will happen at this stage resulting in an IPN in a gradient pattern (Karabanova et al. 2005).

Homo-IPN

This is the model IPN where the monomers of two polymers formed structurally similar networks (Dragan 2014).

Semi-IPN

Semi-IPN is formed by cross-linking one or more polymers (sequentially or simultaneously), exhibits a linear structure (Bashir et al. 2017), and usually involves the polymerization of a monomer in the presence of a polymer. Hence, one of the components has a linear structure instead of a network structure. Sometimes only IPNs designed by sequential process are called semi-IPNs and those made by a simultaneous process are called pseudo-IPNs.

Latex IPN

Since IPNs are thermosetting polymers, it is very difficult to mold it after formation. This issue can be addressed by using latex IPNs where each micro-IPN is a particle prepared in the form of latex. In this method, the first cross-linking monomer of the original seed of latex along with cross-linking agent and initiator will get bound by the second monomers by polymerization technique to get IPN networks of the single latex particle. It is also termed as an interpenetrating elastomeric network (Sperling et al. 1972). Latex IPNs are formed from a mixture of two lattices, frequently exhibiting a “core” and “shell” structure. In a sequential method, if the monomers corresponding to the second polymer react near the surface of the first polymer, latex IPN with shell/core morphology will be obtained (Lipatov and Alekseeva 2007).

Thermoplastic IPN

Thermoplastic IPNs can be molded, extruded, and recycled. In this type of IPN, thermoplastic elastomers are used as physical cross-linkers instead of chemical cross-linkers. The thermoplastic IPN involves two physically cross-linked polymers which arise from an ionic group, glassy domains, and crystallinity. In this type of IPN, the materials flow at elevated temperature, behave like a conventional thermoset IPN where one element is a block copolymer and the other one is the semi-crystalline or a glassy polymer (Ohlsson et al. 1996). Depending on the continuity and proportion of phases, this kind of IPNs can exhibit a wide range of properties, from reinforced rubber to high impact plastics.

Biopolymer-Based Interpenetrating Networks

The first IPN resin developed by Aylsworth in 1914 was produced by heating a mixture of rubber, sulfur, phenol, and formaldehyde to get simultaneous interpenetrating polymer network. Later on, many researchers fabricated different IPNs using bio-polymers, a mix of biopolymers, synthetic polymers, or various mix of polymers to get final products with desirable properties. Semi-interpenetrating Polymer Networks and Interpenetrating Polymer Networks of multicomponent hydrogels are emerging as preferred biomaterials for drug deliverance and tissue engineering. The physico-chemical properties of the IPNs obtained by chemical or physical cross-linking show many desirable characteristics different from those of the macromolecular constituents. Fabrication of various types of IPNs opened a lot

Fig. 4 Schematic representation of biopolymer-based interpenetrating networks

of possibilities in the field of biomaterial research. Many polymers and its precursors with hydrophilic (water loving) nature are used to make hydrogels, most of which belong to natural polymers like polysaccharides and proteins and its derivatives and synthetic polymers containing hydrophilic functional groups. Due to the biocompatibility and biodegradable properties of biopolymers, a lot of attention was given in the design of biopolymer-based IPN especially for applications in therapeutics and tissue engineering. Different biopolymers like polysaccharides, proteins, oils are widely explored for the synthesis of IPNs (Fig. 4). Among various biopolymers, the fabrication and applications of polysaccharides and protein-based IPNs are studied in more detail owing to its ease of availability and properties.

Polysaccharide-Based IPNs

Among the different biopolymers that are used for the fabrication of IPNs, polysaccharides like chitosan, alginate, and starch attracted researchers a lot due to its availability from renewable sources in a large scale and its flexibility for chemical modifications. In the recent years, many polysaccharides were reported to be the material of choice to design IPNs for biomedical applications. The following are the most studied polysaccharide-based IPNs.

Alginate-Based IPNs

Many naturally derived polymers from polysaccharides have been evaluated and extensively used for preparing IPNs for various applications especially in biomedical

fields. Among these, alginate, a group of naturally occurring anionic polysaccharides, is reported to be highly useful to devise IPNs for drug delivery. The ability to form porous networks of high stability and biocompatibility makes sodium alginate-based IPN hydrogels a suitable choice for sustained drug release to target sites without altering the pharmacological effects of the drug.

Chemically, sodium alginate is a linear copolymer of 1,4 β -D-mannuronic acid (M) and α -L-guluronic acid (G) residues (Stanisci et al. 2020) (Fig. 5). The favorable properties like compatibility to biological system and drugs and nontoxicity inspired scientists to investigate more on the development of sodium alginate-based IPN hydrogels.

IPN hydrogels with augmented properties, especially biomedical properties, can be designed by combining sodium alginate with other polymers. Some examples of compounds with high drug encapsulation rate are the combination of sodium alginate with gelatin (Bhutani et al. 2016), or hydroxypropyl methyl cellulose (Hu et al. 2018) and chitosan (cationic polysaccharide polymer) coated beads of sodium alginate (Ramesh et al. 2017). The cross-linked network of sodium alginate with ovalbumin is also reported to be successful in designing alginate-based IPNs (Fang et al. 2007).

In addition to the abovementioned natural polymers, IPN hydrogels of alginate was prepared using combination with different synthetic polymers too (Samanta and Ray 2014). A sequential method of synthesis was used by Kim et al. to fabricate an IPN hydrogel of sodium alginate and poly(diallyldimethylammonium chloride) (PDADMAC), which exhibited response to change in physical parameters like temperature and pH (Kim et al., 2004). Many desirable properties like high porosity (Yin et al. 2007), controlled drug release (Wang et al. 2009), high electrical sensitivity (Kim et al. 2004), and responsive to multiple parameters (Dumitriu et al. 2011) have been achieved by designing sodium alginate-based IPN hydrogels with synthetic polymers containing carboxylic groups. Sodium alginate-g-poly (vinyl caprolactam) IPN beads were fabricated by Swamy et al. as an anticancer drug by exploiting its thermoresponsive nature, where a temperature of 25 °C triggers drug release rather than the usual body temperature of 37 °C. Chen et al. demonstrated the protein drug delivery using an IPN hydrogel of alginate with water-soluble chitosan derivative (N, O-carboxy methyl chitosan) in a pH sensitive manner (Chen et al. 2004). Thus, IPN composite hydrogels of sodium alginate and other natural or synthetic polymers were widely studied and applied in biomedical fields.

Fig. 5 Structural unit of sodium alginate

Chitin-Based IPNs

Chitin is the natural polysaccharide composed of β (1 \rightarrow 4)-linked 2-acetamido-2-deoxy- β -D-glucopyranose units (N-acetylglucosamine) (Dutta et al. 2004). The principle difference of chitin from the most abundant polysaccharide, cellulose, is the presence of acetamide group ($-\text{NHCOCH}_3$) instead of a hydroxyl group at the C2 position. Chitin is considered as a homopolymer even though some of the glucopyranose residues show deacetylation and exists as 2-amino-2-deoxy- β -D-glucopyranose. The degree of acetylation in chitin is generally 0.90, signifying the presence of amino groups (around 5–15%) (Franca et al. 2008). When the degree of acetylation in chitin is very low, it leads to the protonation of amine groups. This produces chitosan, a soluble polysaccharide compound which is slightly different from chitin (Hajji et al. 2014) (Fig. 6).

Both chitin and chitosan are natural polymers with excellent properties like biodegradability, biocompatibility, nontoxicity, and adsorption. One of the successful approaches to improve the quality of chitin-based materials is to combine it with other polymers or particles to get IPN. When the combination is carefully optimized, these interpenetrated polymer networks can give many desirable properties of both polymers in the final material. The chitin and lignin IPN film developed by Duan et al. showed a high adsorption capacity for ferric and cupric compounds from aqueous media (Duan et al. 2018). They developed the films by dissolving lignin and chitin as such (without any modification) in an ionic solution of 1-butyl-3-methylimidazolium and γ -valerolactone. In this film, the presence of chitin contributed to the flexibility and high metal adsorption capacity even at low concentration. The film also exhibited properties like stability in aqueous solution, ease to use, facile desorption, and reusability, which makes it a suitable IPN for water purification processes.

Another interesting blending of polymers is chitin with cellulose due to the insoluble nature of both these natural polymers (Liang et al. 2007; Zhou et al. 2004). Zhou et al. designed a fixed bed column using this blend which can effectively remove heavy metal ions and can regenerate the metal ions from the adsorption column using aqueous solution of 0.1 mol/L HCl. Liang et al. fabricated cellulose/chitin blend membranes, which is biodegradable and highly porous by

Fig. 6 Structural units of chitin and chitosan

blending both polymers in presence of aqueous solutions of 9.5 wt.% NaOH/4.5 wt.% thiourea followed by coagulation with 5.0 wt.% $(\text{NH}_4)_2\text{SO}_4$ (Liang et al. 2007). Researchers have observed that addition of chitin in blend membranes can produce materials of varied permeability due to the modifications in morphology and crystalline nature.

Chitosan-Based IPNs

Chitosan-based IPNs have been extensively studied for its biomedical applications as a suitable drug delivery system. Chitosan exhibits favorable features like the ability to adsorb chemicals like dyes, metal ions, and proteins (biosorbent) due to the presence of amino and hydroxyl functional groups (Crini and Badot 2008) and its IPN hydrogels can act as excellent drug delivery systems.

Chitosan was blended with cellulose (Cai and Kim 2009), its derivatives (Angadi et al. 2010), or acrylamide grafted -dextran (AAM-g-dextran) (Rokhade et al. 2007) using glutaraldehyde as the cross-linker for IPN fabrication. Semi-IPN hydrogels of chitosan and AAM-g-hydroxyethyl cellulose (AAM-g-HEC) showed increased loading capability/encapsulation efficiency with diclofenac sodium (Al-Kahtani Ahmed et al. 2009). In vitro studies on this IPN showed that the drug release is dependent on the ionic strength, the amount of AAM-g-HEC used, degree of cross-linking, and drug loading. Another study targeted the preparation of IPN hydrogels of polyethylene glycol (PEG) grafted on carboxymethyl chitosan and alginate which can discharge drug at pH 7.4, suggesting the feasibility for intestine targeted drug delivery (Yang et al. 2013). In many studies, glutaraldehyde is used as cross-linker for chitosan IPN synthesis due to the fast development of Schiff base between the amino groups of chitosan and aldehyde groups of glutaraldehyde. The high toxicity of glutaraldehyde prompted researchers to find better alternatives like the natural cross-linking agent, genipin in the preparation of chitosan-based hydrogels (Cui et al. 2014).

Chitosan-based IPNs were made with other polymers and tested for its biomedical applications. IPN beads of chitosan-glycine-glutamic acid were prepared with glutaraldehyde as cross-linker for controlled release of compounds. The study observed that the swelling properties and drug release were dependent on acidic strength, degree of cross-linking, and constituent composition (Rani et al. 2011).

In another report by Reddy et al., emulsion-cross-linking was exploited to make IPN microparticles of Ghatti gum and chitosan which were used for intestinal deliverance of diclofenac sodium. This study reported a prolonged drug release up to 12 h (Reddy et al. 2013). Rusu et al. developed IPN hydrogels of poly (2-dimethylaminoethyl methacrylate) and maleoyl-chitosan (water soluble) with self-healing ability, high stability, and exceptional environmental responsiveness. The self-repair ability along with dual pH/thermo-responsiveness and biocompatibility of these hydrogels was suggested to have many bio-applications (Rusu et al. 2019).

Starch-Based IPNs

Starch, the second most abundant polysaccharide, is a water-soluble, bioactive, biodegradable, and biocompatible polymer. Starch granules are made up of amylose and amylopectin: 20–30% consists of linear chains of α -(1–4-linked-D-glucose) units called amylose and remaining is made of branched chains of α -(1–4-linked-D-glucose) units interlinked by α -(1–6-linked-D-glucose) linkages called amylopectin (Fig. 7).

Researchers have carried out many modifications in native starch to improve the hydrophilic nature (Reis et al. 2008) and are used in the fabrication of biodegradable hydrogels for therapeutic applications (Soleimani and Sadeghi 2012). The IPN hydrogels or semi-IPN of starch are used for several applications due to its improved mechanical properties and solute diffusion (Jin et al. 2013). Another group fabricated a semi-IPN hydrogel by cross-linking acrylamide and sodium methacrylate in the presence of starch and observed the swelling/diffusion properties (Keshavara Murthy et al. 2006) and recommended its use as moisture maintenance materials in agriculture fields. Many studies were carried out in various semi-IPN hydrogels composites with starch to study the swelling capability and pH-sensitivity. These studies revealed the efficient swelling capacity and excellent pH-sensitivity of some starch-based semi-IPN hydrogels (Li et al. 2008).

Recently, Wei et al. fabricated starch-cellulose IPN hydrogels by sequential Diels-Alder click reaction and photopolymerization in water. Starch was modified with N-maleoyl- β -alanine to get starch-based dienes, and reaction of cellulose and furfurylamide succinate gave cellulose-based dienophiles. These two along with polymerizable β -cyclodextrin, cross-linker, and acrylamide were dissolved in water to obtain a transparent solution, which was kept at 50 °C for 3 h for Diels-Alder reaction, and then, the photopolymerization was done to get the second network. The hydrogels prepared were checked for the efficiency for sustained release of model drug, 5-fluorouracil. The simple method of catalyst-free, photopolymerization reaction, which can be controlled, was found to be a favorable technique for starch-cellulose IPN hydrogels fabrication (Wei et al. 2022).

Fig. 7 Structural components of starch

Carrageenan-Based IPNs

Carrageenan (CG) is a polysaccharide biopolymer of high molecular weight obtained from seaweeds. Its monomers, galactose, and 3,6-anhydrogalactose (3,6 AG) are arranged in a linear fashion by alternate α -(1,3) and β -(1,4) glycosidic linkages (Bajpai and Pradeep 2013). The name of this polysaccharide is derived from carrageen moss (Scientific name: *Chondrus crispus*), a seaweed species. There are three types of carrageenan: kappa (κ), iota (ι), and lambda (λ) (Fig. 8). κ -carrageenan has the capability to form thermoreversible gel and is commonly used in food industry and pharmaceuticals (Van de Velde et al. 2002) due to its favorable properties like gelling, viscosity, and biocompatibility and biodegradability (Gupta et al. 2001).

The λ -CG can form viscous solutions which cannot form gels, whereas the κ -CG can form a fragile gel. The ι -CG can form elastic gels (Necas et al. 2008).

Carrageenan-alginate IPN hydrogel beads, which can release drugs by controlling pH of the media, were fabricated by Mohamadnia et al. to investigate the potential to deliver standard drug betamethasone acetate. The group studied the properties of the IPN using various analytical techniques and observed the most efficient drug loading capability at a pH of 4.8 and temperature of 55 °C (Mohamadnia et al. 2007). Swain and Bal (2019) synthesized an IPN of Carrageenan-guar gum by microwave irradiation with unique features like thermal sensitivity at 48 °C and degradation above 200 °C. They reported micro rough surface morphology, hydrophilicity, and muco-adhesion properties with honey comb like internal architecture making it suitable for targeted drug delivery (Swain and Bal 2019).

Chen et al. developed an interpenetrating network of Konjac glucomannan (KGM)/kappa-carrageenan (KC) hydrogels, where KGM and borax react to form a chemical gel network and addition of KC component introduced the physical

Fig. 8 Structural units of different types of carrageenan

network. The two networks formed are held together by hydrogen bonds formed between the organosulfate groups ($-\text{OSO}_3-$) present in the KC chains and hydroxyl groups ($-\text{OH}$) in the KGM chains. These IPN hydrogels are reported to exhibit very high tensile strength and is temperature sensitive and recoverable, with excellent self-healing performance (Chen et al. 2019).

Xanthan Gum-Based IPNs

Xanthan gum (XG) is another high molecular weight biopolymer produced by a gram-negative bacterium, *Xanthomonas campestris*, extra cellularly. It is a heterogeneous polysaccharide consisting of β -D-glucose units in the main chain which is linked by trisaccharides α -D-mannose, β -D-mannose, β -D-glucuronic acid in the side chains (Fig. 9). Xanthan gum has a net negative charge (anionic) contributed by the pyruvic acid and glucuronic acid groups in it (Shalviri et al. 2010). This polysaccharide polymer exhibits a lot of applications as thickener, emulsifier, suspending agent, and stabilizer for water-based systems, etc. (Talukdar and Kinget 1995).

IPN hydrogel of polymers based on xanthan gum and poly vinyl alcohol was synthesized as microspheres for the sustained release of drug, ciprofloxacin hydrochloride (Bhattacharya et al. 2013b). Hajikhani et al. produced semi-IPNs by acrylic acid/xanthan gum cross-linking in the presence of N, N'-hexane-1,6-dilbisprop-2-enamide, or 1,4-butandiol dimethacrylate as the cross-linking agent. XG-Poly acrylic acid semi-IPNs exhibited excessive adsorption potential and stability and is

Fig. 9 Structural unit of xanthan gum

suggested as an environmentally benign and nontoxic material for application in drug delivery systems, wound healing, and dye removal (Hajikhani et al. 2019). Another group of scientists developed a xanthan gum/polyvinylpyrrolidone-co-poly acrylic acid hydrogels for controlled delivery of the drug, 5-fluorouracil to the colon region of the intestine. Another xanthan gum-based IPN fabricated for controlled drug delivery is a polymer of XG and polyvinylpyrrolidone (PVP) cross linked by acrylic acid monomers. This XG/PVP-copoly acrylic acid hydrogels used for drug delivery were cross-linked by ethylene glycol dimethacrylate and ammonium per sulfate/sodium hydrogen sulfite as a cross-linker and initiator (Anwar et al. 2021).

Guar Gum-Based IPNs

Guar gum is a biopolymer present in the seeds of guar or cluster bean (*Cyamopsis tetragonolobus* Linn.) in the endosperm region (Tripathy and Das 2013). It consists of repeating units of two 1,4-linked mannopyranosyl and one 1,6-linked galactopyranosyl groups (Fig. 10). The reaction of guar gum with borax produces borate ester bonds, which give the hydrogels formed from these with excellent self-healing properties (Li et al. 2018). In addition, the presence of borate ions makes the hydrogels conductive to electricity. Guar gum is used as an inexpensive and easily manageable carrier for long-lasting delivery of oral drugs (Varshosaz et al. 2006). A semi-IPN made of chitosan-guar gum with glutaraldehyde as cross-linking agent was used for regulated release of drug cefadroxil for almost 10 h by Reddy et al. (2006).

Recently, Cao et al. fabricated IPN hydrogels with guar gum and another natural polysaccharide polymer, gellan gum, by introducing borate and hydrogen bonds (Fig. 11). These IPN hydrogels with gellan gum, borax, and guar gum of appropriate concentrations show good tensile properties, excellent self-healing properties, and conductivity of electricity. The electric signals produced by these hydrogels during show good repeatability and reliability. The authors proposed the excellent mechanics, self-healing, and electrical conductivity of the novel polysaccharide-based IPN hydrogels can find use in human motion monitoring, intelligent wearable devices, etc. (Cao et al. 2021).

Fig. 10 Structural unit of guar gum

Fig. 11 Schematic illustration of the preparation process and structure of the guar gum/gellan gum IPN hydrogels. (Reprinted from Cao et al. (2021))

Hyaluronic Acid-Based IPNs

Hyaluronic acid (HA), frequently known as hyaluronan, is a linear high molecular weight polysaccharide having two alternating disaccharide units of β -1,4-D-glucuronic acid and β -1,3-N-acetyl-D-glucosamine (Kim et al. 2004) (Fig. 12). It exists as polyanion and is most commonly utilized in tissue engineering scaffold assembly and as component of implants. The chemical modifications, processing, polymerization, and bio-applications of HA have been deeply investigated and are used for many applications like ophthalmic surgery, arthritis treatment, scaffolds for wound healing, dermal filling, and tissue augmentation 8–9. The biocompatibility, biodegradability, and versatility make HA-based materials a favorite choice in tissue engineering as scaffolds. But its water solubility makes HA a less stable material and this can be effectively overcome by using other natural or synthetic polymers to fabricate HA-based IPN. Some examples are semi-IPN hydrogels composed of HA and synthetic polymers (Agostino et al. 2012) or natural polymers like HEMA derivatized dextran (Pescosolido et al. 2011b) and collagen (Chen et al. 2020a).

Locust Bean Gum-Based IPNs

Locust bean gum is a branch polysaccharide obtained from the seeds of carob tree (*Ceratonia siliqua*).

It consists of (1,4)-linked β -D-mannopyranose backbone with α -D-galactose (1,6-linked)-D-galactopyranose in the branching at the sixth position of the backbone (Glicksman 1963). Due to its nonionic nature, it is not affected by changes in

Fig. 12 Structural unit of hyaluronic acid

ionic strength. It can be dispersed in water to form a solution of pH 5.4–7.0. This solution can be converted to a gel by adding small amounts of sodium borate. Kaity et al. developed a unique IPN microsphere of locust bean gum and poly (vinyl alcohol) for controlled release of buflomedil hydrochloride orally (Kaity et al. 2013; Kaity and Ghosh 2016). In another study, ionotropic gelation with Al^{3+} ions was explored for fabricating IPN network of etherified locust bean gum and sodium alginate for application in drug release studies. These IPNs have better mechanical strength than homopolymer network and showed high efficiency for entrapping drugs and its sustained release (Dey et al. 2013).

Protein-Based IPNs

Protein biopolymers exhibit many desirable properties such as sustainable nature and its compatibility in body along with good mechanical strength. Various polymer structures like composites, gels, films can be made using these for applications like deliverance of drugs, regeneration of tissues, storage of bioactive compounds like vaccines, antibodies. Many hydrogels used for biomedical applications are fabricated with naturally derived protein biopolymers. Nevertheless, these hydrogels show poor mechanical properties. This problem can be encountered by developing interpenetrating polymer networks by combining natural biopolymers with other natural or synthetic polymers.

Various proteins were used in the preparation of IPN-based hydrogels in combination with either synthetic polymers or with gelatin, the protein derived from collagen. Usually this combination is used to increase the biocompatibility of the IPN hydrogels (Jain et al. 2009) and biological activity of synthetic polymers (Fathi et al. 2013; Singh et al. 2007) or to increase the structural stability of the gelatin nanofibers (Aduba et al. 2013). If the goal is to increase the stability of gelatin, polyethylene glycol diacrylate (PEG-DA) was used as a cross-linker during IPN synthesis. PEG-DA does not interact directly with gelatin rather it undergoes free radical cross-linking polymerization without reacting with the functional groups in gelatin. This results in a matrix with enhanced structural stability in aqueous solutions (Aduba et al. 2013). Cryogelation techniques used to fabricate macro-porous IPN composite hydrogels. Full interpenetrating network of polyacrylonitrile

(PAN)-gelatin was synthesized by Jain et al. with varied gelatin concentrations. The PAN-gelatin IPN is macroporous in nature and exhibits good flow rate and swelling efficiency. Hence, these IPNs have good interconnectivity of pores and convective flow within the network and hence can support cell growth within the scaffolds (Jain et al. 2009).

In a recent study, Chen et al. prepared an IPN of alginate/gelatin hydrogels in which cells can be encapsulated for in vitro three-dimensional cultures and organ bioprinting (Fig. 13). A double cross-linking model using calcium ions and transglutaminase to cross-link alginate and gelatin molecules, respectively, was carried out to improve the physiochemical properties and biochemical properties of the alginate/gelatin hydrogels. By altering the cross-linking and concentration of polymer, the properties of these hydrogels can be tuned to suit various applications. The cellular compatibility of the hydrogels was confirmed by in vitro cultures and bioprinting. These hydrogel is considered as a promising candidate for a range of biomedical applications like bioartificial organ manufacturing, high-throughput drug screening, and pathological mechanism analyses (Chen et al. 2020b).

Silk fibroin (SF), another biopolymer widely used in the preparation of IPN hydrogels, is a fibrous protein of silk fiber consisting of heavy and light chain polypeptides, linked by a disulfide link (Gil and Hudson 2007). The regenerated fiber has been considered as candidate for biomaterials owing to its good mechanical strength in the wet state, biocompatibility for the growth of cells, and high resistance against enzymatic degradation. It is also used to lessen the limitations of hydrogels

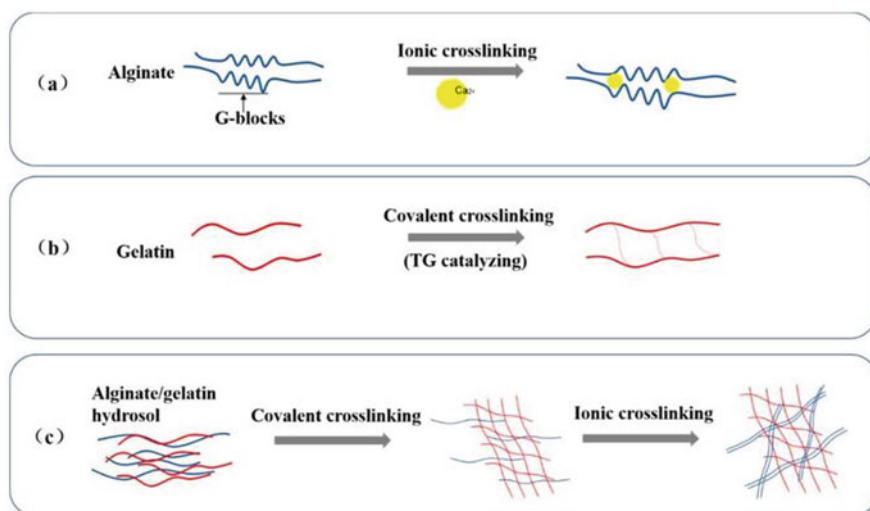

Fig. 13 Schematic description of alginate and gelatin cross-linking in alginate/gelatin IPN. “(a) G-blocks in two alginate chains are chemically (i.e., ionic) crosslinked by Ca^{2+} . (b) Transglutaminase (TG) catalyzed covalent linkages between two gelatin molecules. (c) An interpenetrating network in an alginate/gelatin hydrogel formed through both TG covalent and Ca^{2+} ionic crosslinks.” (Adapted from Chen et al. (2020b))

composed of Poly (N-isopropylacrylamide/PNIPAAm), like lack of biocompatibility, deswelling rate, and mechanical properties. Gil and Hudson (2007) produced IPNs of PNIPAAm and SF to improve the deswelling properties and suppressing the skin layer formation. IPN composite hydrogels composed of SF and other synthetic polymers were also developed by many researchers (Kundu et al. 2012; Mandal et al. 2009) and are of interest in tissue engineering and regenerative medicine.

The excellent biocompatibility makes silk fibroin hydrogel a perfect choice as biomaterial matrix, but the reduced transparency and flexibility limits its applications. This can be addressed by fabricating IPN hydrogels with changing ratios of silk fibroin/N-Vinyl-2-pyrrolidone mixtures cross-linked by H_2O_2 and horseradish peroxidase. These IPN showed high light transmittance capability and elasticity (Kuang et al. 2018). Silk sericin is a water-soluble globular protein derived from silk-worm, which has been used by Wu et al. in the preparation of IPN hydrogels with PNIPAAm (Wu et al. 2006) and PMMA (Wu and Wang 2010).

Fibrin is another biopolymer which exhibits excellent potential for tissue regeneration and wound healing because it can act as a backbone to promote cell adhesion, migration, and proliferation. Fibrin-based hydrogels extensively used in tissue engineering have inadequate mechanical performance, especially at the physiological concentration (2–5 mg/mL) where it quickly degrade, thereby limiting its clinical applications. Several strategies have been used in order to improve its mechanical properties by alteration of various polymerization parameters, but the approach of developing fibrin-based hydrogels IPN by combining fibrin networks with natural or synthetic networks is found to be very useful (Eyrich et al. 2007). A lot of studies reported IPN fabrication using fibrin and other polymers. Lee et al. made a hydrogel with enhanced mechanical strength using a combination of fibrin and hyaluronic acid (Lee and Kurisawa 2013). Shikanov et al. designed an IPN for culturing ovarian follicle by combining fibrin and alginate (Shikanov et al. 2009). Rowe and Stegemann developed IPN of enhanced for mechanical strength for cardio tissue engineering by combining fibrin and collagen (Rowe and Stegemann 2006). These are few systems where fibrin is combined with other naturally derived polymers. The combination of fibrin with synthetic polymers like polyethylene oxide (PEO), polyethylene glycol (PEG), and polyvinyl alcohol (PVA) allow greater flexibility to modify the physical properties and biomedical applications of fibrin-containing IPNs. Other protein-based IPN hydrogels are composed of fibrin and PEG (Akpalo et al. 2011), soy protein and PNIPAAm (Liu and Cui 2011a, b), collagen and hyaluronic acid (Suri and Schmidt 2009), and PAAm and poly (c-glutamic acid) (Rodríguez-Félix et al. 2011).

Other Biopolymer IPNs

In addition to polysaccharides and proteins, different vegetable oils are also used in fabricating IPNs by various groups. Bio-based polymers like poly (3-hydroxy-alkanoate)s (PHAs), synthesized by some microorganisms during stress conditions, provide an environmental-friendly alternative to synthetic polyesters used in

plastics. PHAs are suggested to have high potential for environmental, medical, or pharmaceutical applications such as drug delivery systems and tissue engineering due to its biodegradable and biocompatible properties. Still, few of the well-studied PHA's like poly (3-hydroxybutyrate) PHB and poly(3-hydroxybutyrate-co-hydroxyvalerate) PHBHV are brittle due to its relatively high degree of crystallinity. Thus, the thermal stability and processability of these compounds can be enhanced by cross-linking with vegetable oils to form semi-IPNs. The use of natural oils without any chemical modifications has several advantages such as renewability, availability, versatility, and the presence of reactive unsaturated groups. Carine Mangeon et al. developed a semi-interpenetrating systems based on sunflower oil and trithiol networks in which PHBHV chains are embedded thereby exhibiting a toughening improvement of such polyesters (Fig. 14). These novel cross-linked networks are formed inside the amorphous zones of the matrix, making it possible to significantly increase the elongation at break. Even though this effect is comparable to the plasticizing phenomenon, this also holds the advantage that the networks do not migrate over time and hence can act as long-lasting reinforcements of the matrix. This material also exhibits loss of thermomechanical properties when the cross-linked networks reaches 45% due to phase segregation (Carine Mangeon et al. 2018).

Another group fabricated a two-component IPN of modified castor oil-based polyurethane (PU) and polystyrene (PS) by the sequential method. The modification of castor oil was done by transesterification using triethanolamine to get transesterified castor oil (TCO). The polyurethane network was prepared from TCO using isophorone diisocyanate (IPDI) with dibutyltindilaurate (DBTDL) as catalyst. Concurrently, benzoyl peroxide (BPO) and *N,N'*-Dimehtylaniline were added to styrene as initiator and co-initiator, respectively. Diallyl phthalate was added as a cross-linking agent to form IPN and finally cast into films. These films were characterized by FT-IR, dynamic mechanical analysis, and thermogravimetry

Fig. 14 Synthesis of poly(3-hydroxybutyrate-co-hydroxyvalerate)/sunflower oil and trimethylolpropane tris(3-mercaptopropionate) (TriSH) semi-IPN. (Reprinted (adapted) with permission from Mangeon et al. (2018). Copyright 2018 American Chemical Society)

analysis, and morphology was measured by scanning electron microscopy (Dave and Patel 2017).

Sequential interpenetrating polymer networks were prepared using polyurethane (PUR) synthesized from canola oil-based polyol with terminal primary functional groups and poly(methyl methacrylate) (PMMA). The morphology of the IPNs was investigated using scanning electron microscopy (SEM), modulated differential scanning calorimetry (MDSC), and a five-phase morphology, that is, sol phase, PUR-rich phase, PUR-rich interphase, PMMA-rich interphase, and PMMA-rich phase, and was observed for the IPNs from MDSC. The mechanical properties of the IPNs were observed to be superior to those of the constituent polymers due to the finely divided rubber and plastic combination structures in these IPNs (Kong and Narine 2008).

Applications of IPNs

Some of the inherent properties of biopolymer-based IPNs made them a highly desirable polymer for many applications. They are (a) the biocompatibility/biodegradability, (b) increased mechanical strength and phase stability than its components alone, (c) synergism of individual component properties to produce networks of better features, (d) complete cross-linking/blending and hence thermodynamic incompatibility and phase separation between the component polymers is not usually observed, (e) ability of IPN to keep the phases separate when subjected to stress, and (f) ability for controlled release of drug delivery.

IPNs find its application in many areas like biomedical applications, optical applications, fuel cell applications, coating and adhesives, adsorption of gases, sound and vibration damping, metal ion removal, solar heating, and thermal control applications (Raveendran and Sharma 2016). Among these, biopolymer-based IPNs are extensively studied for its biomedical applications.

Biomedical Applications of IPN

Interpenetrating polymer networks based on biopolymers are investigated with keen interest for its potential applications in biomedical field due to its biocompatibility and biodegradability in addition to other physiochemical factors. Many studies established the excellent capability of various biopolymer IPNs as excipients for sustained and controlled drug delivery, scaffolds in tissue engineering, for gene delivery and other applications.

IPN-Based Drug Delivery System

IPNs of different forms like films, hydrogels, tablets, capsules, microspheres, sheets, sponges, matrix are extensively used for drug delivery. The most important

requirements for an effective drug delivery system are the effective control of drug release and stability of the excipient. IPNs can be used for delivering drugs in a time- and rate-specific manner, and to achieve this, chemical modification with addition of functional groups in the polymeric excipients is usually done (Twaites et al. 2005) without causing issues of limits of toxicity and compatibility. IPN-based drug delivery systems are used to deliver the drug at a definite rate for required period of time. The properties of IPN like enhanced solubility of hydrophobic drugs, good swelling capacity, stable drug formulations, biodegradability, biocompatibility, weak antigenicity, and specific tissue targeting make them suitable for drug delivery applications. The various forms of IPN used for drug delivery are discussed below.

Hydrogel

Smart biomaterial in the form of hydrogel formulation has attained a lot of interest in tissue engineering and drug delivery owing to its physicochemical properties. Hydrogels are cross-linked or physically entangled three-dimensional polymeric networks of hydrophilic nature, which exhibits remarkable swelling capacity (Peppas et al. 2000). The properties of hydrogels can be improved by fabricating IPNs hydrogels, which offer the possibility for a range of physical formulations like microspheres, nanoparticles, and films. In IPN hydrogel-based drug delivery, an exceptional advancement happened with the development of smart drug delivery systems (SDDS), also called stimuli-sensitive delivery systems. The idea of SDDS is based on the conversation of physical and chemical properties of polymer systems by an environmental stimulus, which can be physical stimulus (temperature, electricity, light, and mechanical stress), chemical stimulus (pH and ionic strength), or biological signals (enzymes). Such stimuli can be an internal signal from the body of the living organism where the drug is delivered or external signals which are artificially induced. This nature of hydrogels has made them a polymer of great interest as drug delivery vehicle capable of controlling drug release and drug targeting.

Targeted drug delivery in specific site is achieved by the formulation of pH-sensitive IPN hydrogel beads of ibuprofen, which reduces the release of drug in acidic medium and controls the drug release in alkaline medium (phosphate buffer) depending on the need (Ray et al. 2011). Another team of researchers developed IPN hydrogels of calcium alginate and dextran hydroxyethyl-methacrylate and examined its potential for sustained protein release and chondrocytes (cartilage cells) encapsulation capability. It was found to be a promising system for protein delivery and tissue engineering applications (Pescosolido et al. 2011a).

A soft hydrogel IPN of silicone elastomers with a poly(2-hydroxyethyl methacrylate) (PHEMA) in the range of 13–38% (w/w) was synthesized by using carbon dioxide-based solvent mixtures under high pressure. The IPN material was loaded with the antibiotic ciprofloxacin, and the resulting drug release was shown to inhibit bacterial growth when placed on agar, thus demonstrating the potential of this IPN material for future applications in drug-releasing medical devices (Steffensen et al. 2016).

Shin et al. developed an interpenetrating network of polyacrylic acid (PAA) and polyacrylamide (PAAm) that forms hydrogels with positive thermoresponse, that is,

drug release increases with increasing temperature. These IPN hydrogels swell above its upper critical solution temperature, UCST, due to the disruption of hydrogen bonding between two different networks at higher temperatures, indicating the possibility of enhanced drug release with increase in temperature (Shin et al. 1997). Another work on the same IPN with grafted β -cyclodextrin showed a faster thermoresponse and lower UCST (35 °C) and a lowered effect of salt on the swelling. Incorporation of a model drug, ibuprofen, showed a positive drug release with a controlled rate above and below the UCST (Wang et al. 2009). Semi-interpenetrating networks synthesized by Mundargi et al. formed by cross-linking gellan gum microspheres with interpenetrating poly (*N*-isopropylacrylamide) chains allowed pulsatile drug release below the lower critical solution temperature due to swelling of the spheres and greater water transport through the spheres (Mundargi et al. 2010).

Microspheres

Microspheres, the free flowing tiny spherical powder of natural or synthetic polymers of 1–1000 μm size (Lohani and Gangwar 2012), constitute another important IPN-based drug delivery system. IPN microspheres are regarded as a multipurpose carrier for drug targeting and release due to its capability to entrap drugs without losing its pharmacological properties, its compatibility and degradability in biological systems, bioavailability, and sustained release characteristics. In vitro studies to analyze drug release were carried out by many research groups to identify drug delivery properties of IPN microspheres. Xanthan gum facilitated superabsorbent polymeric microspheres was effectively used for sustained release of ciprofloxacin hydrochloride (Bhattacharya et al. 2013a). Anticancer drug like 5-fluorouracil encapsulated in carbohydrate grafted IPN microspheres were found to have enhanced drug release and bioavailability properties (Sekhar et al. 2012).

Tablets

IPN-based tablets are also prepared by many groups for facilitating sustained release. Calcium ion cross-linked IPN matrix tablets of polyacrylamide-grafted-sodium alginate were prepared for sustained release of diltiazem hydrochloride. The degree of swelling capacity of IPN matrix and viscosity of the gel formed following dissolution of the polymers governs the drug release from the matrix (Mandal et al. 2010). IPN tablets prepared by a wet granulation/covalent cross-linking method matrices were found to be effective for sustained drug release of antihypertensive drug (propranolol hydrochloride) (Kulkarni et al. 2013).

Films

IPN-based films prepared by blending natural polymer collagen and synthetic polymer polyvinyl alcohol were loaded with growth hormone to investigate its potential as a drug delivery system and found that the release of growth hormone is dependent on both initial loading concentration of drug and the content of each polymer in the IPN (Cascone et al. 1995).

Sheet

Sheeting is another method of designing IPN-based drug delivery system. These are mainly used in various types of wound dressings and scar management products. An IPN composed of polymeric material like polyol (allyl carbonate), for example, nouryset[®]200 and epoxy resin, is developed by 70–95 parts by weight of polyol (allyl carbonate) by means of radical initiation and polymerizing partially or completely concurrently is an epoxy resin forming mixture composed of 10–90 weight % of aliphatic or cycloaliphatic epoxide and 90–10 weight % of polyol/anhydride adduct (Dillon 2006).

IPN in Tissue Engineering

Tissue engineering plays an important role in facilitating the repair and regeneration of diseased tissues, and hence, the development of tissue engineering scaffolds has emerged as a topic of great interest in biomedical research. Hydrogels are a potent candidate for scaffold formulation, but control of porosity and the micro-architectural features in hydrogels is a challenging task. These issues can be effectively overcome by designing hydrogel IPNs. Production of the hydrogel IPNs received much attention because it improves the mechanical properties, and more importantly, it mimics the extracellular matrix which can be used as cell culturing scaffolds for tissue engineering. Many synthetic polymers are used for fabricating IPN hydrogels, but it is not preferred for tissue engineering due to its nondegradable nature.

Biologically derived IPNs from collagen and hyaluronic acid have been widely explored for tissue engineering applications. Natural biomaterials-based IPNs possess active cell-responsive mechanical properties that facilitate suitable conditions for tissue growth. For example, an IPN of fibrin and alginate was reported to have mechanical properties for ovarian follicle culture in vitro (Shikanov et al. 2009).

IPN gels are also prepared by separated procedures, in which primal networks, followed by other networks, are formed by adding chemical reagents or subjecting to external stimuli. Recently the study by Ishikawa et al. designed a one-pot and in situ gelation system, which involved strategic selection of precursors for constructing IPN gels by simply mixing them (Fig. 15). The design involved two types of gelation processes: RADA16 peptide self-assembling and covalent bond formation between chitosan (CH) and *N*-hydroxysuccinimide ester-terminated poly(ethylene glycol) (NHS–PEG–NHS). Then they cultured chondrocytes in CH/PEG/RADA16 and showed that construction of the IPN structure promoted the embedded chondrocyte properties for the formation of the articular cartilage. They also reported a lower inflammation and higher protein production in mice implanted with CH/PEG/RADA16-containing chondrocytes than in those with clinically used atelocollagen gel, appealing the feasibility of the proposed IPN hydrogel design for use as cell culturing scaffolds in tissue regeneration (Ishikawa et al. 2020).

Fig. 15 Schematic illustration of “one-pot” synthesis of the CH/PEG/RADA16 injectable hydrogel with interpenetrating polymer network (IPN). (Reprinted (adapted) from Ishikawa et al. (2020). Copyright (2020) American Chemical Society)

Hago and Li developed a polyvinyl alcohol/gelatin (PVA/GE) IPN hydrogels by a combination of enzymatic and cyclic freezing-thawing method. The IPN was prepared by cross-linking of various concentration gelatin in the presence of transglutaminase enzyme by using the freezing-thawing cycles technique. Their study observed that these hydrogels exhibited high fluid absorbing ability, which makes it a suitable choice to treat exudative wounds. The study on proliferative capability of fibroblast cell lines seeded on the IPN hydrogel showed an increased cell viability and proliferation (Hago and Li 2013).

IPN in Gene Delivery

Cationic polymers are the favorite matrices for gene delivery because of their ability to cover the anionic nature of DNA, which can, in turn, lead to efficient transfection (De Smedt et al. 2000). A good gene delivery system should exhibit features like resistance to premature enzymatic degradation and aggregation, target-specific uptake of gene, and controlled release of the genetic material. Semi-IPNs synthesized by dispersing quaternary ammonium salt hydrogels into neutral monomers such as acrylamide or 2-hydroxyethyl methacrylate exhibited gene delivery potential (Sahiner et al. 2006).

IPN in Ophthalmic Applications

IPNs are used to as ophthalmic biomaterial especially as corneal substitute (artificial corneas) for treating blind patients with corneal disease. Glucose-permeable poly

(dimethyl siloxane)–poly(*N*-isopropyl acrylamide) IPNs were proved as a potent ophthalmic biomaterial. Collagen–phosphorylcholine IPN hydrogels were also designed as corneal substitutes to retain the enzymatic resistance, hydrophilicity, and increased mechanical strength (Liu and Sheardown 2005).

Food Packaging Applications of IPN

Plastics, owing to its low cost, water and dirt resistance, favorable mechanical, thermal, and optical properties, are commonly used material of choice for packaging purposes. But the environmental issues caused by plastics prompted researchers to find a sustainable alternative and nowadays, interpenetrating hydrogels are considered a suitable alternative for conventional plastics in packaging industry. Using interpenetrating hydrogels allows the opportunity to generate hydrogels from bio-based materials to develop biodegradable packaging materials. Cellulose interpenetrating hydrogels show considerable significance in biodegradable food packaging. Cellulose-based hydrogels, consisting of cellulose and its derivatives, can be blended with gelatin, polyvinyl pyrrolidone, or polyvinyl alcohol to offer convenient packaging food materials. Introduction of silver nanoparticles and antioxidants can augment the properties of these hydrogel sheets (Amini et al. 2016). Composites based on poly (vinyl alcohol) and micro- and nano-fibrillated cellulose were also prepared. Hydroxyethyl methacrylate can be introduced with photo-initiator helped producing an IPN with improved distribution and interfacial adhesion, which are beneficial for packaging applications (Bai et al. 2015).

Other General Applications of IPN

Due to its unique properties, the applications of IPNs find wide applications in various areas. Most of the applications in fields other than biomedical area mainly exploit the use of synthetic polymers than biopolymers. These wide spread applications are mainly due to its flexibility, controlled phase domain sizes, thermosetting properties, energy absorption potential, etc. Some of the key areas where synthetic polymer-based IPNs are used include (i) selective transportation of liquids and gases for applications in protective coatings, packaging, etc. (George and Thomas 2001), (ii) ion exchange membranes for laboratory use and large-scale applications like effluent treatment, sea water desalination, and concentration or separation of pharmaceutical and food (Xu 2005), (iii) removal of metal ions by designing chelating adsorbing membranes using polymers (Metayer and M'Bareck 1997), (iv) sound and vibration damping properties for applications in automotive, aircraft, construction, and appliance industries (Aklonis and MacKnight 1983), (v) fuel cells and solar cells (Wu et al. 2007), (vi) to improve properties of elastomers, and (vii) in energy, process, aeronautics, and many other applications (Singh 1998).

Conclusion

Biopolymer-based interpenetrating polymer networks is one of the rapidly expanding fields in polymer science with immense applications. Due to the favorable attributes offered by the constituent polymers and the novel properties of the cross-linked network, IPN exhibits unique features, which hold high industrial significance. The value of the cross-linked interpenetrating polymer networks as a bio-compatible biomaterial is immensely explored in the areas of tissue engineering and drug delivery. IPNs are revolutionizing the field of biomaterial science starting from the development of bioengineering tissues, such as bone substitutes, tissue, and cartilage scaffolds to targeted drug and gene delivery. Biopolymer-based IPNs are considered as a sustainable alternative in various fields and hence are highly investigated by polymer scientists. The immense potential that lies in these polymer networks needs to be fine-tuned and explored more deeply to make commercially viable/affordable products in a large scale.

Abstract

A range of applications benefit from the properties of biopolymers, which are organic materials produced by living cells. These properties include biocompatibility, greater stiffness, toughness, flexibility, electrical conductivity, and biodegradability. The applications include edible films, transport materials, biomedicine,

packaging materials for the food industry, emulsions, medication medical implants such wound healing, artificial organs, tissue engineering, and dressing. In this review, commonly known biopolymer-based gels, mechanism of its gelation, applications, and its advantages and disadvantages are briefly explained.

Keywords

Biopolymer · Agarose · Polysaccharide · Drug delivery

Introduction

Biopolymer gels have piqued scholars and their practical curiosity for a long time. Industrial interest, particularly from the food industry, has never been higher than it is currently due to the recent need for low-fat products (Clark 1996). Many biopolymers that can form a gel in aqueous solution, such as agarose, carrageenan, and gelatin, all have one thing in common: the gelation is preceded by a shift from a disordered to an ordered conformation (Viebke et al. 1994). These systems are limited to basically physical gels produced in an aqueous environment from biopolymeric materials (Clark 1991). Hydrocolloid interactions in aqueous environments have been extensively investigated with respect to their thermodynamic compatibility and interbiopolymer complexing (Zasytkin et al. 1997). Biopolymers are made using thermally driven gelation, addition of new component to the start solution, and prepared from the existing gel (Clark 1991). These biopolymers are implicated in various drug delivery applications, antibacterial activity, wastewater treatment, etc. (Samrot et al. 2019, 2020a, b, 2021a, b, c; Chellapan et al. 2018; Justin et al. 2018; Shobana et al. 2019, 2022; Samrot and Sean 2022; Abirami et al. 2021).

Gel Derived from Biopolymer

Natural Polymer: Agarose Gel

Agarose is a polysaccharide derived from the red algae named *Rhodophyceae* (Weinberger 2000). It is composed of nearly 400 repeating units of agarobiose linked together by 1→3 D-galactopyranose and 1→4 3,6-anhydro-α-L-galactopyranose with an average molecular weight of 120,000 Da (Roberts and Martens 2016; Subramanian and Varade 2017). The gelation occurs by dissolving agarose in boiling water as it is insoluble in water and when it is cooled at temperature below 45 °C hydrogen bonds form between the chains (Gustavsson and Son 2003; Mayer and Fiechter 2013). The gelling temperature depends on the concentration of the solution, composition of monomers, and method of derivatives of agarose such as addition of de-structuring salts or by hydroxyethyl derivatization (Medin 1996). Agarose gel is widely used in cartilages, tissue engineering, etc for the encapsulation of cells (Roberts and Martens 2016).

Fig. 1 Application of agarose from seaweed

Biopolymer Gel: Alginates

Alginates are the natural anionic polysaccharides derived from brown algae such as *Macrocystis pyrifera*, *Laminaria hyperborea*, *Ascophyllum nodosum*, and from bacteria such as *Azotobacter* and *Pseudomonas* (Szekalska et al. 2016). It comprises of 1, 4 β -D-mannuronic acid (M block) and 1, 4 α -L-guluronic acid (G block) which are arranged either in homogeneous or heterogenous block-like pattern (Szekalska et al. 2016). Alginate biopolymers are precipitated by dissolving monovalent alginate salts in alginic acid maintained at the pH of 3.38–3.65 (Abasalizadeh et al. 2020). Two types of methods exist for the process of forming gels from alginate which includes ionic cross-linking using cations and acid precipitation (Ching et al. 2015). Alginates are capable of forming gel with multivalent, divalent, and trivalent cations through cross-linking (Ching et al. 2015). The properties of alginate gel such as high water absorbing capacity, porosity, biocompatibility, and permeability makes them an ideal candidate for wound dressing, treatment for cancer, 3D bioprinting, etc. (Abasalizadeh et al. 2020) (Fig. 1).

Collagen-Based Polymer

Collagen is responsible for holding together the body's conjunctive and connective tissues, including skin, joints, and bones. It is a fibrillar protein, a component of extracellular matrix found abundant in most of the living organisms (Avila Rodríguez et al. 2017). The structure of collagen consists of a triple helical region of Gly-x-y motifs where X is proline and Y is hydroxyproline (Gómez-Guillén et al. 2011). There are almost two different forms of collagen, however the ones that are most frequently seen are types I, II, III, and IV (Seth et al. 2018). The sources of collagen include *Althaea cannabina*, *Staphylococcus carnosus*, *Rhopilema asamushi*, *Stomolophus meleagris*, *Catostylus tagi*, and *Rhizostoma pulmo* etc. (Sionkowska et al. 2020). Pro-collagen is produced first, followed by the disintegration of propeptides utilising the enzymes C-proteinase and N-proteinase, respectively, and finally the cross-linking of fibrils (Sionkowska et al. 2020). It is used as the major component in the pharmaceutical industries as it acts as moisturizer and a humectant (Sionkowska et al. 2020) (Fig. 2).

Fig. 2 Production of gelatin powder into collagen

Polymer Derived from Gelatin

Gelatin is a type of protein obtained from collagen by partial hydrolysis present in the skin and bones either in acidic or alkaline conditions (Narayanaswamy et al. 2016; Deshmukh et al. 2017; Mohiti-Asli and Lobo 2016). It is translucent, colorless and tasteless powder consisting of residues like glycine, proline, and 4-hydroxy proline. Gelatin form into gels at a temperature of 35 °C due to the formation of interchain hydrogen bonds, which are transparent, elastic, and permeable to oxygen (Deshmukh et al. 2017). It is widely used in the application of tissue engineering, food industry, pharmaceutical industry, cosmetic industry, photography, and other fields due to the properties such as cell adhesion, high biocompatibility and water solubility, flexibility, adhesiveness, growth, cost-effectiveness, and low immunogenicity as well as the capacity to generate transparent gels under certain conditions (Van Vlierberghe et al. 2014; Deshmukh et al. 2017; Alihosseini 2016).

Using Fibrin as Biopolymer

Fibrin is a protein derived from blood (i.e., fibrinogen and thrombin) (Catelas et al. 2008; Sundararaghavan and Burdick 2011). It is obtained from fibrinogen through the process of cryoprecipitation, ammonium sulfate precipitation, where thrombin degrades fibrinogen to form fibrin monomers, which link together by hydrogen bonding and becomes insoluble through the reaction of thrombin with plasma factor XIIIa (Burdick and Stevens 2005). The applications of fibrin include the formulation of foams, sheets, particle adhesives, and sealants, which are broadly used in encapsulation of cell, growth factor delivery, and in tissue engineering (Burdick and Stevens 2005; Sundararaghavan and Burdick 2011).

Biopolymer Gel: Hyaluronic Acid

Hyaluronic acid (hyaluronan, HA) is a disaccharide made up of (1→3)- β *N*-acetyl-D-glucosamine and (1→4)- β D-glucuronic acid with no sulfate bond, and belongs to a group of glycosaminoglycans (Kogan et al. 2007). It is a component of the extracellular matrix that is secreted by cells like fibroblasts and chondrocyte which play important roles in cell signaling and wound healing (Dovedytis et al. 2020). HA has been extensively used in drug delivery applications in the form of films, microspheres, liposomes, fibers, and hydrogels due to its biocompatibility, biodegradability, and easily changed chemical structure. It is also used in chronic wound repairing, cell migration, and skin healing (Tammi et al. 1989; Shaharudin and Aziz 2016; Litwiniuk et al. 2016).

Structure of Biopolymer Gels

Biopolymer gels tend to be soft solids, where the stress-strain relationship determines the its character and such materials typically do not rupture even after enduring considerable strain intervals under the condition of deformability. In terms of gelling biopolymers, the clustering of disordered molecules, and the association of aligned polymer chains, can be characterized as the mechanism of gelation to give a structural form of it. In addition to electrostatic interactions, ions may also play a role in bonding, and a cross-linking reaction can also be caused by hydrogen bonding between sections of peptide chains. When proteins aggregate, a densely branched cluster of filaments is formed. Through interparticle interaction, specific gels of varying degree of homogeneity can be formed (Clark et al. 1991).

Mechanism of Gelation

Gelation provides information about the structural aspects of biopolymer gels, as well as the mechanism of gel formation. The gelling biopolymer, such as gelatin, is formed by denaturing and hydrolyzing collagen, and sets into a transparent gel when left to cool below 40 °C. In terms of gelling properties, the formation of triple helices is evidently the leading method of cross-linking, since helix-helix cross-linking does not appear to be the primary mechanism in the formation of gels (Clark et al. 1991). In addition to forming physical junctions, chain entanglements can also provide the precursors for the formation of a three-dimensional network of polymer chains of gels and to permit gelation, hydrophilic, and hydrophobic interactions needed to reach a critical value, polymer ionization could be decreased to achieve this value (Montembault et al. 2005).

The molecules or segments of the solution have to be close enough to each other so that the attractive force can fix the structure of the solution. The formation will be a spontaneous reaction if Brownian motion or diffusion occurs. Despite this, the mobility of the molecules or segments may be severely limited due to the high viscosity and hydrogen bonding of the molecules, caused by the long chain and hydration of the sol (Maekaji 1974).

A cross-link is a bond that connects one polymer chain to another where it can be ionic or covalent. During the cross-linking process, a liquid polymer becomes a “solid” or a “gel” by reducing its mobility. In simple words, the chains of a liquid polymer can be linked together to form a solid or a gel. It has more molecular mass, so it is mechanically stronger and is resistant to heat, wear, and chemical attack. Cross-linked polymers are important because they provide resistance to heat, wear, and chemical attack (Maitra and Shukla 2014). This mechanism can be done in two properties such as chemical cross-linking and physical cross-linking.

Chemical Cross-Linking

The cross-linking of biopolymer gels can be accomplished by chain growth polymerization, addition and condensation polymerization, as well as by gamma or

electron beam polymerization. It includes free radical polymerization, controlled free radical polymerization, anionic polymerization, and cationic polymerization. During this process, a free radical active site is generated that adds monomers in a chain-like formation (Maitra and Shukla 2014). Gelation of biopolymer gels are produced by chemically cross-linking gelatin, where gelatin gels are not stable as the cross-linked network can be rapidly hydrolyzed by protease. Therefore, gelatin gel degradation can be accelerated or adjusted by introducing various chemical cross-links (Li et al. 2012).

Physical Cross-Linking

The process of making physically cross-linked hydrogels involves interactions between ions, crystallization, formation of stereocomplexes, hydrophobic polysaccharides, hydrophilic polymer chains, and hydrogen bonds with proteins (Maitra and Shukla 2014). The physical cross-linking of the structures of biopolymer gel defines the physical factors, such as pH, temperature, etc. The thermodynamics of cross-linking gelatin hydrogels are affected by the temperature of the solution. Aqueous gelatin solutions become aqueous gels when cooled below 30 °C. (Li et al. 2012). Under certain conditions, hydrogels can be cross-linked under physiological pH conditions at room temperature without the need for ionic groups in the polymer. Metallic ions which are naturally present in the hydrogel produce stronger bonds (Hennink and Nostrum 2002).

The Volume Phase Transition (VPT) in Polymer Gels

A volume phase transition (VPT) occurs when the degree of swelling changes “abruptly” (continuously), and when there exist a possibility of coexisting gel phases with differing swelling degrees. The phase equilibrium of swollen and cross-linked systems is unique to this type of system (Millar et al. 1965). When networks are forming, phase separation is a consideration that leads to the concept of volume phase transition. Macroporous cross-linked ion exchange resins became relevant in the early 1960s due to their combination of ion exchange and selective adsorption abilities (Millar 1960). The matrices were fabricated by cross-linking free radical copolymerization, diluted with both low-molecular-weight diluents and a soluble polymer, in the presence of additives. In the USA, there was someone working on practical problems (R. Kunin), but in one of the Czech research centers a broader focus was being developed (Seidl et al. 1967). In addition to evolving methodologies for gel permeation chromatography, research on ion-exchange matrix was focused on a variety of separation materials (Rosi et al. 2003). The formation of pores was analyzed empirically at first, but we were eager to integrate them into the polymer theories represented at that time by P. J. Flory Handbook (Flory 1953). Toward the incipient stage of phase separation, we considered the formation of heterogeneous structures as a thermodynamic process. Phase separation was characterized by the cross-link density (a function of the polymerization conversion) reaching a value of 12 such that the ultimate swell in the existing liquid (diluent plus monomer) occurred

($\varphi_2 = \varphi_0/2$) (Millar et al. 1965). The degrees of cross-linking, molar volume of the diluent, and dilution all contributed to improved phase separation. Phase separation became understandable for the first time when it became apparent that good solvents and soluble polymers with similar chemical compositions to network chains are so effective (Dušek and Sedláček 1969).

Studies of phase separation in gels provided further insights into why phase separation may occur in a microscopically or macroscopically organized form in some cases (Alberti et al. 2019). Approximations were made in regard to the evolution of structure, the role played by sol fraction, system dispersion, and interactions among the component systems. Analyzing the effect of various phase separation factors, it was discovered that the chemical potential of the dilute ($(\Delta\mu_1/RT)$ or its Maxwell construction form $(\Delta\mu_1/RT\varphi_2)$) passed through two extremes with respect to the polymer fraction (φ_2) passing through two extremes, which satisfy the condition $\Delta\mu_1 = 0$ for pure diluent. Using three-phase equilibrium, two gel phases of differing swelling levels and satisfying a particular condition could maintain an equilibrium between two phases of gel

$$\begin{aligned}\mu' \\ 1 &= \mu'' \\ 1 &= 0; \mu'/2 = \mu''\end{aligned}$$

Here, μ_2 (φ_2) is the equation determined by the Gibbs-Duhem equation or ΔG_{sw} showing two minima.

The function of phase separation in gels was also explained further by Alberti et al. who revealed that in some cases phase separation takes place on a micro- or a macrolevel. In order to model changes in structure, sol fraction, system dispersion, multicomponent interactions, etc., a number of approximations were adopted (Dušek and Patterson 1968). It was found that the adjustment of the chemical potential ($\Delta\mu_1/RT$) or its Maxwell construction form $(\Delta\mu_1/RT\varphi_2)$ for phase separation passed through two extremes where the roots satisfy the condition $\Delta\mu_1 = 0$ for pure diluent. In other words, it could be that two gel phases with differing degrees of swelling could achieve equilibrium and satisfy the condition of three-phase equilibrium. The Gibbs-Duhem equation or simply ΔG_{sw} , a two-minimum equation could be used to calculate φ_2 . The underlying phase diagrams for these systems show abrupt changes of the degree of swelling with temperature or other stimuli, which can be mapped out to the values of the chain concentrations, concentration coefficients, and Flory-Huggins interaction parameters (Dušek and Sedláček 1969).

Methods for Enhancing the Stability of Biopolymer Gels

Synthetic polymers are proving to be a natural mimic for biopolymers due to the enormous capacity and prospective applications (Jaspers et al. 2014). Poly-isocyanopeptides (PICs) are a class of artificial polymers with an attractive helical structure and a high helical inversion barrier (Yashima et al. 2016). A peptide

hydrogen bond network between n and $n + 4$ along the polymer spine stabilizes an $\sim 4_1$ (four repeats per turn) β helical conformation (Cornelissen et al. 2001). In addition, this hexagonal structure grants the polymer a high degree of stiffness (van Buul et al. 2013). Polyisocyanopeptide gels enhanced by ethylene glycol are similar in nearly all aspects to biologic gels and are more complex biomaterials (Jaspers et al. 2016). These gels display ultrasensitive mechanical response due to the formation of a network of flexible bundles when heated into the mesophilic region (37 °C). In addition, these gels decorated with GRGDS peptides can be used as three-dimensional scaffolds to manipulate stem cell differentiation (Das et al. 2015). The number of synthetic biomimetic polymers with high thermal stability is still relatively low.

Three adjacent alanine groups give TriPIC its exceptional stability. As the amide groups both run parallel to the polyisocyanide backbone, they create two parallel arrays of hydrogen bonds that stabilize the rigid, helical backbone of TriPIC (Yashima et al. 2016). A hydrophobic core surrounds the polymer backbone after the amide regions become partly inaccessible to water. The first hydrogen bond (A, not accessible to water) keeps stable as heat is applied, whereas the second bond (B), which is stretched, results in a more defined helix, and stiffer polymer (Van Buul et al. 2013). The hydrophobic interactions of the glycol tails drive the assembly of polymers once a gelation temperature has been reached. This induces an unusual thermal stability of the gels, which can remain stable for hours at 80 °C (Das et al. 2015).

Host-Guest Macromers (HGMS)

As they present a translucent appearance to HGM hydrogels, such heterogeneity can be correlated with the heterogeneous domains observed in chemical hydrogels prepared from UV cross-linked macromers (Waters et al. 2010). The hydrogels of HGM reflect this heterogeneity in the way they appear translucent. Studying the nanostructure of HGM hydrogels using Small-Angle X-ray Scattering (SAXS) and Transmission Electron Microscopy (TEM) is one of our main research objectives (Xia et al. 2013). Since the AD functionalization of HA is not position dependent, the entire heterogeneous structure of the nanoclusters is formed during UV-induced polymerization of the HGMS. Based on this data, a SAXS analysis found broad correlation peaks within the q (covariance matrix, $q = [4\pi/\lambda] \sin \theta$) range, from 0.4 to 1 nm⁻¹. The large peaks are due to scattering centers that are distributed randomly in the matrix of the hydrogel. These peaks are influenced by the AdxHA modification degree. With more modification degrees, the peak is located closer to $q = 1$. The spacing between host and guest nanoclusters can be estimated using Bragg's law (Eq. 1) $\lambda \theta \pi d = 2 \sin q$ 2 max, where d equals the distance between scattering centers and q_{max} is the peak position (Alberts et al. 2002).

Compressive Properties of the HGM Hydrogels

In addition, host-guest interactions are reversible, which means that they can easily be rearranged and regrouped upon compression. Therefore, the compressible HGM

hydrogels are much stronger and softer than the chemical MeHA hydrogels. MEHA hydrogel ruptures at stress levels below 50%. Conversely, the HGM hydrogels (4 wt% AdxHA) can withstand substantially more strain, up to about 80% (Zhao et al. 2010).

Host-Guest Macromer Hydrogels for Cartilage Regeneration

Human mesenchymal stem cells (hMSCs) can differentiate into several mesenchymal lineages, including cartilage, and our HGM hydrogels are demonstrated to be promising biomaterials for tissue regeneration. During such conditions, it appears that the cells do not affect the gelation process (Shanshan et al. 2010). This indicating that host-guest complexation is robust enough for cell-related applications.

Polymer Inclusion Complexes (PIC)

In the late 1940s, Fuoss and Sadek published a turbidimetric study on polyion condensation (Dautzenberg and Rother 2004). With more sophisticated instrumentation, the process of particle assembly has been better understood for the past few decades. According to recent research, particles are formed when nonstoichiometric mixtures of oppositely charged polyions combine, creating a neutral core enclosed in a shell of excess polyion chains (Buchhammer et al. 2003). Researchers have established that mixtures of oppositely charged polyions in solution cause the formation of PIC particles that are reinforced by a charged corona, which repels neighboring particles. The hydrophobic attraction between neutral coacervates in stoichiometric polyions occurs during flocculation rather than equilibrium, and can lead to unstable shell-deficient PIC particles (Dautzenberg and Jaeger 2002).

Discrete polydisperse particles are typically composed of diameters between ten nanometers (nm) and one micrometer (mm). Indirect methods, such as static and dynamic light scattering, are typically used to determine particle size, which preserves the integrity of nanoparticles in solution. In addition to light scattering, imaging techniques are often used as a support technique; however, particles are often affected by various processes during the preparation and analysis of the samples (especially in the case of drying and staining) (Patterson et al. 2014). It has been demonstrated that the increase in entropy subsequent to counterion release from polyelectrolyte is a result of electrostatic attraction between polyions charged oppositely (Ueno et al. 2012). However, it has been demonstrated that the increase in entropy caused by counterions released from polyelectrolytes explains the overall behavior of PIC particles (Bucur et al. 2006).

Nanoparticles and free polyions in solution coexist in equilibrium during the self-assembly of PIC particles (Zintchenko et al. 2003). PIC particles are inherently unstable due to their dynamic nature, making them vulnerable to corrosion and electrostatic shielding with addition of other charged species (Sui et al. 2003). Therefore, the stability of PIC particles in biological environments may be seriously compromised, as they may be exposed to high concentrations of electrolytes and proteins with charges (Dash et al. 1999). By using cross-linking of the polyelectrolyte components, PIC particles can be easily stabilized, which would drastically

reduce the exchange with free polymers in solution. Conversely, damaging PIC particles with physiological electrolytes improves their permeability, allowing them to release preloaded charges (Cai et al. 2012).

A final point to note is that only certain polyelectrolytes can form stable PIC particles if they are mixed correctly under suitable conditions. It is important to optimize several factors during the formulation of these nanomaterials, including chemical composition, charge density, and charge concentration of the polyelectrolytes, pH, ionic strength, and relative ratios of both polyelectrolytes. It is essential to optimize all of these parameters at once since they are interdependent (Cheow and Hadinoto 2012). In certain conditions, coacervates separate from solution and coalesce into dense materials, which also show great promise for biomedical applications, such as synthetic cartilages and enzymatically active biocomposites (Fu and Schlenoff 2016).

Nanofillers

Polymer matrix nanofillers fill specific volumes, alter conformational states, and immobilize nearby molecular groups. In order to choose the right nanofiller, it is necessary to consider its physical and dimensional properties. In contrast to earlier composites, carbon nanotubes (CNTs) combine superior mechanical, thermal, electrical, and thermal properties (Yuan et al. 2017; Jeevanandam et al. 2018; Al Sheheri et al. 2019). An important aspect of characterizing nanofiller's application in polymer composites is their size (Lagarón 2011). The 3D, 2D, and 1D nanofillers fall under this category.

One-Dimensional Nanofillers

A one-dimensional (1D) nanofiller is defined as a filler with one dimension smaller than 100 nm (Lagarón 2011). In the form of individual sheets or hundreds and thousands of nanometer long sheets of material, they can be between one and a few nanometers thick. A common example of a 1D nanofiller is montmorillonite clay and nanographene platelets. Furthermore, nanostructures are also known as nanoprisms, nanosheets, multibranched structures, nanoplates, and nanowalls (Mittal 2015), and other shapes (Akpan et al. 2019). Layered silicates, MMT, graphite nanoplatelets (GNP), ZnO nanoplatelets, ZnO nanodiscs, carbon nanowalls, amphiphilic graphene plates, and ZnO nanosheets are noteworthy examples (Mittal 2015). The shape-dependent properties of most 1D nanofillers make them useful in the fabrication of nanodevice components. Microelectronics, biosensors, and sensors are among the applications that they are used for. These properties are due to their excellent electrical, magnetic, and optical characteristics (Akpan et al. 2019). Electrical and thermal applications are beneficial to 1D nanofillers due to their dimensionality.

Two-Dimensional Nanofillers

Two-dimensional (2D) nanofillers have less than 100 nanometers in their dimensions (Lagarón 2011). Tubes, fibers, and filaments are usually the most common shapes. The

most common 2D nanofillers include 2D graphene, black phosphorus, clay nanotubes, carbon nanotubes (CNTs), cellulose whiskers, boron oxide tubes, boron carbon oxide tubes, and gold or silver nanotubes. Polymer nanocomposites can be manufactured using 2D fillers. There are several others, including molybdenum disulfide (MoS₂), hexagonal boron nitride (h-BN) (Ribeiro et al. 2017), graphene, MoS₂, and graphene oxide. There are many applications for 2D nanofillers, including photocatalysis, nanocontainers, nanoreactors, energy, sensors, catalysis, electronics, and optoelectronics. In comparison with 3D and 1D nanofillers, they are found to confer superior flame-retardant properties. As well as providing more reinforcement, they are also shown to be less expensive than 3D fillers (Araby et al. 2021).

Three-Dimensional Nanofillers

An example would be nanoparticles with three dimensions that are relatively equiaxed in the nanoscale (nanometer). Nanoparticles are usually isodimensional or zero-dimensional, and are usually in spherical and cube shapes. A 3D nanofiller is also known as a nanosphere, nanogranule, or nanocrystal. The materials used to form 3D nanofillers include semiconductor nanoclusters, carbon black, silicon carbide, nanosilica, nanoalumina, nanotitanium oxide, polyhedral oligomeric silsesquioxane (POSS), nanomagnesium hydroxide, silica, and quantum dots (QDs) (Lagarón 2011). Polymer nanocomposites are formulated with 3D nanofillers because of their inherent properties. Nanoparticles (e.g., Fe₃O₄, ZnO, TiO₂, Ag, and SiO₂) exhibit high stability, hydrophilicity, and ultraviolet (UV) resistance along with excellent transparency to visible light, nontoxicity, and high photocatalytic activity. They are useful in applications like coatings, separation and purification, and biomedicine when coupled with polymers that have suitable properties (Mittal 2015).

Amphiphiles

An amphiphile is a chemical molecule that exhibits both hydrophilic (attracted to both water and fat) and lipophilic (attracted to fat) qualities. Amphiphile comes from the Greek words: *αμφίς*, *amphis*: both and *φιλία*, *philia*: love, friendship. Such substances include amphiphilic or amphipathic compounds. Lipoproteins, detergents, and soaps are examples of amphiphilic substances. Cell membranes are highly structured by phospholipid amphiphiles (Schubert et al. 1995). Researchers in chemistry and biochemistry consider amphiphiles central to several areas of study, including polymorphism of lipids. The chemical compound bolaamphiphilic contains hydrophilic groups at both ends of the molecule. These micelles are prolate. Often, amphiphilic species have a majority of hydrophilic parts, a majority of lipophilic parts, or a mixture of the two (Phillips 2015). An example would be proteins or block copolymers. Amphiphilic compounds have hydrophilic polar functional groups (representing either ions or anions). Amphiphilic compounds are also capable of dissolving in water and, to a lesser extent, in nonpolar organic solvents due to the existence of both lipophilic and hydrophilic parts. A compound that is amphiphilic will partition aqueous and organic solvents when it is placed in an

immiscible biphasic system. In particular, the extent of partitioning (Schubert et al. 1995) depends on the length of the hydrophobic and hydrophilic portions.

Biological Role

Membrane components are phospholipids, an amphiphilic class of molecules. Molecular membranes are formed as a result of their amphiphilic nature. Using two layers of lipids to form a sheet, they mutually organize themselves into lipid bilayers. Lipophilic chains form a layer by being positioned on the same side. The layers are then stacked so their polar groups are outside and the lipophilic chains touch on the inside. There is thus an internal nonpolar region to the bilayer sheet, which is patched between the two polar sheets (Schubert et al. 1995).

Biological membranes are largely composed of phospholipids, but also contain another class of fatty acids, cholesterol, and glycolipids, that confer different physical and biological properties to them (Watson 2015).

Many of these derivatives interact with biological membranes, making the hydrophobic part of them adhere to lipid membranes while exposing the hydrophilic part to water, altering the physical behavior of the compound (Peetla et al. 2009).

Antiparallel A β sheets form toxic oxidative A β fibrils, formed by bilayers of A β sheets which are strong amphiphilic. As the name implies, A β proteins are a combination of double β sandwiches consisting of 13-mer modules. In addition to describing the small fragments of A β (with 40 and 42 amino acids), hydropathic waves can also present a better description of plaques (Schubert et al. 1995).

AMPs with anti-gram-negative bacteria activities are another class of amphiphilic molecules. A study revealed that amphipathicity is the most useful measure for determining which AMPs possess these abilities. Antibacterial and antifungal dual-activity AMPs have a better chance of having high amphipathicity (Ramazi et al. 2022).

General Applications of Polysaccharide-Based Gels

Utilization of Agarose Gel

Agarose is made up of repeating agarobiose (L- and D-galactose) subunits and is found in the seaweed species like *Gelidium* and *Gracilaria*. A noncovalent network of agarose polymers controls the molecular sieving capabilities of gel during gelation by controlling the pore size (Lee et al. 2012). It is used in the separation of DNA fragments called agarose gel electrophoresis (AGE) (Lee et al. 2012). In electro-membrane extraction, an agarose gel can be used as a supported liquid membrane (SLM) between the acceptor and donor phases (Tabani et al. 2017). It is also used in the liquid phase microextraction for high extraction efficiency (Prosen 2014).

Alginate's Uses

Brown algae (*Phaeophyceae*) such as *Laminaria hyperborea*, *Laminaria digitata*, *Laminaria japonica*, *Ascophyllum nodosum*, and *Macrocystis pyrifera* are the main

sources of alginate. Sodium alginate has been widely used in biomaterial applications because of its biocompatibility and hydrophilic nature (Sahoo and Biswal 2021). They are used in the delivery of low-molecular-weight drugs to the target site. The alginate beads are used for the formation of primary and secondary bonding with the drugs which can be used for control drug release kinetics (Li and Mooney 2016). The benefits of alginate gel for bone and cartilage regeneration include their minimally invasive surgical techniques, ability to fix irregularly shaped defects, and ability to release tissue-inducing factors such as BMP and TGF- β (Lee et al. 2012). They are used as the physical barrier in the reduction of reflux episodes and in the treatment of heartburn and esophagitis exist (Szekalska et al. 2016). It can also be used in the treatment of obesity as it dissolves in stomach and stretches into a soft, gel-like substance that remains stable in the gastric acid environment and maintains satiety for 6–8 h, after which it dissolves in the small intestine due to the neutral or alkaline environment by formulating with standalone or various foods (Sarkar et al. 2020). Intake of alginate at higher dosage decreases the hunger and food uptake by increasing viscosity and tendency of feeling full due to the formation of alginate gel in the contents of intestine (Maljaars et al. 2008). In food industry, alginate beads are used in encapsulation of probiotics in order to increase the cell viability and storage stability (Gheorghita Puscaselu et al. 2020). It is also used in the reduction of ice crystal formation during freezing of ice creams, in order to prepare smooth product. Alginates were used in the preparation of dessert and jellies which do not melt but only at body temperatures (Qin et al. 2018). Frozen fishes are preserved using the utilization of calcium alginate films and coatings. Due to the property of forming viscous solution by dissolving in water, alginates are used as thickening, stabilizing, emulsifying, and gelling agent. These are also used in the immobilization of enzymes in fruit juices, syrups, oils, etc. (Brownlee et al. 2009). In cosmetic industries, it is used in the formation of skin-protective creams in order to prevent industrial dermatitis and in shaving preparation as stabilizer for easier spreading, rinsing, and lowering the solid content of the cream (lesser, 1950) (Fig. 3).

Employment of Collagen and Fibrin

Collagen's biological function makes it very promising for use in the pharmaceutical, therapeutic, and aesthetic sectors (Avila Rodríguez et al. 2017). It is used in the cosmetics formulation as it has property of film formation, regeneration, and skin moisturization (Sionkowska et al. 2020). Collagen is used in the production of beauty masks (hydrogel) which helps in the restoration of skin's elasticity and helps in the promotion of antiaging performance (Sionkowska et al. 2020). The topical administration of fish collagen contained negatively surface-modified nanoliposomes promotes antiaging performance by increasing the Type I procollagen protein expression (Subhan et al. 2020). Collagens are used as edible films and coatings for preventing the migration of oxygen (O_2), moisture, and solute, for providing the structural integrity and permeability of vapor (Hashim et al. 2015).

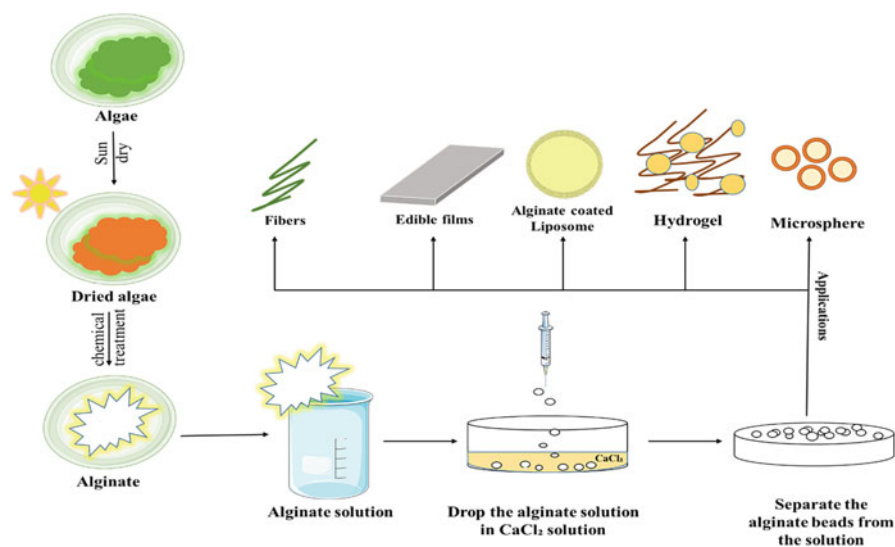

Fig. 3 Uses of alginate extracted from algae

It is also used as food additives such as colorants, antioxidants, preservatives, emulsifiers, and thickeners (Hashim et al. 2015). Fibrin, an extracellular matrix, is used in the cell-matrix interactions and in tissue engineering such as cardiac micro-environment designing, tissue transplantation, and bone regeneration (Litvinov and Weisel 2016). It also plays a major role in drug delivery by loading of drug through impregnation (Ahmad et al. 2015). Fibrin is used as a coating agent in bone tissue engineering for cell growth factor attachment and scaffold distribution (Noori et al. 2017).

The Role Played by Gelatin

Gelatin is used in the food industry for manufacturing desserts, for texture foaming clarity and as a stabilizing agent (Alipal et al. 2021). It is also broadly used in the field of cosmetics as gelling agent in shampoos, hair sprays, sunscreens, body lotions, and facial creams (Kamatchi et al. 2016). In pharmaceutical industry, gelatin is used as topical drug delivery system such as skin burns, capsule coats, binding tablets, sponges for treating wounds, and for vitamin formulations (Petros et al. 2020). Gelatin is widely used in the production of capsule which is mostly preferred over tablet in medicine administration (Sebastian 2014). In food industry, 1% gelatin is used as coating in lozenges, candies, and wafers and used as clarifying agents in juice industry to remove the suspended particles in juice (Petros et al. 2020). Two-dimensional gelatin substrates were used in the cell and tissue cultures, especially the fibronectin-

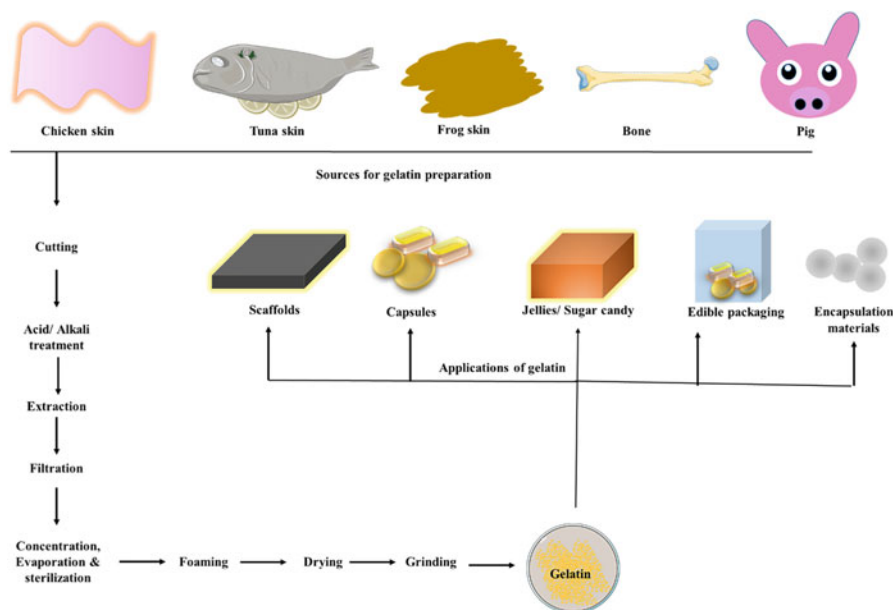

Fig. 4 Preparation of gelatin from various animal sources and its applications

producing cells as it binds with dishes coated with gelatin more efficiently (Bello et al. 2020). In earlier studies, it has been reported that channel catfish skin gelatin–incorporated ice cream had enhanced mouthfeel by stabilizing high emulsion foaming (Ranasinghe et al. 2022). Channel catfish gelatin is also used in the clarification of beer by protein flocculation (Duan et al. 2018) (Fig. 4).

Hyaluronic Acid

Hyaluronic acid is used in the treatment of cancers such as prostate and carcinomas as tumor marker and in monitoring the mucoadhesive progression (Lokeshwar et al. 2014). It is used in the targeted drug delivery due to the binding of hyaluronic acid and its derivative to specific cell surface receptors mainly present in liver, kidney, blood vessels, and body fluids (Gupta et al. 2019). Due to degradation of the components like hyaluronic acid, extracellular matrix is the cause of skin aging which leads to decrease in skin tone, wrinkles, and sagging (Papakonstantinou et al. 2012). Hyaluronic acid is used as skin patch in order to overcome the above issues (Juncan et al. 2021). It is used in osteoarthritis for the restoration of synovial fluid viscoelasticity (Saranraj and Naidu 2013). It plays important role in the cellular and matrix meditation, hence used in wounds healing such as abrasions, donarsites, postoperative incisions, and ulcer (Saranraj and Naidu 2013).

Pros and Cons of Using Biopolymer Gels

Biopolymer-Based Gels	Pros	Cons
Chitosan	It is used as antimicrobial and antioxidant (Schueller and Romanowski 1999)	Chitosan intrinsic properties are affected by cross-linking of chitosan gel (Ishihara et al. 2001)
	It has excellent adhesion with cells	It has high viscosity to the solution
	It is from renewable resources	Transformation into nanofiber is difficult It is insoluble in many solvents
Collagen	It enhances the skin hydration and skin elasticity. It reduces wrinkles (Goodarzi et al. 2019)	It results in cutaneous necrosis and inflammatory reactions on a local level (Seal et al. 2001)
Alginate	It smoothes out fine creases and improves skin elasticity and strength. It gives the appearance of younger skin (Kozłowska et al. 2018)	The resulting gel may have an unpleasant odor (Takahashi et al. 1990)
Xanthan gum	It withstands a wide variety of temperatures and pH levels, has skin-conditioning effects, and is nontoxic (Lopes et al. 2015)	It irritates the skin (Lopes et al. 2015)
Kappa-carrageenan	It attracts water to the skin and hair. It is utilized as a hair conditioning agent. It has a moisturizing effect (Noor 2018)	It might cause irritation (Noor 2018)
Pectin	It strengthens skin (Ammala 2013)	Pectin from a few sources may have low gelling ability on occasion (Ammala 2013)
Guar gum	It enhances hair and skin. It keeps water from evaporating. It extends the life of the product (Singh et al. 2014)	It is hypersensitive towards allergens (Singh et al. 2014)

Conclusion and Future Perspectives

Cellulose, polysaccharide, starch, and chitin are used to create biopolymer-based gels, which are renewable, biocompatible, and biodegradable. However, recent studies are primarily focused on potential applications of biopolymer gel based water purification and pharmaceutical and medical systems, with less attention paid to other areas such as electrical sector. The development of new biopolymer-based gels using natural or chemically modified biopolymers have gained substantial interest as a result of recent improvements in our understanding of how to isolate, describe, and use different types of biopolymers. The development of scattering and microscopical approaches, the incorporation of structural and rheological techniques

in the study of gelation kinetics, the use of mean field theories, and the pursuit of new simulation techniques are some of the major accomplishments in the field of biopolymer gels.

Abstract

The current era is challenged with depleting oil reserves and ever-increasing pollution from petroleum-based fuel pollutants. Faced with this challenge, there is a growing need for the development of renewable and sustainable materials that can potentially replace the conventional materials. The present governments and world organizations have instilled a major focus in making the world cleaner, pollution free, and reducing the usage of fossil fuel. This focus has driven industrial and governmental entities to stress on the research, development and fabrication of finished materials from sustainable, renewable, and recyclable biopolymer-based composites. As alternates to conventional materials, biopolymer-based composites are expected to attain the same or even better performance. Biopolymers possess the inherent property of being functionalized during their preparation enabling better compatibility and efficient models for preparing composites. This book chapter gives an overview of biopolymer-based composites; their physical, chemical, and material characteristics, the various synthesis approaches and their applications in automobile industries, medical field, biosensing, food packaging, water treatment, and energy storage devices.

Keywords

Biopolymer · Composites · Sustainable · Fibers · Polymer

Introduction

The demand for sustainable materials with prominent properties increasing which could mitigate the environmental issues posed by fossil fuels. To fulfil these requirements, materials that are stand alone have few intrinsic limitations to be utilized in high performance applications. However, interesting, fascinating, and high-performance property materials can be achieved by the development of composite materials. A composite is developed from two or more materials with distinct varying properties, the unification of these materials results in the formation of materials possessing the properties of its precursors. Composite materials result in enhanced and multifunctional superior materials. Biopolymers being renewable and biodegradable have garnered immense interest and are predicted to replace the largely popular petroleum-based polymers. Biopolymer-based composites are

prepared with the aim of achieving good mechanical behavior, durability, properties of both natural fiber and biopolymer (Ramamoorthy et al. 2015). In this regard, biopolymer composites are biopolymers that are reinforced by natural fibers, polymers, fillers, etc. The reinforcing of biopolymers affects their crystallinity, thermal properties, morphology, production cost, and durability. Biopolymer composites have also gained immense popularity in light of the commonly used polymers ill-effects on the ecosystem due to their non-biodegradability. The recycling of these commonly used polymers by the popular recycling process, i.e., thermal recycling more commonly called incineration ends up affecting the overall quality of stability. Biopolymer-based composites on the other hand can be recycled by similar recycling process for several cycles with minimal change in its properties (Ngaowthong et al. 2019). These qualities of biopolymer-based composites show great promise for scaling and widespread usage as end products/commercial products. Biopolymer-based composites have already found their place in various applications like food industry, biomedical applications, packaging, water purification, and structural constructions (Mohan et al. 2016).

Biopolymer-based composites that are naturally available are classified into wood-based fibers and non-wood-based fibers. Biopolymer-based composites of varying type is made up largely of lignin and cellulose; the difference in percentage of these two components play a huge role in the physical property and performance like tensility, crystallinity, and strength.

This chapter discusses the preparation methods of biopolymer-based composites, their properties, and their application in various fields.

Preparation of Biopolymer-Based Composites

Biopolymer composites can be synthesized from various methods from wide variety of biopolymers and natural fibers. The combination of different biopolymers with different natural fibers can result in various innumerable outcomes. Many approaches can be taken while developing a biopolymer composite depending on utility, starting materials employed, time, and resource availability. There are advantages because the biopolymer-based composites can overcome individual limitations of the starting materials used. Some of the more popular preparation techniques have been described in this section.

Graft Polymerization

Graft polymerization is the process in which a polymer chain serves as the backbone upon which different monomers get bonded to it and polymerase as side chains. Graft polymer involves two types of polymers where the polymer that make up the main chain and the side polymer chain are distinct and different. The monomers that made up the side chains can be of different types hence making this technique an attractive technique for grafting different functional groups to the main polymer

chain. There are two grafting approaches, i.e., “grafting to” and “grafting from,” the “grafting to” involves the monomers reacting with the polymer backbone, the “grafting from” involves polymer backbone being functionalized to bind with monomers. Grafting process can be initiated by chemical treatment, ionizing radiation, enzymatic grafting, plasma-induced, photochemical treatment, and radiation (Sherazi 2016). Grafting polymerization is one of the most popular methods of functionalizing cellulose that is carried out mostly by free radical polymerization, living radical polymerization and ionic and ring opening polymerization (Udayakumar et al. 2021).

In-situ Polymerization

This technique involves the formation of a reinforced phase, it involves the dispersion of the fiber along with the monomer in solution followed thorough mixing and homogenization of the precursor solution. An initiator or catalyst is added to the system to assist in the formation of free radicals by breaking bonds as part of the chain reaction; this system is simultaneously treated by light or heat for curing. In case of thermoplastics, the initiator and monomer are directly added to mold resulting in the formation of matrix with the mold in a single step. This process is unique because the molecular weight of the composite can be manipulated by manipulation of the amount of initiator in the monomer solution. This technique can be used for making complicated shapes and is a useful fabrication tool for making implant materials (Sadasivuni et al. 2020).

Infiltration Method

This method consists of four steps (i) Pre-form fabrication, (ii) Interphase deposition, (iii) Infiltration, and (iv) Thermal processing. In pre-form fabrication, the shape of the desired product is molded to form the fiber reinforcing phase, this is followed by interphase deposition where the fibers are coated by means of interphases to form a fibrous pre-form. The reinforced fibrous perform is filled by infiltration with ceramic matrix that contains fillers and particulates of interest, this is followed by thermal treating of the ceramic matrix with reinforced fiber to yield the desired product of desired shape. There are various infiltration methods for fabricating biopolymer-based composites like polymer infiltration and pyrolysis, slurry infiltration, sol-gel infiltration, chemical vapor infiltration, direct melt oxidation, liquid silicon infiltration, etc. (Sadasivuni et al. 2020).

Phase Separation

Phase separation, also referred to as phase inversion is a versatile technique for preparing biopolymer composites. It is centered on the precipitation or solidification

of the phase with polymer from a system that was originally homogeneous. The homogeneous solution is prepared by dissolving the polymer in an appropriate solvent. The thermodynamics behind this process is the miscibility gap that exists between the polymer and the solvent. Conditions are applied such that polymer starts to precipitate due to the dissolving ability of solvent reducing with respect to the polymer. There are various ways to carry out phase separation, among them thermally induced phase separation (TIPS) is the most widely accepted and known method. TIPS employs an apt solvent that does not dissolve the polymer at normal room temperature but is able to dissolve at lower temperatures to obtain a homogeneous solution. The homogeneous solution is casted or extruded with different architecture with lower temperature to induce phase separation. The solvent is then exchanged with volatile organic solvent so that the solvent can be dried and removed easily. TIPS is aided with binary phase diagram to understand phenomenon of the phases between the polymer and solvent that are stable, unstable and metastable. TIPS is commonly used for the preparation of biopolymer composite membranes that are porous, lightweight and flexible (Figoli 2020).

Intercalation

This method involves the insertion of polymers into layered substrates like silicates and is particularly useful for preparing organic-inorganic hybrids. There are three types of intercalations depending on the processing technique and the starting materials used: *in situ* polymerization intercalation, melt intercalation and polymer solution intercalation. Among the three processes, polymer solution, intercalation, and melt intercalation are the more commonly used. Polymer solution intercalation involves dissolving the polymer/monomer with appropriate solvent and swelling of the layered substrate. The layered substrate is swollen using a solvent which is mixed with polymer and the polymer intercalates and ejects the solvent in the layered substrate to produce intercalated structure. This is useful when employing water soluble polymers, however this system is only possible for a few selected polymers. However, the excessive use of solvents that are harmful and expensive makes this method difficult to scale. The limitations of polymer solution intercalation have enabled melt intercalation, this method is eco-friendly since harmful organic solvents are not needed and the scaling and processing process is easier. This method can use polymers which are not suitable in the other two methods (Shen et al. 2002).

This intercalation technique is especially helpful for the preparing metal-based composites by the mixing of metal precursors and biopolymer; however, this technique is limited to very few biopolymers like poly-lactic acid, cellulose, lignin and is not suitable for polymers like chitosan and poly(vinyl alcohol).

Solvent Casting

Solvent casting, also referred to as wet processing or solution casting is a popular method that is simple and does not require specialized instruments. Solvent casting

mixes the polymer matrix and filler by continually stirring and agitating, the mixture is used for casting followed by eventual solvent evaporation and drying. The first step is dissolving the polymer to make a polymer solution with an appropriate solvent, most commonly used solvents are water and alcohols. The polymer solution is often heated or the pH is changed to enable optimum conditions for the formation of the film. The polymer solution is employed for casting into a mold or a film by casting on a flat surface, this is followed by the removal of the solvent. The film maybe subjected to heat treatment to remove stress. There are several criteria's that should be considered in this process: the polymer should be soluble in the solvent; minimal solid content should be present; viscosity, the film should be as homogeneous as possible. Factors like the choice of solvent and the molecular weight of polymer play an important role in the quality of the film formed. There are also several limitations in employing this process such as the requirement of large amounts of solvent which hinders its scaling for industrial applications, the possibility of toxic solvent being retained, time consuming, the possibility of proteins and drugs denaturation due to the solvents employed, solvent recovery is difficult. Despite these limitations, it is still considered one of the best choices for fabrication quality high films and better performance which is difficult with other methods. This method is widely used for preparing coating for biological applications and packaging applications (Kong et al. 2015).

Layer-by-Layer Deposition (LBL)

This method is another popular and sustainable route for developing thin film biopolymer-based composites. This technique involves the deposition and stacking of thin films of different materials alternately with the different layers of films complementary to each other. The LBL technique is one of the most common methods for developing bilayer material. It is also complimented by other techniques like spray coating, dip coating, spin coating, etc. It has been employed as a technique for depositing materials like nanoparticles (NP), carbon nanotubes (CNT), biological molecules, electrolytes, etc. (Sadasivuni et al. 2020). Another advantage, it offers precise control of the film. The bonding and interaction involved in LBL composites are covalent bonding, hydrogen bonding, electrostatic forces, and weak intermolecular interactions. Other advantages of using this technique is that it is highly facile and feasible (Tang et al. 2012).

Coagulation Spinning

This technique is more commonly employed for fabricating polymer yarns, fibers and polymer- nanotubes composites. There are two types of spinning, i.e., wet and dry spinning. In dry spinning, the solvent present in the fiber is evaporated by heating whereas in wet spinning, the solvent is removed by coagulating with another solvent. This technique involves injection of surfactant-stabilized filler dispersion into polymer solution like PVA in a rotating bath. The NTs and polymers are made to

flow in the same direction by injection, the polymer molecules ensue in replacing the surfactant thereby destabilizing the nanotube (NT) dispersion. The replacing of surfactant and destabilizing of the NT dispersion makes it collapse to form a fiber, which is extracted and derived by coagulation from coagulation bath (Sadasivuni et al. 2020). This method is a popular method for fabricating CNTs by either wet spinning or dry spinning. There are two types of spinning, i.e., wet and dry spinning. In dry spinning, the solvent present in the fiber is evaporated by heating. In some instances, the mechanical property dry spinning is superior to wet spinning; however, it has several limitations like its scalability and less production quantity which affects the overall production quality. Wet spinning on the other hand is scalable, simple, easily produced and requires mild temperature conditions (Berber and Hafez 2016).

Electrospinning

This is one of the most preferred techniques for synthesizing biopolymer composites from their respective melts and solutions. It employs a high electrical field where a polymer is charged and accelerated to form ultrafine NFs ranging from 10 nm to 1 μ m. A conventional electrospinning is made up of a syringe that is filled with polymer either in solution or melt form, the tip of the metallic syringe is connected to either the positive or negative terminal of the power supply with the other terminal usually grounded. The syringe is connected to a pump which constantly pumps out polymer producing nanofibers (NF) that is collected at the other end of the terminal. There are several parameters that regulate the formation of polymer NF like the solvent employed, the concentration of solvent, concentration of polymer, applied voltage, viscosity of solution, surface tension, distance between tip and collector, flow rate, collector type, temperature of the system, etc. Composites produced from electrospinning are used in applications ranging from sensors, filters, scaffolds for biomedical purposes to fuel cell membranes, organic electronic, energy storage devices, etc.

Electropolymerization

This method is utilized for depositing polymers onto a conductive surface or substrate and is particularly used for coating small areas. Electropolymerization works on the principle of applied current or potential resulting in the oxidation of monomers and depositing the polymer film onto the surface. The electrochemical polymerization is usually carried out in an electrolytic cell that contains the conductive substrate on which the coating or film formation will be done and is called the working electrode. The electrolytic cell also contains inert electrodes, i.e., reference electrode and counter electrode against which the potential and current applied in the cell is measured. The cell is filled with the electrolyte which contains dissolved monomer, metal salts, redox active molecules, etc. The electrolyte may also contain

a supporting electrolyte to render the electrolyte more conductive so as to enhance the polymerization rate. Electropolymerization can be divided into potentiodynamic, potentiostatic and galvanostatic methods for polymerization. Potentiodynamic technique involves a sweeping of potential between two points in which the monomer oxidizes. The polymer film grows with increasing sweeps and is accompanied by adsorption and desorption of the electrolyte to stabilize the polymer film. Galvanostatic electropolymerization works on the principle of applying a fixed current at which the monomer oxidizes at a constant rate. Potentiostatic electropolymerization is similar to galvanostatic, however in this technique a constant potential is applied. Electropolymerization is a technique that is limited to monomers that are electroactive and thus this limits its application. This technique has been extensively used for polymerizing redox active small biomolecules that contain quinones and functional groups. An advantage of this technique is the ability to simultaneously deposit other electroactive materials like metals, conducting polymers, while polymerizing the redox active biomolecules/ bio-monomers. This method is advantageous in that high-quality polymer chain and uniform polymer deposition is achieved. This technique is particularly useful for the construction of energy storage devices. The limitations of this technique is the scalability issues and the requirement for the monomer to dissolve in the electrolyte (de Leon and Advincula 2015; Nagaraju et al. 2014).

3D Printing

3D printing is grabbing lots of attention in the fabrication of biopolymer-based composites and scaffolds particular for biomedical applications like tissue engineering and regenerative medicines. 3D printing has advantages over other fabrication methods due to its more precise control over the geometrical parameters like porosity, pore size, and pore interconnection size. 3D printing is a method of fabricating 3D materials and objects with shapes that are designed digitally. It is an additive manufacturing technology that is used for fabricating a target shade by addition of layers successively. It is a technique that is used for both designing the prototypes and manufacturing the products which are used in a wide array of applications. In 3D printing, the first step is designing the model by means of computer-aided designs (CAD) and other modeling softwares that directs the machine in the successive printing process. The second step is the printing where the machine interprets and analyses the data and model that has been designed and starts laying/printing successive layers with the material which can be in liquid, powder, or a combination of both. In most instances, the 3D printing employs several materials for the printing process and supports are also employed sometimes for the printing which are removed upon the completion of the printing. Depending on the application of the printed object, post processing may also be carried out. The additive process can vary from materials and applications, some of the more popular processes that uses biopolymers are fused deposition modeling, direct metal laser sintering, stereolithography, and selective laser sintering. Some of the most commonly used biopolymers used in 3D printing are poly(lactic acid) (PLA), poly

(glycolic acid) (PGA), poly(lactic-*co*-glycolic acid), etc. (Li et al. 2014). Fig. 1 show different types of architectures that can be constructed with different printing process (Elomaa et al. 2011; Kalita et al. 2003).

Other Methods

Extrusion is a method used for producing composites of fixed cross-sectional area by pushing the material through a die of the required cross-sectional area. Common examples of materials produced through this process are polymers, ceramics, metals, modelling clay, etc.

Pultrusion is a method similar to extrusion used for producing fiber-reinforced materials, compared to extrusion, it pulls the material instead of pushing like in extrusion.

Filament winding involves the winding fibers on a rotating mandrel, the fibers are then mounted and processed to form fibers that are wrap in different configuration like helical, hoop winding or arranged longitudinal (Verma and Fortunati 2019).

Properties of Biopolymer-Based Composites

The properties of biopolymer composites are attributes of the intrinsic property of the starting materials, processing conditions and the state of the final product. The intrinsic property are characteristics like crystallinity, density, chemical structure and

composition, solubility, transparency, gas properties, etc. The processing characteristics are the dependent of the melt temperature, viscosity, index, strength, etc. The combination of the both the intrinsic and processing properties influences the product properties like its heat resistance, water resistance, aesthetic properties, electrical properties, mechanical properties, physical properties, biocompatibility, etc. Some of the important properties that are considered in the construction of the biopolymer-based composites will be described in this section.

Mechanical Properties

The mechanical integrity of the biopolymer-based composite is highly dependent on the application and the purpose for which it was constructed. The biopolymer-based composite is scrutinized for its mechanical properties like tensile test, compressive, creep behavior, flexural, flexibility, impact, hardness, shear, etc. These mechanical properties are governed by factors like the polymer type, molecular weight, crystallinity, chemical composition, type of linkage, orientation, morphology, and concentration. It has been shown in various studies that the tensile strength of the material can be enhanced by reducing the hydrophilicity. The tensile strength has also been found to be increased by treating the fiber involved. The orientation of fiber either in longitudinal or transversal direction also influenced the tensile strength which can be employed for designing composites. The mechanical properties can also be enhanced the addition of nanofibers, nanomaterials, nanoparticles into the polymer matrix (Ramamoorthy et al. [2019](#)).

Dynamic Mechanical Thermal Properties

This analysis is an extension of mechanical analysis and heat which investigates the composites' ability to deflect heat, it gives information of the composite with regard to the elastic property/storage modulus, viscosity/loss modulus, and material damping ($\tan \delta$) as a function of temperature. These properties are analyzed by thermal analysis techniques like thermogravimetric and differential scanning calorimetry. The dynamic property of the material is associated and affected by the polymer, plasticizer, and the reinforcement technique employed (Aaliya et al. [2021](#)).

Thermal Properties

Thermal property like the thermal stability and conductivity of a biopolymer-based composites in an important parameter in determining the scope of the composite that is fabricated. There are various factors that determine the thermal property of the composite like the crystallization temperature, melting temperature, glass transition temperature, thermal degradation rate, heat of fusion, degree of crystallinity, etc. These parameters can be determined by using thermal analytical techniques like

differential scanning calorimetry and thermal gravimetry analysis. The thermal stability of a biopolymer composite can be enhanced by the addition of other biopolymers, one such instance is the combination of lignin with other copolymers. Lignin, an aromatic molecule that has numerous phenolic hydroxyls in its structure, results in various intermolecular hydrogen bonding with polymers that contain electronegative groups. This bonding between the polymers largely increases the thermal stability of the composite (Sen et al. 2015).

Tribological Properties

Tribology is the study of friction, wear and lubrication between two interacting surfaces in natural and artificial environments. It is most commonly investigated by “Pinon disc” test which involves the sliding wear between two surfaces within a fixed contact area. The property is crucial in determining the biopolymer-based composites durability and performance for practical applications in various scenarios and physical conditions. It has been pointed out that the inclusion of natural fibers enhances the tribological properties of the composite (Vinod et al. 2020).

Flame Retardancy

Biopolymer composites are becoming more commonly used in construction materials, textiles, parts of machines, etc. In view of their increasing usage and abundance, the flammability and flame retardancy of the composites is an important parameter that should be checked before being issued and used commercially. Natural fibers in its nature are highly flammable and produce heat exothermically on burning and for this reason they are commonly used as fuel in fire making since the primitive ages. There are various factors that affect the flammability of biopolymer-based composites like the type of fiber and biopolymer, structure of composite, adhesion between the matrix and reinforcement. The chemical composition and structure of fibers differ from one to another and hence the flame retardancy also varies. Cellulose which constitutes majority of the chemical composition of natural fibers is highly flammable and the increase in its content increases the flammability. It decomposes and emits flammable volatiles, tar which leads to char formation and non-flammable gases. Lignin, on the other hand, enables the char formation and protects the biopolymer composites as an insulator. It may be noted that high crystallinity and low polymerization of a polymer increases the flame retardancy. Flame retardancy of biopolymer composites are tested by Bunsen burner test by either vertical or horizontal test or the combination of both the test. To improve the fire retardancy of biopolymer composites, there are various techniques like the addition and dispersion of fire retardant agents in the composite, the addition of fillers that are endothermic in nature and the employment of intumescent systems that are painted over the composites which on exposure to fire expand and suffocate the burning by limiting excess to oxygen (Faruk and Ain 2013). Despite the

advantages that comes with employing various flame retardant agents, there are also limitations that are imposed on the biopolymer composite wherein the addition of flame retardant agents like halloysite NT was found to inhibit the mechanical ability of the composites. Therefore, there is a need to fabricate and seek new routes where the addition and inclusion of flame retardant agents to biopolymer composite does not affect either its properties or its performance.

Optical Properties

The commercialization of biopolymer composites in various industries requires thorough determination of their stability and its behavior. Optical property and stability of the composites play a crucial role in their employment as viable materials for coating, plastics, transparent materials and glazing agents. Factors like refractive index, dielectric constant, light transmission and absorption, color, polarizability, transparency and absorption coefficients are major areas where the composites are tested and considered. The stability of the composites when exposed to UV radiation is an important factor when considering the scalability of a composite. Natural fibers which contain lignin on exposure to UV radiation degrades giving out yellow discoloration and exposes other constituents to UV light. Sunlight cleaves the covalent bonds that is present in majority of the biopolymers causing degradation mechanically, discoloration, physicality and roughens the composite. Biopolymers composites are largely used in food packaging, the food should be preserved and ensured protection from UV light. This task can be achieved by increasing the refractive index of the composite, increasing the opacity by increasing the crystallinity of the biopolymers. There are various routes to achieve this target some examples are the addition of thyme essential oil to reduce transparency in starch-chitosan composites, addition of nanoparticles of silver, titanium, and copper to increase the refractive index (Jafarzadeh and Jafari [2020](#)).

Moisture Absorption

The performance of biopolymer composites reacts negatively to moisture, composites when they come in contact with moisture tends to plasticize and lose its toughness. The degree of expansion of biopolymer and the natural fiber varies which causes compatibility issue between the two and damages the interface between the two. Natural fiber on absorbing moisture swells up and shrink affecting its physical characteristics like flexural and tension modulus negatively. The swelling of fibers decreases the dimensional stability and allows for moisture to come in contact with the fiber-matrix interface causing delamination. This results in the fiber-matrix debonding caused by the osmotic pressure developed due to the leaching of water-soluble substances. This problem can be solved by avoiding the usage of hydrophilic biopolymers like cellulose and starch and switching to hydrophobic

polymers like poly(hydroxybutyrate-cohydroxyvalerate) (PHBV) and poly-hydroxybutyrate (PHB) (Christian 2019).

Biodegradability

Biodegradability of a biopolymer composite is another important aspect of biopolymer composite that depicts the microbial growth on it. The study of how various biopolymer composite degrade should be observed carefully to ascertain their application. Composites degrade in various conditions, for example natural fiber-reinforced biopolymer composites like PLA, PBS (polybutylene succinate) and PHB degrade by means of enzymatic degradation and anaerobic degradation. The process of biodegradation has been studied extensively and one such study evidenced the composites degrade by microbes making holes and cracking it to reduce its mechanical property (Alvarez et al. 2006). The protection of the composites from biodegradation is another important task, this can be achieved by making the composites less hygroscopic and enzyme resistant, surface modification to reduce the moisture content to inhibit microbial growth, delaying microbial growth by using harsh chemicals against microbes. The fabrication of composites using materials like lignin and PLA has been found to make the composite more resistant to microbial attack. The monitoring of biodegradability of biopolymer composites or any other material is however can be very difficult to consider because there is no standard procedure or test to monitor biodegradability. This issue leads to difficulty in testing of composites and the eventual optimisation of the composites toward biodegradation. This issue ultimately must be compensated by employing eco-friendly raw materials when constructing composites by considering its proposed functionality and applications. The considerations should be encompassed on properties like thermal stability, moisture adsorption and mechanical properties of the raw materials. The matrix of the biopolymer and the fiber should also be considered to yield the optimum properties for the biopolymer composite (Aaliya et al. 2021).

Applications

Water Treatment

Increased demand for and better quality of water has invented various methods and techniques to recycle, reuse and purify water for human needs. Water contains impurities in the form of total dissolved salts, natural organic matter, and heavy metal ions; other factors that ensure the safeness of the water are the alkalinity, hardness, biochemical and chemical oxygen demand, pH, and color of water. The purification of water from these impurities as well as ensuring the quality of water can be achieved in different stages of water treatment like coagulation, flocculation, remediation using membranes, physicochemical treatment methods like aeration, agitation, chemical precipitation, oxidation, disinfection, enzymatic decomposition,

halogenation, flotation, adsorption, ion-exchange, electrolysis, photolysis, etc. Traditionally coagulation and flocculation were the major methods used for treatment of water, the advancement in membrane technology as more cost effective and eco-friendly has made the two methods obsolete. Recent advances in water treatment using membranes are shifting in the direction of reverse osmosis and electrodialysis. Among the various methods that are present, choosing the appropriate treatment method depending on the pollutant and quality of the water ensures for more efficient usage of resources.

Heavy metal ions are becoming more distributed and widespread in the environment and their toxicity has become a serious concern. The removal of these metal ions in waste water discharged from industries is extremely important. One of the most effective methods to remove heavy metal ions is by using materials that occur naturally like alginate and chitosan. Alginate is a polysaccharide biopolymer made up of D-mannurinic acid and L-guluronic acid that are linked by β -1,4 linkage. It is known to have high affinity toward divalent metal ions and on contact with the metal ions forms gels. Chitosan another biopolymer that is derived from chitin has also been found to have high affinity toward heavy metal ions, the amine groups that are present on chitosan undergo chelation with heavy metal ions and neutralize their toxicity. In a study, the combination of these two naturally occurring biopolymers for the construction of adsorbent was examined. The alginic acid and the chitosan were used for preparing gel beads by the cross-linking between the amino and carboxyl group of the chitosan and the alginic acid, respectively. The gel was further treated with CuCl_2 to form gel bead particles, the gel was found highly durable in acidic conditions and adsorbed heavy metal ions of Cu(II) , Co(II) , and Cd(II) reaching equilibrium within 10 mins at 25 °C (Gotoh et al. 2004).

The combination of these two biopolymers has also been used for the preparation of membranes for remediation of herbicides, herbicides at various concentration ranging from 200 Mm to 5 mM were adsorbed by the membrane made from alginate and chitosan. The herbicides diquat and difenzoquat were tested, and it was found that the bilayer membranes adsorbed around 95% of diquat and 12% of difenzoquat at 120 min. These results were attributed to the coulombic interactions between the carboxyl group of alginate in the bilayer membrane and the positive charge on the herbicide, other factors like dissociation constant, partition coefficients, and electrostatic charge also influenced the performance of the membrane (Agostini de Moraes et al. 2013).

Biopolymer composites can also be used as adsorbents for remediation of fluorosis caused by the presence of fluoride ions in drinking water. There are so many prevalent materials that are used as adsorbents for fluoride treatment. Biopolymer composites as materials have advantages over other materials in terms of its biodegradability, low cost, and biocompatibility. One such example is the treatment of fluoride ions by development of adsorbent from alumina and chitosan. Alumina as a material has high textural and physical properties, low cost, easy regeneration, and high affinity for fluoride ions. These features of alumina have made it a common filler for removal of fluoride. Much like alumina, chitosan has excellent biodegradability, biocompatibility, non-toxicity and adsorption properties as highlighted in this

section. The combination of these two materials resulted in excellent fluoride removal and is evidenced by the SEM micrographs in Fig. 2a, b, where the particle size of the composite increases on adsorption of fluoride, the Energy Dispersive X-Ray Analysis (EDAX) spectra also confirms this as shown in Fig. 2c, d. The IR spectra of the composites before and after fluoride adsorption is also shown in Fig. 2e (a and b) wherein the band at 1379 cm^{-1} is sharper, stronger, and shifts to 1385 cm^{-1} after fluoride adsorption. The removal of fluoride ion by the composite is attributed to the electrostatic adsorption wherein Al^{3+} attracts the fluoride ions that are negatively charged. Simultaneously, there is complexation of the positive surface to the fluoride ions with fluoride as chelating agent. The defluoridation capacity was found to be higher than most fluoride adsorbents reported (Viswanathan and Meenakshi 2010).

Another major water pollution issue is the presence of dyes in water bodies; dyes which are discharged from textile industries pose a major threat to the environment due to its intense color and its carcinogenicity. A huge percentage of dye is lost from industries during the dyeing and printing process which hugely perturbs and causes eutrophication in the environment. Among the various methods that can be used for treating dyes, the most popular and economic is the photocatalytic degradation which ensures that the pollutant is not just transferred from one phase to another

but degrades the dye molecule. The photocatalytic degradation implores on using highly effective and benign oxidation process for degradation using semiconductor materials. Among the semiconductor materials used, TiO_2 is the most commonly and effective semiconductor owing to its low cost, benign nature, high activity, and its chemical stability during irradiation. However, TiO_2 as a standalone material is difficult to recover thereby causing secondary pollution. This issue can be prevented by immobilizing it on biopolymers which are also environmentally benign among its other properties like its high surface area. A compatible pairing is the encapsulation of TiO_2 NPs in alginate-carboxymethyl cellulose composite gels and crosslinking with barium ion. This biopolymer composite was used for the degradation of congo red into various by products. The degradation ensued by the benzene ring breaking, -C-S- bond present the aromatic ring and sulfonate group breaking, the various -C-N and -C-C- bonds present in the chromophore groups breaking and the cleavage of the azo bond. The mechanism of photocatalytic degradation of Congo red is shown in Fig. 3 (Thomas et al. 2016).

Food Packaging

Food safety and packaging is a major concern that is being faced by the food industry currently. The short shelf life of food is a challenging issue and there have been many efforts to tackle this limitation. Food needs to be protected from any biological, chemical, and physical contaminations and kept fresh; however, there are major challenges as to which kind of packaging will be the best. Presently majority of the

food packing is based on synthetic polymers which are non-biodegradable and this causes major environmental concern. The cost of the packaging material also affects the total cost and the consideration of cheap and widely available eco-friendly materials is of huge interest. Biopolymers like cellulose and its derivatives, chitosan, alginates, etc. are some of the most abundant economical biopolymers available and their combination with other fillers have found huge success in food packaging and preservation industry. Chitosan has been used as a biomolecule-based films for packaging and has shown great promise because of its chelating ability and its antibacterial properties. The combination of chitosan with other fillers has also found be very advantageous in food packaging. An instance is the usage of PVA and chitosan that have been cross-linked by glutaraldehyde, the composite was used as both film and solution for food packaging. The composite solution was tested for preserving tomato as shown in Fig. 4, the composite film and solution was also tested for antimicrobial activity against *E. coli*, *S. aureus*, and *B. subtilis*, the chitosan-PVA film exhibited inhibition of 1.5, 1.2, and 1.4 cm against *E. coli*, *S. aureus*, and *B. subtilis*, respectively (Tripathi et al. 2009).

Another biopolymer that has been extensively used in food packaging industry is cellulose and its derivatives. Cellulose is one of the most abundant, sustainable, and eco-friendly biopolymers that is available. Cellulose can be derived from wood, plants, and it can also be extracted from organic waste of vegetables, stalks, fruits, stems, etc. Their usage in food packaging application also helps perturbs pollution and encourages recycling. Its mechanical properties also attract attention from textile industries, its thermal resistance enables it to shield food from UV rays. Furthermore, it has the ability to act as substrate for carrying antibacterial and antioxidant agents. These advantages have enabled cellulose and its derivatives to be crucial game changers in the food packaging industry (Liu et al. 2021). Despite these advantages, cellulose cannot function alone and it must be functionalized and these compatibility and combination has proved successful. A study that was carried out fabricated a composite from chitosan, carboxymethyl cellulose and ZnO NPs which provides antibacterial properties to the composite. The composite employed as a packaging film was able to store white cheese for 30 days at 7 °C, other properties like color, moisture, pH,

Fig. 4 Preservation of tomato in Chitosan–PVA solution: (a) as a whole and (b) into 2 pieces. Reprinted with permission from (Tripathi et al. 2009). Copyright Elsevier 2009

rheological properties were also tested. The composite film against pathogenic strain showed an inhibition of 5 to 15 mm and showed good influence on the total bacterial counts, yeast, mold and coliform. The prepared film was also compared against polystyrene packaging and showed good results (Youssef et al. 2016). Biopolymer-based composites have also been employed as edible films which can be consumed along with food. Biopolymers by virtue of its origin are mostly polysaccharides and proteins which are environmentally benign and are non-toxic to human beings. The purpose of adding edible biopolymer-based composite films in food is to increase the shelf life and food quality. The properties of composites that include antimicrobial, antibacterial, and antifungal are also added advantages and prevent the food from getting contaminated. The addition of edible biofilms also protect the food from UV radiation, moisture adsorption, and also increase the mechanical property of the processed food (Liu et al. 2021; Udayakumar et al. 2021).

Pharmaceutical Industry

Biopolymer composites are non-toxic, biocompatible, and influences cellular interactions for tissue development. Biopolymer composites by nature are similar to biological macromolecules that are present and utilized biologically. These qualities render biopolymer-based composites compatible to be used for biomedical applications. The most commonly used biopolymers range from polysaccharides like starch, alginate, chitosan, etc. to proteins like collagen, gelatin, and silk and microbial polymers like PLA, bacterial cellulose (BC), dextran, etc. Biopolymer composites can be constructed with two or more materials depending on the demands and the application to be used for. They can also be modelled to provide a suitable environment for growing and differentiation of cells. They also hold great advantage because of their high abundance and immunogenic potential. Biopolymer composites in this regard have been employed in a wide array of biomedical application, few examples that highlights the scope of biopolymer composites have been mentioned below.

Biopolymer composites have been used for wound dressing and there are also several commercial dressings like Xcell[®], Bioprocess[®], and Biofill[®]. Reports have shown that Bacterial-based coverings for wound treatment can reduce the pain, decrease infection and scarring and accelerate re-epithelization. The inclusion of metal NPs have also been found to assist in the regeneration, repairing of wounds, acts as oxidant, decreases inflammation, etc. These properties of NPs in composites resulted in a study where a Chitin/AgNPs composite hydrogel shown in Fig. 5 was employed for blood-clotting, and it was also studied for its antimicrobial activity (Kumar et al. 2010).

Biopolymer composites exhibit high bioactivity, flexibility and they can be molded to fit bone defects. These reasons including mechanical properties and osteoconductivity have influenced in the application of bone tissue engineering. Bone is made up of an organic phase and inorganic phase, similar to this biopolymer composites can be engineered where the inorganic phase can be incorporated to various polymer matrices particles and fibers. A study used calcium chloride and sodium

carbonate to induce deposition of calcium carbonate on BC membranes which could mimic collagen nanofibers and promote biomineralization (Stoica-Guzun et al. 2012). There are other studies that have employed BC composites for bone tissue repair as well as cartilage replacement. A study performed evidenced that mechanical properties of BC/poly(dimethylacrylamide) double network gel resembled the cartilage that are present in the body and could be used to possibly replace artificial cartilage (Azuma et al. 2007). There has been major advances with BC-based materials in other medical fields as well with BC tubes used for replacing carotid artery in rats, the BC/carotid artery was found covered connective tissue indicating the success of BC as future replacement of blood vessels (Park et al. 2017).

Biopolymer composites have also been used as stent, an implanted device that is used for restoring normal blood flow. Biopolymer-based composites are safer compared to metal one since they are less obtrusive, biocompatible and biodegradable. The biopolymer composite stent consists of anti-restenosis which prevents toxicity and heals the blood vessels. Biopolymer composite has also been used as drug delivery systems; the functional groups present on the biopolymers enables in designing specific carriers that are either negatively or positively charged and interact biologically with the target sites. Chitosan has been found to have high affinity to cell membranes and due to its positive charge, it can be used for delivering a wide array of medicines via nasal, intravenous, oral, and ocular routes. Alginate-chitosan microsphere could also be prepared for delivering insulin, confocal images and schematic shown in Fig. 6a, b. The insulin showed higher loading and activity maintenance when it is loaded during the chitosan solidification. The *in vitro* release of insulin was investigated and found that the pH controlled how the insulin was released. The optimal release was in pH of blood environment, and it was found to be stable and sustained over 14 days shown in Fig. 6c with decreasing intensity of insulin with time (Zhang et al. 2011).

Automobiles Industries

The usage of plastics in automobile industries has become limited due to eventual exhaustion of cruel reserves worldwide and the environmental issues that are evident

Fig. 6 (A) Confocal image of alginate-chitosan microsphere loaded with Alex Fluoresce-488-insulin. (B) Schematic image of the alginate chitosan microsphere loaded with insulin. due to their usage. This concern has struck at the core of the automobile industries that are hugely dependent on plastics and synthetic fibers for their interior and exterior parts. Biopolymers and their composites have received renewed interest as substitutes for designing and fabrication of car parts based on plastics and glass fibers. Despite the long history and attempt of employing bio-based materials for commercial applications in the past by visionaries like Henry Ford (Fig. 7a shows henry ford testing a vehicle based on soyabeans composites) who started developing and employing composites derived from soyabeans for plastic-based car parts like a car foam shown in Fig. 7b. However, at that time the cost and concern of petroleum-based products outweighed the benefits that came with using natural fiber-based composites. But the eventual and increasing concern with depleting petroleum reserves and the pollution crisis, there has been revived interest in developing and commercializing composites based on natural fibers.

Over the years there has been huge leaps in the development of natural fiber-based products like kenaf and hemp, these materials are excellent candidates to replace glass fibers due to its low cost, low density, energy recovery, biodegradability, and CO₂ sequestration. These qualities they possess identify with the requirements the modern automobile industries are focused on. Automobile companies are hugely investing of materials with sound abatement properties along with reducing weight of vehicles for better fuel efficiency which can be increased to 75%. Natural fibers-based composites show excellent sound adsorbing properties, they are also lightweight, shatter resistant and enable the vehicle to save more energy. The mass of fiber-based composites car parts is not only lighter but their production also requires

Fig. 7 (A) Henry Ford testing a car developed from soybeans composites. (B) A soy-based polyurethane foam introduced by Ford in 2008 for the Mustang

80% lesser energy. It takes around 23,500 British thermal units to produce a pound of glass fiber while it takes only 6500 British thermal units to produce a pound of kenaf fiber. There are also other added advantages of using natural fiber-based composites like its lower specific weight, easier processing and does not wear out tooling. There are several bast fibers that are at the forefront of replacing traditional fibers like hemp, flax, jute, and kenaf; other fibers like sisal, abaca, and banana leaves are also being considered. Natural fibers which were traditionally used only in making baskets, ropes, rugs, clothing, etc. and only employed as thermosets are now being intensively explored as thermoplastics. Their utility has been seen in various products ranging from household construction items like fencing, door profiles, siding, railings, furniture, etc. to automotive parts and even in marine components. In Germany, home to one of the most respected, innovative and competitive automobile industry in the world is leading in the usage of natural fiber composites. Its prestigious auto-manufacturers like Audi, BMW, Mercedes, and Volkswagen have started using natural fiber composites in both the interior and exterior parts of the automobile. One of the first example of commercialization of natural fiber composites was the inner door panel of 1999 S-class Mercedes-Benz made of 35% Baypreg F semi-rigid elastomer and 65% blend of hemp, flax, and sisal. There have been huge strides in the usage of natural fibers from other companies like Cambridge Industries that used flax/polypropylene composites in heavy trucks and rear-shelf trim panels. Dexter Corps makes sisal-based nonwoven mats for thermoforming. Georgia Composites' developed PP/sisal composites for boosting the performance of "Woodstock" -type materials. Mats and blends from hemp, flax, jute, and recycled polyethylene has also been produced by Kenex Hemp Ltd. There has also been tremendous contribution and collaboration between government agencies and industries to promote more sustainable materials like the collaboration between Pinnacle and U.S. Dept. of Agriculture in promoting agro-plastic. Several research institutions and industries across Europe are collaborating in the ECOFINA European project

aimed at substituting fibers and mineral fillers used in automotive industries with more sustainable materials and polymer matrix composites. These collaboration aims at producing auto components that are recyclable and lowering the weight of automobiles by using natural fiber-based composites which have lesser density to reduce the gas emissions from automobiles (Biagiotti et al. 2004; Mohanty et al. 2001).

Biosensing and Sensing

Biopolymers are three dimensional materials that are crafted by nature with origins from either plant or animal sources. The three-dimensional structure on biopolymers plays an integral role in their bioresponsive nature where they exhibit change in their properties and respond when they interact with other biological molecules like ATP, enzymes, glucose, antibodies, etc. The recognition of these biomolecules by biopolymers trigger events in the interaction and behavior of the biopolymers which are translated into responses that can be quantified and analyzed. The efficient analysis of interaction between the biopolymer and the analyte biomolecules is the heart in the development of biosensors. This can be achieved by effective attachment and immobilization of the biopolymer to the sensor interface. There are other attributes like the sensitivity toward pH and temperature that should be possessed by the biosensor. Although biopolymers possess many of the pre-requisites of biosensors, it suffers from limitations like low mechanical and chemical resistance. Biopolymers affinity toward water and its water absorbing characteristics also hinders their development as efficient biosensors. Biopolymers by virtue of their structures are poor electrical conductors, hence this also renders its viability as biosensors. In regards to all these limitations and to overcome them biopolymers are used for preparing composites with functional materials like carbon materials, metal oxides, enzymes, conductive polymers, etc. Biopolymer can also be used for designing molecularly imprinted polymer materials that is fabricated by polymerizing a functional monomer with a template or target molecule. The process termed as molecular imprinting in polymer matrices enables the formation of specific recognition sites. This property allows the polymer to highly specificity for the target molecule, where they can rebind to target molecules with same mechanism present between antibody and antigen.

Among the biopolymers, chitosan is the most widely used biopolymer for sensing and biosensing application due to its non-toxic, biocompatibility, bioresponsive and its fil-forming ability. The macromolecular chain of chitosan can also be modified with ease by conductive polymers and other functional materials for preparing composites with high specific surface area and electron transfer rate. The presence of amine and alcohol groups enables for easy immobilization of biomolecules like DNA, enzymes, and antibodies/antigens.

A study reports the fabrication of a DNA biosensor from $\alpha\text{-Fe}_2\text{O}_3$ microparticles and chitosan with terephthalaldehyde (TPA) as a bifunctional linker. The Fe_2O_3 microparticles impart high specific surface area and high electrical conductivity

while chitosan imparts the film stability. The amino groups of chitosan are covalently coupled with aldehyde groups of TPA on one end and on the other end of TPA the aldehydes react with modified amino of the DNA. $[\text{Fe}(\text{CN})_6]^{-3/-4}$ is used as the indicating probe with electrochemical impedance spectroscopy (EIS), and the biosensor was employed for measuring the hybridization capacity with good reproducibility and selectivity (Xu et al. 2015a).

Enzymes have also been incorporated with biopolymer composites, one such study is the inclusion of tyrosinase, a plant extract that was entrapped by polysaccharide-polysaccharide binding. The biopolymer composite was fabricated from biopolymers guar gum and agarose. The composite overcame the limitation of individual biopolymer like the brittleness of pure guar gum matrix. The two biopolymers are biocompatible and showed long-term stability of the developed sensor. The biosensor containing the enzyme forms a self-adhered layer on the working electrode and used for selectively and sensitively sensing phenols. Dopa and dopamine are detected by the reduction of the quinone species that are liberated biocatalytically. Despite the presence of enzyme which suffer from stability issues, the composite biosensor showed a low detection limit, reusability, pH, and storage stability (Tembe et al. 2006).

Aptasensors can also be developed from biopolymer composites. Evidence of this is the development of an electrochemical label-free sensor from a robust composite of MWCNT, ionic liquid and chitosan with a half-duplex hybridized capture-aptamer probe immobilized to the composite using glutaraldehyde (the schematic of the fabrication of the sensor is shown in the Fig. 8). Methylene blue was used as

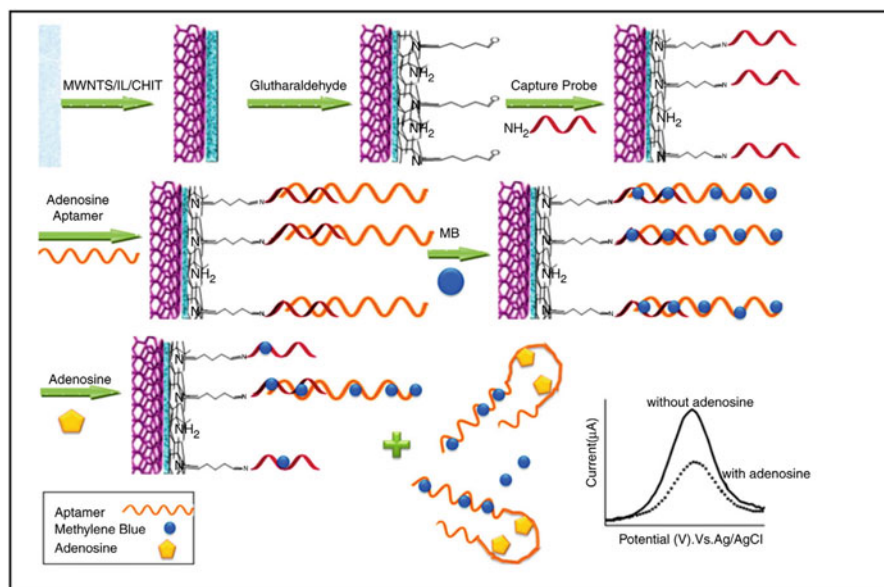

Fig. 8 Illustration of the fabrication of aptasensor from chitosan, MWCNT and ionic liquid. Reprinted with permission from (Shahdost-fard et al. 2013). Copyright Elsevier 2013

redox probe and the peak current intensity of the redox probe decreased with increasing adenosine concentration, these results due to the formation of aptamer-adenosine complex and displacement of aptamer from the electrode. The sensor had a low limit of detection and was successfully tested in blood serum and drug formation samples and showed excellent sensitivity toward adenosine in the presence of other interfering species such as cytidine, guanosine, and uridine (Shahdostfard et al. 2013).

Biopolymer-based composites have also been employed for development of bi-enzyme amperometric sensor for detecting organophosphorus pesticides. The amperometric sensor is fabricated from the electrodeposition of chitosan with carboxylated MWCNT entrapped, organophosphorus hydrolase and horseradish peroxidase. The sensor was employed for sensing prothiofos in the presence of H_2O_2 , the sensor could selectively detect prothiofos in the presence of interference nitrophenyl-substituted organophosphates because of pH and concentration of H_2O_2 (Stoytcheva et al. 2017).

Other than the studies mentioned here, there has been a wide range of sensors and biosensors that have been developed from biopolymer and its composites. They have been used for fabricating whole cell-based sensors, antibody-based sensors, aptamer-based sensors, nuclei acid-based sensors, enzymatic sensors, etc. The fast-paced advancement of biopolymer-based composites as sensors is the simultaneous advancement in the synthesis and tuning of biopolymer-based composites. The ultimate goal is the development of biopolymer composites as low cost, portable, fast data processing and reliable point-of-care-devices for detection of various organic and inorganic analytes (Karrat et al. 2020; Sawant 2017).

Energy Storage Materials

The energy crisis due to the depleting oil reserves is becoming more prominent and solutions are required. One of the possible pathways in easing this crisis is the development of more reliable and durable energy storage systems. Presently, majority of the commercial energy storage materials are based on heavy metals and non-renewable materials. There is a need for fabrication of more sustainable energy storage systems that are constructed from sustainable and renewable sources that can be disposed without causing any environmental damage. This requirement for sustainable energy systems has seen a surge in development of bio-based energy storage devices that are environmentally friendly from its source to its eventual disposing. Biopolymers as source for fabrication for sustainable energy storage devices is highly attractive due to its low cost, easy processing, renewability, environmental benignity and abundance. Although the advantages of employing biopolymers for energy storage devices are numerous, there are still issues due to its low electrical conductivity and their insulator properties. Among the biopolymers present majority of them are insulators and this hinders their viability as energy storage devices. There are several approaches when it comes to overcoming this advantage, the first is the conversion of the biopolymers into carbonized biomass to

increase its conductivity another approach is the inclusion of conductive materials and dopant. Biopolymers that contain redox active groups like quinones, flavins, and carboxylates show charge storage properties and with very little modification they can be used for the fabrication of energy storage devices as either supercapacitor or batteries. The attempts for developing sustainable batteries and supercapacitors began in the 2000s and there have been huge advancements since then. One of the breakthroughs in using biopolymer-based composites in energy storage devices is the development of polymer electrode from pyrrole and lignin. The presence of quinone in lignin enables it as proton and electron exchange and storage by redox cycling, this process when combined with the charge storage and conductivity of polypyrrole showed excellent charge properties. The two monomers are polymerized electrochemically to form interpenetrating networks and showed excellent scaling potential. The interpenetrating networks of the two polymers can also allow for the accommodation of smaller anions which can be pursued to increase its charge storage. It was found the addition of quinone groups to the interpenetrating network could enhance the charge storage properties, as such anthraquinone sulfonate was added to the polymer network and displayed an increased discharge capacitance of 147 mAh g^{-1} . This particular process opens up lot of avenues for enhancing the charge storage of the biopolymer composite by the addition of conductive materials like CNT, reduced graphene oxies, graphenes, metal oxides, small redox molecules, etc. (Nagaraju et al. 2014).

Other biopolymers composites have also been employed for the construction of energy storage devices. A common biopolymer that has been used for the fabrication of composites is cellulose. Cellulose is the most abundant biopolymer that has been used for other applications, however it does not possess redox active molecule. This makes cellulose an electrical insulator but its abundance in nature, cost efficiency, flexibility, light weight, wettability, and renewability has made them attractive biopolymers counterparts for fabricating energy storage devices. Cellulose, due to its insulating nature, has been paired with an array of materials that can impart electrical conductivity and enhance the charge storage property of the biopolymer composite. One of the most efficient methods of preparing a biopolymer composite with cellulose is the inclusion of conducting polymers in the composite matrix. An example of this success is the construction of a polymer paper battery from cellulose and polypyrrole (PPy), polypyrrole is coated thinly on the cellulose substrate. The material displayed a specific surface area of $80 \text{ m}^2 \text{ g}^{-1}$ and was employed for the construction of an aqueous battery (shown in Fig. 9) exhibiting a charge capacities between 38 and 50 mAh g^{-1} (Nyström et al. 2009).

Biopolymers are chemically composed of mostly hydrogen, carbon and oxygen, with carbon having much higher percentage composition than the other two. Due to this, biopolymers are an excellent source for the fabrication of carbon materials and raw materials for carbonization. Carbon materials prepared can exhibit various morphologies and properties depending on the raw material and the fabrication method employed. One of the most attractive carbon materials is porous carbon which have attracted significant attention due to its high electrical conductivity, electrochemical stability and specific surface area. High specific surface is highly

Fig. 9 (A) Schematic of polymer battery fabricated from cellulose and PPy composite. (B) Image of the fabricated cell with and without polymer aluminum pouch. Reprinted with permission from (Nyström et al. 2009). Copyright American Chemical Society 2009

sought after in carbon materials because of more active sites for storing charge. Hierarchical porous carbon is another type of carbon material with interconnected macro-meso-micro pores which enhances the ion adsorption and ion transport leading to increase rate capability and capacitance. Over the years, carbon-based materials have received a lot of attention and have been employed in various applications. Biopolymers like chitin, chitosan, cellulose, wood, lignin, etc. have been some of the most commonly used biopolymers for deriving carbon. Chitin, generally derived from seafood wastes can be sustainably used and one such study has employed for the fabrication of hierarchical porous carbon microspheres (shown in figure). The hierarchical porous carbon microspheres displaying a specific surface area of $1450 \text{ m}^2 \text{ g}^{-1}$ are employed along with polyaniline (PANI) nanoclusters. The composite employed for supercapacitor applications displayed a capacitance of 88 F g^{-1} with excellent capacitance retention (Gao et al. 2018).

The possibility of combination of more than one biopolymer with other materials for the construction of energy storage devices was also found viable. This was exhibited in a study where Lignin-resorcinol-formaldehyde (LRF) aerogels was paired with carbon aerogel using BC. The BC-LRF aerogel displayed a high gravimetric capacitance of 124 F g^{-1} . The aerogels of LRF and carbon, which are brittle are made superior and tougher by the addition of BC nanofiber network. The composite material activity makes it potential candidate for construction of flexible energy storage devices (Xu et al. 2015b).

Other than the few instances of employing biopolymer composites for the development of electrodes for supercapacitors and batteries. Biopolymer composites have also been utilized in the fabrication of separators for batteries due to its excellent wettability, high porosity, mechanical properties, flexibility, and low processing cost. They have also been employed for the fabrication of gel polymer electrolytes which is an interface between liquid electrolyte and solid electrolyte.

The characteristics of both the electrolytes are present in gel polymer electrolytes and they can act as both ionic conductors as well as insulators of the electrode. Biopolymer-based composites have also been employed as binders. Biopolymer composites for energy storage applications are still being studied but the versatility and multifunctionality of the materials offers huge scope in the future (Jabbour et al. 2013).

Concerns in the Sustainable Application of Biopolymer Composites

There are several challenges that need to be addressed for sustainable scaling-up synthesis and commercialization of biopolymer composites. The pairing issue of biopolymers with additives, poor moisture resistance, the tendency of the natural fibers to clump together, and low thermal stability are some of the major concerns. The growth and production of biopolymers and natural fibers are relatively easy and cheap and mostly done so by weavers, workers, and farmers. Natural fibers are grown depending on demand and can be grown quickly. Composite manufacturing on the other hand is more tedious and requires more capital investment, energy consumption, and specialized instrument/tools. Each composite manufacturing requires a different approach and usually different sources. Physical characteristics and behavior of biopolymer composites like fatigue, creep behaviors, moisture adsorption, and lifetime of biopolymer composites may vary depending on the source material and the physical conditions of location of the utilization of the biopolymer composites. The commercial production of biopolymer composites is still emerging and there is major focus in enhancing the processing and production. It may be noted that biopolymers despite being renewable and easily available, their processing, separation, and purification is another major challenge. This makes the supply, cultivation, transport, and storage of biopolymers complex; thus, a standard protocol is paramount to effectively utilize biopolymers, natural fibers along with the responsible waste treatment management. There is major research that is being concentrated on scalability, reducing the production cost and improving the yield and purity. The gradual advancement of the biopolymer industries has already resulted in the decrease of biopolymer prices.

As replacements for commercial materials and composites that are not sustainable, the performance and durability of the biopolymer composites should equal or be better than the material/composite it is replacing.

The challenge of recycling is another point that has been resounded frequently and stressed on. The recyclability of biopolymer and biopolymer composites although crucial is difficult to achieve, since the inclusion of recycled biopolymer and biopolymer composites may affect the properties and effectiveness of the overall composite. The recycled biopolymer or composite should be reconfigurable and replenishable to its pristine condition by treatment methods that also follow the themes of sustainability. This should be the key when designing biopolymer composites for application that are short lived. Another challenge with recycling is

the location at which the recycling plant is located to avoid extra expenses and manpower. Biopolymer composites as the name suggests contains two or more materials which may or may not be naturally derived. The extent and effectiveness of segregation of the materials is another crucial parameter when considering and designing recycling routes.

The understanding of the decomposing characteristics of biopolymer composites is also insightful when designing composites for particular applications. The conditions and time frame under which a biopolymer or natural fiber decomposes should be studied and analyzed critically. Establishing the accurate degradation properties of biopolymer composites is desirable and ensures that the degraded fragments do not affect the various biological pathways operating simultaneously in nature (Bari et al. 2021; Christian 2020).

Performance and Optimization of Biopolymer Composites

The careful and calculated choosing of biopolymer-based composites for a particular application ensures that the biopolymer performs well and is durable. Biopolymer-based composites are materials that react easily to environment, in many cases this is an added advantage but it can also be a hindrance in their performance in unfavorable environmental conditions. The location where the composite will be employed for different applications is an important parameter in the composite's performance. The decision of employing the composite where it will have maximum advantages is one of the most easy and apt methods in ensuring durability of the composite. The understanding of this dynamism between the composite and conditions under which it will perform is one of the most crucial steps in the success of implementing composites. The design of composites must be ensued according to performance criterions and standards for individual applications. The design of the composite should be accompanied with the aim of multifunctionality starting from its processing to its application. This multifunctional design of the composite would allow for fine tuning so as hasten its implementation. Systematic analysis of the variables that affect the composite and the influence it has in various applications, its performance and its durability for better decision-making should be focused in research.

Conclusion

This chapter gives a brief overview on biopolymer-based composites that is developed from a biopolymer reinforced with natural fibers, synthetic fibers, polymers, metal-based materials, other fillers, and dopants. Biopolymers-based composites by virtue of their raw materials and mode of preparation are designed with the intentions of renewability, sustainability, ease of manufacturing, biodegradability, lightweight, high specific area, durability, and easy tunability. The design of biopolymer-based composites is aimed at overcoming the limitations observed in individual materials and foster unique and useful functions not possessed by the either of the raw

materials. Most raw materials used in preparing composites can be obtained using simple methods, this promotes sericulture, farming, and waste management reducing pollution of all sorts and improves the overall quality of life. Biopolymer-based composites as evident from the studies are versatile materials and depending on the pairing of the materials and synthesis conditions, they can be employed in various industries like food packaging, automotive, medical, sensors, energy storage, and water treatment. They have huge potential and they are already being used in some already mentioned applications. The scaling and prospects of biopolymer-based composites are huge and can replace commercial materials that are petroleum-based or being deemed unsustainable. With the addressing of issues like durability in different environmental conditions, standard synthesis and assessment procedures and reducing the cost of production of biopolymers. Biopolymer-based composites have high chances in becoming more consistent materials and become an industry for replacing conventional materials that pose a threat to the well-being of the environment.

Abstract

Agricultural, industrial, and household waste is a huge threat to environmental sustainability in recent years. Plastics that are non-biodegradable are causing serious health issues also. Hence the development of biodegradable functional materials is a necessity in the current scenario. The quality of such materials is a major environmental concern, and the production of nanocomposites may decrease the impact of the problem. Biopolymer reinforced with nanofillers is a potential solution to the issue. Functional nanomaterials can be fabricated by the effective interaction between nanofillers and eco-friendly biopolymers. This interaction also enhances physicochemical features and biological properties. These biopolymer nanocomposites act as a substitute for conventional polymers due to their relatively better properties than pure biopolymers. This chapter

A. Paul (✉) · S. S. Sharma

compiles the details about biopolymers and their nanocomposites. The applications of biopolymer-based nanocomposites in various fields are also summarized.

Keywords

Biopolymer · Nanocomposite · Food packaging · Biomedical · Drug delivery · Tissue engineering · Sensing

Introduction

Nanoscience and nanotechnology have developed as a flourishing field in research in recent years expanding applications in agriculture, biomedical applications, energy production, cosmetics, pharmaceuticals, and diagnostics. Large surface area to volume ratio provided by nanosized materials enhances the properties. Not only pure nanoparticles but also nanocomposites have remarkable applications. Nanocomposites are hybrid materials obtained by combining two or more nanomaterials with different physical and chemical features. Their properties are much better than microcomposites.

Nanofillers can be dispersed in polymeric matrices in various quantities to obtain polymeric nanocomposites (Bustamante-Torres et al. 2021). Such dispersion will improve the mechanical and physical properties of the matrix. The features of the nanocomposite will be much better than the individual constituents in the matrix. Combining the features of polymer matrix and nanofillers results in a synergic effect, and high performance, unique nanocomposites can be produced. Polymeric nanocomposites possess excellent thermal, magnetic, electrical, optical, and mechanical properties which pave the way for a variety of applications (de Oliveira and Beatrice 2019). Polymer matrix and nanofillers are chosen according to the requirement in properties for various fields. Polymers may be categorized into biopolymers and synthetic polymers based on their origin. Biopolymers are obtained from animals, plants, and microorganisms. Since they are generated from renewable natural sources, they can replace synthetic polymers which have an origin from petroleum resources. They are exceptional biomaterials owing to their features such as biodegradability, lack of toxicity, cost-effective production, eco-friendliness, and biocompatibility. Also, they can be conveniently degraded by the action of microorganisms or inorganic compounds, which also reduce the possibility of environmental pollution caused by synthetic polymers (Folino et al. 2020). Thus, biopolymers such as polysaccharides, proteins, and lipids find applications in pharmaceutical, biomedical, and many other applications. Biopolymer nanocomposites are composed of two or more components, in which the bulk phase is a biopolymer, and the minor phase consists of nanofillers. This chapter discusses the most recent developments in research on biopolymeric nanocomposites for a variety of applications.

Another new generation material having wide applications is nanocomposite films. Such a film is produced by the combination of a biopolymer with a nanofiller and is processed to develop a film. In nanocomposite films, the major matrix is a

biopolymer and the dispersion of nanofillers in this matrix enhances the properties. Also, many limitations of biopolymers can be overcome by the addition of nanofillers. The addition of nanofillers can reinforce the matrix and create properties that are inherently absent in biopolymers. Some fillers are capable of improving the antibacterial and antimicrobial properties of the matrix which may assist in biomedical applications (Wrońska et al. 2021). It can improve the shelf life of food such as fruits, fish, vegetables, and so on in packaging applications also.

While considering food packaging applications, many synthetic polymers could satisfy all the requirements. Since these materials are non-biodegradable, they cause serious environmental pollution issues. A suitable methodology for the waste disposal of such synthetic polymers is not found till today. The increase in population always multiplies the usage of such synthetic polymers and their aftereffects happening worldwide over generations (Basavegowda and Baek 2021). Therefore, replacement of these polymers is a necessity, and current research is focusing on developing biopolymers that can reduce waste disposal. These biopolymers are degradable under biological decomposition without much affecting the sustainability of the environment. Their degradation produces harmless products which cause fewer disturbances to the earth's crust. Biopolymers are made of monomeric units combined by covalent bonds, and hence, these biopolymers may also be degraded by microorganisms via their enzymatic activities (Sorrentino et al. 2007).

Biopolymers can be derived from a variety of sources such as agricultural feedstock, industrial waste, animal and marine sources, polysaccharides, proteins, and so on. Biopolymers can be obtained from renewable and non-renewable natural sources. Natural biopolymers include polysaccharides, proteins, and lipids. Polysaccharides may be classified as wheat, pectin, chitosan, starch, and cellulose. Proteins and lipids include casein, collagen, soya, gelatin, and zein.

Even though, biopolymers act as potential candidates for food packaging, they are limited in use due to some disadvantages. They display poor mechanical and barrier properties which in turn affect their ability in processing. Industrial end-use applications are limited by the low heat distortion temperature, brittleness, and high gas permeability of biopolymers (Koh et al. 2008). These issues can be solved by the fabrication of biopolymer nanocomposites by adding nanofillers to biopolymer matrix. Mechanical, thermal, and physical properties can be enhanced by the incorporation of such nanofillers.

Earlier, major applications were completely occupied by the plastic industry. But, nowadays, bio-derived products are produced for such applications in an economical and sustainable way. Polypeptides and polysaccharides are utilized owing to their biocompatibility, biodegradability, sustainability, and minimum cytotoxicity (Wu et al. 2021). In the case of mechanical and thermal features, research is still going on to get the expected results. Industries always opt for petroleum-based polymers since they are cheap when compared to biopolymers. It exists as a threat to the sustainability of nature, and hence developing biopolymers in an economical strategy that is competitive with synthetic polymers is the future concern in this research area. Table 1 shows the source of biopolymers and their properties.

Table 1 Sources of biopolymers and their properties

No.	Source	Biopolymer	Properties	Reference
1	Crab	Chitosan	Good mechanical properties and antimicrobial properties less barrier properties	Sirisha Nallan Chakravartula et al. (2020)
2	Red algae	Agar	Good transparency and permeability, and high thermal stability	Mostafavi and Zaeim (2020)
3	Corn	Starch	Improved gas barrier features and good antimicrobial and antioxidant properties	Lu et al. (2009)
4	Fish skin	Collagen	Enhanced rheological features and high-moisture absorption	Lionetto and Corcione (2021)
5	Citrus peel	Pectin	Good chemical features, biodegradable, biocompatible, and edible	Espitia et al. (2014)
6	Milk	Casein	Nontoxic, biodegradable, and thermally stable	Chen et al. (2019a)
7	Cattle bone	Gelatin	Improved optical, mechanical, and barrier properties	Ramos et al. (2016)
8	Agricultural waste	Cellulose	Antimicrobial property, thermally and chemically stable, and crystalline	Wu et al. (2019)
9	Brown algae	Alginate	Aqueous solubility and flexibility	Katiyar and Tripathi (2019)
10	Soybean	Soy protein	Antimicrobial and gas barrier properties	Gautam et al. (2021)

Biopolymers

Biopolymers are considered as high-demand products since they can be easily degraded by microorganisms without adversely affecting the environment. Based on origin, biopolymers may be natural polymers or synthetic polymers (Muhammed Lamin Sanyang and Jawaid 2019). Natural polymers are obtained from natural renewable sources whereas synthetic polymers are obtained by polymerization or condensation reactions. Natural polymers include polysaccharides, proteins and lipids, and polymers such as polycaprolactone (PCL) and polylactic acid (PLA) are examples of synthetic biopolymers. Polymers such as polyhydroxybutyrate (PHB), polyhydroxyalkanoates (PHA), and polyhydroxybutyrate-valerate (PHBV) are produced by microorganisms like bacteria and are also considered as biopolymers (Mangaraj et al. 2019).

Among natural polymers, polysaccharides are produced from renewable sources, and they are made of monosaccharides linked by glycosidic bonds. Cellulose, starch, and chitosan are widely used natural polymers for different applications since they are cheap, non-toxic, and abundantly available (Sanyang et al. 2017). Among them,

starch consists of two varieties of D-glucopyranose including amylose and amylopectin (Mangaraj et al. 2019). It is generated from wheat, corn, and rice. Some disadvantages of starch being used as an efficient biopolymer are its high brittleness, high hydrophilicity, and difficulty in processing. Hence surface modification is a necessity to achieve the expected properties. It can be done by the addition of plasticizers or nanofillers. Such nanocomposites were found to have good tensile strength and mechanical properties. Another natural polymer widely used in various applications is cellulose. It is a biodegradable, hydrophilic polysaccharide comprising D-glucose repeating units and are linked by glycosidic bonds. It can be extracted from plants such as wood, cereal, and cotton. It is considered as a non-toxic, renewable, and easily available cheap biomaterial for packaging applications (Walzl et al. 2019). One of the drawbacks is its low water vapor barrier features. In order to improve mechanical properties, nanocomposites are formed by incorporating nanofillers such as metal and metal oxides such as copper oxide, zinc oxide, and so on (Anastasiou et al. 2014). The enhanced tensile strength can be obtained by the addition of silver nanoparticles along with better antibacterial properties. Shells of crabs, insects, and shrimps contain enormous amount of natural polymer, chitosan (Abdul Khalil et al. 2017). As in the case of starch and cellulose, chitosan is also biocompatible and biodegradable. It is the second most available polysaccharide and is made up of D-glucosamine and *N*-acetyl D-glucosamine. It is non-toxic and displays antimicrobial activity against yeast and bacteria. Even though, pure chitosan possesses good properties and enhancement in features can be obtained by adding plasticizers or nanofillers. Another animal-originated protein gelatin also finds immense applications in various fields. Denaturation of collagen results in gelatin and the features of gelatin are affected by the type of collagen (Roy and Rhim 2021). Copolymerization with other natural polymers such as chitosan and starch as well as incorporation of nanofillers can enhance various properties of gelatin.

Poly(lactic acid) is a synthetic aliphatic polyester obtained by the polymerization of lactic acid. It is a biodegradable polymer produced by fermentation of sources like rice, corn, and so on. It is an efficient biocompatible polymer having good mechanical strength and barrier properties. It is convenient to process to produce end use products. The brittleness of the polymer can be reduced by blending it with plasticizers or forming nanocomposites. Another commercially important synthetic biopolymer is polycaprolactone. It is a semicrystalline, linear, and hydrophobic polyester having good flexibility and elongation (Ortega-Toro et al. 2015). But poor mechanical and barrier properties limit its applications in packaging. In the case of polycaprolactone also, addition of nanofillers and formation of blends improves the properties.

Nanofillers

Novel trends and new perspectives that emerged in nanotechnology have created creative paths to facilitate the usage of nanofillers in various applications. Biopolymer nanocomposites cannot completely replace synthetic nanomaterials, but they can substitute plastic materials to a great extent (Saba et al. 2014). Nanofillers can

reinforce the biopolymer matrix thereby improving mechanical properties. Nanofillers have a size below 100 nm in any one of the three dimensions. They possess different shapes such as spherical, rod-shaped, needle-shaped, etc. The size and shape of the nanofiller greatly influence the features of the polymer matrix. Nano-sized materials will have a larger surface area which enhances the interaction of polymer matrix and filler. This betterment in interaction improves mechanical, physical, electrical, barrier, and thermal properties.

There are different types of nanofillers. They are organic, inorganic, clay, and carbon-based nanofillers. Organic fillers like cellulose, chitosan, and inorganic fillers like metals and metal oxides can act as efficient nanofillers. Fullerenes, carbon nanotubes, graphene, and graphene oxide are various carbon nanostructures that act as fillers (Youssef and El-Sayed 2018). Among the above nanofillers, clay is a cost-effective fine-grained material that can reinforce the polymer matrix. It can have a sheet or platelet-like structure. Different types of clay used as nanofillers are montmorillonite, halloysite, etc. Montmorillonite contains silica sheets attached to aluminum oxide sheets whereas halloysite is aluminosilicate with nanotubes having a cylindrical shapes. Halloysite possess good antimicrobial activity in addition to mechanical properties (Shankar et al. 2018). Among natural nanofillers, cellulose, chitin, and collagen are extensively used owing to the exceptional features such as easy availability, biodegradability, mechanical strength, and biocompatibility. Surface features can be improved by the reactive hydroxyl groups on the surface in the case of nanocellulose. Nanocellulose can be classified into three on the basis of crystallinity, size, and morphology. They are nanofibrillated cellulose, bacterial nanocellulose, and nanocrystalline nanocellulose. The difference in their structure, shape, and composition is due to variations in sources and synthetic methodologies. The functional groups present on the nanofiller also depend on the source. High surface area, non-toxicity, biodegradability, and biocompatibility of chitosan make it an excellent nanofiller in the production of various nanocomposites (Marín-Silva et al. 2019). But its use is limited due to poor solubility and stability in many applications.

Among inorganic nanofillers, metals and metal oxides are an important class that act as functional agents in reinforcement. They possess antibacterial and antimicrobial activity in addition to physiochemical properties. Copper nanoparticles are excellent candidates which exhibit antimicrobial properties. Similarly, silver nanoparticles display exceptional biological properties, and many research works have reported the applications in food packaging, drug delivery, wound healing, and biomedical applications. Besides metal nanoparticles, metal oxides like titanium oxide, zinc oxide, cerium oxide, aluminum oxide, copper oxide, iron oxide, etc., can also act as functional nanofillers. When exposed to ultraviolet radiations, reactive oxygen species in titanium dioxide assist in photocatalytic activity in many reactions (Juliet and Isaac 2015). Moisture penetration into the polymer matrix is prevented by the low hydrophilicity of titanium dioxide. Zinc oxide also shows antimicrobial activity which plays a good role in biomedical applications. Small particle size, high surface area, and UV- blocking effect of copper nanoparticles provide antioxidant and antibacterial properties for copper oxide nanoparticles.

Another class of nanofillers is carbon-based nanomaterials like fullerenes, carbon nanotubes, graphene, and graphene oxide. Significant electron mobility in carbon-

based nanomaterials creates excellent mechanical properties in the nanocomposite. Among these nanofillers, graphene has a high surface area as compared to others which enable good interaction with the matrix (Gan et al. 2017). But graphene has a tendency to agglomerate, and this limitation can be overcome by graphene oxide. Hence graphene oxide is the potential nanofiller among the carbon family. Graphene oxide has low solubility, and chemical modification and surface functionalization can help in improving solubility. Carbon dots are an emerging class in the field of biomedical applications as their biodegradability, photostability, and biocompatibility make them a promising material in different fields. They are quasispherical, amorphous nanomaterials having a size of less than 10 nm. Another advantage of carbon dots is that they are simple to synthesize and sources are easily available. They find many applications in cell imaging and sensing.

While optical properties are concerned, semiconductor quantum dots are gaining much attention in recent research works. Since they are very small in size, they have a great tendency to agglomerate and oxidize (Guo et al. 2016). Optoelectronic applications always choose graphene quantum dots-based nanocomposites due to their cost-effectiveness, availability, and biodegradability. Table 2 shows the properties of nanocomposites by the incorporation of nanofillers.

Table 2 Properties of biopolymer-based nanocomposites

No.	Biopolymer	Nanofiller	Properties	Reference
1	Gelatin	Clay	Improved mechanical properties than the pure polymer matrix	Baab and Zude (2008)
2	Chitosan	Silver/titanium dioxide	Excellent antibacterial properties enhanced shelf life in food storage	Lin et al. (2015)
3	Chitosan	Clay	Excellent mechanical properties, water vapor permeability is decreased	Lavorgna et al. (2010)
4	Poly(lactic acid)	Zinc oxide	Good antibacterial property	Materials (2019)
5	Poly(butylene adipate-coterephthalate)	Silicon dioxide	Excellent antimicrobial activity, Enhancement in mechanical and barrier properties	Venkatesan and Rajeswari (2019)
6	Starch	Clay	Increased stiffness and tensile strength	Sanyang et al. (2017)
7	Gelatin	Silver	Superior antibacterial and antimicrobial properties	Kanmani and Rhim (2014)
8	Starch	Silver/zinc oxide/copper oxide	Enhancement in mechanical properties	Peighambardoust et al. (2019)
9	Poly(lactic acid)	Zinc oxide	Better barrier and mechanical properties	Tang et al. (2020)
10	Chitosan	Curcumin	Water vapor permeability is reduced, and good antioxidant activity	Rachtanapun et al. (2021)

Synthetic Methodologies of Biopolymer Nanocomposites

Since the use of non-biodegradable materials is increasing day by day, environmental issues are also raising. For instance, the greenhouse effect is considered a huge environmental issue. So, it is high time to develop some functional compounds which act as alternatives for these synthetic materials. But the synthesis of eco-friendly products is very costly and it cannot be compared with synthetic materials in terms of cost. It is one of the limitations to use eco-friendly materials at a commercial level. While economic sustainability is concerned, the production of biopolymer nanocomposites at a cost comparable to synthetic polymers is a hot topic under discussion. In this matter, processing methodologies play a significant role. Both the cost and quality of the product are directly influenced by the synthetic strategy. Usually, biopolymer blends or nanocomposites are developed for improving the features. Methods such as electrospinning, solution casting, ultrasonication, etc., are used to fabricate nanocomposites. Very thin nanofibers can be developed by the process of electrospinning. The spinning technique can improve both the thermal and mechanical properties. Bio nanocomposites are developed by mixing the biopolymer and nanofiller and then heating and stirring till we get a homogenous suspension. It is dried out to get nanocomposites by means of solution casting. Another method of synthesis is ultrasonication which is a more sophisticated technique to disperse the nanofiller in the polymer matrix without agglomeration. The uniform distribution of the nanofiller in turn improves the properties of the material also (Abral et al. 2018).

Properties of Biopolymer Nanocomposites

Many polysaccharides act as a matrix to form biopolymer nanocomposites. Among them, chitosan, starch, and hyaluronic acid are widely used. Tissue engineering is one of the major applications in which biopolymers find their use. Biodegradability, oxygen permeability, water sorption, and blood coagulation of chitosan make it an efficient material in scaffolding. When chitosan is composited with nanoclay, it was found that there was a significant improvement in mechanical properties owing to the effective interaction and uniform dispersion of nanoclay in the chitosan polymer matrix (Cano et al. 2017). Such a biodegradable nanocomposite was used as a packaging material. Similarly, biofilms can be fabricated by mixing bacterial cellulose in hyaluronic acid for healing wounds. It was found that the incorporation of cellulose improved roughness and thermal stability. These properties assist the material in tissue engineering applications (de Oliveira et al. 2017). In another work, cellulose is dispersed in alginate by means of solution casting. There was a significant improvement in tensile strength in addition to the decrease in water vapor permeability and water solubility. In another work, cellulose dispersed in starch and as a result, thermal and mechanical properties are improved when compared to pure starch matrix. Uniform dispersion and excellent interaction of cellulose in starch are found to be the reason for the enhancement in the properties (Ghanbari et al. 2018).

Collagen and gelatin are also considered as a potential biopolymers which can act as an excellent matrix for the formation of nanocomposites. Polylactic acid is another renewable biopolymer which finds applications in various fields.

Applications of Biopolymers

While biopolymer acts as the raw material to produce different end use products, the features enhanced by the incorporation of nanofillers decides the design of each application (Vlăsceanu et al. 2019). For example, mechanical properties are necessary for developing biofilm for packaging applications, at the same time antimicrobial activity is essential for biological applications like drug delivery and tissue engineering. Hence, enhancements in specific properties needed to be targeted to reach the final aimed product. In the case of 3D printing thermomechanical factors play a key role. In such cases, proteins are added as plasticizers to increase the thermal stability.

Among various applications, the most important one which needs biodegradable biopolymer as a raw material is packaging. The material for such a purpose should be cost-effective, easy to decompose and recycle, biodegradable, and easy to transport. Research is still continuing to develop a raw material that can satisfy all the above features. There are inventions at the laboratory level. But the material still needs optimization to take it to commercial level. Biopolymer nanocomposites are widely used in biomedical applications also. Tissue engineering, drug delivery, and wound healing are a few biological applications. Biopolymer nanocomposites are also utilized as supercapacitors since the potential of electrode material can be improved by using nanofillers. Specific capacitance can be enhanced by the usage of biopolymers like lignin. Similarly, carbon nanomaterials like graphene, carbon nanotube, and carbon fibers find applications in the field of supercapacitors (Okonkwo et al. 2017).

Packaging

Efficient packaging is a necessity in the food industry. Good packaging provides expansion of the shelf life of food materials against decay via chemical, microbial, or any other hazards. It also retains safety and maintains quality (Cakmak and Sogut 2020). These packaging materials should maintain food quality and are to be convenient for processing till it reaches end-use product. Usually, materials such as glass, metal, plastic, or paper are used as packaging materials. Among plastics, petroleum-based materials are mainly used owing to their lightweight, availability, flexibility, good mechanical properties, and low cost (Wang et al. 2019). But the disadvantage of these petroleum-based packing materials is their non-biodegradability. Some of them take more than 15 years to degrade which is a severe issue while environmental sustainability is concerned. These polymers are a severe threat to nature by causing soil and water pollution. Due to this drawback, there is a high demand for eco-friendly

biopolymers with good mechanical properties for the food industry. Excellent biocompatibility and biodegradability make them ideal candidates for this purpose. While using biopolymers as packaging materials, waste disposal and composting them are comparatively easy and safe since they can be degraded by microorganisms in the soil (Abdul Khalil et al. 2017). High price, low mechanical, barrier, and processing properties limit the use of biopolymers. But it is a challenge to develop biopolymers that can compete with the mechanical and barrier properties of petroleum-based polymers. Economical production cost is also a major criterion in packaging applications.

Structure modification of biopolymers via copolymerization and nanocomposite fabrication are the methodologies to attain these expected properties. In some cases, plasticizers are added to the biopolymer to enhance the properties. These plasticizers can exchange intermolecular bonds thereby strengthening the polymer chains (Mulla et al. 2021). They also provide flexibility by creating variations in conformation and hence brittleness of the polymer can be reduced. Glycerol, triacetin, sorbitol, and polyethylene glycol are used as plasticizers in the food industry. The quantity of plasticizers should be controlled since their over usage may cause health and environmental issues. Copolymerization is also a suitable method to attain properties. Compatibility, uniform dispersion, and miscibility have to be checked while copolymerization is done. Another method to improve the properties of biopolymers is nanocomposite formation by dispersing nanofiller in the biopolymer matrix (Zhong et al. 2020). It is a thrust area of research in recent years and studies prove that water and gas barrier properties can be improved along with mechanical properties by developing nanocomposites. This in turn increases the shelf life of packed foodstuff since many of the nanofillers possess antimicrobial and antibacterial properties.

For safe and secure food transport, efficient packaging of food is necessary. For this purpose, reducing microbial growth is essential. Antimicrobial packaging will inhibit the growth of microorganisms to a great extent so that shelf life can be improved (Kumar et al. 2018). Furthermore, the quality of the food can be maintained with a good appearance, and eventually it can reduce wastage. Organic materials like polymers, acids, and enzymes, and inorganic materials like metal oxides and metals can be used as antimicrobial agents. Other examples of antimicrobial agents are essential oils, peptides, and plant extracts. Metal nanoparticles like zinc, copper, and silver display antimicrobial activity. Zinc oxide, titanium oxide, and copper oxide are examples of metal oxides possessing the same property. There are research works reported for chitosan-based nanocomposites utilized in the packaging industry (Nonato et al. 2019). It is found that chitosan-based films could inhibit the multiplication of microorganisms. Like any other biopolymer, temperature, molecular weight, concentration, and type of microorganism affect the activities of microorganisms. The incorporation of metal oxides into chitosan-based films improves the antimicrobial property.

Reducing the growth of microorganisms and lipid oxidation are the ways to improve the shelf-life of food materials. By delaying the process of oxidation, better maintenance of food quality may be obtained. Prevention of food oxidation by the

use of antioxidants is one of the methods to improve the same. Both synthetic antioxidants and natural antioxidants can be used to preserve food. Examples of natural antioxidants are curcumin, catechin, quercetin, mint, oregano, cinnamon, and so on (Vilela et al. 2018). In many biopolymers, these antioxidants are incorporated to get the expected results. Based on the action of antioxidants, they can again be classified as primary and secondary antioxidants. Secondary antioxidants are able to absorb ultraviolet radiation thereby preventing oxidative effects on the food products. Benzophenones, zinc oxide, titanium oxide, etc., are examples of such secondary antioxidants (Goudarzi et al. 2017).

Biopolymer-Based Nanocomposites for Drug Delivery and Wound Healing Applications

Biopolymer-based nanocomposites have been widely employed in drug delivery systems due to their biocompatible and biodegradable nature (Azmana et al. 2021; Kurakula et al. 2020). They have been used in different routes of drug delivery and have revolutionized the field of drug delivery by improvising the routes as well as vehicles for drug delivery.

Cellulose and Cellulose Derivatives

Bacterial cellulose derived from bamboo and sodium alginate was employed in developing a hydrogel nanocomposite system for controlled protein delivery by Li Ji et al. Bacterial cellulose was obtained by the inoculation of *Acetobacter xylinum* employing Moso Bamboo enzymatic hydrolysate as a carbon source and different weight % (0.25, 0.5, 0.75, and 1.0) of sodium alginate (SA) was added at the time of inoculation so as to obtain the nanocomposite hydrogels. The morphological analysis revealed the formation of interconnected porous structure and the pore size increased with increasing concentration of sodium alginate. The maximum pore size (50–70 nm) and uniformity in pore distribution was attained with 0.75 SA added hydrogel and at 1% SA concentration, the interconnected porous structure disappeared resulting in a structure with line-shaped nanofibrils. The drug release mechanism and pH responsiveness of two model drugs namely bovine serum albumin (BSA) and lysozyme (LYZ) entrapped in the nanocomposite hydrogel were evaluated. The results of the study indicated that LYZ has a better pH-dependent releasing ability as a result of electrostatic forces of adsorption between hydrogel and LYZ. However, due to hydrophobic adsorption between BSA and hydrogel, the drug release of BSA was poorer compared to LYZ. Overall, the study demonstrated that the hydrogel nanocomposites based on SA–BC are promising in delivering hydrophilic drugs such as proteins (Ji et al. 2021).

Nusheng Chen et al. synthesized nanocomposite hydrogels based on modified carboxy methyl cellulose (CMC) and diblock copolymer as hydrophobic micelle cores for controlled and localized release of hydrophobic drugs. The modification of CMC was done by hydrazide and aldehyde and the micelle core was based on a copolymer system which is pH-responsive, poly(ethylene oxide) (PEO) -block-poly

(2-(diisopropylamino) ethyl methacrylate (PDPA). The injectable nanocomposite hydrogel was obtained by dissolving the two modified CMC precursors in a micelle solution loaded with drug and then co-extruding with the help of a double barrel syringe. The cross-linking in hydrogel composites is facilitated through a Schiff base reaction. Nile red was chosen as a model hydrophobic dye to test the efficiency of the copolymer micelle's loading ability since it will exhibit fluorescence only in hydrophobic environments. The in vitro release of doxorubicin was also evaluated in simulated body fluids having physiological conditions. The hydrogel composites based on CMC and PEO-b-PDPA micelles exhibited negligible cytotoxicity and was successful in slow and controlled drug release which can be tuned by varying the pH as well as by varying the hydrogel precursor concentrations (Chen et al. 2019b).

In order to improve the mechanical properties of hydrogels of carboxy methyl cellulose (CMC), carboxy methyl β -cyclodextrin (cm- β CD) was cross-linked with CMC to form a hydrogel composite. The incorporation of cm- β CD has significantly improved the mechanical performance of the hydrogel as well as the storage modulus and swelling properties. The drug release study conducted using Tetracycline (TC) as a model drug revealed that the CMC- cm- β CD hydrogel was able to release TC in an effective manner both at high and low TC loading. The effective release of TC after crosslinking with cm- β CD is due to the complexation of the drug with cm- β CD. The antibacterial activity tested using *S. aureus* bacteria was also found to be better in the case of CMC- cm- β CD hydrogel loaded with 50 mg TC (Jeong et al. 2018).

J.T Orasugh et al. employed cellulose nanofibrils (CNF) isolated from jute fiber for the preparation of nanocomposite film with hydroxy propyl methyl cellulose (HPMF) and tested for transdermal drug delivery of an analgesic Ketorolac tromethamine (KT). The in vitro release studies of KT revealed that the drug was released from the composite film in a controlled manner for a prolonged time period of 8 h. The precise release of KT from the HPMF-CNF was ascribed to the three-dimensional structure and less swelling property of CNF (Orasugh et al. 2018).

Chitosan

Chitosan mainly seen in crustacean shells of marine organisms is another widely used biopolymer for developing drug delivery systems with improved biocompatibility and biodegradability. The free amino groups present in the chitosan backbone help in encapsulating hydrophobic drugs and also help in the incorporation of proteins and peptides which are negatively charged. The ability to get fabricated into various structures and shapes makes chitosan adaptable for performing different functions in drug delivery systems (Tao et al. 2021).

Deformable liposomes (DL) based on chitosan loaded with flurbiprofen was proposed by Chen et al. as an ocular delivery system for delivering flurbiprofen with a view to overcome conventional eyedrops. The coating of chitosan on DL improved the penetration as well as absorption leading to greater bioavailability of the drug in the ocular region. Moreover, the chitosan-coated DL showed reduced ocular irritation of flurbiprofen and also favored the biocompatibility of the drug in the ocular region (Chen et al. 2016).

An effective transdermal (TD) drug delivery option based on chitosan modified with glycidyl and butyl methacrylate and hyaluronic acid was developed by

Anirudhan et al. for lidocaine (LD) delivery directly into the systemic circulatory system. The TD device was tested for *in vitro* release and *in vivo* skin adhesion as well as skin irritation assay. The results indicated that the transdermal patch performed controlled release of lidocaine in a sustained manner with improved antimicrobial activity and with no skin irritation (Anirudhan et al. 2016).

In another study, the inclusion complex of amlodipine besylate (APB) and β -cyclodextrin was prepared by two different methods, namely kneading method and microwave method initially, and then mixed with a nanocomposite of chitosan-graphene oxide and sodium alginate by microwave-assisted synthesis. The nanocomposite containing inclusion complex was further analyzed for drug release kinetics by varying the pH using six different kinetic models. The best-fitting kinetic model was selected on the basis of the correlation coefficient (R^2). Accordingly, the influence of relaxation and diffusion on the drug release process was explained using the Peppas-Sehlin equation (Khushbu and Jindal 2021).

A nanocomposite hydrogel based on modified chitosan (modified with methacrylated glycol-MeGC) and montmorillonite (MMT) for bone tissue engineering application was proposed by Cui Z. K et al. The MMT was introduced into MeGC hydrogel systems and was photopolymerized using a photo initiator (riboflavin) to obtain an injectable bone regeneration biomaterial with improved osteoconductive nature. The incorporation of MMT in the hydrogel helped in the formation of a microporous structure having interconnectivity and better mechanical stability. The *in vitro* studies showed better proliferation and differentiation of mesenchymal stem cells. The *in vivo* study conducted using a mouse calvarial defect model showed that the nanocomposite hydrogel can employ new cells and can also help in calvarial healing indicating its potential in tissue engineering and regenerative medicine field (Cui et al. 2019).

A piezopolymer nanocomposite system based on chitosan and hydroxylated barium titanate (BaTiO_3) was reported for tissue engineering by Prokhorov et al. The nanocomposite exhibited biocompatibility with fibroblast cells and also the presence of BaTiO_3 does not cause any cytotoxicity issues as revealed by the cell viability. Hence, the nanocomposite film can be used as a flexible platform for cell proliferation and also for skin regeneration (Prokhorov et al. 2020). A brief list of other bionanocomposites based on chitosan and the relevant application is listed in Table 3.

Silk Fibroin

Silk fibroin (SF) based nanocomposites are widely employed for tissue engineering mainly for repairing nerves, cartilage, and skin due to its superior mechanical properties, biocompatible nature, and its ability in producing lower immunogenic responses. Y. Wang et al. reported sodium alginate (SA) and silk fibroin (SF) composite hydrogel for the delivery of bovine serum albumin (BSA) and tetracycline hydrochloride. The hydrogel composites were made flexible by improving the crosslinking between SA and SF employing a carbodiimide. The composite hydrogel's swelling and mechanical properties as well as their gelation time, biodegradation, and biocompatibility were evaluated. The hydrogel composite exhibited a sustained release of micro and

Table 3 List of chitosan-based bionanocomposites and applications in the biomedical field

Composite system	Synthesis method	Application	Reference
Chitosan, cellulose, and hydroxyapatite	Solvent exchange method	Bone tissue engineering	Synthesis et al. (2021)
Chitosan and iron oxide	Green synthesis	Antibacterial and antioxidant activity	Bharathi et al. (2019)
Chitosan, reduced graphene oxide, and iron oxide	One pot synthesis-solvent casting	Hyperthermia treatment	Barra et al. (2020)
Chitosan and cellulose loaded with betamethasone/silver sulfadiazine	Solvent casting	Wound dressing	Riccio et al. (2021)
Chitosan and cellulose encapsulated with 5-Fluorouracil	Ionic gelation using a crosslinking agent (sodium tripolyphosphate)	Treatment of colorectal cancer	Yusefi et al. (2021)
Chitosan and silver nanoparticles	Green synthesis	Antibacterial agent and drug delivery	(Saruchi et al. 2022)
Chitosan and graphene oxide	Gelation method	Metronidazole oral drug delivery	Kumar et al. (2021)

macromolecular drugs with no cytotoxicity and also showed appreciable biodegradation within 14 days duration (Wang et al. 2021).

A ternary nanocomposite scaffold based on silk fibroin, carboxy methyl cellulose, and magnesium hydroxide nanoparticles was envisaged for wound dressing applications by R.E. Keihan et al. The hybrid composite showed to be promising for wound healing applications as revealed by the in vivo assay results for wound healing with 82.29% healing in 12 days. The composite also showed good biocompatibility and higher bactericidal activity recommending the possibility of the compound in diverse biomedical applications (Eivazzadeh-Keihan et al. 2021).

Another group reported chitosan nanoparticle-incorporated silk fibroin hydrogel composite for delivering dexamethasone sodium phosphate (DEX). For preparing the drug release device, the DEX was incorporated in chitosan nanoparticles by gelation (ionotropic) and then it was transferred to SF solution and sonicated to induce gelation. The in vitro drug release studies indicated that the chitosan nanoparticles helped in encapsulating the DEX for controlled release of the drug while SF acted as a matrix for prolonging the drug release (Akrami-Hasan-Kohal et al. 2021).

Biopolymer-Based Nanocomposites for Tissue Engineering Applications

Tissue engineering aims to develop functional constructs by making use of a scaffold, functional tissues, cells, and other biologically relevant molecules with a

view to restore or maintain damaged tissues or whole organs (Zhao et al. 2020). Biopolymers and their nanocomposites are frequently being used as scaffolds since they can meet the prerequisites of a scaffold material such as porosity (to endorse vascularization and integration of tissues), structural resemblance with bioactive molecules, biocompatible, and controlled biodegradation (Islam et al. 2020).

Bacterial cellulose (BC) is commonly employed for tissue engineering applications compared to plant cellulose on account of the ease of production, purity, and adaptable nature. The slowly degradable nature of BC can be altered by the addition of other components. The modification can be done either at the time of synthesis of BC or post-synthesis using other biomaterials such as collagen, hydroxy apatite, hyaluronic acid, pectin, etc., Z. Keskin et al. prepared BC composite modified with keratin for tissue engineering of the skin. The main reason for the addition of keratin was to increase the bonding of fibroblasts of skin on the surface of BC. Cytotoxicity of the composites was checked using mouse fibroblast cells (L929) and also by MTT assay. The BC-keratin composites exhibited appreciable viability and biocompatibility and also showed better adhesion of fibroblasts. The group has studied both in situ and post-modified keratin-BC composites, and both composites were found to be effective for use in dermal tissue engineering applications (Keskin et al. 2017).

Conductive scaffolds based on cellulose and polypyrrole (Ppy) for nerve regeneration have been reported by R. Elashnikov et al. The surface of cellulose acetate butyrate nanofibers obtained by electrospinning was modified using polypyrrole (Ppy) and was used for the preparation of scaffolds. The coating of Ppy on cellulose helped in improving the conductivity of the scaffold for use in tissue engineering of neural tissues. The cytotoxicity of the composite fibers by LDH assay also revealed the non-toxic nature of the scaffold even after Ppy coating. The adhering of Ppy particles on the cellulose surface enhanced the roughness and subsequently helped in promoting the adhesion of human neural cells (SH-SY5Y) and also increased the viability of SH-SY5Y cells up to a period of 15 days (Lyutakov 2019).

The approach of electrical stimulation for nerve regeneration was adopted by another group (Zha et al. 2020). Cellulose and two conducting polymers (poly (N-vinyl pyrrole (PNVPY) and poly (3-hexyl thiophene (P3HT) were made into a nanofibrous mat by polymerization (in situ). The thickness as well as the porosity of the composite mats was superior to electrospun cellulose mats which helped in improving the adhesion of PC12 cells. The application of electrical stimuli augmented the proliferation of PC12 cells and the fibrous mats also showed excellent biocompatibility.

Waghmare et al. suggested the chemical alteration of carboxy methyl cellulose by the introduction of sulfate groups for constructing injectable scaffold tissue engineering cartilage. The macroporous nature of the scaffold helped in the chondrogenesis of mesenchymal stem cells as a result of the binding of growth factors through ionic interactions. The highly porous nature with and strong pore wall, the injectable scaffolds showed good resilience and were able to retain their initial shape making them suitable for engineering the load-bearing tissues (Waghmare et al. 2018).

Table 4 Synthesis methods and tissue engineering applications of biopolymer nanocomposites

Components of composite	Synthesis method	Application	Reference
Carboxymethylcellulose, hydroxy apatite, and gelatin	Freeze drying followed by crosslinking	Bone tissue engineering	Karvandian et al. (2020)
Carboxymethylcellulose and polyethylene glycol	Solution casting	Skin tissue engineering	Zennifer et al. (2021)
Bacterial cellulose, β -glucan, graphene oxide (GO), and hydroxy apatite	Free radical polymerization & freeze drying	Bone tissue engineering	Umar Aslam Khan et al. (2021)
Collagen and tricalcium phosphate	3-D printing technique	Hard tissue regeneration	Kim et al. (2017)
Starch nanocrystals and gelatin	3-D printing technique	Cartilage tissue engineering	Piluso et al. (2019)

Poly(butylene succinate) (PBS) and cellulose nanocrystals (CNC) bionanocomposites as the scaffold was prepared by electrospinning for tissue engineering application by Huang et al. Thermal and mechanical properties as well as the porosity of PBS/CNC scaffold were found to be superior at 3 wt% composition of CNC. The scaffold exhibited appreciable biodegradation compared to neat PBS and the cell viability of fibroblast cells (3 T3 cells) remained 100% even after culturing for 7 days suggesting good biocompatibility. The incorporation of CNC helped in improving cell proliferation and biodegradation of the scaffold (Huang et al. 2018).

A nanocomposite of chitosan incorporated with gold, hydroxyapatite, and graphene was prepared by hydrothermal method and was cast into a film using poly vinyl alcohol (PVA) by gel casting technique. The polymeric film showed significant differentiation and viability of osteoblasts and was also effective against both strains (gram positive and gram negative) of bacteria indicating its potential in the field of bone tissue engineering applications (Prakash et al. 2020).

The various strategies and the composition of biopolymer composites employed in tissue engineering applications are given in Table 4.

Biopolymer-Based Nanocomposites for Biosensing Applications

Biopolymer nanocomposites have also been recognized in the field of sensing especially biomolecules such as enzymes, nucleic acids, antibodies, proteins, enzymes, etc., and also other chemical species. Due to the unique biocompatible nature of biopolymers, several sensing technologies with high selectivity and specificity have been devised based on the composites of biopolymers. Biosensors are used in the detection of biomolecules and the detection is made possible by visualizing the change in optical, chemical, mechanical, or thermal properties (Subhedar et al. 2021).

The detection of purine bases such as adenine and purine employing cellulose (NC) and CNT nanohorns (SWCNHs) was reported by Ortolani et al. A thin film

comprising of NC and SWCNHs with higher sensitivity and selectivity was fabricated and the detection was done using linear sweep voltammetry (LSV). The fabricated electrode demonstrated a lower detection limit (LOD) of $1.5 \times 10^{-7} \text{ mol L}^{-1}$ for guanine and $1.9 \times 10^{-7} \text{ mol L}^{-1}$ for adenine. The electrode was also successful in the real-time monitoring of purine bases in human serum and fish sperm (Ortolani et al. 2019).

An enzymatic biofuel cell was developed for the selective detection of glucose using bacterial cellulose (BC) modified with gold nanoparticles (AuNP) as the electrode material. The synergic combination of BC and AuNP in transferring the electrons from the enzyme (glucose/ O_2) to the surface of the electrode helped in achieving a lower LOD value ($2.874 \mu\text{M}$) and a broader detection limit ($0\text{--}50 \text{ mM}$). The biofuel also exhibited a higher value of power density ($345.14 \mu\text{W cm}^{-3}$) indicating its possibility to be used as a self-powered biosensor for selective detection of glucose (Lv et al. 2018).

Hemoglobin impregnated on GCE modified using a nanocomposite of cellulose microfiber and graphene (GR-CMF) was used for quantifying hydrogen peroxide (H_2O_2). The electrode showed good electrochemical behavior in the detection of H_2O_2 even in the presence of other interfering compounds with a selectivity of ($0.49 \mu\text{A} \mu\text{M}^{-1} \text{ cm}^{-2}$). The biosensor also exhibited appreciable stability under operating conditions, lower LOD value (10 nM) and can be used for the detection of H_2O_2 in biological as well as pharmaceutical models (Velusamy et al. 2017).

Detection of glucose by in vivo (oral) and dermal monitoring was reported by C. T Tracey et al. using hybrid composite films of cellulose nanocrystals and magnetite. Both the methods of sensing (dermal and oral) displayed peroxidase-like activity and the lower level of detection of glucose was 5 mM . The sensing was based on observing the color change (colorimetry) and hence can replace the amperometry technique used in glucometers. Moreover, the sensor exhibited better selectivity in an acidic environment and hence can be employed to monitor glucose levels through saliva and sweat instead of using blood for detecting biological glucose levels (Tracey et al. 2020).

Enzymatic biosensor for detecting lactose based on molecular organic framework of Co-hemin (Co-hemin MOF) and chitosan composite was developed by Choi et al. (2020). The biosensor demonstrated a broad linear detection range ($10\text{--}100 \text{ nM}$) and selectivity in the presence of similar interfering molecules (galactose, ascorbic acid, dopamine, glucose, and uric acid). The real-time detection of lactose in dairy products using the biosensor was compared with HPLC results and the results clearly proved the applicability of the study in the detection of lactose in commercially available dairy products.

The detection of Zidovudine (ZDV) used in the treatment of AIDS is necessary to study the adverse effects as well as the side effects caused by higher doses. Graphite electrode modified by a hybrid composite consisting of DNA, chitosan, graphene oxide, and bimetallic Au-Pt nanoparticles was reported by H.R. Akbari Hasanjani and K. Zarei (2021). The biosensor showed remarkable selectivity, a wider detection range ($0.01 \text{ pM}\text{--}10 \text{ nM}$), and a much lower LOD (0.03 pM). The real-time analysis of ZDV in human serum also produced reasonable results.

Electrospinning was employed to produce composite nanofibers of collagen, hemoglobin, and carbon nanotubes. The composite was further used for the electrochemical detection of hydrogen peroxide by amperometric and cyclic voltammetric methods. The higher surface area and porous nature of the nanofiber composites facilitated the direct transfer of electrons accelerating the electro catalysis and selective detection of H_2O_2 (Li et al. 2014).

The detection of physiological levels of dopamine using an apt sensor based on collagen (glass carp skin derived – GCSC) -graphene oxide composite system (GCSC-GO) was reported by Wei et al. (2019). The composite GCSC-GO was used as the transducer part and the biological recognition of dopamine was made possible using a label-free aptamer. The developed biosensor showed better selectivity, superior robustness, and feasibility during the amperometric determination of dopamine in human blood serum and hence can be utilized for dopamine sensing in clinical samples.

Immobilization of enzymes for optical sensing of biomolecules can be done using suitable matrix materials. Accordingly, hydrothermally grown titanium dioxide nanotubes (TNT-TiO₂) were incorporated in a polymeric matrix of alginate and then cross-linking using calcium ions (Ca^{2+} -cationic cross-linking) was done to get the nanocomposite hydrogel. The composite was initially screened for colorimetric sensing (blue color formation) of lactate and glucose in artificial sweat. The detection was very rapid in the case of TNT-alginate scaffold compared to bare alginate scaffold; 4 min and 6 min for lactate and glucose colorimetric sensing. The TNT-alginate scaffold was then impregnated on a cellulose paper strip and colorimetric detection of lactate and glucose was studied. The paper scaffold displayed homogeneity in sensing and a quicker response indicating the potential of the scaffold in devising wearable devices for real-time detection of glucose and lactate in sweat (Gunatilake et al. 2021).

A biosensor for the detection of histamine using a cryogel composite of chitosan and gold (Au) nanoparticles was reported by N. Nontipichet et al. Electrodeposition of Prussian blue (PB) was initially done on multiwalled carbon nanotubes coated on a carbon electrode (SPCE). The composite cryogel helped in the immobilization of the enzyme diamine oxidase (DAO). The method of preparation of the electrode and detection using amperometry is depicted in Fig. 1. The current generated during the reduction of PB during enzyme catalyzed oxidation of histamine was measured. The modified electrode showed two broad linear detection ranges with exceptional stability (operational and long-term storage), selectivity, and lower detection limit ($1.81 \mu\text{mol L}^{-1}$). The sensor showed exceptional recovery during the detection of histamine in shrimp and fish samples, and the results obtained using the biosensor were consistent with that of the results using the ELISA test (Nontipichet et al. 2021).

Chitosan was employed to increase the stability of carbon nanotubes in an aqueous solution to form a well-dispersed composite for the detection of the hormone leptin in blood serum. The single-walled carbon nanotubes (SWNTs) were functionalized using a cross-linking agent for 30 min in order to activate the functional group (carboxyl group) and dispersed in a chitosan matrix followed by the addition of leptin (with the non-specific sites of binding blocked using bovine serum

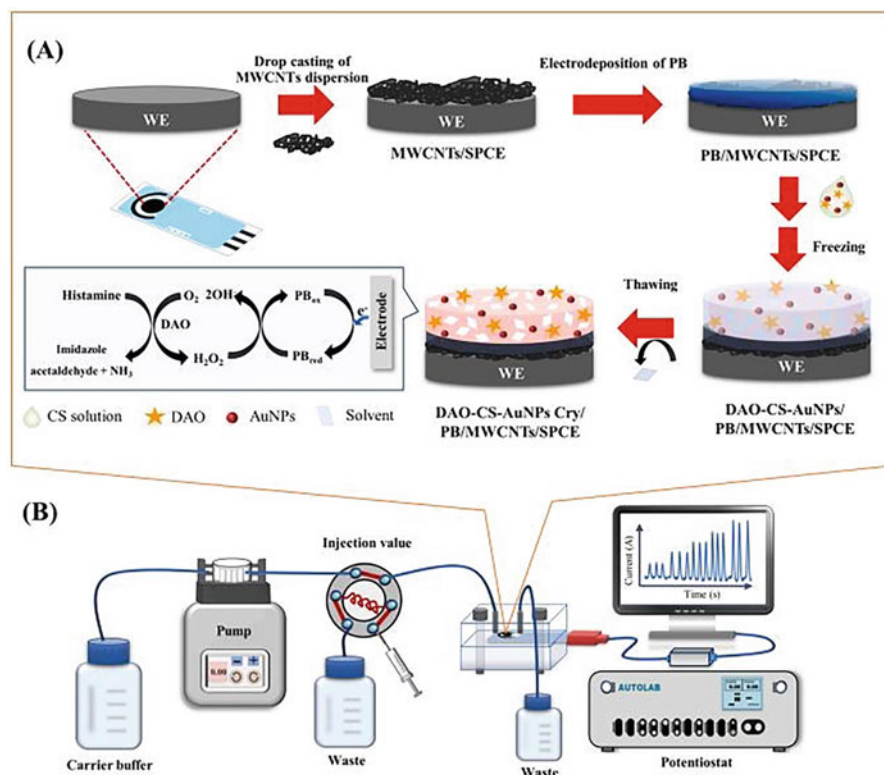

Fig. 1 Schematic representation of the preparation of modified composite electrode and the amperometric method employed for the detection of histamine

albumin) to obtain the biosensor. The sensor exhibited an appreciable recovery rate and the study can be extended for real-time detection of leptin in clinical samples (Zhang et al. 2018).

Miscellaneous Applications of Biopolymer-Based Nanocomposites

Biopolymers are used in developing hybrid composites with improved properties because of their biocompatible and biodegradable nature. In addition, the presence of multiple functional groups present in biopolymers helps in controlling the properties when combined with other nanomaterials. Biopolymer composites of cellulose, collagen, gelatin, proteins, alginate along with metal nanoparticles, metal oxides, carbon nanomaterials, etc., have received more consideration in the field of optics and electronics (Colusso and Martucci 2021).

Conducting a biopolymer composite film of collagen and copper nanoparticles has been reported by K. Cheirmadurai et al. The copper nanoparticles were prepared following a green procedure using henna leaf extract and discarded collagen was

utilized to develop the conducting film. The improved electrical conductivity of the films suggests the potential of the composite for various electronic applications. The film when introduced between batteries was capable of illuminating a LED lamp demonstrating its excellent electrical conductivity (Cheirmadurai et al. 2014).

Bacterial cellulose (BNC) possessing high purity has been used in combination with gold nanorods for developing Surface Enhanced Raman scattering (SERS) composite for the detection of bacteria, and lower concentrations of rhodamine have been reported by Tian et al. The porous and 3D structure of BNC helped in enhancing SERS making the composite beneficial for catalysis as well as energy storage applications (Tian et al. 2016).

Cellulose was employed as the template for developing a hierarchical nanocomposite consisting of phosphotungstic acid (HPW) and TiO_2 for photocatalysis applications. The composite was further evaluated as a photocatalyst for the degradation of methylene blue (Lin and Huang 2021). Another group reported the use of cellulose to properly disperse silver nanoparticles and zinc oxide nanoparticles for fabricating a composite for photocatalysis. The composite displayed better degradation of methyl orange (92% in 2 h) under sunlight as well as UV light (Shi et al. 2021).

A photocatalyst (TFCM) employing chitosan microspheres as a matrix for the effective dispersion of ferrite nanoparticles was reported by Nawaz et al. The degradation of methylene blue was investigated and the results obtained indicated the efficiency of TFCM as a photocatalyst in degrading 93% of the dye in 150 min (Nawaz et al. 2020). The relevant biopolymer-based nanocomposites reported for photocatalytic applications are given in Table 5.

Biopolymer-based supercapacitor electrodes have been reported because of their natural abundance, the easiest way of extraction, multifunctional nature, etc. (Pandiselvi and Thambidurai 2014). Cellulose and chitosan are the most exploited biopolymers for supercapacitor applications (Roy et al. 2021). They are either used in the form of composites with conductive materials or as a renewable source of carbon precursor.

Active electrode material based on chitosan and polyorthoamino phenol (POAP) for developing supercapacitors was reported by Ehsani et al. The electrode material

Table 5 Photocatalytic applications of biopolymer nanocomposites

Photocatalyst	Pollutant	Degradation efficiency and time	Reference
Chitosan loaded with Zr/ZnO	Hexavalent chromium	94.6% in 60 min	Preethi et al. (2020)
Carboxy methyl cellulose with Zinc ferrite (ZnFe_2O_4)	Ciprofloxacin	87% in 100 min	Malakootian et al. (2019)
Starch, bismuth tungstate, and graphene oxide	Ethylene	88.4% in 200 min	Xie et al. (2020)
Sodium alginate and TiO_2	Tartrazine	89% in 180 min	Dalponete et al. (2019)
Bacterial cellulose, SiO_2 , and TiO_2	Crystal violet	97% in 50 min	Rahman et al. (2021)

exhibited superior mechanical stability due to the incorporation of chitosan and demonstrated a higher value of specific capacitance (345 F/g at 100 mVs^{-1}) and retention of initial capacitance after 1000 cycles (Ehsani et al. 2019). Another study reported on chitosan and polyvinyl alcohol incorporated hydrogel electrodes with remarkable energy density (10.03 Wh kg^{-1}) and cycling stability (up to 5000 cycles) (Li et al. 2022). Cellulose aerogel and carbon composite were employed in developing an asymmetrical supercapacitor. The 3D porous hierarchical percolation of cellulose aided in electrolyte penetration, faster electron, and ion transport resulting in higher power (23 WL^{-1}), and energy densities (3.4 Wh L^{-1}) (Lei et al. 2021). Another group reported on cellulose nanofiber and graphene oxide fabricated as composite foam with improved electrochemical activity as an electrode for the supercapacitor. The foam electrode showed a higher specific capacitance (398.47 F/g at 0.5 A/g current density) and outstanding cycling stability even up to 10,000 cycles (Liu et al. 2021).

Future Outlook

Biopolymers have a significant role in various fields of applications owing to their good mechanical, thermal, and barrier properties. The development of biopolymers is necessary to reduce atmospheric pollution caused by synthetic polymers. But the cost of biopolymers is a factor that has to be addressed in further research. It is essential that biopolymers should be produced at a commercial level at a price comparable to synthetic polymers. The properties of biopolymers can be manipulated by the incorporation of various nanofillers in different compositions. In this respect, nanotechnology has a prominent role in improving the existing features of a biopolymer. The replacement of plastic materials that are used today has to be completely substituted with biodegradable polymers. Reusability of these plastics is not a final solution for the environmental issues. An ultimate solution will be possible only by the complete substitution of plastics for biopolymers. Such a process will assist in reducing pollution issues and leads to a sustainable future.

Conclusions

When environmental issues are concerned, recent research focuses on biopolymer-based nanocomposites for a variety of applications. However, many limitations in the processing and production of biopolymer-based nanocomposites have to be nullified in order to reach a commercial level. In this regard, a thorough study of natural biopolymers indicating the challenges faced in this area. This chapter summarizes the properties of biopolymers, the introduction of nanofillers to form bio nanocomposites, and their properties and applications in food packaging, drug delivery, wound healing, tissue engineering, and sensing. From recent studies, it is clear that blending of biopolymers and fabrication of nanocomposites are effective ways to get the desired results. The incorporation of nanofillers can optimize the

properties of the matrix along with the reinforcement provided. The chapter recommends novel, economic synthetic strategies of bio nanocomposites that can pave a new way in the field of polymers and can contribute new opportunities in various applications.

Abstract

Biopolymer-based blend nanocomposites can eliminate the adverse effects of plastic wastes and severe environmental problems. In recent years, researchers are attracted toward the development of new polymeric materials with desired properties without environmental impacts. The biodegradable blend nanocomposites can perform smart applications in industrial, pharmaceutical, and biomedical fields by tailoring its properties. The enhancement in properties of blends can be achieved by the addition of nanofillers with or without modifications. This chapter discusses the properties of biopolymer blend nanocomposites prepared from agro-resources and chemically synthesized using agro-based monomers in

detail. The applications and processing techniques of biopolymer blend nanocomposites are also summarized in this chapter.

Keywords

Biopolymers · Nanocomposite · Mechanical property · Thermal stability · Packaging application

Introduction

Biopolymers are a type of polymer that is derived from natural resources. Polymers can be derived from biological systems such as microorganisms, plants, crustacean shells, woods, mushrooms, and other organisms known as biopolymers. Cellulose, silk, lignin, hemicelluloses, and starch are some of the examples of biopolymers that occur in nature as macromolecules. Depending on the synthesis and sources biopolymers are classified into: (1) polymers from agro-resources (starch, cellulosic products, chitosan/chitin, etc.) and proteins and lipids from animals and plants (casein, whey, soya, and gluten), (2) polymers from microbial action (poly[hydroxybutyrate] [PHB] and poly[hydroxybutyrate cohydroxyvalerate] [PHBV]), and (3) chemically prepared polymers from agro-based monomers (polylactic acid [PLA]). Bio-based plastics are gaining popularity as a potential solution to problems caused by petroleum-based plastics.

The studies in the field of bio-based plastics are increased due to their similarities in the values of tensile strength and elastic modulus as that of synthetic polymers (D'Anna et al. 2022). However, brittleness and poor barrier properties limit their application in many fields and these limits can be overcome by blending with other biopolymers. Simple mixing of polymers without chemical reaction refers to blending and is the best way to create new materials with the desired properties. This technology can provide various advantages such as maximize material's performance, improvement in properties in relation to a specific application, decrease sensitivity to water, as well as application requirements at the lowest possible cost and in the shortest amount of time.

Blending is the frequently used method in the industrial sector because it is more practical and cost-effective. In some cases, the final properties of polymer blends can be done by modification of the blend using chemically modified polymers, or by mixing polymers with nanofillers at the time of processing to get good molecular interaction of the two polymeric phases present in the blend. For instance, PLA-PHB polymer blends are immiscible and their properties can be enhanced by modifying the blend with nanoclay (D'Anna et al. 2022). The nanofillers that are used in nanocomposites are divided on the basis of number of dimensions as fibers (1D), nanoplatelets (2D), and particles (3D) (Mochane et al. 2020). One-dimensional nanomaterials consist of nanorods, nanowires, and nanotubes. Two-dimensional nanomaterials exhibit plate-like shapes and nanolayers, nanocoatings and nanofilms are included in this category. Graphene is the well-known example for 2D material.

Three-dimensional nanomaterials may include nanoparticle dispersions, nanowire bundles, multilayers, and nanotubes.

The nanofillers may have an impact on the morphology of polymer blends by (a) changing the viscoelastic properties, (b) increasing component compatibility, and (c) changing physical barrier effect on the mixing of the blends (Vatansever et al. 2019). The localization of nanoparticles within the polymer blends has significant effect on the properties of the final product. The localization of nanoparticles in the polymer matrix leads to the breakup of the minor phase by immobilizing the polymer chains of the matrix. But, when the nanoparticles localize at the interface, it can act as a barrier between two phases and they can suppress the coalescence of the droplets. The morphology of the composites can be balanced with nanoparticles by reducing the interfacial interactions. When the nanoparticles located in the minor phase, nanoparticles can decrease the droplet size in the minor phase via “*cutting effect*” mechanism and it is observed when platelet-like nanoparticles such as nanoclays are used (Vatansever et al. 2019).

The thermodynamic factors originated from polar and the filler-polymer interactions control the localization of the filler in blend composites. It is observed from many studies that the filler has the tendency to locate in high-affinity polymer phase during mixing (Mochane et al. 2020). The filler concentrates at one phase in such a way that the interfacial energy gets reduced and filler prefers less viscous phase to minimize the interfacial energy. In addition to thermodynamic effect, kinetic effect plays a role in the localization of fillers in polymer blends. The kinetic effects like melt viscosity, shear rate, compounding sequence, and melt compounding time also affect the localization of the filler (Mochane et al. 2020). Melt viscosity has an important role in deciding the final morphology and final filler localization in polymer blends. Less-viscosity polymers possess better wetting coefficient and nanoparticles can easily diffuse into it. In compounding sequence, filler is premixed with less affinity phase and then mixed with second component, based on the concept of migrating filler toward more interacting phase from noninteracting phase. Different mixing times play a role in the localization of nanofillers in polymer blends and more mixing time is necessary for nanofillers to move from one phase to another.

Processing Techniques of Biopolymers-Based Blend Nanocomposites

Different methods are adopted for the synthesis of bio-based polymer blend nanocomposites. One of the methods for the preparation of biopolymer blend nanocomposites is solution casting method. Polyvinyl alcohol/starch/zinc oxide nanoparticle-based nanocomposite films were prepared using solution casting (Hu et al. 2022). Solution casting method of preparation of polyvinyl alcohol/starch/graphene oxide nanocomposites were reported elsewhere (Atta et al. 2021). Silver modified with hydroxyapatite nanoparticles AgHA-NPs/polyvinyl alcohol (PVA)/carboxymethyl cellulose (CMC) nanocomposites was also prepared by

solution casting technique (Nasrallah and Ibrahim 2022). Stearate Mg-Al layered double hydroxide (LDH)-based polyhydroxybutyrate (PHB)/polycaprolactone (PCL) blend nanocomposites were fabricated via solution casting intercalation method (Liau et al. 2014). Solution blending technique is used for PLA/starch/modified TiO₂/multifunctionalized graphene oxide nanocomposites (Wang et al. 2020). Melt blending is another method and used for the preparation of thermoplastic starch/poly(lactic acid) (TPS/PLA)/graphene blends (Solati et al. 2019). Melt blending is also used for fabrication of PCL/TPS/nanoclay blends (Guarás et al. 2016). Melt blending and compression moulding method is used for preparing thermoplastic starch (TPS)/poly(lactic acid) (PLA)/nanocellulose fibers composites (Nazrin et al. 2020). Melt mixing followed by hot pressing method is used for the preparation of cellulose nanocrystal/poly (lactic acid) (PLA)/poly (butylene succinate) (PBS) composites (Rasheed et al. 2021). Extrusion blowing method of preparation of starch/PBAT (poly[butylene adipate-co-terephthalate]) films containing silver nanoparticles (AgNPs) and zinc oxide nanoparticles (ZnONPs) was studied (Zhai et al. 2022). PLA/PHB/clay blend nanocomposites were manufactured by twin-screw extrusion method (D'Anna et al. 2022). Twin-screw extruder and injection molding are other methods for the preparation of poly(ϵ -caprolactone)/starch/cellulose nanocrystals films (Manoel et al. 2022). Laser ablation technique is applied for the synthesis of carboxymethyl cellulose (CMC)/polyvinyl alcohol (PVA)/tungsten trioxide composites (Askary et al. 2022). PLA/PHB blends with GO and cinnamaldehyde were successfully achieved through a combined extrusion and impregnation process (Villegas et al. 2021). PLA/PHB/CNC composites were obtained using electrospinning method (Arrieta et al. 2016). PCL/gelatin/CNF-based nanocomposites were also manufactured via electrospun method (Moazzami Goudarzi et al. 2020).

Starch Blend Polymer Nanocomposites

Starch (ST) is a biodegradable and renewable natural biopolymer and it is one of the most important polysaccharides. It has been employed to develop environmentally friendly materials due to the rapid biodegradability and low cost. It consists of linear amylose with a spiral structure and highly branched amylopectin (Hu et al. 2022). The physical properties of starch are controlled by the ratio of amylose to amylopectin (Atta et al. 2021). The usage of starch in many applications, especially for packaging, is limited because of its great water sensitivity, low processability, and poor mechanical properties. These drawbacks of starch can be minimized by mixing starch with polyvinyl alcohol (PVA). PVA is a nontoxic and biodegradable material possessing high mechanical strength and high polar solubility in water. However, PVA has some drawbacks like high manufacturing cost, weak dimensional stability, and high water uptake. PVA and starch blends provide moisture-resistant, rapid biodegradable, low-cost, stable supporting medium with higher mechanical properties. The physical and functional features of PVA/ST blends can be improved by

adding various nanofillers like clay, graphene, cellulose nanocrystals, carbon nanotubes, halloysite, etc.

Hu et al. (2022) prepared polyvinyl alcohol/starch (PVA/ST) film filled with ZnO nanofillers (rod like) for food packaging. The stress-strain diagram for PVA/ST/ZnO nanocomposites is given in Fig. 1a–d. Tensile strength of virgin PVA/ST film is 15.6 MPa and elastic modulus around 114.7 MPa; for about 5 wt% of ZnO, the tensile strength of PVA/ST/ZnO composite was 22.9 MPa and elastic modulus was 182.6 MPa. About 46.8% rise in tensile strength and 59.2% rise in modulus of elasticity are observed as compared to neat PVA/ST composite. The nanocomposite films exhibit excellent water barrier performances, antibacterial activity against both *E. coli* and *S. aureus*, and outstanding UV-blocking ability. The nanocomposite films were found having application in active food packaging.

The physical properties of polyvinyl alcohol/starch blend composites can be improved by the incorporation of fillers such as graphene, biochar, and graphitic carbon nitride. Brittleness, flexibility, and processability of the composites can be improved by the addition of glycerol as a plasticizer in PVA/starch composites (Atta et al. 2021). The physical properties of polymers can be improved by adding graphene oxide (GO) as nanofiller, which consists of carbonyl, carboxyl, and

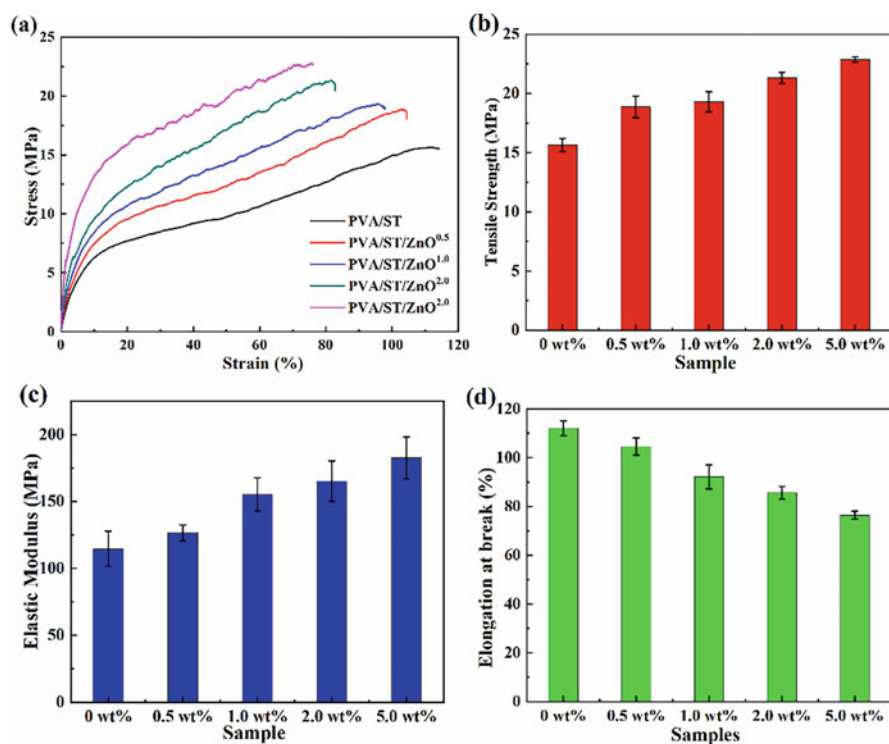

Fig. 1 (a) Stress–strain, (b) tensile strength, (c) elastic modulus, and (d) elongation at break for PVA/ST/ZnO nanocomposites (Hu et al. 2022)

epoxy functional groups. The presence of these functional groups helps in forming of strong bonds between GO and starch. On adding GO, an increase is observed in the tensile strength and moisture resistance of PVA/starch blend containing glycerol. Atta and coworkers (2021) successfully prepared PVA/starch/GO nanocomposite by solution casting technique and also studied the effect of various times of nitrogen plasma irradiation on nanocomposite. The plasma irradiation time has an influence on the thermal properties of nanocomposites and the results exhibited that the worst thermal stability of composites is observed after 10 min and best thermal stability is observed after 30 min. There is a decrease in storage modulus of unirradiated composites which is observed from 6.3 to 4.5 Mpa upon irradiation for 10 min and the storage modulus of nanocomposites enhanced to its maximum value after 30 min with further increasing exposure time.

Zhai and colleagues (2022) prepared starch/poly(butylene adipate co-terephthalate) PBAT films with silver nanoparticles (AgNPs) and zinc oxide nanoparticles (ZnONPs) by extrusion blowing method. They studied the physicochemical properties and antimicrobial activity of the films and found that the nanocomposite films containing silver and ZnO nanoparticles prevented the penetration of UV light. The addition of these nanoparticles increased the mechanical and barrier properties. SP-Ag(0.8)-ZnO (0.2) had the greatest inhibitory effect on *S. aureus* and *E. coli* because of the synergistic effect of silver and ZnO nanoparticles. Furthermore, initial packaging testing for nectarines and peaches revealed that the developed films possess excellent ability to prevent rot and maintain new product quality.

PLA-starch composites were prepared by Wang and coworkers (2020) using silanlated nano-TiO₂ (MTiO₂, 1% and 2%) and graphene oxide modified with maleic anhydride (f-GO, 0.1%, 0.2%, and 0.4%) at different combinations by solution blending technique. They investigated the collective effects of modified TiO₂/graphene oxide at various ratios on the structural characterization, morphology, thermal stability, crystallinity, and dynamic mechanical and antiaging properties. An obvious improvement in properties was observed in PLA-starch composites because of the better interfacial interaction and the collective effect from the combination of 1% MTiO₂ and 0.2% f-GO. The results showed that fabricated high-performance nanocomposites found application in food packaging. Solati et al. (2019) also studied the effect of graphene nanoplatelets on thermoplastic starch/poly(lactic acid) (TPS/PLA) blends and analyzed the compatibility, morphology, and crystallinity of the blend nanocomposites. SEM images were used to study the morphology of the blends and nanocomposites and found that the content of graphene sheets and blend composition determines the size of dispersed droplets (TPS). The DSC results showed that the addition of nanoparticles to the blend, cold crystallization temperature is decreased to zero and wetting coefficient values showed that the nanoplatelets were localized at the interface of PLA and TPS phases. From dynamic mechanical thermal analysis (DMTA), they found that the compatibility of PLA and TPS phases can be increased by adding about 1 wt% graphene nanoplatelets into the blend. Generally, the characteristic properties of thermoplastic starch/poly (lactic acid) blends can be improved by the addition of graphene nanoplatelets and are located at the interface

of the PLA and TPS phases. Also, the samples with graphene showed high percentage of crystallinity greater than TPS/PLA mixtures (Solati et al. 2019).

Manoel and colleagues (2022) extracted cellulose nanocrystals (CNCs) by acid hydrolysis and CNCs were incorporated into thermoplastic starch (TPS) phase mixed with poly(ϵ -caprolactone) (PCL) by higher shear rate corotating extrusion. About 3.25, 6.5, and 13 wt% CNCs were incorporated into TPS mass and only 3.25 wt% showed improvement in tensile strength by three times (12 MPa) and the elastic modulus by more than six times (1 GPa). The interactions between TPS molecules and CNCs with small concentration improved stability of the TPS/PCL nanocomposites ($\sim 250^\circ\text{C}$). Nanocellulose fibers obtained from sugar palm is used as reinforcement in TPS/PLA blend and investigated the thermal, mechanical, physical, and water barrier properties of nanocomposites from the group of Nazrin (2020). The morphology of the nanocomposites depends on TPS loading and the lower content leads to cracks and voids, while high content results in agglomeration. The prepared sample consists of 20%, 30%, 40%, 60%, and 80% TPS concentrations with constant palm nanocellulose fibers (0.5%). The Young's modulus of nanocomposites increased from 1.19–1.56 GPa up to 60% of TPS content and a decrease in the thermal stability is observed with increase in TPS loading.

The compatibility of hydrophilic starch with hydrophobic poly(lactic acid) (PLA) and poly(ϵ -caprolactone) (PCL) can be increased by adding polyhedral oligomeric silsesquioxane (POSS) nanoparticles. Oshani and coworkers (2019) studied the morphology, crystallinity, and thermal stability of nanocomposites and the results showed that 0.5 and 1 wt% POSS enhanced the compatibility of the system, while the higher contents of POSS resulted in the formation of aggregates. Transmission electron microscopy analysis showed that POSS is primarily localized within the PLA and PCL phases and PCL acts as an intermediate between PLA and starch. With a very low content of POSS of about 0.5 wt%, PLA's crystallinity increases from 22.9% to 31.6%, but the crystallinity of PCL is slightly hampered because of the formation of PLA crystallites. About 3 and 5 wt% of POSS increased the thermal stability of nanocomposites and good POSS dispersion within the matrix at lower contents is observed from the dynamic mechanical analysis.

A lot of research works were done in the field of PLA/TPS blend with different types of nanofillers. The addition of silica nanoparticles to PLA/TPS blend increased the elongation at break of the nanocomposites in the presence of maleated PLA (MPLA), which is hardened with polydimethylsiloxanol. Research works on nanoclays-incorporated PLA/TPS blends were reported and the presence of nanoclays improved the mechanical properties because of good adhesion between the two phases.

Cellulose-Based Blend Nanocomposites

Cellulose nanocrystals such as whiskers and nanospheres, nanofibers produced by electrospinning, cellulose nanofibrils, regenerated cellulose nanoparticles, etc. are the different cellulose-based nanomaterials. Cellulose nanowhiskers (BCNW)

obtained from bacteria is incorporated into gelatin-polyvinyl alcohol (GL/PVA) blend and analyzed the structural, mechanical, and water barrier properties (Haghighi et al. 2021). Needle-shaped BCNW with 7.5% content in GL/PVA blend showed decrease in water barrier properties and increase in mechanical properties. The developed blend composites were environmentally friendly and found application in packaging. Figure 2a shows the SEM images of the cross-section with compatibility and structural integrity between GL and PVA. A compact and repeated structure without air bubbles or pores with no phase separation is observed. Figure 2b–e showed the cross-section of films containing BCNW up to 7.5 wt% indicates homogeneous dispersion of BCNW and good miscibility of components. Figure 2f represents 10 wt% BCNW sponge-shaped and irregular structures because of poor interfacial bonding.

Polyvinyl alcohol (PVA) is a synthetic biopolymer which possesses significant tensile strength, nontoxicity, high crystallinity, and water solubility. PVA found applications in optical, biological, and electrical fields (Askary et al. 2022). Carboxymethyl cellulose (CMC) is a derivative of cellulose, nontoxic, biodegradable polymer. However, CMC possesses low chemical and physical properties and can be improved by blending. CMC/PVA blends nanocomposites with tungsten trioxide which were fabricated using laser ablation method and their optical, thermal, and electrical properties were studied (Askary et al. 2022). Thermal stability studies showed that nanocomposites exhibit higher stability with the addition of tungsten trioxide. Electrical property studies showed a decreasing trend in dielectric constant due to interaction between dipoles and applied field, but at high frequency constant values were obtained due to absence of interaction of dipoles.

Fig. 2 SEM images of films based on (a) gelatin-polyvinyl alcohol blend (GL/PVA), (b) GL/PVA/bacterial cellulose nanowhiskers (BCNW) 1%, (c) GL/PVA/BCNW 2.5%, (d) GL/PVA/BCNW 5%, (e) GL/PVA/BCNW 7.5%, and (f) GL/PVA/BCNW 10% (Haghighi et al. 2021)

Silver-doped hydroxyapatite nanoparticles were incorporated into polyvinyl alcohol (PVA)/carboxymethyl cellulose (CMC) and investigated the morphology, optical properties, dielectric constant, and antibacterial activity of blends (Nasrallah and Ibrahim 2022). The results showed that the antimicrobial and electrical conductivity of the blend composites improved with the addition of nanoparticles and it is found that it has application in infection control and wound dressing. L-alanine amino acid-modified CuO nanorods were used as nanofiller in PVA/CMC matrix and the mechanical properties were investigated (Amaregouda et al. 2022). The studies showed that the resultant composites with 8 wt% CuO-L-alanine showed improved tensile strength and highly enhanced water vapors barrier and UV shielding ability. These nanocomposite films found application in food packaging. PVA/CMC matrix with graphene nanoplates (GNPs)/MWCNTs were prepared and examined the electrical properties along with structural and optical properties (Abutalib and Rajeh 2022). The highest AC conductivity of nanocomposite film was 4.53×10^{-4} S/cm (30 °C) and the improved optical properties made them good materials for electrochemical applications. Sharma and colleagues (2021) prepared TiO₂ sols and blended with cellulose/PVA film and SEM images showed that TiO₂ particles were distributed homogeneously throughout the film. The prepared films were thermally stable with enhanced photocatalytic activity by showing the degradation of 98.10% methylene blue under sunlight within 120 min. CNCs were modified using PVAc and reinforced in poly(L-lactic acid) (PLLA) matrix by industrial melt compounding method (Wu et al. 2022). CNCs-PVAc with 5 wt% in PLLA improved notched impact toughness by 57.0% and inter-layer adhesion strength by 103%.

Perumal et al. (2018) isolated cellulose nanocrystals (CNC) from agricultural waste rice straw (RS) that acts as reinforcement in polyvinyl alcohol/chitosan (PVA/CS) used for the preparation of bionanocomposite films. They found that the tensile strength (98.15 MPa) and thermal stability of the bionanocomposite films increased with increase in weight percentage of CNC (1–5 wt%). PVA/CS/CNC blend nanocomposite films show excellent antifungal property and it has applications in food packaging. The dispersion of cellulose nanocrystals and interfacial adhesion in PLA matrix is enhanced by grafting of CNC with glycidyl methacrylate (GMA) and an emulsion of CNC in poly(vinyl acetate) (PVAc) is prepared (Pracella et al. 2014). The morphology analysis showed better dispersion of CNC in all types of composites and high thermal stability is observed for CNCs dispersed in PVAc. PVAc dispersed CNCs composites with weight percentages less than 5 wt% showed high mechanical properties.

Cellulose nanocrystals (CNC) is usually obtained from sugarcane bagasse and possesses low density (1.566 g cm^{-3}), high elastic modulus (150 Gpa), and specific surface area, which makes them a good candidate for polymer reinforcement agent (Mofokeng and Luyt 2015a). Chitosan (CS) is a biopolymer, derivative of chitin and a linear polysaccharide, that found its applications in the field of pharmaceuticals, materials science, etc. (Miri et al. 2015) prepared the bionanocomposite films based on CNC/PVA/CS and studied the structural, morphological, mechanical, and thermal properties. They found that with the addition of 5 wt% CNC into PVA/CS blend improved the 105% increase in Young's modulus, 77% in tensile strength, and 68%

in toughness. Studies on cellulose nanostructures obtained from bacteria used as reinforcement in gelatin-polyvinyl alcohol (GL/PVA) blend were also reported (Haghighi et al. 2021). Miri and colleagues (2015) also developed biopolymer blend based on carboxymethyl cellulose (CMC) and starch (ST) using CNC as nanofiller. The resultant blend nanocomposites showed good optical transparency (80–95%) with 94.77% increase in elastic modulus. The increase in properties is attributed to the hydrogen bonding interactions between the functional groups of mixed components present in the blend. The developed blend composites found application in the field of packaging.

Pectin-Based Blend Nanocomposites

Pectin is a natural, nontoxic, water-soluble polysaccharide with β -(1–4)-D-galacturonic acid with arabinose, rhamnose, and galactose. It is present in plant cell walls. The presence of free carboxyl groups in pectin solutions shows acidic pH values. It is suitable for the synthesis of bio-based food packaging films because of its biodegradability, film-forming ability, gelling ability, and biocompatibility. It is used as additive in beverage and food industry, and colloidal stabilizer or thickener in ice creams, jams, milk drinks, etc. Its cytocompatibility helps to find applications in drug delivery, wound dressing, and tissue engineering (Priyadarshi et al. 2021).

Cavallaro and coworkers (2013) prepared pectin/polyethylene glycol 20,000 (PEG) films with halloysite nanotubes (HNTs) and studied its crystallinity, tensile properties, water uptake, tensile properties, and thermal stability. The factors that depend on wettability of developed films are distribution and composition of HNT and the surface roughness of the material. The results showed that nanoclays help to improve the tensile properties and reduced PEG crystallinity, and can be maintained by the addition of pectin. The developed film found application in packaging. Roy et al. (Roy and Rhim 2021) prepared pectin/agar composite films which were reinforced with melanin nanoparticles (MNP) and grapefruit seed extract (GSE). The presence of MNP improved the mechanical property of the film, whereas the inclusion of MNP and GSE increased strength of the film. The developed films exhibit excellent antibacterial activity against foodborne pathogens and antioxidant activity with the addition of MNP and GSE. Figure 3 represents the thermal stability analysis of pectin/agar-based films. The moisture in the film was evaporated at 50–110 °C and the second weight loss at 130–250 °C. The maximum decomposition occurred at 220 °C due to breakdown of glycerol and final weight loss occurred at 250–350 °C because of the decomposition of pectin and agar. The thermal stability of composite film is not much affected by the addition of fillers.

Saha and colleagues (2016) prepared pectin (PEC)/methylcellulose (MC) blended with sodium montmorillonite (MMT) nanocomposites films and studied the mechanical, thermal, and moisture absorption properties. Nanocomposites with 3 wt% MMT showed better mechanical properties and water vapor permeability, suitable for packaging applications. But 1–5 wt% MMT showed better thermal stability, and time of drug release suitable for drug delivery applications. The effects of TiO₂

Fig. 3 (a) TGA and (b) DTG of pectin/agar-based bioactive composite films (Roy and Rhim 2021)

nanoparticles in starch-pectin edible films were studied and results showed that addition of low concentrations improved the moisture barrier and mechanical properties (Dash et al. 2019). The thermal stability of the composite films increased with increase in TiO_2 concentrations and the developed films found applications in food grade packaging.

Pectin and kappa-carrageenan biodegradable membranes were prepared with organically modified nanoclays using solution intercalation method and casting (Coelhoso et al. 2014). It is observed that about 10% of nanoclay decreased the water vapor permeability to 35% and 50% decrease in CO_2 permeability for 1% nanoclay; however, the increase in nanoclay content decreased the mechanical properties. Sodium alginate (SA) is an unbranched copolymer. In food, pharmaceutical, and medical fields it is used as film-forming agent and stabilizing thickener. SA/citrus pectin blends reinforced with nano- SiO_2 and the morphological, structural, and mechanical properties of the blend films were studied (Marangoni Júnior et al. 2022). The addition of 5% SiO_2 produced a significant improvement in barrier and mechanical properties (40.6 ± 4.5 Mpa) of films. The developed biopolymer nanocomposites were suitable for packaging. Biocomposites of hemicelluloses/pectin/nanocellulose were prepared and the effect of hemicellulose/pectin content from 0% to 100% with 25% nanocellulose on films was studied (Mugwagwa and Chimphango 2022). Pectin >50% biocomposites showed improved tensile strength and Young's modulus than hemicellulose-based biocomposites. The biopolymers exhibited slow release of antioxidant and are used for the packaging of fatty foods.

Gluten-Based Blend Nanocomposites

Gluten is the protein portion of the wheat. About 75–85% of dry weight of wheat is gluten and water insoluble. Gluten can be easily extracted from raw wheat, which consists of fat, carbohydrate, protein, and fiber. About more than hundreds of protein components are present in gluten.

Biodegradable nanocomposites films based on wheat gluten (WG), carboxymethyl cellulose (CMC), and cellulose nanofiber (CNF) were optimized using response surface methodology (RSM) (Bagheri et al. 2019). RSM method optimizes the response using various independent variables. It provides complete more accurate data with minimum number of experiments and optimizes the film formulation. The effect of WG, CMC, and CNF on color, water vapor permeability, and mechanical properties of the films were studied using RSM method. The experimental response values and predicted values were in good agreement with each other. The surface roughness of the film increases with CNF concentration and XRD results confirmed the amorphous nature of the films. Wheat gluten/carboxymethyl cellulose/cellulose nanofiber (WG/CMC/CNF) were prepared and investigated color and mechanical properties of nanocomposites using RSM (Bagheri et al. 2019). The results showed that there was good agreement between experimental response values and predicted values. The AFM results showed that surface roughness of samples increased with increase in the amount of CNF and XRD results confirmed the presence of amorphous nature of the films.

Baishya and colleagues (2018) prepared wood-starch-gluten nanocomposites and studied the morphological, mechanical, and thermal properties. Different ratios (70/30 and 50/50) of starch/wheat gluten blends were prepared and grafted with methylmethacrylate (MMA). To improve the properties of the blends modified TiO₂ nanoparticles were incorporated into the matrix and studied its effects on the properties of the composites. The morphological analysis showed that with 5 phr TiO₂ agglomeration of nanoparticles occurs and adversely affected the properties of the nanocomposites. Excellent mechanical properties as well as water and thermal resistance was observed for composites from 50/50 starch and gluten blend with 3 phr TiO₂.

Wheat-gluten/Cloisite 30B nanoclay-based composites were prepared by dispersing nanofiller into plasticized gluten via thermal processing (Zhang et al. 2007). The WG systems were strengthened by blending PVA with glyoxal cross-linking. The solid-state NMR study showed molecular-level distribution of polymer chain mobility and interactions between polymer and nanoparticles restricted the motion of all components in mobile phases. The nanoparticles had no significant influence in the mobility of the rigid phase. Wood starch gluten nanocomposites (WSGNC) were prepared by solution blending followed by compression molding and later TiO₂ nanoparticles were added to improve flammability and UV stability (Afnas et al. 2021). The results revealed that the presence of 3 phr TiO₂ in composites improved hardness and dimensional UV stability of the nanocomposites.

Gelatin-Based Blend Nanocomposites

Gelatin (GL) a mixture of polypeptide and protein, obtained from partial hydrolysis of collagen present in connective tissue, bone, and skin of various animals. It is abundant, low cost, and has no apparent color or flavor. GL films can prevent lipid and photo oxidation and act as good barrier to UV rays, light, and oxygen. These

properties improve the shelf life and quality of preservation of foods. However, poor water barrier as well as thermal and mechanical properties shorten the GL films food shelf life as compared to plastic films (Haghighi et al. 2021).

Afnas and coworkers (2021) successfully prepared PVA/gelatin/chitin blend and studied electrical, mechanical, water sorption, and antibacterial properties. The increase in chitin content produces an increase in electrical conductivity and possesses good antibacterial activity against gram-positive bacteria. The results of the study suggested that antimicrobial humidity sensors can be developed from blend nanocomposites. Roy et al. (Roy and Rhim 2022) developed sulfur nanoparticles (SNP) and incorporated them into gelatin/CNF composite films and used enoki mushroom extract for stabilizing SNP. The fabricated films exhibited UV protection and about 25% improvement in tensile strength. It also exhibited strong antibacterial activity toward bacteria and applicable for food packaging. The time-dependent antimicrobial activity of films toward *E. coli* and *L. monocytogenes* showed that there is no antibacterial activity observed for neat gelatin/CNF films; however, SNP filled films showed antibacterial action against both bacteria. The higher antibacterial activity of green SNP-based nanocomposite derived toward *L. monocytogenes* is due to the variation in cell wall construction and permeability.

A smart/active packaging materials based on gelatin/ κ -carrageenan with TiO_2 and anthocyanins were prepared by casting method (Sani et al. 2022). The moisture resistance as well as optical and mechanical properties of the composites were enhanced by TiO_2 and anthocyanins. The developed films were capable to inhibit oxidative reactions and great bacteriostatic properties. These biodegradable films can replace plastic packaging materials.

Gelatin/polyvinyl alcohol (GL/PVA) blended with bacterial cellulose nanowhiskers (BCNW) and the effect of BCNW on morphological, mechanical, and water barrier properties of the film was analyzed (Haghighi et al. 2021). Morphological results showed that with about 7.5 wt% BCNW there was good miscibility between GL/PVA and nanofiller. The concentration of BCNW up to 7.5% reduced water vapor permeability and increased the tensile strength (21.5%) and elastic modulus (19%). The GL/PVA/BCNW film was found useful in environmentally friendly packaging applications. Cellulose nanocrystals separated from water hyacinth fiber (WHF) were used for the preparation of PVA/gelatine/CNC composite films (Oyeoka et al. 2021). The addition of CNC improved the thermal stability and 5 wt% CNC provides maximum value of storage modulus (3 GPa). CNC incorporation decreased the water vapor permeability (WVP), moisture uptake, and water absorption. PVA/gelatine/CNC nanocomposites found application in food wrappers.

Gelatin-chitosan/MMT nanocomposites were prepared by electrospinning and morphology of the developed nanocomposites was studied (Habibi et al. 2019). The exfoliation of MMT layers in gelatin-chitosan matrix is observed from the XRD result and nanocomposites can act as great candidate in biomedical application. Poly (caprolactone) (PCL)/gelatin (GL) composites were blended with cellulose nanofibers (CNF) by electrospun (Moazzami Goudarzi et al. 2020). Different concentrations of CNF were incorporated into different PCL/GL ratio and studies showed that

the highest tensile strength is observed for P70/2CNF and maximum modulus is associated with P30/2CNF. GL blending and electrospinning decreased the crystallinity of PCL but the addition of CNF increased PCL/GL blends crystallinity. Cao and coworkers (2020) used catechol-modified chitosan (CSCT) for the reduction of Ag NPs and prepared CSCT/gelatin (G)/Ag NP film. The studies showed that the water vapor resistance and tensile strength of the composites increased by the presence of Ag NPs and G. The antibacterial activities of the chitosan (CS), CSCT, and CSCT/G/Ag NPs membranes against *S. aureus* and *E. coli* were shown in Fig. 4. The bactericidal rates of CS membrane against *S. aureus* and *E. coli* are 20.5% and 23.7%, respectively, because of electrostatic interaction between the negative charge present on microbial cells and positively charged CS. The presence of positively charged amino groups on CSCT causes antimicrobial activity. CSCT-Ag NPs showed higher bactericidal ratio which is due to greater antibacterial activity of the silver nanoparticles. The superior antibacterial activity of silver nanoparticles against gram-negative bacteria is because of decrease in the anchoring sites on the bacterial cell wall as a result of rigid structure of polysaccharide chain.

Studies on chitosan/gelatin films with tannic acid/bacterial nanocellulose were reported and are applicable for wound healing purpose (Taheri et al. 2020). Aldehyde-modified carrageenan/gelatin/halloysite nanotubes (AD-Carr/Gel/HNTs) nontoxic composites were prepared and act as a good candidate for tissue engineering purposes (Akrami-Hasan-Kohal et al. 2020). Low cost, biologically safe PVA/gelatin/0.01 CuO nanocomposites can absorb various UV subtypes and used for UV shielding applications (Ebnalwaled and Ismaiel 2019). These nanocomposites also found applications in γ -ray sensors and optical communications.

Fig. 4 Bactericidal ratios of CS, CSCT, and CSCT/G/Ag NP films (Cao et al. 2020)

Soy Protein–Based Blend Nanocomposites

Soy protein isolate (SPI), a by-product obtained from soybean oil industry, is abundant, low cost, and possesses film-forming property. It consists of 90% pure protein and tough substance. However, SPI films possess some drawbacks such as high water sensitivity, low mechanical strength, and poor thermal and barrier properties. Due to these drawbacks its application is limited in packaging industry (Xiao et al. 2020).

Sasmal and coworkers (2009) prepared maleated polycaprolactone/soy protein/clay-based eco-friendly bionanocomposites and studied the tensile and dynamic mechanical properties. Tensile strength and storage modulus of the nanocomposites are higher for clay-based nanocomposites. The biodegradability studies of the nanocomposites showed that increase clay content decreases the degradation time. The water absorption rate of nanocomposites with a rapid increase is observed in first 50 h and reaches equilibrium. A decrease in equilibrium water uptake and diffusion coefficient is due to (1) better interaction between groups on MMT nanolayer and amide groups on SPI and (2) large number of physical cross-linking formed by strong hydrogen bonding, limit swelling, and low water absorption.

Polycaprolactone (PCL)/soy protein isolate (SPI)/organoclay composites were prepared and morphology studies revealed that silicate layers were homogeneously dispersed at nanometer range (Nayak et al. 2008). The dynamic mechanical and tensile properties of the nanocomposites showed remarkable enhancement because of stiffening effect of nanoclay. Montmorillonite (MMT) was used as nanofiller in soy protein isolate (SPI)/polyvinyl alcohol (PVA) blends and the results concluded that MMT content had significant effect on the structure of composites (Guo et al. 2019). Due to the better reinforcing effect between MMT and polymers Young's modulus, tensile strength of the composites increased with rise in MMT content. Thermal stability of the composites improved, while the water sensitivity decreased because of the restriction of MMT lamellae on polymer segment. The developed nanocomposite found application as green packaging films.

Mansoori and colleagues (2019) prepared corn starch (CS)/soy protein isolate (SPI) blended with graphene (G) and graphene oxide (GO). They investigated the effects of G and GO in mechanical and physical properties of nanocomposite films. The modulus of 0.5 wt% G showed 578 Mpa while 2 wt% GO showed 449 Mpa. CS/SPI/GO (2 wt %) are thermally stable than pure starch/protein composite and exhibits lowest oxygen permeation rate. The addition of polyvinyl alcohol (PVA), 1,2,3-propanetriol-diglycidyl-ether (PTGE), and halloysite nanotubes (HNTs) into SPI matrix resulted in the formation of nanocomposite films (Liu et al. 2017). About 329.3% increase in tensile strength and 5.1% decrease in water absorption properties is observed. The green and transparent film can replace nonrenewable films in packaging.

Poly-Lactic Acid (PLA) Blend Polymer Nanocomposites

Polylactic acid (PLA) is a biopolymer derived from plants and it can be prepared synthetically by direct polycondensation and ring-opening polymerization (ROP) of lactide. PLA is biocompatible and biodegradable that degrades into water and carbon

dioxide but the properties like poor processability, slow crystallization rate, and vulnerable to aging have limited its applications in food packaging. The low degradation rate of PLA can be overcome by blending it with other biopolymers (with higher degradation rates).

D'Anna and colleagues (2022) studied the influence of process parameters on the microstructure and properties of PLA/PHB/clay blend nanocomposites. The crystallinity content of PLA (+25%) is increased by the nucleating action of clay nanofillers that are localized at the interface between PLA and PHB. They found that the thermomechanical properties of clay-filled blends processed through screw profiles 1 and 3 show 20% improvement in modulus due to the reinforcing effect of the clay. While in the case of blend processed through screw profile 2 only 9% increase in modulus is observed. The developed PLA/PHB/clay blend nanocomposites found potential applications in rigid packaging, personal care and cosmetic products, and toys.

Multifunctionalized graphene oxide was added to poly(lactide)-starch matrix by Wang et al. (2019) using solution casting method. For this study they used graphene oxide (GO) grafted with maleic anhydride and subsequently modified by dodecyl amine and analyzed morphology, crystallization property, dynamic mechanical properties, aging resistance, and surface wettability of the nanocomposite. The prepared f-GO-reinforced nanocomposites showed significant improvements in thermal stability, storage modulus, UV shielding capacity, surface hydrophobicity, and aging resistance properties.

The effect of TiO_2 nanoparticles on melt-mixed poly(lactic acid) (PLA)/poly(ϵ -caprolactone) (PCL) blend nanocomposites was studied by Mofokeng and coworkers (Mofokeng and Luyt 2015b). They give importance to the morphology and thermal stability analysis of blend nanocomposites. The morphology studies showed that the nanoparticles were localized in the PLA phase of the PLA/PCL blends, because of the larger affinity between PLA and TiO_2 due to slight difference in relative polarities between them. TGA analysis showed that the thermal stabilities of both polymers in the blends increased due to the presence of TiO_2 nanoparticles. The titania nanoparticles also affect the evaporation of degradation products from the blend by acting as degradation catalyst or prevent the escape of volatile degradation products.

Poly(lactic acid)/chitosan/functionalized graphene nanoplatelet PLA/CS/FGNP blend nanocomposites were successfully prepared by Paydayesh et al. (2022). The morphological, mechanical, and electrical conductivity and biodegradability of blend nanocomposites were investigated. The finest morphology of blend nanocomposites is observed with 3 phr FGNP (PLA75/CS25/FGNP3) with narrowest size distribution. Blend nanocomposites with 3 phr FGNP shows approximately 142% increase in tensile strength and 261% increase in Young's modulus with improvement in thermal stability. Moreover, in the case of electrical conductivity, there is a good agreement between the experimental data and model predictions. The electrical conductivity of PLA/CS/FGNP blend increases from 10^{-12} to 2.42 S/cm and threshold value was 0.48 vol%.

The cellulose nanocrystals (CNC) obtained from bamboo fiber can be used as filler in (PLA)/poly (butylene succinate) (PBS) composites. Rasheed and colleagues (2021) studied the physiochemical, morphological, thermal, and crystalline properties and tensile properties of the composites prepared via melt mixing followed by hot pressing. The morphological results showed that rod-like CNC particles are embedded in the homogeneous PLA-PBS blend and 1 wt% of CNC exhibited top value of tensile strength, tensile modulus, and thermal stability. PLA-PBS/CNC polymer blend found applications in packaging. The toughness of PLA can be boosted with epoxidized natural rubber (ENR) and nano-SiO₂ (Boonmahitthisud et al. 2021). In this work, 30 mol% epoxidation of ENR was synthesized and melt-mixed with PLA by changing weight percentages of ENR. The 80/20 PLA/ENR-30 composite showed better mechanical properties and selected for the preparation of SiO₂-filled nanocomposites. The distribution of SiO₂ is observed in the ENR-30 phase and not in PLA phase with improved thermal stability and decrease in mechanical property.

Polyhydroxybutyrate (PHB) Blend Polymer Nanocomposites

Polyhydroxybutyrate (PHB) is biocompatible, nontoxic, and hydrophobic material which can be synthesized biologically or chemically. PHB-based composites found applications in various fields like agriculture, health, bioremediation, and food packaging (Moreira et al. 2022). Tensile yield strength of PHB is found to be <10 MPa and the elongation at break is observed to be ~5%. Due to these low-value commercial applications of PHB, it is limited and can be improved by adding a variety of additives.

Cinnamaldehyde (Ci) was incorporated into PLA/PHB blends PLA/PHB/GO bionanocomposites using supercritical CO₂ and results showed that GO maintains thermal stability of PLA film while PHB decreases degradation temperature of PLA (Villegas et al. 2021). More flexible materials with 16% of increase in elongation percentage were observed and the bionanocomposites found application in drug delivery platforms. Poly(propylene carbonate) (PPC)/PHB bionanocomposites were blended with CNC 18 times and increase in oxygen barrier properties increases with 1 wt% CNC. The developed PPC/PHB/CNC nanocomposites can be used as degradable material for food packaging (Jiang et al. 2020).

PHB/thermoplastic starch (TPS) bionanocomposites were reinforced with montmorillonite clay using melt-blending and the mechanical and thermal properties were investigated (Garrido-Miranda et al. 2017). The studies showed that degree of crystallinity decreased with increase in amount of clay without significant change in thermal properties. About 22% increase in elastic modulus was observed when the amount of organically modified montmorillonite (OMMT) is 5%. The effect of Ag and Cu nanoparticles on properties of PLA and PHB blend were reported and resultant nanocomposites showed significant improvement in tensile properties (Cárdenas-Triviño et al. 2019).

TGA tests of PLA/PHB and PLA/PHB/nanoparticle (NP) mixtures show two decomposition temperatures except PLA/PHB in 70/30 ratio due to miscibility. PHB/PCL blends reinforced with Fe_3O_4 and CNFs and the mechanical properties and shape-memory performance of 3D-printed products were investigated (Yue et al. 2021a). The addition of Fe_3O_4 causes an increase in tensile strength of PHB/PCL blend while 10 wt% Fe_3O_4 and 0.5 wt% CNFs affected the strength and toughness of PHB/PCL blend. The optimum mechanical and shape-memory properties were exhibited by PHB/PCL blends in the ratio 80:20 with 0.5 wt% CNFs and 10 wt% Fe_3O_4 . The key thermodynamic parameters help in shaping memory behavior and measuring storage modulus and glass transition temperature (T_g). Figure 5 represents the storage modulus and $\tan \delta$ with temperature and E' curve that shows three areas, the glassy state ($>45^\circ\text{C}$), glass transition state ($45\text{--}65^\circ\text{C}$), and the rubbery state (above 65°C). A high value of E' is observed in PHB/PCL matrix when there is an increase in Fe_3O_4 content. In composites with Fe_3O_4 , JF20% shows E' value of 6436 MPa, higher than composites without Fe_3O_4 , because of increase in interaction between Fe_3O_4 and matrix. Figure 5c shows addition of rigid CNFs has little effect on E' of JF10% sample due to decrease in molecular chain entanglement. Fe_3O_4 increases the T_g because of the strong interaction between Fe_3O_4 and the matrix

Fig. 5 E' (a and c) and $\tan \delta$ (b and d) of composites with different Fe_3O_4 and CNFs contents (Yue et al. 2021a)

(Fig. 5b) and CNFs have little effect on the T_g with 10 wt% Fe_3O_4 because small amount of CNFs has no influence in polymer chain mobility.

Yue and coworkers (2021b) also studied the effect of CNFs in PHB/PCL composites and found that 1 wt% CNF in 80:20 PHB/PCL composites exhibited the excellent mechanical and shape-memory properties. The synthesized PHB80/PCL20/CNFs nanocomposites found applications in bone tissue implants, smart robotics, four-dimensional (4D) printing, and expandable structures. The PLA/PHB/CNF blend improves the mechanical properties of PHB due to good interaction between CNF and polymers (Aydemir and Gardner 2020). DSC results showed that PLA improved thermal stability but CNF does not produce change in thermal stability of the composites. The mechanical properties of PHB can be improved by PLA and CNCs from sugarcane with a green plasticizer, epoxidized canola oil (eCO) (Lopera-Valle et al. 2019). The blending of PHB and PLA was improved by adding zinc acetate. The results showed that PLA (25 wt%) and CNCs at low concentration improved the Young's modulus while eCO (10 wt%) leads to an increase in strain at break.

Arrieta and coworkers (2014a) prepared nanocomposites PLA/PHB blends with CNC or surfactant-modified CNCs and found that CNCs improved the thermal stability, Young modulus, and elongation at break. The prepared nanocomposites opened a new perspective for food packaging application for short-term period. In another work reported by Arrieta (Arrieta et al. 2014b), surfactant-modified CNC for the preparation of nanocomposites with PLA/PHB blends was used and the morphology and thermal stability were investigated. The nucleation effect of PHB increased the crystallinity of PLA and well-dispersed nanofillers increased the thermal stability and interaction between PLA and PHB. Studies based on 15 wt% of acetyl(tributylcitrate) (ATBC) plasticized PLA-based PLA-PHB-ATBC with CNC or surfactant-modified CNCs bionanocomposite films were also reported from the group of Arrieta (Arrieta et al. 2015). Better results were observed for composites with modified CNCs due to synergic effect of plasticizer and nanofiller. In another work from (Arrieta et al. 2016), biodegradable nanocomposites were developed by electrospinning PLA with PHB and plasticized with 15 wt% ATBC and reinforced with CNC. They studied the morphological, mechanical, and thermal properties of the electrospun bionanocomposites. The results showed that ATBC decreased T_g and improved elongation at break, and CNC enhanced the thermal and mechanical properties with 1 wt% of CNC-filled bionanocomposites.

Vermiculite (VMT) is a type of silicate used for nanocomposite production and is hydrophilic in nature. Blends based on PHB/PP-g-MA (polypropylene grafted with maleic anhydride) and PHB/PP-g-MA/vermiculite nanocomposites were prepared by melt intercalation method and then compression molded (de Mesquita et al. 2016). The thermal behavior of blends and bionanocomposites showed that onset degradation temperature and T_m (melting temperature) get decreased. The decrease is high for bionanocomposites due to the interactions between clay and the maleic anhydride groups. The interactions helpful for biodegradation makes the system more amorphous and favors microbial attack.

Polycaprolactone Blend Nanocomposites

Polyhedral oligomeric silsesquioxane functionalized with glycidylisobutyl (G-POSS) is used as a filler in polycaprolactone/polypropylene carbonate ((PCL/PPC) blends and the shape memory properties along with morphological and mechanical properties were investigated (Kamyab et al. 2021). Scanning electron microscopy results of blends showed droplet-matrix morphology and it changed to co-continuous one with the addition of nanoparticles. The nanoparticle content and polymers mixing ratio affect the shape memory properties and optimum properties were observed for 20/80 PCL/PPC ratio with 5 wt% G-POSS. Studies on the effect of POSS on thermal stability and crystallization of PLA/PCL blends were reported (Moeinifar et al. 2020). The crystallization of blends was studied using differential scanning calorimetry (DSC) and the results showed that the solution crystallization of PLA is suppressed at low concentrations of POSS. The decrease is due to the better interaction between PLA and PCL. A higher degree of crystallinity is observed at concentration of POSS because of the nucleating effect of the nanoparticles. From TGA studies, it is found that the increase in thermal stability is observed for composites with low POSS content. The high content of POSS decreased the thermal stability and the reason for the increase or decrease in thermal stability is the decreased compatibility between PLA and POSS.

Layered silicate/starch polycaprolactone blends were prepared using three different clays and the mechanical properties of the composites were studied (Pérez et al. 2007). X-ray diffraction studies showed that clays were intercalated within the matrix and mechanical properties improved with increase in clay content. The greatest compatibility of Cloisite 10A with the matrix makes them to achieve best properties among other clay-based composites. They have also studied the water uptake behavior of composites and the results revealed that water absorption decreases with increase in content of clay (Pérez et al. 2008). The decrease in mean free path of water molecule leads to decrease in water absorption.

PHB/PCL/stearate Mg-Al layered double hydroxide (LDH) blends were prepared by Liao and colleagues (2014) and the structural, morphological, and mechanical properties were analyzed. XRD analysis showed that low filler concentration results in exfoliated nanocomposites. Transmission electron microscopy (TEM) images indicated the homogeneous distribution of LDH layers in the PHB/PCL blend. With 1 wt% nanofiller filled blends showed 66% enhancement in tensile strength than PHB/PCL blends. PCL/TPS (thermoplastic starch) and PCL/PCL-g-MA (anhydride-functional polycaprolactone)/TPS blends reinforced with natural montmorillonite and organomodified montmorillonite was fabricated by Guarás et al. (2016). XRD results showed the intercalated structure of nanoclays in the matrices and modified clays showed higher dispersion. There was no significant change in the thermal stability of pure PCL and TPS with addition of clay or TPS/PCL compatibilization. The Young's modulus increased with the addition of nanoclays, while a decrease is observed in the water adsorption of the compatibilized matrix.

Vinyl functionalized graphene (VGN) acts as an efficient compatibilizer for PLA/PCL blends that resulted in mechanically strong nanocomposites (Wang et al.

2022). It was observed that with 0.5, 1.0, and 2.0 wt% of VGN, a decrease in the phase size of co-continuous PLA/PCL blends with increase in tensile strength by 200%, 280%, and 253%, respectively.

Tubular bionanocomposite blends of PCL/PGS filled with nanoclay or GO (graphene oxide) were prepared successfully and the dynamic morphological, mechanical, and thermal properties (Davoodi et al. 2022) were studied. FESEM results revealed the droplet-matrix morphology throughout PCL/PGS blend and nanoparticles in ordered porous zones in PCL/PGS blend. Addition of GO increases the storage modulus and Tg from -25°C to -17°C of the PCL/PGS blend.

Polyhydroxybutyrate Valerate Blend Nanocomposites

Poly(hydroxybutyrate-co-valerate)/poly(ϵ -caprolactone) (PHBV/PCL) blends filled with TiO_2 nanoparticles were prepared and the morphology and thermal stability were investigated (Mofokeng and Luyt 2015c). The morphology analysis showed that the nanoparticles were dispersed well in PHBV/PCL blend with co-continuous morphology. Thermally stable PCL improved the thermal stability of PHBV but PHBV makes decrease the thermal stability of PCL. The improvement in thermal stabilities of PHBV and PCL in blend was observed only with 1 wt% of TiO_2 . Another work reported in PLA/PHBV/ TiO_2 nanocomposites analyzed the morphology, mechanical properties, and crystallization behavior (Gasmi et al. 2019). The increase in PLA content showed some uncommon morphology such as isothermal crystallization, which complicated the crystallization kinetics of the samples. The tensile properties of nanocomposite depend on blend and nanocomposite composition, which in turn relates to morphology. Zhao and coworkers (2013) prepared PLA/PHBV blends and PLA/PHBV/clay nanocomposites. PLA/PHBV/clay nanocomposites exhibited high melting strength and modulus than PLA/PHBV and nanoclay raises the cell density and decreased the average cell size of microcellular blend. The crystallinity of PHBV is improved due to the nucleating action of nanoclay. The addition of nanoclay improved Young's modulus of blends, but there is no improvement for the tensile strength.

Chitin nanowhisker filled PLA and PLA/PHBV blended nanocomposites and the corresponding nanocomposite foams were prepared by Guan et al. (Guan and Naguib 2014). They developed solid nanocomposites by melt blending and porous nanocomposite foams by batch foaming process using CO_2 as blowing agent. The results revealed that chitin nanowhiskers less than 2 wt% improved the mechanical properties of solid nanocomposites. PHBV/PBS blends with different ratios (80/20, 50/50, and 20/80 w/w) were reinforced with halloysite nanotubes (HNT) and the morphological and thermal properties of the blend nanocomposites were studied (Kennouche et al. 2016). Morphological studies showed that the dispersion of PBS in PHBV/PBS 80/20 blends was improved due to the diffusion and emulsifying effect of maleic anhydride-grafted PHBV. Addition of HNT in the blends improved fire reaction, decreased thermal stability, but the presence of PHBV-g-MA balances the two effects.

Applications of Biopolymers-Based Blend Nanocomposites

With the growing consumer concerns about the environmental impact of modern food packaging system, there has been great importance given to environmentally friendly packaging materials. Starch-based biopolymer blend nanocomposites with different nanofillers like ZnO, silver nanoparticle, TiO₂, etc. were used as packaging materials (Hu et al. 2022; Wang et al. 2020; Zhai et al. 2022). PVA/elatine/chitin ternary blend composites were identified for developing humidity-sensing user-friendly materials (Afnas et al. 2021). Anthocyanin-loaded gelatin/κ-carrageenan films reinforced with TiO₂ nanoparticles found application as smart and active packaging materials (Sani et al. 2022). Gelatin/polyvinyl alcohol filled with bacterial cellulose nanowhiskers was also used for food packaging applications (Haghighi et al. 2021). Chitosan/gelatin/tannic acid/bacterial nanocellulose films found application in wound healing purpose (Taheri et al. 2020). Carrageenan/gelatin/halloysite-based nanocomposite is used for tissue engineering applications (Akrami-Hasan-Kohal et al. 2020). Soy protein isolate-based nanocomposite containing cellulose nanocrystals and zinc oxide nanoparticles films is used for pork preservation (Xiao et al. 2020). PLA-PHB blends filled with functionalized CNCs can be used as short-term food packaging in industry (Arrieta et al. 2014b). Functionalized graphene oxide/poly(lactide)/starch nanocomposites pave the way for the development of nanohybrids in food packaging and pharmaceutical industries (Wang et al. 2019). Nanocomposite films based on PLA/PHB/cellulose nanocrystal are best for food packaging industry (Arrieta et al. 2014b). Composites based on polylactide/thermoplastic starch/nanosilica were found as good for applications in electronics materials, tissue engineering, disposable goods, surgical sutures, and drug delivery. Aldehyde-modified kappacarrageenan/gelatin blend modified with halloysite nanotubes act as good candidate for biomedical applications (Akrami-Hasan-Kohal et al. 2020).

Conclusion

The studies on the properties of biobased blend nanocomposites for the development of novel materials with specialized properties depend on the nature of nanofillers and method of synthesis. The incorporation of functionalized nanofiller into biopolymer blends decreases the agglomeration and water absorption properties while the mechanical, thermal, and electrical properties of the blends increase. The improvement in properties is due to the interfacial interactions of the groups such as carboxyl and hydroxyl present in the polymer matrix with nanofiller. The selection process of the combinations of biopolymer blends and nanofillers for the synthesis composites followed without a well-established scientific principle and as a result some composites exhibit excellent physicochemical properties and reinforcement effects. On considering the cost, availability, processing methods, and applications in various fields, there have been more chances for success in commercialization of biopolymer-based blend nanocomposites. More research is essential for utilizing various nanoparticles for producing new blend nanocomposites with improved properties.

Abstract

Biopolymers contribute from naturally occurring as well as synthesized formats. This chapter exemplifies the significant nature of biopolymers, which originated from various sources such as plants, microbial, algae, animal, or botanical sources. These biopolymers are manufactured into electrospun fibers and membranes via multiple techniques. The processing parameters and ensuing fibers were characterized by many sophisticated analytical, microscopic, and spectroscopic methods. The numerous applications of membranes and fibers were also

Introduction

Biopolymers are classes of materials originating from natural resources or biosynthesized materials obtained from living organisms or chemical derivatives of biological materials. These materials, which are nontoxic, biodegradable, and economically feasible, have a wide range of potential uses in the sectors of electronics, medical devices, energy, food packaging, and the environment. The biopolymers are classified according to their sources and presented in Fig. 1. Biopolymers are a diverse group of materials obtained from biological sources, including trees/plants, animals, and microbes, and also involve materials chemically synthesized from biological sources like sugars, oils, proteins, fats, exudates, and resins (Venkateshaiah et al. 2020).

Biopolymers have several unique characteristics, including renewability, natural abundance, low cost, unique structures, nontoxicity, biodegradability, noncarcinogenic,

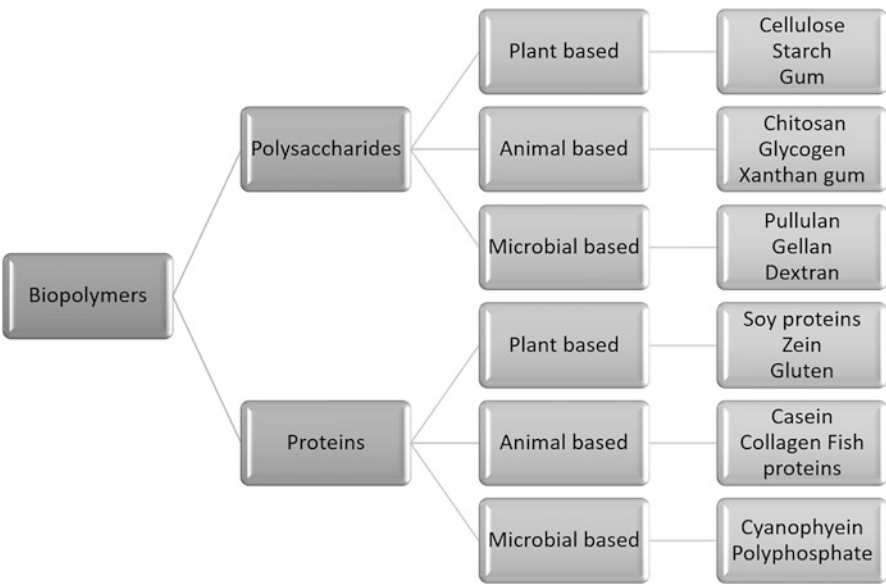

Fig. 1 Classification of biopolymers

nonthrombogenic, and biocompatibility, and are carbon neutral (Gheorghita et al. 2021). Nature-derived biopolymers, in contrast to conventional polymers with a simpler structure, have a broad range of structural complexity, which are frequently dependent on several factors such as the species, source, technique of extraction, and the age of the plant. However, the commercialization of these natural polymers is hindered by economic and engineering constraints. Nevertheless, due to their versatility, abundance, and low cost, biopolymers hold tremendous potential to replace petroleum-based conventional polymers in various applications, including packaging, biomedical, textile, structural materials, cosmetics, drug delivery, and food technology.

Biopolymers are classified using various criteria in the literature; however, they may be roughly classified into natural and synthetic biopolymers. Natural biopolymers are those that are acquired directly from nature while synthetic biopolymers are those that involve human intervention and chemical synthesis techniques to obtain the polymers. Natural biopolymers extracted from biomass can be further subclassified as polysaccharides, proteins, and lipids. Polysaccharides are the most abundant and diverse group of biopolymers available on the planet and are an essential component that performs various biological functions including communication between the cells, molecular recognition, and cell adhesion (Mohammed et al. 2021). These are complex carbohydrate polymers composed of monosaccharide units connected through glycosidic linkages forming linear or branched chain molecules of various lengths. They are either glycosidically connected sugar residues or covalently bound to other structures such as amino acids, peptides, and lipids. The physical and chemical characteristics of the polysaccharides are influenced by the monosaccharide unit type, chain configuration, molecular weight, branching, type of linkages, and its anomeric configuration (Mohammed et al. 2021). The most common polysaccharides obtained from biomass are cellulose, starch, chitin/chitosan, and gums.

The various fabrication techniques have been developed such as microextrusion, microfluidic spinning, and electrospinning (conventional, dry, and wet) to produce fibers and membranes. The ensued fibers showed various kinds of applications with respect to their fiber diameter and morphology.

Nanofibers: Preparation Techniques and Properties

During the last few decades, natural nanofibers (NFs) have shown outstanding performance in various applications, including energy, environment, water purification, sensor technology, tissue engineering scaffolds, wound dressings, drug delivery, healthcare, etc. (Wang et al. 2023; Jain et al. 2020). Electrospinning is one of the most effective and sophisticated methods for the large-scale production of nanofibers with a high surface area, consistent porosity, and high efficiency. The literature has extensively reported the electrospinning process parameters, such as system and process variable requirements. This method creates flexible, nano- to microscale fibers with a high surface-to-volume ratio, different sizes and geometries, and high membrane porosity (Jain et al. 2020). In this chapter, the multiple biopolymers outlined in Fig. 1 and their engineering variables that influence the morphology of

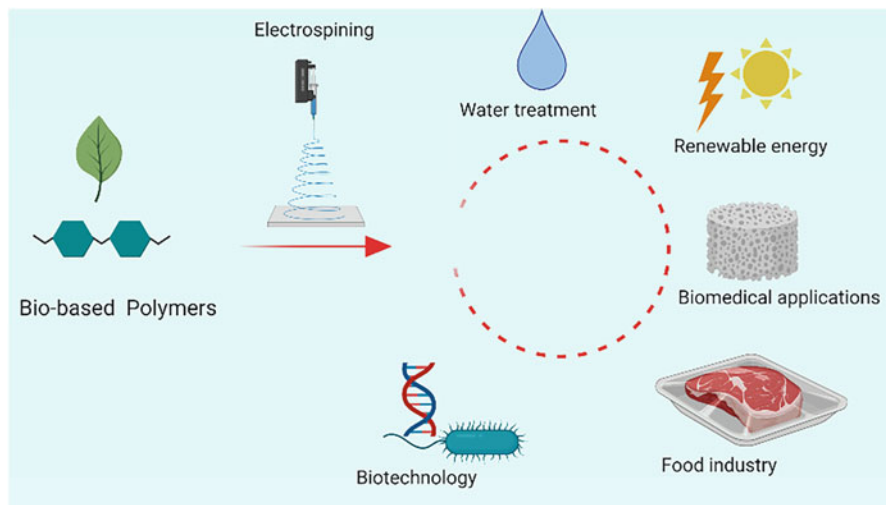

Fig. 2 Biopolymer-based electrospun fibers, membranes, and their applications. (Reproduced with permission from Ref. (Akshay Kumar et al. 2021))

nanofibers or membranes, systems, and processing parameters, and the effect of solvents' applications (outlined in Fig. 2) and other various types of electrospinning techniques have been discussed.

Nanofibers Based on Cellulose

Cellulose extracted from plants is profusely available on the earth. Cellulose, one of the abundant earth's materials, is a renewable product with exceptional qualities like worthier physical robustness, biocompatibility, and excellent environmental credentials. It has tremendous potential for industrial, pharmaceutical, environmental, and medical applications (Wei et al. 2014; Credou and Berthelot 2014). The important structural links in cellulose are represented by $-(1-4)\text{-D-glucopyranosyl}$ residues, and the molecule's β -sheet symmetry harbors intra- and intermolecular hydrogen bonds (Klemm et al. 2005). High-crystalline native cellulose is insoluble in aqueous and common organic solvents (Moon et al. 2011). Cellulose is derived mainly from plant materials, viz., wood pulp, disintegrating wood chips, cotton, cotton linter, and other fiber pulps courtesy of photosynthesis. In contrast, other sources, e.g., animals, algae, fungi, bacteria, invertebrates, and amoeba, also generate cellulose (Valencia et al. 2019; Eyley and Thielemans 2014; Prakash Menon et al. 2017). They can be used to make paper, casing, sanitary items, rayon, cellophane derivatives, textile materials, additives, medicinal fabrics, and various other things (Hon 1994; Lejeune and Deprez 2010; Barhoum et al. 2017).

Electrospinning is the most promising method to generate cellulose nanofibers (Fig. 3).

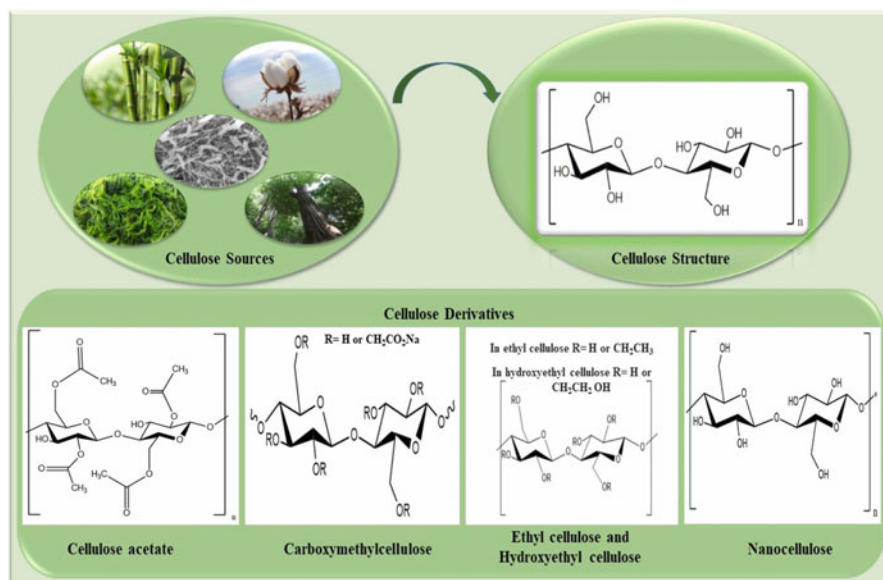

Fig. 3 The various sources of cellulose and their derivatives with formed structural attributes. (Reprinted from the permission from Ref. (Marques-Marinho and Vianna-Soares 2013; Mahsa Janmohammadi et al. 2023))

To create the corresponding nanofibers, many natural polymers rely on a “top-down” approach. Natural polymers are exposed to acid or alkali treatment to cleave the noncrystalline portions in their structures to achieve high solubility and homogeneity in diverse solvents. Furthermore, the smooth electrospinning of natural polysaccharides is skeptically influenced by variables including high solution viscosity, inter/intramolecular hydrogen bonding, gelling behavior, and peculiar rheological features (Moon et al. 2011; Wen et al. 2017).

Various physical, chemical, biological, and oxidative techniques are frequently employed to create cellulose nanofibers. The available approaches used to produce the appropriate cellulose nanofibers include ultracentrifugation, high-speed homogenization, ultrasonication, acid/alkali digestion, enzymatic degradation, and (2,2,6,6-tetramethyl piperidine-1-yl)oxyl radical (TEMPO) oxidation (Kousaku 2015). Cellulose extracted from bacteria and plant systems has also been successfully transformed into cellulose fibers (Prakash Menon et al. 2017; Eichhorn et al. 2010; Chirayil et al. 2014).

There are many methods to prepare the cellulose composite membranes, such as alkali treatment, polymerization, isocyanate grafting, acetylation, dewaxing, and periodate treatment (Zhang et al. 2022a) (Fig. 4).

The various methods used and their processing parameters and applications of cellulose-based nanofibers and membranes are deliberated in Table 1.

Fig. 4 Cellulose composite membrane preparation methods. (Reproduced with permission from Ref. (Zhang et al. 2022a))

Starch-Based Nanofibers and Membranes

Starch, generated as a storage material in most higher plant species, has been widely used in food and nonfood applications. It comprises complex polysaccharides – amylose and amylopectin – having α -D-glucopyranosyl (α -D-Glcp) units. The amylase-to-amylopectin ratios in starches vary depending on their source. Glycosyl residues [α -(1 \rightarrow 4) links in amylose and (1 \rightarrow 4)-linked α -D-Glcp units, as well as a high number of branch points α -(1 \rightarrow 6) connected in amylopectin], are found in wheat, corn, grain, potato, sugarcane, cassava flour, rye, barley, and oats (Dziedzic and Kearsley 1995; Xie et al. 2013; Li et al. 2014; Ambigaipalan et al. 2011; Stephen et al. 2006). Aside from dietary uses, starch and its chemical derivatives with carboxyl, acetyl, and hydroxypropyl functional groups produced via cross-linking, grafting, and esterification have received a great deal of attention in the environmental and biomedical applications (Moad 2011; Chen et al. 2015; Ashogbon and Akintayo 2014; Tharanathan 2005). Recently, a detailed review on the chemical derivatives of starch, particularly etherification and esterification, was published (Gilet et al. 2018; Meli et al. 2010).

The literature and patented technologies have documented the electrospinning of starch and its derivatives (Liu et al. 2017; Hemamalini and Giri Dev 2018; Woranuch et al. 2017; BeMiller and Whistler 2009). Polymers' diverse nonstarch materials, copolymers, (such as polycaprolactone (Jukola et al. 2008) polylactic acid (Sunthornvarabhas et al. 2011)), plasticizers, and cross-linkers blended with starch were successfully electrospun into fibers. The prerequisite for electrospinning is that the

polymer concentration be double that of the entanglement concentration for efficient electrospinning (McKee et al. 2004).

The method of developing electrospinning solutions by dissolving high amylose content starch (15% w/w) in a 95% aqueous DMSO solution (Kong and Ziegler 2014a) outperformed electrospinning starch with inclusion complexes (for example, palmitic acid) in ethanol or ethanol/water systems (Kong and Ziegler 2014b). Using DMSO as the solvent, Kong et al. (Kong and Ziegler 2012) assessed molecular entanglement, conformation, and shear viscosity, all of which are crucial factors in starch electrospinning. The results suggested that the starch concentration needs to be higher than 1.2–2.7 times the entanglement concentration.

Starch-based nanofibers were used in various applications. MWCNT/starch/PVA nanofiber webs were fabricated and carbonized onto CNT/C nanofibers and subsequently developed as electrochemical capacitor electrodes with high specific capacitance (170 F g^{-1}) and electrical conductivity (2.1 S cm^{-1}). Lancuški et al. produced electrospun fibers with sizes ranging from 80 to 300 nm by electrospinning high-amylose starch formate in aqueous formic acid. Furthermore, Xu et al. reported electrospun starch acetate fibers by dissolving it in formic acid.

In another study, high-amylose Hylon VII maize starch and starch-derived nanographene oxide (nGO) (via carbonization) were electrospun using formic acid as solvent (Wu et al. 2017), where the incorporation of nGO into starch improved fiber diameter, hydrophilicity, thermal stability, and electrospinnability. Li et al. (2018b) have demonstrated that starch-based fiber can spin centrifugally, and Jeong et al. (2016) reported on the utilization of carbon nanofibers (CNFs) generated from starch and carbon nanotubes (CNTs) in rechargeable batteries. The constructed electrode performed admirably (510 mAh g^{-1} after 30 cycles), which can be attributed to its huge surface area.

Pectin Nanofibers

Pectin is a naturally occurring heteropolysaccharide derived from terrestrial plant tissues that is primarily constituted of poly (α -1, 4-D-galacturonic acid) inserted with α -1, 2-L-rhamnopyranose unit (Maxwell et al. 2012; Yapo 2011; Williams et al. 2011). Citrus peel, apple pomace, and sugar beet pulp are the most common commercial sources of pectin. It is used in the food industry as a thickening, gelling, and stabilizing agent and has incredible potential in biomedical applications. Adding metal salts can increase the viscosity of pectin (Löfgren et al. 2006; Pina et al. 2015; Munarin et al. 2011, 2012). Pectin with PEO (polyethylene oxide) as a copolymer and Triton X-100 as additives were successfully electrospun into fibers in a DMSO/aqueous mixture (Cui et al. 2016). The aqueous solutions of pectin (5–8 wt.%) and PEO (5 wt.%) were mixed in various weight ratios (pectin/PEO: 60/40, 70/30, 80/20, and 90/10) before being blended with 1% and 5% Triton X-100 and DMSO, respectively. After that, the dispersions were mixed for 3 h before electrospinning. In the blends of pectin/PEO, all other combinations except the 90/10 ratio gave uniform and smooth nanofibers. The electrospinning of charged natural

polysaccharides (e.g., chitosan and alginate) proved difficult on their own, emphasizing the importance of copolymers, additives, and appropriate solvents. This is because such systems contain complicated molecular chain entanglements in solution and different rheological characteristics (Nie et al. 2009; Klossner et al. 2008; Stijnman et al. 2011).

Additionally, alginate/PVA electrospun fibers in combination with therapeutic (chemical) cargo (viz. Lidocaine, Neomycin, and Papain) have demonstrated their potential both as dressing materials and as media or conduits for transdermal delivery of an antibiotic drug (ciprofloxacin) (Pegg et al. 2014; Kataria et al. 2014). In another study, nanofibers of alginate/PEO and lavender essential oil were used to cure UV-induced skin burns. They showed good antibacterial activity against *S. aureus* exhibiting anti-inflammatory properties under both, in vivo and in vitro experimental conditions (Hajiali et al. 2016). Composite electrospun fibers based on alginate (2 wt. %)/PVA (16 wt. %) in a 1:1 blended solution of PVA/alginate with ZnO NPs (0.5, 1.2, and 5%) were fabricated by Shalumon et al. (2011). Higher thermal stability, antibacterial, and cytotoxicity attributes were exhibited by alginate/PVA/ZnO composite fibers compared to the pristine sample (PVA/alginate fibers).

Fabrication of “Green” Electrospun Fibers Based on Tree Gums

The development of “green electrospinning” technology requires nontoxic and inexpensive biodegradable ingredients and environmentally friendly solvents. Green technology aims to environmental protection in contrast to the current electrospinning method, which requires destructive and hostile organic solvents.

Electrospun fibers and membranes based on natural renewable resources are continuously being developed for energy and environmental purposes. To create electrospun fibers and membranes, “green” electrospinning technology focuses on developing nontoxic, low-cost, and environmentally friendly polymers and solvents (such as water or ionic solvents). Natural biopolymers such as chitin, chitosan, cellulose, starch, gums, etc., have been successfully electrospun into fibers. Many of them are blended with other natural or synthetic fibers to formulate their blend to make uniform and smooth fibers.

Tree gums exemplify sustainable and renewable biomacromolecules abundantly available from nature and possess excellent biodegradability, nontoxicity, low cost, physicochemical properties, structural attributes, and diverse functional groups. Gum hydrocolloids, often known as tree gum polysaccharides, are obtained as the natural exudates of different tree species and represent a largely unexplored source of valuable natural products. Exudate gums have wide range of applications in food and pharmaceutical industries as stabilizers, thickening agents, emulsifying agents, and binding agents. Recently there is a growing interest in the use of these exudate gums for nonfood applications including biomedical, food and pharmaceutical packaging, and energy and environmental applications. The discovery of novel uses for these gums has piqued people’s attention in recent years.

Abundant availability and biodegradability coupled with nontoxicity and low cost can make these materials ideal for the fabrication of packaging films to replace conventional plastics. However, these exudate gums have intrinsic limitations including high hydrophilicity, poor film-forming ability, and low mechanical properties. To overcome these drawbacks, researchers employed different strategies including chemical modifications, blending with different nanomaterials (graphene oxide, nanocellulose), 2D nanoclay coating, and blending with other natural polymers. The obtained blended component demonstrated significant improvement in the physicochemical, mechanical, thermal, and barrier properties while retaining the biodegradability of the gums.

Additionally, many nanotechnological and biotechnological approaches are recently used as novel and green applications to valorize tree gum wastes and other bio-wastes. The carbon-rich structure of the gum wastes has been utilized in the growth of carbon nanostructures with exceptionally high surface area. These carbon nanostructures have been further used in the development of energy harvesters. The large functional groups of the gums have been used in the product of graphene-supported nanoparticles for environmental remediation applications.

Electrospinning of Tree Gum Exudates

Many researchers have reported on the electrospinning of tree gums and their blended solutions containing various natural or synthetic polymers in the last 5 years. The system and process parameters for the electrospinning of tree-gum-based nanofibers are the critical criteria to strictly follow to produce nanofibers of smooth beads and uniform diameters (Table 2).

Electrospinning of Pullulan (PU)

PU is a commercial, neutral carbohydrate polysaccharide that is widely used in a variety of sectors, including the production of cosmetics, drugs, and food. It is a nonionic microbial polysaccharide that the fungus *Aureobasidium pullulans* produces. Pullulan's structure is α -(16)-linked (14)- α -D-triglucoside (maltotriose), and it is dependent on water solubility and structural flexibility.

Deniz Atila et al. (2015) electrospun PU and cellulose acetate in a variety of ratios (80/20, 50/50, and 20/80 wt/wt) to create 3-D fibers. DMAC/DMSO (55/45 v/v%) was the solvent used for electrospinning, and the effects of different parameters have been researched. The fiber diameter, porosity, and thickness of the fiber scaffolds of the resulting nanofibers were all affected by the amount of PU in the blended mixture. The 50/50 wt/wt ratio was discovered to be the ideal ratio, demonstrating the efficacy of 3-D scaffolds in tissue engineering.

Pullulan, PVA, and rutin mixes have been electrospun into mats for use in ultraviolet (UV) resistance applications, and the fiber homogeneity and diameter have been measured. Rutin's presence and concentration also blocked UV radiation,

lowering UVA and UVB radiation transmission by 5% (Qian et al. [2016](#)). By using PU and whey protein conjugates, the techniques of electrospinning and electro-spraying have been successfully used to create nano-/micro capsules for the probiotic encapsulation of bifidobacterium (Senthil Muthu Kumar et al. [2019](#)).

Dextran Nanofibers via Electrospinning

A polysaccharide obtained from bacteria is dextran. It has a linear structure made up of repeated α -1,6-linked D-glucopyranosyl units containing α (1 \rightarrow 2)-, α (1 \rightarrow 3)- or α (1 \rightarrow 4)- glycosidic linkages connecting the backbone to branches of shorter chains of D-glucose (Cheetham et al. [1990](#); Naessens et al. [2005](#); Gulke [1989](#)).

Due to dextran's great water solubility, its solutions exhibit Newtonian fluid behavior. The concentration, temperature, and molecular weight of the solution significantly affect its viscosity. Dextran has been utilized as a food additive in the pharmaceutical and cosmetic industries due to its biodegradability and biocompatibility. Additional uses in biomedicine include drug therapy, protein and enzyme

imaging agents, and plasma volume expanders (Hennink and van Nostrum 2012; Lipman 1993). Dextran's main functional group, like -OH, is in charge of conjugating other molecules. Most notably, dextran is easily blended with hydrophobic polymers (like PLGA) to create composite electrospun fibers since it is soluble in both water and organic solvents. Dextran's mechanical strength, the swelling characteristics of water, and biological activity can all be managed in this way.

Wang et al. conducted electrospinning of dextran to create random polymer fibers with different molecular weights (50, 100, 500, and 2000 kDa) and polymer concentration, influencing fiber diameters and structures. The variation of morphology is dependent on attention and applied voltages. Using fiber orientation to control cell adherence and spreading by electrospinning has been made possible by this research (Wang et al. 2018). By electrospinning acetylated dextran, Borteh et al. created a scaffold for the release of resiquimod (4-amino-, -dimethyl-2-ethoxymethyl-1Himidazo[4,5-c]quinoline-1-ethanol). The synthesized acetylated dextran scaffold is a strong contender for biomedical applications due to its cytocompatibility, flexibility, tenability, and controlled drug-releasing ability (Borteh et al. 2013). The process parameters and solvent systems used to electrospin dextran fibers in water, DMSO/water, and DMSO/DMF have been optimized by Jiang et al. (2004). The bovine serum albumin (BSA) or lysozyme 10% (w/w) addition had no effect on the electrospun dextran fibers. Additionally, the viability of creating electrospun membranes by utilizing methacrylate dextran to photo-crosslink in the solid state has been examined.

Electrospinning of Hyaluronic Acid

An anionic, nonsulfated glycosaminoglycan, hyaluronic acid (HA) is composed of chains of repeating units that connect [β -1 \rightarrow 3] D-glucuronic acid and [β -1 \rightarrow 4] N-acetyl-D-glucosamine. All higher animal species have it in their extracellular matrix of tissues, and certain microorganisms also make it (Laurent and Fraser 1992; DeAngelis 1999; Campoccia et al. 1998; Bulpitt and Aeschlimann 1999; Shu et al. 2004). Potential uses for HA and its derivatives include tissue engineering and drug delivery in medicine, as well as biotechnology, pharmaceuticals, and cosmetics (Purcell et al. 2014; Makvandi et al. 2019, 2020).

The sulfated HA macromers were electrospun into fibers by Purcell et al. (2014). These nanofibers could be used for tissue engineering and drug delivery, specifically. They could also be used to convey heparin and cause protein interaction.

Li et al. (2006a) investigated the formation of HA and HA/gelatin electrospun fibers (with diameters of 200 nm and 190–500 nm, respectively) and the electrospinning properties of HA and blended mixes of HA/gelatin in N, N-dimethylformamide (DMF)/water-mixed solvent systems. Another study that involved electrospinning gelatin/HA blends into electrospun fibers demonstrated that the addition of HA could enhance the electrospinning and processability of aqueous gelatin solutions, increasing the viscosity and conductivity of the blended solutions (Li et al. 2006b).

Heparin Electrospun Fibers

A naturally occurring glycosaminoglycan, heparin, is composed of D-glucuronic acid, L-iduronic acid, and D-glucosamine units and has a high concentration of sulfonate and carboxylic functions. Heparin has a number of important biomedical uses that depend on its antiviral, anticoagulant, and anticancer properties. Additionally, it encourages angiogenesis, the growth of new blood vessels, which is essential for the development of functioning tissues (Capila and Linhardt 2002; Mizrahy and Peer 2012; Liu et al. 2014; Cheng et al. 2014). Vascular tissue engineering and drug delivery systems are two important areas where heparin-conjugated electrospun nanofibrous scaffolds are used. Feng et al. (Feng et al. 2017) investigated the creation of core-shell-type fibers using electrospinning of heparin, Rosuvastatin calcium (a drug used to treat hyperlipidemia), and poly(L-lactide-co-caprolactone) blended solutions with the appropriate solvents. The diameter distribution, water contact angles, and cell survival of the nanofibers are also summarized. The study demonstrated that electrospun fibers can be produced, retain bioactivity, and be used as a framework for stent grafts to treat aneurysms while also releasing heparin and rosuvastatin calcium in a sustained manner.

Several heparin-based electrospun scaffolds have been constructed. Casper et al. (2005) monitored the electrospinning of a combination of PEO and heparin or PEG-low molecular weight heparin in aqueous media or DMF. In another study by Kwon et al. (Kwon and Matsuda 2005), nanofibrous heparin-TBA (tri-n-butylamine) were conjugated via electrospinning poly (L-lactide-co- ϵ -caprolactone) or PLCL with the tri-n-butylamine salt of heparin, using various blended ratios. Luong-Van et al. (2006) incorporated heparin into electrospun poly (epsilon-caprolactone) or PCL fiber mats in the solvent systems. It was found that the fibers could release heparin over 14 days without triggering an inflammatory response.

In another study, heparin was conjugated via hydrogen bonding with SF (silk fibers), and the electrospun SF-heparin nanofibrous scaffolds were suitable for biomedical applications. The electrospun fibers of PCL and heparin-conjugated scaffolds loaded with FGF2 (Fibroblast Growth Factor 2) or VEGF (vascular endothelial growth factor) have been successfully utilized for vascular tissue engineering (Ye et al. 2011, 2012). Wang et al. (2011) demonstrated that electrospun heparin/gelatin fibers could be prepared using a gelatin/acetic acid solution, which was then cross-linked with a glutaraldehyde/ethanol solution. Coaxial electrospinning was used to create a core-shell fibrous membrane, with PCL serving as the core section and cationized gelatin (CG) as the shell material. Onto these core-shell fibrous scaffolds, macromolecular bioactive substances, such as FITC-BSA and FITC-heparin, may be adsorbed. A core-shell fibrous membrane with cationized gelatin (CG) as the shell material and PCL as the core section was established via coaxial electrospinning (Lu et al. 2009). Onto these core-shell fibrous scaffolds, macromolecular bioactive substances, such as FITC-BSA and FITC-heparin, may be adsorbed.

Chitin and Chitosan Nanofibers and Membranes

The animal polysaccharide chitin is the second most prevalent biopolymer after cellulose, found in nature, and has a wide range of uses in the domains of biocatalysis, energy storage, filtration, biosensing, and biomedicine (Jayakumar et al. 2010; Ding et al. 2014; Schiffman and Schauer 2008). When compared to its derivative (chitosan), chitin is made up of (1, 4)-linked *N*-acetyl- β -D-glucosamine, while chitosan is made up of (1–4)-linked 2-acetamide-2-deoxy- β -D-glucopyranose and 2-amino-2-deoxy- β -D-glucopyranose.

One major setback of the electrospinning of chitin and chitosan is the inability to precisely select the optimal solvent for processing. Additionally, the polycationic structure of chitin and chitosan as well as the existence of hydrogen bonds could prevent them from electrospinning smoothly (Ding et al. 2014). Chitin has been solubilized using a variety of systems that contain acidic components, such as methane sulfonic acid, hexafluoroisopropanol, and lithium chloride/dimethyl acetamide (Muzzarelli 2011). Ionic liquids have lately been investigated as promising solvents for chitin and chitosan. The prime goal was to ensure the two aforementioned animal-sourced polysaccharides' physicochemical properties were not to be altered prior to their usage in electrospinning (Wang et al. 2012; Zakrzewska et al. 2010). Chitin and chitosan, as well as their nanofibers, have been widely used in biotechnological fields due to their essential biological characteristics (Ignatova et al. 2009; Zhong et al. 2010).

Three different varieties of chitin – P-Chitin (Temperature-Preprocessed Shrimp Shells), R-Chitin (Unrefined Shrimp Shells), and PG-Chitin (Useful Grade Chitin) – were electrospun using an ionic liquid (1-ethyl-3-methylimidazolium acetate) by Zavgorodnya et al. (2017). Chitin content and viscosity were found to be the main determinants of the electrospinning process in studies of a multitude of factors, including conductivity, polymer concentration, viscosity, and surface tension of the electrospinning fluid. Contrary to what has been reported elsewhere (Jarusuwannapoom et al. 2005; Pattamaprom et al. 2006), solution conductivity and surface tension are not the dominant factors when volatile organic chemicals are utilized.

For application in oil-in-water emulsion separation, Wu et al. created a filtering membrane using chitin nanowhiskers and poly *N*-isopropyl acrylamide-co-*N*-methylol acrylamide (PNIPAm-co-NMA). By electrospinning PNIPAm-co-NMA and ChNW at a concentration of 15 wt% in a water/THF mixture, the electrospun membrane (PNIPAm-co-NMA)/ChNW was generated (in a 1:2 solvent ratio). It outperforms alternative methods by five-fold in terms of cleaning oil-in-water emulsions under high salinity and wide pH range conditions (Croisier et al. 2015).

Park et al. prepared a blend of chitin/poly (glycolic acid) nanofibers using HFIP as a solvent via electrospinning (Park et al. 2006a). The scaffolds, which might be used in tissue engineering, demonstrated outstanding cell adhesion and spreading capabilities for regular human fibroblasts. Chitin-/silk-blended nanofibers were also produced using the same solvent (Park et al. 2006b), where the resulting blended nanofibers exhibited 140 nm average diameter. The diameters of the nanofibers

dropped from 920 to 340 nm as the chitin concentration of the composite compositions increased.

Chitosan nanofibers coupled with the polyelectrolyte poly(acrylic acid) (PAA) were produced by electrospinning a ternary solvent solution of formic acid, glacial acetic acid, and water (Zhang et al. 2018). The mechanical and swelling features of the films and fibers are pH dependent, and hence the transport and release of pharmaceuticals is the enticing potential of these materials. It has also been observed in another study that the degree of deacetylation (DD) affects the gelation of chitosan (in relation to particle size and the conductive, dielectric, and rheological characteristics under electric field).

Using the electrospinning process, Koosha et al. (2015) created Na-montmorillonite (MMT) nanoclays and chitosan/poly (vinyl alcohol)-based nanofibrous nanocomposites. The viability of the A-431 cell line, which was discovered to be properly adherent to the surface of the mats, was tested using an MTT assay to determine the cytotoxicity of nanocomposite mats. The results revealed that the mats had no adverse impacts on the viability of the cell line. Croisier et al. reported a method for electrospinning a mixture of PCL with a poly (MMA-MA) copolymer of methyl methacrylate and maleic anhydride, resulting in negatively charged electrospun fibers with chitosan coating (Croisier et al. 2015). The carboxylic acid was deprotonated in neutral or basic aqueous conditions to achieve this.

Electrospun chitosan/polyethylene oxide (PEO) fibers containing silver nanoparticles (Ag NPs) were created by Annur et al. (2015) by reducing AgNO_3 on the surface of the nanofibers using an argon plasma treatment. The data showed an improvement in the antibacterial efficacy of the nanofibers after argon plasma treatment, and the average diameter of the Ag NPs deposited on the surface of the nanofibers was 1.5 nm. This is explained by the strong contact between the amino group of chitosan and the silver nanoparticles, which resulted in the silver nanoparticles remaining exposed on the nanofiber surfaces for an extended period of time.

Chitosan-based nanofibers are employed in water purification purposes as well, e.g., removal of heavy metal ions. By electrospinning chitosan, PVA, and Fe (III) in aqueous/acetic acid, Chauhan et al. produced biopolymeric nanofibers, which were further used to remove As (III), As (V), Cr (VI), and F⁻ ions successfully from contaminated water (Chauhan et al. 2014). Additionally, they showed promising antibacterial potential against *Escherichia coli*, a Gram-negative, optional anaerobic, rod-shaped coliform bacterium. Chen et al. (Chen and Huang 2016) exploited N-maleoyl-functionalized chitosan (MCS)/PVA in an aqueous medium to electrospin ecofriendly fibers. Through using allyl disulfide as the cross-linker and UV radiation to cross-link the fibers, hazardous chemicals were avoided. Suitable antibacterial agents were added to the produced nanofibers, which were then used in applications for wound healing. Makaremi et al. (2016) created electrospun PAN nanofibrous membranes with a layer of

electrospun chitosan and functionalized zinc oxide (ZnO) nanoparticles (Cs). Improved mechanical, antibacterial, and water-filtering performance was the objective. The conjugated fiber layers showed high mechanical characteristics (tensile strength and Young's modulus) after the addition of chitosan fibers. The adsorption capability of Cr(III) was further improved by the addition of ZnO NPs. Furthermore, the high water permeability and antibacterial effectiveness of this sandwiched membrane suggested that it was suitable for water filtration. Desai et al. (2008) produced uniform-sized electrospun nanofibers of chitosan with a small amount of PEO (5%) using acetic acid as the solvent high-durability chitosan mats (up to 6 months) were prepared by Eroglu et al. (2012) which support algal growth and removal of nitrate ions from water. Horzum et al. (2010) accomplished the electrospinning of chitosan in 1,1,1,3,3,3-hexafluoroisopropanol (HFIP), the ensuing electrospun fibers being utilized for sorption of Fe(III), Cu(II), Ag(I), and Cd (II) ions from aqueous solutions. Lu et al. (2012) prepared graphene impregnated with chitosan nanofibers with antibacterial efficiency for application in wound dressing.

Coaxial electrospinning was utilized to regulate L-ascorbic acid/poly(vinyl alcohol)-chitosan core-shell nanofibers; acetic acid was employed as the chitosan shell and ethanol/propylene glycol/water as the L-ascorbic acid core solution. It assessed how well the model medicine ascorbic acid was released from the core-shell fibers. The outcomes showed that functionalizing such materials for transdermal medication delivery devices is appropriate (Najafi-Taher et al. 2015). Pakravan et al. (2012) produced core-shell-structured PEO-chitosan nanofibers by coaxial electrospinning with the inner layer and outer sphere membrane consisting of PEO. The chitosan was fabricated in acetic acid (solvent), and PEO was later washed out using water to sustain the core-shell structure of the chitosan nanofibers.

Electrospinning of Gelatin

Gelatin, derived from animal tissue, possesses a high level of denatured collagens. Mammalian source, e.g., pig skin and bovine hides, is the primary source of gelatin production. Gelatin has many applications in the pharmaceutical industry, for instance, the main ingredient of hard capsules that melt in water (at $> 30^{\circ}\text{C}$) and release their therapeutic agents (Sadat-Shojai et al. 2016).

Hydrogels have been exploited as possible scaffolds for demanding tissue-engineering applications. However, their low mechanical properties and bioactivity make them unsuitable for hard tissue. One strategy is to improve their physical properties by adding electrospun fibers. Having this in mind, Mehdi-Sahad and coworkers (Sadat-Shojai et al. 2016) developed a three-layered hybrid scaffold based on hydroxyapatite fibers between two layers of methacrylate gelatin/hydroxyapatite (Table 3).

Table 3 Various proteins electrospun fibers using solvents or additives

Proteins	Solvents or additives	Ref.
Gelatin	PCL/TFE, acetic acid, TFE, PHBV/HFIP, water, PLGA/TFE, and nylon-6/formic acid; acetic acid, HFIP; ethyl acetate	(Xue et al. 2014; Gomes et al. 2015; Zhang et al. 2006; Wang et al. 2016; Tonda-Turo et al. 2013; Song et al. 2008)
Collagen	Water/ethanol/ salt, PHBV/HFIP, and AA/DMSO	(Wang et al. 2016; Punnoose et al. 2015; Rnjak-Kovacina et al. 2012)
Elastin	HFIP, collagen/HFIP	(Rnjak-Kovacina et al. 2012; Araujo et al. 2014)
Soy	PVA/water; PEO/water and PEO/HFIP	(Cho et al. 2010; Ramji and Shah 2014)
Zein	Ethanol, isopropanol	(Erdogan et al. 2015)
Whey	PEO/water	(Colín-Orozco et al. 2015)
Amaranth	Pullulan/formic acid	(Aceituno-Medina et al. 2015)

Electrospinning of Collagen

About one-fourth of the total protein in the human body belongs to this class of fibrous proteins (Gelse et al. 2003). These proteins maintain internal organs, connect tendons and muscles, and are crucial for the structure of cartilage, skin, bones, and teeth. The triple-helical structure of collagens is remarkably similar across a wide range of animal species, and they are relatively nonimmunogenic. These factors drive research into electrospun collagens for use in tissue engineering, wound healing, and other broad biomedical applications.

However, electrospinning collagens have shown to be challenging. It was necessary to find a solvent that could dissolve the protein at concentrations suited for bead-free fiber creation, permit quick drying of fiber mats, and be compatible with copolymers for improving mechanical qualities. According to Zeugolisa et al., the fluoroalcohol-induced dissolution of collagen causes significant protein denaturation in fibers (Zeugolis et al. 2008). Wnek and colleagues revealed that basic mixes of phosphate buffered saline and ethanol can facilitate electrospinning and protein dissolution while maintaining triple-helical structure (Dong et al. 2009).

Conclusion

The successful electrospinning of abundant biopolymers from plant, animal, bacterial, and seaweed sources has been implemented worldwide. The methodology produced electrospun fibers of uniform dimensions, making use of mainly natural materials, a proper choice of solvents (aqueous/organic), and the suitable system and processing parameters. Inadequate evaluation tools for measuring stability, fiber diameter, aspect ratio, and morphology have been a significant drawback of this technology. Another difficulty was that it was difficult to determine which particular

application would suit the resulting nanofibers best because of their varied physical, chemical, and mechanical properties.

A variety of natural biomaterials and their electrospun fibers have been widely used in energy, environmental, and medicinal applications (such as scaffolds for tissue engineering, drug delivery, and reduce inflammation) by virtue of their functional groups with medicinal value available in their structures, biocompatibility, nontoxicity, and biodegradable nature. The commercialization of these goods in packaging materials, bioengineering, and disposable sanitary items is essential for the enormous possibilities for natural polymer-based electrospun fibers. In this context, the newer nanofiber-derived goods will be promoted by academic and business institutions, as well as through their improved network and interaction. The use of biopolymers-based membranes and nanofibers will allay safety worries, which will make them highly sought after in a variety of industries, especially the medical, food, and pharmaceuticals.

Abstract

Biopolymers (natural polymers) are exuded by micro- and macro-organisms (bacteria, plants, etc.) and have been shown to affect the geotechnical engineering behavior and properties of different soil types for low dosage levels. The long-chain structure of biopolymers and certain constituting chemicals (e.g., hydroxyl, ester, or amines) supply adhesive forces that help coating and binding together the soil particles. This chapter presents a review of the state of the art in biopolymer-based soil treatment (BBST), aimed at focusing more attention on the various potential uses of biopolymers, as alternatives to conventional (cement and lime) binders, for a variety of applications in the geotechnical and geoenvironmental engineering sectors. Compared to conventional binders, the benefits of BBST

include its low environmental impact, non-toxicity, and non-secondary pollution. This chapter also discusses various challenges and issues related to the field application of BBST and identifies various research needs.

Keywords

Biopolymer-treated soil · Geotechnical properties · Soil improvement

Abbreviations

BBST	Biopolymer-based soil treatment
CG	Carrageenan gum
CH	Chitosan
CMC	Carboxymethyl cellulose
GG	Guar gum
LL	Liquid limit
PAM	Polyacrylamide
SA	Sodium alginate
SSA	Specific surface area
UCS	Unconfined compressive strength
XG	Xanthan gum

Introduction

The geotechnical engineering sector consumes vast amounts of chemical additives (conventionally cement and lime), as binders, for various ground improvement and soil stabilization applications. These chemical additives permanently alter the treated soil environment, and they can also result in pollution of the groundwater. Biological methods represent green and sustainable alternatives, being broadly categorized as: (i) mineral precipitation – that is, methods that produce mineral precipitation in the pore voids to increase the soil particle bonding and/or reduced the soil permeability; (ii) mineral transformation – that is, methods that transform clay minerals from one form to another; and (iii) biopolymer-based soil treatment (BBST) that can improve the strength, and reduce the permeability, of the treated soil through ionic bond and hydrogel formation. The focus of this chapter is on the BBST.

Biopolymers are non-toxic and non-polluting polymers, produced naturally by microorganisms, animals, and plants, or synthesized chemically from materials of biologic origin, including sugars, amino acids, oils, etc. (Kavazanjian et al. 2009). Based on their composition, biopolymers can be classified as polyesters, proteins, or polysaccharides (Nair and Laurencin 2007); the latter being an important fraction of soil organic matter. As such, polysaccharide additives may be considered more suitable for BBST field applications, particularly those designed to improve the erosion resistance of surficial soil layers (Rabiei et al. 2022). Polysaccharides are produced from bacteria, fungi, plant and algae, and animal sources. Those produced from bacteria include xanthan gum (XG), gellan gum, dextran, levan, and curdian.

Common fungal polysaccharides include yeast glucans, pullulan, and elsinan. Examples of polysaccharides from plant and algal sources are starch, cellulose, agar, guar, and alginate, while those from animal sources include chitosan (CH), chitin, polyphenols, and hyaluronic acid.

Biopolymers are used extensively in various industries (e.g., food, textile, oil exploration, pharmaceuticals, and drug delivery) as thickeners, adhesives, lubricants, and adsorbents. The focus of this chapter is on BBST for various geotechnical and geoenvironmental engineering applications, including stabilization of weak soils, slopes, and excavations, for modifying marginal soil as contaminant barrier material and/or for compacted covers, and in resisting water- and wind-induced erosion of surficial soil layers. Table 1 lists the common biopolymer types presently employed in BBST to improve the geotechnical/geoenvironmental engineering behavior and properties of different soil types. Introducing biopolymers into the soil may be achieved by various methods, such as grouting, injection, mixing, and surface-spray application. The interaction between the soil particles and biopolymer additive is influenced by several factors, including the surface characteristics of the soil particles, the structural flexibility of the biopolymer (i.e., regarding van der Waal's interaction (Chang et al. 2015)), the presence of hydroxyl groups on the biopolymer and soil particles (i.e., regarding hydrogen bonding), and the presence of carboxyl groups (i.e., regarding ionic bonding between charged particles (Martin 1971)).

In addition to their ecofriendly nature, another major advantage of using biopolymers, as binders, for ground engineering applications is the relatively low dosage (as compared to cement and lime additives) required to achieve a comparable compressive strength of the treated soil. Furthermore, while most conventional grouts or other bonding agents are strong but brittle, and thus susceptible to fracture in a porous medium, BBST generally offers a more resilient response to stress concentration (Assadi-Langroudi et al. 2022). Biopolymers are stable over a broad range of temperatures and pH, with many of them forming viscous suspensions with water (Kumar and Sujatha 2021). Their properties, including a tendency to gel, pseudo-plastic behavior, and resistance to shear degradation, help in plugging the soil pore-void spaces (Wiszniewski and Cabalar 2014). However, it should be noted, as discussed later in the chapter, that biodegradability may limit biopolymer durability (Assadi-Langroudi et al. 2022). Grouting of biopolymers for ground engineering applications also requires higher inject pressures that depend on the biopolymer concentration/grout viscosity (Khatami and O'Kelly 2022).

BBST Applications in Geotechnical and Geoenvironmental Engineering

BBST has shown much promise in various geotechnical and geoenvironmental engineering applications. For instance, biopolymers XG and guar gum (GG) have been used to stabilize mine tailings (Chen et al. 2013) and for fugitive dust control. XG, GG, β -glucan, and carboxymethyl cellulose (CMC) have been successfully employed to improve the soil erosion resistance (Chang et al. 2019; Nikolovska et al.

Table 1 Properties of select biopolymers and their various applications in geotechnical and geoenvironmental engineering

Biopolymer	Source	Property	Application	References
Sodium-CMC	Ether derivative of natural cellulose from plants	Anionic Viscosity: 200–500 cP for 1% solution Density: 500–700 kg/m ³	1.0% dosage is sufficient to erect low-rise buildings on treated soil	(Ma and Ma 2019)
CH	Crustacean shells	Cationic Insoluble in water, soluble in 1% acetic acid solution.	Strength improvement – soil stabilization	(Hataf et al. 2018; Shariatmadari et al. 2020)
Gellan gum	<i>Sphingomonas elodea</i> microbes	Anionic	Strength improvement – soil stabilization	(Chang et al. 2016)
GG	Endosperm of guar seed	Nonionic pH: 7.47 Viscosity: 12 cP for 0.25% solution	Clay liners, ground improvement for foundations slope stabilization	(El-Daw 1994; Caballero et al. 2016; Anandha Kumar and Sujatha 2021)
Starch	Plant extracts	Ionic nature Molecular weight depends on source and production methods	Soil strengthening, erosion reduction	(Khatami and O'Kelly 2013; Chang et al. 2020)
XG	Aerobic fermentation of sugars by the bacterium <i>Xanthomonas campestris</i>	Anionic pH: 8.2 Viscosity: 174 cP for 0.25% solution	Landfill liners, ground improvement for foundations	(Ayeldeen et al. 2017; Anandha Kumar and Sujatha 2021)
β-Glucan	<i>Saccharomyces cerevisiae</i> yeast	Anionic pH: 6.95 Insoluble in water	Landfill liners	(Chang and Cho 2014; Anandha Kumar and Sujatha 2021)
Agar	Cell walls of red algae	Non-ionic	Foundation applications	(Khatami and O'Kelly 2013; Fatehi et al. 2021)
Persian gum	Plant exudate	Anionic pH: 4.4 Viscosity: 48 cP for 1% solution.	Soil stabilizer and purifier	(Ghasemzadeh and Modiri 2020)
Casein	Dairy products	Anionic Insoluble in water	Soil stabilizer	(Fatehi et al. 2021)
Albumen	Egg shells	pH: 8–9.5 Hydrophilic	Strength improvement	(Zarei et al. 2022)

Note: CH chitosan, CMC carboxymethyl cellulose, GG guar gum, XG xanthan gum

2019; Ko and Kang 2020; Kwon et al. 2020; Devrani et al. 2021; Mahamaya et al. 2021). Ayeldeen et al. (2016) used modified starch in combination with XG and GG for improving the soil erosion resistance against various wind speeds. Wade et al. (2021) used GG and alginate to improve soil aggregation and crust integrity, as these polysaccharides strengthen the soil crust. As BBST increases soil cohesion, it can be employed to improve the stability of the soil slopes, and to prevent shallow landslides (Caballero et al. 2016; Acharya et al. 2017; Zhang et al. 2021; Che et al. 2022; Kar et al. 2022). GG slurry has been used to prevent the sidewall collapse during trench excavations (Aminpour and O’Kelly 2015). Ko and Kang (2020) demonstrated the potential application of BBST to resist levee breach, and they observed that the biopolymer-stabilized soil approach provided better flood protection compared to vegetated levees. Lee et al. (2019) used bottom ash along with XG to stabilize the road shoulder, with XG addition producing significant improvements in the subgrade strength. Aminpour and O’Kelly (2015) reported that biopolymers find various applications in dam construction and operation activities. Bouazza et al. (2009) recommended BBST for conditioning soil used as liners in waste and hazardous contaminant facilities, since the biopolymer additives were found to significantly reduce the soil permeability. Aminpour and O’Kelly (2015) and Anandha Kumar and Sujatha (2021) reported that BBST can modify the soil into a low permeability medium, thereby facilitating its use in barrier and clay-liner applications. Biopolymers can withstand environmental conditions of wetting–drying and freezing–thawing (Chang et al. 2015; Sujatha and Saisree 2019; Singh and Das 2020). Here, the soil–biopolymer interaction mimics adhesive action that helps to resist degradation of the treated soil, thereby achieving reduced volumetric change with water content variation (Chang et al. 2015; Sujatha and Saisree 2019). Khatami and O’Kelly (2018) added XG and diutan gum to superfine ground-granulated blast-furnace slag (GGBS) cement, and explored ways to increase the zeta potential of fine grout particles such that they remain in suspension for reasonable time periods to allow successful implementation of the grouting processes. The purpose of including these biopolymers in the cement grout was to fortify the grout composition to have a sedimentation/bleeding resistance.

Changes in Soil Plasticity for Biopolymer Addition

Biopolymers modify the particle aggregation and water absorption in treated soils making investigations of Atterberg’s (consistency) limits and other indices for the treated soil a necessity in advocating BBST considering various geotechnical and geoenvironmental applications. Hydrophilic biopolymers, including XG, GG, cellulose, sodium alginate (SA), agar, carrageenan gum (CG), and β -glucan, generally cause an increase in the liquid limit (LL) water content. For instance, Nugent et al. (2009) investigated the effect of XG and GG additions on kaolinite clay and found that LL tends to increase with biopolymer dosage on account of the increase in viscosity of the pore fluid, especially at higher concentration. Whereas at a lower concentration, these authors observed that the biopolymers tended to aggregate the

soil particles causing a small decrease in LL. Furthermore, GG addition resulted in a higher LL than XG because of the abundant network of hydrogen bonding between the GG and kaolinite particles. Kwon et al. (2019) and Sujatha et al. (2021) also observed a similar increase in LL for XG-treated soft marine clay and clayey sand, respectively. These authors attributed the increase in LL to hydrogel formation in the soil–biopolymer matrix and to electrical interaction between the XG and clay component in the soil. Cabalar et al. (2018) recorded similar results of increasing LL with XG addition. These authors also observed a marginal change in linear shrinkage on addition of XG (attributed to retardation in the rate of water evaporation), although the swell ratio was found to increase (from approx. 1.5% to 8.5%) with increasing XG dosage. This retardation in the evaporation rate in the presence of XG may influence soil shrinkage and control differential movement, potentially limiting damage to infrastructure built on clay soil deposits (Cabalar et al. 2018).

Zhanbo et al. (2020) investigated the effect of six different biopolymers (i.e., XG, GG, SA, agar, locust bean gum, and CG) on kaolinite. The observations from their study showed that CG, locust bean gum, and GG caused a greater increase in LL compared to agar, XG, and SA. For non-viscous biopolymers, like β -glucan, a marginal increase in LL was observed for increasing biopolymer dosage, although there was a slight decrease in plasticity index (Chang and Cho 2014; Kumara and Sujatha 2020). The decrease in plasticity index occurs because the thread-like fibers (formed on β -glucan addition) rendered the soil matrix stiffer. Similar behavior was also observed by Abd et al. (2022) on addition of cellulose (low viscous biopolymer) to clay soil, with the LL increasing appreciably (from 39% to 72%), but the plasticity index decreasing marginally from 25% to 19%.

The above literature shows that viscosity plays an important role in modifying the plastic nature of biopolymer-treated soil. Judge et al. (2022) reported that the polarity and viscosity of the biopolymers modify the LL of soft clay soils. The size of the molecules and their shapes control the viscosity, while polarity dictates the interaction between the charged soil particles and biopolymers. Judge et al. (2022) noted that the addition of GG and CG, both of which have high viscosity, caused a significant increase in LL for the biopolymer-treated soils.

Biopolymers for Strength Improvement

Various biopolymers, including XG, GG, gellan gum, SA, β -glucan, CH, casein, modified starch, and agar, have been used, as additives, to improve the strength of different soil types; that is, sand, silt, clay, and organic soils. Ivanov and Chu (2008) reported the mechanisms that improve the strength, and reduce the permeability, of biopolymer-treated soil, as being biocementation and bioclogging, respectively. BBST, with the biopolymer molecules having electrical charge and a high specific surface area (SSA), creates a soil–biopolymer matrix that mobilizes higher strength compared to the untreated soil (Chang et al. 2016).

For coarse-grained soil, BBST improves the interparticle cohesion (and soil friction angle) through particle aggregation. The friction angle increases on account

of the larger particle contact area facilitated by biopolymer gel formation in the pore-void spaces (Chang et al. 2016). On drying, the gel stiffens and provides greater strength (than when wet). For clay soil, or soil with clay in its matrix, the biopolymer and clay particles bond with each other, owing to their charged surfaces, thereby forming a coating with enhanced interparticle contact (Chang and Cho 2019).

Cabalar et al. (2018) investigated the effect of XG dosage on clay soil for different curing periods. The fall cone and vane-shear undrained shear strengths of the treated soil was found to increase for increasing XG dosage and longer curing period. Here, the high SSA of XG enables better interaction between the soil matrix and biopolymer, thereby producing improved strength, although XG addition did not influence the soil stiffness, owing to electrostatic repulsion between the XG strands and clay particles. Chen et al. (2019) employed XG to improve the shear strength of sand, and observed that drying had a considerable effect on the mobilized strength. Also, their study showed that moisture content was the determining factor for soil strengthening, i.e., at higher water contents, the adhesive stress was low, whereas for the same dosage the adhesive stress nearly doubled on drying.

CH is also effective in improving the strength of clay soil through interparticle interaction that depends on the moisture content and curing period (Hataf et al. 2018). The cationic nature of CH enables electrical interactions to occur between the biopolymer and the diffuse double-layer of the clay particles, and thereby improves the interaction between the soil particles. Zinchenko et al. (2022) proposed the in-situ gelation of CH (cationic) and CMC (anionic) to improve the strengths of sand, clay, and sand–clay mixtures. This in-situ gelation technique offers a more flexible design for soil improvement. Clay treated with the poly-ions showed significant strength improvement, which was attributed to large ionic bonds formed between the clay particles and poly-ion solution, owing to the large SSA of the clay particles. However, for the sand, the strength decreased because of its small SSA and more porous structure.

Chang and Cho (2019) investigated the effect of gellan gum on the strength of clay, sand, and sand–clay mixtures through a program of direct shear and vane-shear strength tests. Gellan gum improved the strength of the selected soils for all dosages and water contents investigated. The shear strength of the gellan gum-treated sand was lower compared to gellan gum-treated soil containing clay, that is, the sand–clay mixtures. The increase in the cohesion and friction angle parameters was dependent on the gellan gum dosage, and was higher for the sand–clay mixtures. Also, for higher gellan gum dosage, the soil exhibited brittle and dilatative behaviors, which these authors attributed to the soil agglomeration effect. Smitha et al. (2021) used agar solution prepared at 100 °C to improve the strength of silty soil samples, employing 0.5%, 1%, and 2% agar dosage. The samples were cured at 30 °C for 0, 1, 3, 7, and 28 days, with the maximum strength gain observed for 2% agar at 28 day curing. As fitting parameters for the Mohr–Coulomb strength (failure) envelope, the deduced cohesion parameter was found to increase with agar dosage and for a longer curing period, but the deduced friction angle did not show such a characteristic response, instead tending to decrease for a longer curing period. Wen et al. (2019) investigated the strength improvement of sand impregnated by a

hydrogel of SA, with the unconfined compressive strength (UCS) of the sand treated with 0.4% SA dosage improved to 430 kPa.

Chang and Cho (2012) examined the strength behavior of β -glucan treated Korean residual soil. These authors found that the UCS of the treated soil increased by nearly 200%, which they explained by the soil particles accumulating around bundles of β -glucan (on account of the negative charge of the residual soil), thereby improving the ionic bond between the β -glucan chains and the soil particles. These authors also investigated the UCS of the β -glucan treated residual soil for different temperatures of 20 °C, 60 °C, and 100 °C, with the UCS mobilized at 60 °C substantially improved for the maximum dosage of 4.92 g/kg (of β -glucan to soil) investigated. Kumara and Sujatha (2020) also found β -glucan effective in improving the strength of lean clay, with both the deduced cohesion and friction angle parameters increasing for greater dosage and longer curing period, i.e., from a UCS of 62 kPa for the unamended soil, to 180 and 610 kPa for 2% β -glucan dosage, investigating one-day and 28 day curing, respectively. These authors attributed the strength increase to ionic bond formation because of the charged surfaces in clay and β -glucan.

Ayeldeen et al. (2017) used XG and GG to improve the mechanical behavior of collapsible soil. The shear strength parameters for dry and soaked conditions were measured immediately after adding the biopolymers to the soil, and then for seven-day curing. Both biopolymers were found to appreciably reduce the collapse potential of the treated soil, with GG performing significantly better than XG for both the immediate and seven-day curing scenarios investigated. These authors credited the better performance of GG to its higher molecular weight, which enabled the biopolymer to cross-link between the soil particles, and also reduced the soil permeability. Numerical analysis performed as part of their study showed that biopolymer addition improved the bearing capacity, and additionally reduces the settlement and effect of saturation for the studied collapsible soil. Dehghan et al. (2019) also investigated XG and GG to stabilize collapsible soil and to reduce the collapse potential. Both of these biopolymers improved the soil strength for all dosages and curing periods investigated. Kumar and Sujatha (2021) investigated XG and GG to improve the strength of clayey sand and found that XG showed better performance than GG, although both biopolymers were found to appreciably improve the soil strength. These authors concluded that the charged nature of XG enabled ionic bond formation that was responsible for the superior behavior of the XG additive.

Erosion Resistance of Biopolymer-Treated Soils

BBST is a promising technique for improving the mechanical stability of soil prone to erosion, and it can also promote an improvement in soil health (Wade et al. 2021). For example, biopolymer treatment improves both vegetation germination and soil water-retention characteristics against evaporation (Chang et al. 2015).

Kavazanjian et al. (2009) investigated spraying of 0.5–2 g/l XG solutions on the soil surface and performed simulated wind-erosion tests, observing a reduction in

soil loss to as little as 1 wt%. Ayeldeen et al. (2016) compared different polysaccharides, including XG, GG, CG, and modified starch, for improving the soil erosion resistance, and found that GG mobilized the maximum shear strength against wind erosion, and thereby experienced the least erosion (loss in soil mass). Ham et al. (2018) investigated the choice of an in-situ microbial biopolymer formation technique to deter soil susceptibility to erosion. These authors suggested increasing the sucrose concentration in the nutrient solution, and/or the volume of nutrient solution being injected, to augment the in-situ microbial biopolymer formation.

Joga and Varaprasad (2020) reported that XG effectively reduced the dispersive potential at 0.5–2% dosage by reducing the percentage of sodium in the dispersive soil investigated. They observed that 1% XG was the optimum dosage for mobilizing the maximum erosion resistance, which was attributed to gel plug formation and ionic bonds holding the soil particles together, thereby preventing them from being lifting off the soil surface. Wade et al. (2021) found an improvement in wind erosion resistance achieved by spray application of GG and SA solution. By allowing better diffusion, as SA (of low viscosity) was employed at a higher dosage of 5 g/l, this improved the aggregate size and UCS of the treated soil. Their study also showed that alginate produced stronger clods, resulting in stronger soil crust formation. Devrani et al. (2021) investigated various XG solution dosages, as well as the microbial-induced calcium carbonate precipitation (MICP) technique, to assess their efficiency in controlling the erosion of Rajasthan desert sand. [See, for example, Shahrokhi-Shahraki et al. (2015), Zomorodian et al. (2019) and Choi et al. (2020) for elaboration on the MICP technique] Both methods were found to significantly reduce the soil erosion (mass loss). For instance, the 0.25% XG-treated sand sample (with soil crust thickness of 2 cm) was able to resist a maximum wind velocity of 45 km/h. Shabani et al. (2022) investigated the biopolymer serish, a polysaccharide extracted from the root of the Eremuurs plant, for improving the strength and erosion resistance of dune sand, with, for instance, 2% serish-treated sand experiencing a soil mass loss of <1.21% when exposed to a wind speed of 25.2 km/h.

Orts et al. (2000) examined different biopolymers, including polyacrylamide (PAM), cellulose xanthate, starch xanthate, acid-hydrolyzed cellulose microfibrils, and CH, for reducing soil loss during irrigation. Their investigations comprised laboratory tests on a furrow arrangement for clay loam soil, and also field tests on furrows. Of the studied biopolymers, PAM was found the most efficient additive in resisting soil erosion during irrigation, with cellulose xanthate, starch xanthate, and acid-hydrolyzed cellulose microfibrils also producing good results. Based on their findings, Orts et al. (2000) recommended the use of BBST for various geotechnical engineering applications, including to mitigate erosion resistance of surficial soil layers at construction sites, and also for highway embankments. Through a series of laboratory simulations, Chang et al. (2015) demonstrated the potential of XG and β -glucan for improving the soil erosion resistance to heavy rainfall, and to deter desertification by promoting the growth of vegetative cover. Their study also underlined the capacity of BBST to improve interparticle cohesion and the soil's water-retention capacity, owing to hydrogel formation. Reddy et al. (2018)

investigated the stabilization of red mud (a dispersive industrial byproduct) using XG and GG additives. Their results showed that, whereas XG was not effective, 2–3% GG was found successful in arresting the dispersion phenomenon. Ko and Kang (2018, 2020) explored the possibility of reinforcing a levee slope employing a biopolymer additive, and found that the erosion resistance of the biopolymer-treated slope was 50% greater compared to the untreated slope. Their study also demonstrated that the breach mechanism for untreated and biopolymer-treated slopes was different, with delayed/inhibited initial erosion resulting in the water level reduction occurring at a slower rate for the biopolymer-treated levee. Mahamaya et al. (2021) investigated XG, GG, and CMC additives for improving the erosion resistance of two different dispersive materials, i.e., fly ash and organic silt, against both water- and wind-induced erosion. Their study reported that all three biopolymers produced appreciable improvements against water-induced erosion, as evaluated from pinhole and dispersion tests, with CMC showing superior performance compared to XG and GG. CMC also produced higher resistance to wind erosion, based on the reduced loss in soil mass for treated samples, evaluated for various wind velocities in wind tunnel experiments. These biopolymers coated the soil grains and bridged the pore-void spaces, either by gel-plugs or gel-threads, causing an increase in interparticle cohesion, thereby resulting in improved erosion resistance (Chang and Cho 2012; Ham et al. 2018). Greater erosion resistance can also be attributed to reduced seepage flow, owing to clogging of the pore spaces by gel-plugs.

The rheology of biopolymer-treated soil is distinct from the untreated soil, and is characterized by the absorption of moisture by the biopolymers due to their hydrophilic nature, plugging of the pore-void spaces, reduced seepage flow, and the hydrophobic behavior of the coated soil particles that cause high run-off (Chang et al. 2015). Furthermore, on drying, the hydrogel attaches itself to the soil particles, thereby forming a surface coating. The dehydrated soil matrix is stiff and resists volume reduction, thereby maintaining pores that are more open. This results in higher porosity, allowing more flow paths or easier root penetration to occur. For heavy rainfall, the hydrophilic nature of the biopolymers enables them to absorb more moisture, increasing their size, and thereby to fill (plug) the pore-void spaces and consequently reduce the infiltration by the bioclogging mechanism (Chang et al. 2015). Figure 1 presents the schematic process of improved resistance achieved for biopolymer-treated soil against water- and wind-induced erosion.

Biopolymer Applications in Contaminant Barriers and Clay Liners

Permeability is a critical factor to consider in selecting soil for use as a liner or contaminant barrier. Here, biopolymers can be employed to form gel-plugs that clog the soil's pore voids, thereby causing an exponential reduction in soil permeability (Bouazza et al. 2009; Wiszniewski et al. 2018; Sujatha and Saisree 2019; Anandha Kumar and Sujatha 2021). Also, with further moisture ingress, the hydrogel expands in volume resulting in filling of the pore voids. This characteristic makes

Fig. 1 Schematic representation of improved resistance achieved for biopolymer-treated soil against water- and wind-induced erosion

biopolymer-treated soil suitable for the construction of seepage barriers and slurry walls (Chang et al. 2016).

Various factors (e.g., the fines content and type of clay mineral in the soil, the biopolymer type and concentration, temperature, and aging (Choi et al. 2020)) affect the permeability of biopolymer-treated soil. Khachatoorian et al. (2003) investigated XG, GG, CH, polyglutamic acid, and polyhydroxy butyrate biopolymers for reducing soil permeability, and observed that they all produced substantial reductions in permeability. Over an 11 day curing period investigated, polyhydroxy butyrate achieved the maximum permeability reduction (of the order of 10^9 fold), while CH and polyglutamic acid biopolymers produced 10^6 fold reductions. Similarly, Bouazza et al. (2009) observed that XG, GG, and SA effectively reduced the permeability of silty sand, with, for instance, a 0.5% SA dosage reducing its permeability to (of the order of) 10^{-12} m/s for 70 day curing. Their study concluded that BBST can transform silty sand for use as a temporary seepage barrier material. Chang et al. (2016) investigated saturated gellan gum-treated soil, and found that it also exhibited a decrease in permeability due to the pore-plugging effect. Their study showed that 2% gellan gum additive produced a five order of magnitude reduction in permeability.

Ayeldeen et al. (2017) observed that XG, GG, and modified starch substantially reduced the permeability of treated sand and silt. A similar effect on the permeability of XG-treated sand was reported by Cabalar et al. (2018). For example, the permeability of 0.5% XG-treated sand showed a decrease from (of the order of) 10^{-6} to 10^{-11} m/s, and on increasing to 2% XG dosage, the permeability was reduced further (to 10^{-12} m/s). XG and GG were used to treat low-plasticity silty clay, and the results showed that the permeability reduction was dependent on the packing density,

biopolymer dosage, and curing period (Dehghan et al. 2019). Owing to its anionic nature, XG was also found to modify the permeability of soft marine clay (Kwon et al. 2019). The feasibility of using ϵ -polylysine, a cationic polymer, to reduce the permeability of high-plasticity clay was investigated by Kwon et al. (2019). Their results showed that although there was a permeability reduction for the clay, it was less than that achieved for XG treatment. Singh and Das (2020) reported a sharp reduction in the permeability of XG-treated expansive silt for various dosages and applied consolidation pressures investigated. Sujatha and Saisree (2019) observed that GG additive slightly reduced the permeability of silty clay – after full saturation for 6 h, the permeability had decreased from (of the order of) 10^{-6} to 10^{-7} m/s for 2% GG dosage. Biju and Arnepalli (2020) noted that for 0.5–3% dosages, both XG and GG increased the permeability of sand–bentonite mixtures. These authors concluded that the aggregation of the clay particles promoted by the biopolymer additives widened the pore void spaces, thereby causing the observed increase in permeability. Their study emphasizes the importance of considering both the type of soil and biopolymer when seeking to modify the soil permeability by BBST.

Using bacterial biopolymers produced from indigenous bacterial species, Kim et al. (2019) investigated the bioclogging mechanism in coarse sands to arrest leakage in waterfront structures. Their study showed that the soil's particle-size distribution, the choice of buffer, and the applied backpressure contributed to the change in permeability, with, for instance, greater permeability reduction achieved for fine sand (than coarse sand) due to its smaller pore-void spaces. SA effectively reduced the permeability of poorly graded sand (Wen et al. 2019), with, for example, the permeability decreasing from the order of 10^{-5} (for the untreated sand) to 10^{-7} m/s for the 0.4% SA-treated sand. Anandha Kumar and Sujatha (2021) evaluated the choice of XG, GG, and β -glucan for modifying clayey sand as a contaminant barrier/liner material. Their study also reported on the influence of the biopolymer type, its dosage, and the curing period on the change in permeability, with biopolymer-treated soil undergoing a remarkable permeability reduction of 3–5 orders of magnitude relative to the permeability of the untreated soil. With aging, a slight increase in permeability was observed owing to the hydrogel shrinkage on dehydration, but in all cases investigated the permeability remained much lower than that of the untreated soil. These authors argued that the slight increase in permeability would not negate the choice of these biopolymers for modifying soil into impermeable barriers for landfills or contamination facilities. They also studied the leachate-attenuation capacity of the selected biopolymers, and observed that XG showed the best performance in absorbing almost all heavy metals. Anandha Kumar and Sujatha (2022) compared the performance of calcium bentonite-modified silty clay and XG-treated silty clay for use as clay liner material and found that the XG-treated silty clay had higher strength and lower permeability when compared to the calcium bentonite modified soil. For instance, the 1% XG-treated soil had permeability nearly 30% lower than the calcium bentonite-modified soil. These authors advocated the choice of XG additive to modify soil for construction of clay liners on the merits of its environmentally friendly nature, negative carbon production, and non-polluting behavior. The bioclogging mechanism responsible for reducing the permeability of the biopolymer-treated soil is shown in Fig. 2.

Fig. 2 Bioclogging mechanism for biopolymer-treated soil

Challenges and Future Research Needs

To date, only a few studies have investigated the economic aspect and environmental impact of BBST application on a large scale. Biopolymers are presently less competitive economically compared to conventional soil binders, like cement and lime. However, since biopolymers also find various applications in other fields (e.g., the food, textile, cosmetic, pharmaceutical, and medical industries), there is scope for their mass production, which in-turn can bring about a reduction in their cost. For instance, in the 1960s, the cost of XG was 30,000 US\$/ton, but this had reduced to 1500–4000 US\$/ton by 2020, providing an expectation of its large-scale geotechnical/geoenvironmental engineering application in the near future. Possible environmental impacts of BBST application that require investigation include the effects of the consequent elevated soil temperature and change in soil pH, and that biodegradability may affect its durability. For instance, the way that biopolymers are degraded when used in large volume raises concerns about potential contamination of the terrestrial environment. Sensitivity to water is another major consideration; strength loss and apparent swell/shrink behavior are the drawbacks (Fatehi et al. 2021).

Limited field studies have been performed to evaluate BBST, or to investigate the changing characteristics of biopolymer-treated soil under real environmental conditions, for example, varying temperature and pH, wetting–drying cycles, and micro-organism and (for surface-treated soils) ultraviolet-radiation attacks. Chang et al. (2020) reported a trial field study investigating XG, casein, and XG–starch combination for stabilizing, and promoting vegetative growth on, the side slopes of an embankment at a pilot construction site in Seosan, Korea. On-site observations after 100 days showed increased shear strength and vegetation density.

Biopolymer durability in long-term field applications requires more investigation to understand how different biopolymer types behave under various environmental and loading conditions. For instance, since many biopolymers are soluble in water, exposure to water would likely affect the BBST performance during wetting–drying cycles. Grouting/injection of biopolymers in soil also remains a practical drawback (Khatami and O’Kelly 2022), with field applications of BBST limited by the development of necessary equipment that is compatible with the rheology of the biopolymers. Due to increased viscosity, injection of biopolymer-added grout

typically requires higher injection pressures that depend on the biopolymer concentration/grout viscosity (Khatami and O’Kelly 2022).

Summary and Conclusions

The geotechnical engineering sector consumes huge amounts of chemical additives (conventionally cement and lime), as binders, most of which are not ecofriendly. Of the various biological methods, BBST represents a promising green and sustainable alternative for soil strengthening (i.e., biocementation) and in reducing the soil permeability (i.e., bioclogging). This chapter elucidated the potentials of BBST for various geotechnical and geoenvironmental engineering applications, including the stabilization of weak soils, slopes, and excavations, for modifying marginal soil as contaminant barrier material, and in providing improved resistance to combat erosion of surficial soil layers, to name a few. For instance, their tendency to improve the interparticle cohesion potentially makes BBST particularly suitable to resist water- and wind-induced surface erosion. Furthermore, BBST may improve soil health, that is, by increasing the soil’s organic matter content and water-retention capacity, thereby promoting the growth of vegetative cover.

On the technical side, various factors must be carefully considered to achieve optimum BBST results, including the type of soil (i.e., its gradation, fines content, and the clay mineral type present), the biopolymer type and dosage, the moisture condition (saturation level), and curing period. Biopolymers modify the plasticity characteristics of fine-grained soil owing to their hydrophilic nature and, in the case of gelling biopolymers, the viscosity of the pore-fluid. Biopolymers also reduce the permeability of the treated soils, as the hydrogels tend to swell when in contact with water, thereby clogging the pore-void spaces.

The limited field implementation trials performed, to date, have reported enhanced engineering performance achieved by BBST. However, more studies are needed on the technical, environmental, and economic aspects of BBST application on a large scale. Additional research by way of comprehensive field trials are still required to translate and upscale the promising experimental outcomes to geotechnical and geoenvironmental engineering practice, investigating, for instance, the changing characteristics of biopolymer-treated soil for real environmental and loading conditions (e.g., involving wetting–drying cycles and microorganism attack). Grouting/injection of biopolymers also remains a practical issue, with the development of field equipment that is compatible with the biopolymer rheology necessary.

Abstract

The search for eco-friendly and renewable resources endowed with high stability and low toxicity has directed researchers around the globe to focus their attention on biomaterials, namely, biopolymers, which reduce the pollution caused by the rise in synthetic material-mediated pollution. As investment and research into biopolymers increases, several conventional material utilities are reduced in various optoelectrical, biological, and technological applications. Biopolymers in conjunction with nanotechnology have opened up novel and extremely useful arenas for their applications, namely, in the biomedical, energy sector, etc. This chapter is envisioned to outline the significant status of biopolymers as a

Introduction

Biopolymers are polymers manufactured chemically from biological compounds or derived by biosynthesis. They have several pros over synthetic polymers, such as more complex, well-defined structure, renewability, and degradability (Cziple and Marques 2008; Augustine et al. 2013). The distinction between biomolecules and biopolymers is often misunderstood. Biomolecules like the polyamine acid family are found in living organisms, and natural organic substances are not engineering materials. Hence, these biogenic macromolecules are not biopolymeric materials. Biomolecules that can be biotechnologically further converted into raw ingredients for polymer production are an exception. Polysaccharides and some bio-based acids and vegetable oils that can be used directly as raw materials are examples of exceptions.

Degradability is ultimately determined by the chemical as well as physical microstructure of the polymer and is independent of the source of the raw components employed or the manufacturing process. A polymer substance satisfies at least one of the following criteria, according to the best current generic definition of biopolymers:

- It is made up (in part) of sustainable raw materials.
- It is biodegradable.

As a result, biopolymers do not have to be made entirely from renewable resources. Petrochemical raw ingredients such as polyvinyl alcohols, polycaprolactone, copolyester, and polyester amide can also be used to make biodegradable biopolymers.

Biopolymers derived from various sources have been studied for pharmacological and biological applications for many years. Currently, biopolymers are used as an efficient active ingredient of medication or various healthcare products on the market. Biopolymers attract attention owing to their various compositions, tunable physical characteristics, and plenty of interesting options. Furthermore, the comparatively cheap cost and sustainable nature allow such materials to be significantly interesting for expensive industries like pharmaceutical and biomedical (Niaounakis 2015).

The only polymer materials developed from renewable resources at the start of industrialization were cellulose derivatives and rubber. At that time, natural raw

materials were only available in sufficient quantities. With the successful advancement of the petrochemical industry, renewable resources such as polymer raw materials were suppressed in favor of petrochemical-based raw materials (Stevens 2004). In recent decades, the first biologically degradable polymer compounds, such as polyvinyl alcohols or polycaprolactone, were produced based on these petrochemical raw ingredients for specific niche applications (Imam et al. 1999). Even though petrochemical-based plastics offered unparalleled processing and use features, the reliance on limited foreign resources for raw ingredients and the unfavorable disposal properties prompted a shift in focus. Since the end of the 1980s, polymers' disposable and recycling ability received more attraction and a growing number of degradable polymers based mostly on renewable resources have been industrialized. Meanwhile, the anticipated scarcity of resources and steadily rising prices of petrochemical raw materials have turned the focus of attention to biopolymer materials. Compostability is no longer the most important factor; instead, the use of renewable, i.e., long-term available resources for manufacturing raw materials, has taken precedence.

Innovative biopolymers, particularly those based on starch and polyhydroxy alkanooates produced by fermentation, were first introduced to the market more than 30 years ago, i.e., in the early 1990s. Despite some euphoria and promising prognoses, these biologically degradable first-generation biopolymers were unable to establish themselves in the market, owing to their yet-to-be-tested material properties, unfavorable political and economic conditions, and a lack of political resolve among industry and policy decision-makers (Endres et al. 2007).

Of late, work has begun on the development and optimization of a wide variety of biopolymers as the regulatory framework has changed. In terms of manufacturing and use qualities, improved second-generation biopolymer materials are currently on the market and are substantially comparable to traditional bulk plastics. They are becoming a progressively exceptional utility as packaging components (Platt 2006). Biopolymeric materials are now subject to slight economic drawbacks, owing to their still limited production volume. Once disposal expenses are factored in and/or production levels are increased further, this will be offset. The second-generation biopolymers find their utility as sustainable materials. These second-generation biopolymers are now being used to make polymer materials for engineering applications, and they are gaining popularity as they make their way into other industries like automotive and textiles (Holm Vibeke et al. 2006).

The trend in third-generation biopolymer materials is toward resistance rather than degradability. Simultaneously, in light of the restricted availability of petrochemical raw materials, the utilization of renewable resources for material manufacturing is gaining traction. One factor to examine is the long-term availability of the raw material base. Beyond that, further technological features such as heat resistance, odor, brittle fracture behavior, color, UV stabilization, and long-term reliability will be prioritized in the development of these biopolymer materials. The invention, testing, and application of relevant biopolymer additives, as well as the optimization of biopolymer production and processing properties, will be hot subjects (Smith 2005) (Fig. 1).

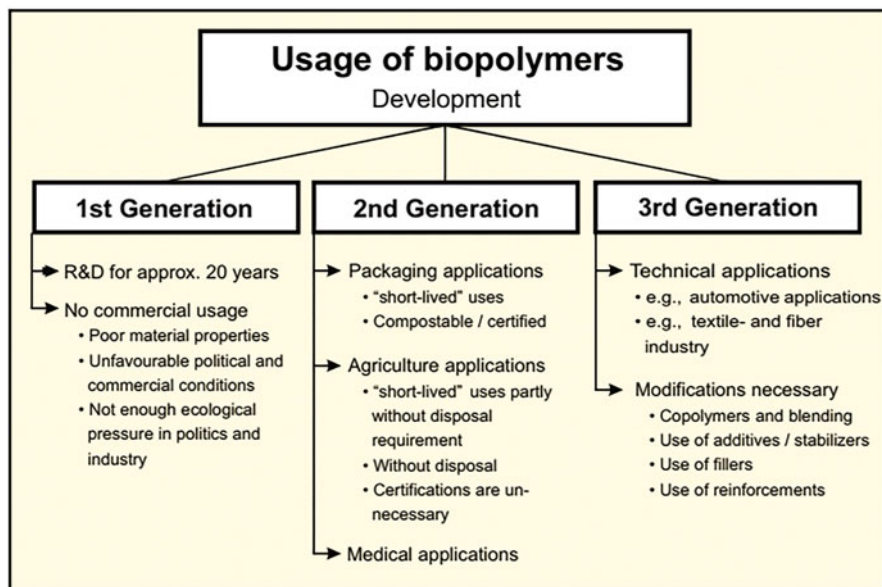

Fig. 1 Development of biopolymer (Endres 2011)

Rubber, linoleum, celluloid, and cellophane were among the first present-day biomaterials created from natural biopolymers. Cellulose is the source of the latter two and is the most abundant organic biopolymeric material. Petrochemical-based materials have largely supplanted human-made biopolymers that have attracted extraordinary interest from industry, the academic community, and policymakers (Baillie 2004) as a result of growing ecological concerns. Biopolymers have plenty of utility as packaging materials, medical field, food additives, cosmetics, adsorbents, textiles, sustainable plastic, biosensors, etc. Biopolymers are promising materials because of their abundance, biocompatibility, and unique qualities such as nontoxicity, among others. Biopolymers are being explored for use in a growing number of ways using nanosized reinforcements to improve their characteristics and practical uses (Bastioli 2005).

Classification

Biopolymers are giant macromolecules consisting of a large number of identical units (Guzman et al. 2011). In comparison to synthetic plastics, these polymers have been in the biosphere for billions of years. As compared to their synthetic analogs, biopolymers exist in an orderly fashion disintegrating long chains by various bioprocesses like metabolic degradation by enzymes and other environmental factors (Wang et al. 2015). The presence of the hydroxyl group causes the breakdown of biopolymer creating hydrophilic metabolites.

Biopolymers can be categorized in several different ways, namely, their origin, degradability, and polymer backbones. Biopolymers are separated into natural, synthetic, and microbial biopolymers based on their origin. Classification based on degradability has resulted in two groups, namely, biodegradable and non-biodegradable, while they are divided into many groups based on the polymeric backbone or functional group they possess. We can divide monomers into three categories based on their type: polysaccharide, protein, and nucleic acid. Another classification of biopolymers is based on their heat sensitivity, namely, elastomers, thermoplastics, and thermosets (Leja and Lewandowicz 2010) (Fig. 2).

Some of the classifications are

(a) Based on the origin:

- **Sugar-derived polymers:** In these types of biopolymers, sucrose is utilized as the basic production input. Lactic acid polymers are made from lactose from potatoes, maize, and other sources. Polyhydroxybutyrate is made using starch or sucrose as an input. Blowing, injection, vacuum shaping, and extrusion can all be used to make them. Lactic acid polymers (polylactides) derived from lactose obtained from potatoes, wheat, and sugar beet are found to be water-resistant (Monzer 2014).
- **Starch-derived polymers:** Polymers based on starch – starch is a natural polymer made up of glucose molecules. It is present in the tissues of plants. Wheat, tapioca, and potatoes all contain starch, which functions as a natural polymer. The substance is kept as one-way sugars in plant tissues. It is made up of glucose and is made by melting starch. Animal tissues do not contain this polymer. Tapioca, corn, wheat, and potatoes are examples of vegetables that contain them. Dextrins is a category of low-molecular-weight

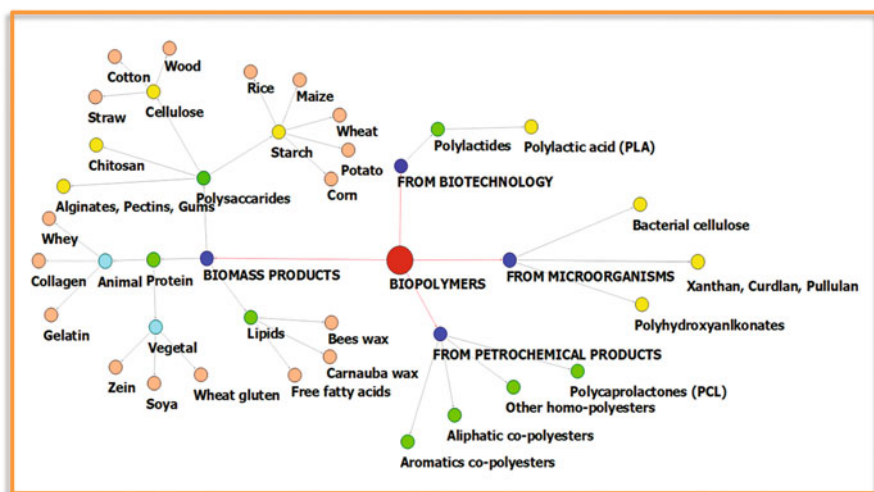

Fig. 2 Classification of biopolymer (Gheorghita et al. 2021)

carbohydrates generated by starch hydrolysis and enzymatically synthesized onto biopolymer carriers by immobilized *Enterococcus faecalis* Esawy dextranase (Esawy et al. 2016; Hashem et al. 2016).

- **Cellulose-based biopolymers:** This polymer is composed of glucose derived from natural sources such as cotton and is used for packaging. Consider cellophane. These are utilized in the packaging of cigarettes, CDs, and candy. The fundamental constituent of plant cellulose walls is this polymer, which is mainly composed of glucose. Cotton, wool, wheat, and corn are among the natural resources used to make them (Kaurov 2011).
- **Synthetic materials:** Synthetic materials derived from petroleum can be used to create biodegradable polymers. Biopolymers based on synthetic chemicals, such as aliphatic-aromatic copolyesters derived from petroleum, are also employed to make biodegradable polymers. Even though they are made of synthetic materials, they are entirely compostable and biodegradable (Kaurov 2011).

(b) Based on monomeric units:

- **Polysaccharides:** They are carbohydrate chains that are either branched or linear, for example, starch and cellulose.
- **Proteins:** Polymers built up of amino acids are known as proteins. Collagen, fibrin, and other proteins are examples.
- **Polynucleotides:** Nucleic acids are lengthy polymer chains made up of 13 monomeric units or more. DNA, RNA, and other similar molecules are examples (Nioounakis 2013).

The use of biopolymers is becoming increasingly popular among scientists. Because of their environmentally friendly nature, they can be used in a variety of settings. Because of their low cost, a variety of biopolymers are now utilized in industry. Because of their low cost and environmentally benign characteristics, these polymers will be used somewhat shortly. Blending and grafting are two techniques for increasing biopolymer characteristics. Biopolymers have been used to make a variety of composites and nanocomposites. Biopolymers are known to play an integral role in automotive, regenerative medicine, and packaging applications

The basic motive to promote the use of biopolymers is to replace many of the products we use every day that are manufactured from petroleum. This implies they will require qualities that are equal to, if not better than, the materials they are replacing to be suitable for the different applications they will be used in. Factors like the extent of polymerization and presence of additives and reinforcement agents and the quantity of these elements define the property and quality of the biopolymers. Lots of such efforts have been recorded by scientists around the world to study their thermophysical and mechanical properties (Augustine et al. 2013). Electro-active biopolymers derived from biological sources like starch, cellulose, chitosan, and pectin possessing electrical and ionic conductivity (EABP) are actively pursued to replace other synthetic nonrenewable materials (Niaounakis 2015).

Biopolymers as Engineering Materials

Biopolymers have various industrial applications in the area of food packaging, agriculture, medicine, and cosmetics (Fakirov and Bhattacharyya 2007). Some of them were found to be capable of replacing petroleum-based plastics and also fit for specific applications where plastic does not work, like artificial tissue development. The major requirement of such applications is a material with biodegradability and biocompatibility, and also sensitive to pH changes, as well as thermal and physico-chemical fluctuations (Imam et al. 1999).

When compared to synthetic polymers, biopolymers show poor chemical resistance, mechanical properties, and processability. Biopolymers reinforced with fillers called biopolymer composites were found more fit for specific uses owing to a drastic improvement in these properties. Of late, the demand for biopolymers surged, with the advent of novel and potential applications apart from being an integral part of being utilized in everyday life offering a sustainable substitute to plastic. Some of the major applications of biopolymers are summarized below.

Biopolymer-Based Antimicrobial Packaging

Environmental and microbial degradation of food products upon storage is a big challenge to the quality of food. The damage to food is due to the changes occurring in the food components and its exposure to processing conditions and environmental factors (Balasubramaniam and Chinnan 1997; Labuza and Breene 1989). Prevention of such damage from manufacturing time to consumption is the main objective of food packaging. The protective covering provided at the time of processing and storage prevents harmful deterioration of food and also enhances the food quality.

Packaging using raw materials of agricultural and marine origin is termed biopolymer-based packaging. They improve food safety as well as shelf life. Moreover, they effectively bring down the global carbon footprint arising from packaging systems specifically designed for food. The commonly used bio-based polymers for food packaging include polylactic acid, chitosan, cellulose, and starch. In addition, bio-based films and containers have the potential to replace oil-based packing materials providing enhanced technical properties and giving a sustainable and greener face (Vermeiren et al. 1999).

Polysaccharides are nontoxic biopolymers widely distributed in nature. Their selective permeability to CO_2 and O_2 retards the ripening of many vegetables and fruits by limiting respiration. Starch is an environmentally friendly, low-cost biopolymer with hydrophilic nature. Starch-based films show mediocre gas barrier properties while they lack better mechanical properties when compared to synthetic polymers. The addition of water acts as a plasticizer that imparts a thermoplastic behavior to starch. Starch-based coatings that contain potassium sorbate are reported to enhance the shelf life and reduce the microbial count (García et al. 1998)

Alginate is the salts of alginic acid and react with di- and trivalent cations which are utilized to form alginate films. Studies were carried out on the efficacy of a

calcium alginate film to prevent microorganism growth on beef and were found to have more acceptance from consumers (Williams et al. 1978)

Protein-based coatings on different vegetables and fruits obtained from milk, gelatin, wheat, etc., exhibit adequate barrier properties toward oxygen and carbon dioxide and are ineffective in the case of water. The WVP of the laminates was improved by incorporating corn zein but failed to improve the oxygen barrier property in contrast to SPI film (Anker et al. 1999).

In the beginning, the packaging mainly focused on the protection of food from physical damage, appearance, and durability of the package. Recently, the packaging technology stepped into the next level of development, giving more emphasis on safety traits with add-on antibacterial activity. The incorporation of antimicrobial agents into the packaging matrix is a big challenge as many of them studied are not suitable for food application. The selection of an antimicrobial agent is based both on its compatibility with the packaging material to be used and also on the heat liability of the antimicrobial compound during extrusion. Recent research has mainly focused on the development of new methods and their testing on model systems, but not in real food products. Technical feasibility, safety features of food antimicrobials, and consumer acceptance, along with the physiological, chemical, and microbial action of the packaging, must be the main focus of the food packing technology (Cha and Chinnan 2004).

Cosmetics

Cosmetic ingredients derived from living world (plants, animals, microbes, etc.) consist mainly of proteins. The cosmetic value of these proteins relies on their hydrophobicity and molecular backbone. Water-soluble hydrolysate of protein segregated from collagen is utilized in hair care products. Biopolymers like Gum Arabica are frequently used in the cosmetics industry owing to their nontoxic and nonallergenic properties. Furthermore, it stabilizes emulsions, aids in the rise of viscosity, gives the skin a smooth sensation, and produces a protective coating in creams and lotions apart from being utilized as a foam stabilizer.

Human and bovine collagen implants are exploited very well in cosmetic surgeries like dermatological healing, wrinkle removal, bone rebuilding, and dental and orthopedic surgeries. Due to the insolubility of collagen, only hydrolyzed collagen is employed in cosmetic formulations. Water-soluble small peptides and short polypeptides can be easily included in a variety of cosmetic compositions (Sionkowska et al. 2017). The lyophilization method is employed for the manufacture of collagen hydrogels and aerogels (Van Duong et al. 2018). The soluble collagen administered subcutaneously for healing dermatological defects is one of the most rewarding collagen applications boosting its popularity in cosmetic dermatology (Sionkowska et al. 2017). The types of chemicals that are added to a collagen filler formulation may vary depending on the requirements. Several research groups across the world are investigating collagen for improving cosmetic uses.

Keratin is the primary constituent of hair mainly utilized for conditioning though water-soluble hydrolyzed keratin is also employed in hair sprays and body creams (Jay et al. 1998). Crosslinkable keratin-based hydrogels are found to have enormous applications in mending wounds. This property of human hair-derived keratin-based hydrogels boosts its application in cosmetics as well. Apart from the gelling qualities, several natural polymers like cellulose gum find a key role as thickening agents. For instance, cellulose gum is a carboxymethyl cellulose derivative that is a water-soluble polymer and can be rheologically tuned by formulation specialists to have various physical properties like film formation, suspension, emulsion stabilization, etc. Cellulose gums have a thick, nonadherent surface whereas nanocellulose hydrogels, in particular, appear to have tremendous potential in energy storage, biomedical, culinary, cosmetic, and construction applications (Mezzenga et al. 2005; Coffey et al. 2006). Dextran-derived hydrogels have immense cosmetic potential (De Vuyst and Degeest 1999; Shahidi and Han 1993).

In many countries, notably in India (Biswas et al. 2001), placental protein is frequently employed in cosmetics and products used to cure an injury. Skin-whitening agents or UV-protective creams, antioxidants, or rejuvenation of skin help in maintaining youthful skin and thereby appear to have a good substitute for glutathione-based products. It bears exceptional antioxidative properties that decelerate the aging process by actively stimulating skin cell replenishment and actively by virtue of the natural components present in them and suppressing melanin production (Togashi et al. 2002; Olaiwan et al. 2010).

The aesthetics, biodegradability, and physiological benefits of the products are improved immensely by employing biopolymers as cosmeceuticals and additives. Swelling ability and mechanical strength are two important characteristics of hydrogel networks for cosmetics applications. The biodegradability of these biopolymers is an additional advantage. The advent of the twentieth century saw the boom of the polysaccharide industry followed by hydrocolloids based on pectins, chitosan, xanthan gum, alginates, etc. Polymers based on polysaccharides imparted water solubility and are functional food and cosmetic additives (Manjanna et al. 2010; Timerbaeva et al. 2007) whereas hydrocolloids derived from plants and microbes were utilized to give cosmetic and toiletry compositions a variety of distinct properties, namely, enhancement of water resistance, gloss, adhesion, and flexibility. The cosmetic industry relies heavily upon both animals and plants to provide proteinaceous components. Fungi and algae-derived proteins are gaining more popularity as protein sources with positive effects as topical agents (Secchi 2008). Protein's capacity to hold water to the peripheral skin layer is essential for the well-being of skin and hair. Simple proteins are utilized to make the majority of aesthetic protein derivatives, as opposed to conjugated proteins. The amphoteric and buffering capabilities of proteins are known to protect hair fibers (Chvapli and Eckmayer 1985). Chvapli et al. (Montecucco and Molgó 2005) explored the significance of proteins, especially collagen in cosmetics, with a specific focus on its use in conjunction with detergents. The authors addressed a number of misconceptions about collagen's mechanism of action, as well as potential hazards if collagen-containing formulations are not administered on intact skin.

The replacement of synthetic analogs with biodegradable polymers by the researchers was mainly due to economic, environmental, and technological reasons. Producing renewable polymers from mature plants is a daunting challenge that includes successful collaborations between many sectors. Crop plant advantages will improve with a greater understanding of their chemical, biological, and physical activity. The success of biopolymer utilization is linked to various fields spanning science and technology streams, such as biotechnology, chemical engineering, genetics, and novel experiments, including extraction of efficient polymer and monomer extraction from plants and its amalgamation into biorefining facilities. Biopolymer's success will be aided by advancements in all of these sectors. Polymer chemistry, in particular, will play a key part in the economical and energy-saving translation of building blocks into polymers, as well as the alteration of the extracted polymers for use in a variety of products (Augustine et al. 2013).

In Geotechnical Engineering

In geotechnical engineering, improving soil qualities has been a long-standing effort and progress. Researchers have discovered several soil improvement techniques like reinforcement, stabilization, grouting, etc., of which some are found to have harmful effects on the environment. As a result, we have to take corrective action with environmentally friendly technology. To reduce carbon emissions in the cement manufacturing process, bio-mediated geochemical soil improvement strategies are devised (Cole et al. 2012; Mitchell and Santamarina 2005; Ringelberg et al. 2014). Alternatives to standard soil treatment and enhancement approaches include greener materials (Tran et al. 2019; Jeong et al. 2019; Lee et al. 2019) and procedures (Qabany and Soga 2013; Chang et al. 2015; Lin et al. 2016) (i.e., mechanical improvement and chemical treatment).

The bacterium *Xanthomonas campestris* produces an anionic polysaccharide called xanthan gum (Chang et al. 2016). Xanthan gum is utilized to decrease the porosity of sandy soils by stuffing their pores (Gioia and Ciriello 2006) and improving water retention and preventing soil erosion. In geotechnical engineering (Brune et al. 2010), reduced mechanical, chemical, and structural characteristics, as well as less biodegradation stability, are the main drawbacks of employing biopolymers in tissue engineering. As a result, further research is needed to change biopolymers so that new adaptable materials can be developed that are better suited for tissue engineering applications.

Polyacrylamide (PAM) is an effective water-soluble low-cost polymer widely utilized for water treatment, enhanced oil recovery (EOR), and soil improvement effects (Flanagan et al. 2002; Jung et al. 2013; Xiong et al. 2018). Partially hydrolyzed PAM containing 0.5 wt% NaOH performed better than a polymer flood when tested for EOR (Jung et al. 2013). Recent research has demonstrated that biopolymers can be utilized to improve and stabilize soil and that they offer a number of benefits. Adding biopolymers to soils has been shown in several studies to improve soil strength.

Cyamopsis tetragonoloba seeds yield a polysaccharide, guar gum, on extraction (Smitha and Sachan 2016; Chudzikowski 1971). Addition of guar gum to silt increased permeability, sand cohesiveness, and unlike other biopolymers like modified starch and xanthan gum. Over the ages, soil improvement strategies have been extensively researched and improved. The simplest and most straightforward approach for improving soil is to add cement to it. However, due to serious environmental concerns, the need for environmentally friendly construction technologies is growing. Adding biopolymers to soils has been shown in several studies to improve soil strength. Biopolymers interact with soils depending on the temperature, type, ratio, and response to the water offering several benefits for the stabilization of soil. Biopolymers deployed are considered to be in sync with the geographical characteristics in near future.

Civil Engineering Applications

Biopolymers enjoy a niche stature in civil engineering practices with substantial turnover in sales. The world's urban center population is expected to grow from 3.4 to 6.4 billion people between 2009 and 2050. To handle the growing population of people in the world's big cities, the construction sector is expected to increase at an exponential rate (Daramola and Ibem 2010). Seto et al. (2012) calculated that by 2030 there will be civil engineering structures based on biopolymers (Ashby 2015). Soil incorporated with biopolymers lowers the water conductivity while increasing absolute strength (Kavazanjian Jr. et al. 2009; Nugent et al. 2010). Biopolymers have a tendency to plug the holes and are used for biodegradable borehole drilling (DeJong et al. 2013). Biopolymers can be used to construct permeable reactive barriers for groundwater correction as temporary excavation support fluids. When sand is treated with biopolymer slurry, the permeability of the sand can be reduced in as little as 2 weeks. The hydraulic conductivity of sand is found to decrease while extracellular polymers are added to create hydraulic barriers (Khachatourian et al. 2003; Reddi and Bonala 1998).

Microbial polysaccharides can be employed as cement admixtures. Temporary structures are made of biodegradable microbial bioplastics. Biotechnologically produced bioagents like soil microbes or active cultures of native microorganisms can be employed in construction. In the building industry, biotechnology is used for soil bio-clogging, bio-desaturation, bio-cementation, and bio-aggregation. Biotechnologically produced construction materials and processes are superior to their traditional counterparts and if utilized to their full potential they might yield significant economic and environmental benefits (Çabalar and Çanakci 2005).

Use of lignosulfonate in construction is bound to decrease mainly due to lack of start material and shift in technology of modern times. Polymer composites containing biopolymers like starch, cellulose, or other synthetic polymers were being used in drilling oil well. Starch and cellulose-derived compounds rule the construction scenario as newer and advanced technological advancements were utilized to make it industrially viable and profitable business as it can be tuned

accordingly by chemical blending and introducing additives or modifiers. Microbial biopolymers offer extensive potential especially in providing sheer thinning rheological effect compared to synthetic and other biopolymeric competitors in this arena. Novel industrial products with superior potential with high-temperature tolerance were produced by mutant or novel species of microorganisms. Even though it is an expensive process, the advantages it imparts make it highly sought after despite the costs incurred. Moreover, in case of microbial biopolymers, existing microbes improve capacity to develop more fruitful organisms that ultimately advance the production of more similar microbes that make better nutrients, thereby improving the economics in the long run. Researchers are currently interested in finding new technological innovations to expand their production and utility, which already is superior to synthetic polymers.

Farm products are not damaged by biopolymers and are superior to petroleum-based polymers. Biomass and agricultural waste recycling boost environmental conservation, ecological equilibrium, and environmental cleaning (Gopalakrishnan et al. 2013; Gopalakrishnan et al. 2012; Hottle et al. 2013). The perceived advantage of biological polymers has been found to be appealing to the consumers as they are environmentally benign and the previous experiences with natural components with synthetic polymers have resulted in potential health hazards over the years due to toxicity associated with the majority of the synthetic analogs.

Agriculture

The financial damage in agriculture and food production is attributed mainly to pathogens and pests affecting the crop yields. Hence, ensuring excellent seed quality and their protection from disease-causing agents using various chemical agents has been a norm. Since the 1930s, all existing classes of synthetic polymers have found utility in various aspects of agriculture in controlling release of nutrients and pesticides, fumigation, conditioning of soil, etc. The advent of biopolymers allowed added excellent features like biodegradability and circular economy into the field of agriculture, which can convert the polymers into soil-enriching raw materials.

Agriculture is interested in investing in biopolymers due to scientific and commercial motives. Seed coating done by biopolymers offers stabilization, protection, enhancement of yield, and growth regulation of plants. Biodegradability and sufficient action lifetime of starch-based polymers make them attractive to be put into agricultural use, especially as nutrients and insecticides incorporated as controlled release agents. Its ability to disseminate, dissolve, and encapsulate the active ingredient helps the polymer matrix or coating as an attractive candidate in agriculture. It can also exist as a part of a macromolecular scaffold or as a peripheral substitution of a pendant. Chitin, alginic acid, cellulose, lignin, and starch can function as biopolymers commonly employed in controlled release systems (Prasad et al. 2007).

Carbohydrate-derivatized biopolymers, owing to their biocompatible, atoxic nature, are definitely a greener substitute for potentially hazardous fungicides and have been proved to be an efficient and a versatile competitor as they can be elicitors

or matrix component or even active constituent carriers. The antifungal property can be enhanced by effective amalgamation of antifungal agents with these biopolymers resulting in innocuous fungicides. Chitosan is one such polymer shown to be a potent fungicide that enables the plant to initiate defense mechanism against microbes, especially against fungal infections. Pretreatment of seeds with chitosan as a coating or even soaking has proved to be beneficial as it impedes the spore formation and mycellar growth while it improves seedling growth. Even nanoparticles based on chitosan exhibited antifungal properties, and edible coatings of chitosan are very potent alternatives for improving the shelf life of fruits like apples against microbes. Apart from this, coatings using alginates stimulate the development of different plant parts of both aerial and roots, consequently improving their resistance toward pathogens. Nanoparticle addition to these coatings can be used to improve their antifungal activity.

Cellulose and its derivatives have been found to be effective carriers and binders of active ingredients and control agents apart from being used as protective barriers and biodegradable plant membranes. Ether derivatives like carboxymethyl cellulose (CMC) are efficacious fungicidal seed coatings while hydroxypropyl methylcellulose (HPMC) are edible vegetable/fruit coating used in conjunction with preservatives. They constitute a class of promptly biodegraded polymers with finite shelf life, which requires a preservative that is integral to prolong their biochemical properties. Apart from this, such cellulose-derived biopolymers from various sources lack safety and efficacy profiling mainly due to polydispersity and structural heterogeneity arising from their sources and it is complicated to refine these raw materials as it is an expensive and incompetent process.

To summarize all three biopolymers, it was noted that even though cellulose is inexpensive and easily available its effective applications require better assessment procedures to cater to its disadvantages like high lipophilicity and safety concerns. Chitosan is an expensive alternative but is an effective antifungal agent, while alginate is very hydrophilic but has to be mixed with other microbes.

Degradable manure has advantages of not hindering the natural processes of successive plantations and fumigant mulches that effectively require films imparting low porosity, thereby decreasing application cycles of pesticides. Naturally occurring polymeric compositions that can enhance the pesticidal activity under ambient climatic conditions and pH are being designed, genetically tailored, and developed with improved shelf life, and a safer, broader spectrum of antimicrobial activity, which can be integrated into current pest management game plan.

Biopolymers for Biomedical Applications

Biopolymers are frequently employed in biomedical applications. They are employed in tissue engineering, pharmaceutical industry, medications, drug delivery, tissue engineering, pharmaceutical carriers, medical devices, and so on because of their features, including degradability and nontoxicity. Polypeptides are cheap and easy to come by, thus they are used in a variety of biomedical products. Biopolymers

can be used in a variety of biomedical applications when conventional polymers are ineffective. Biopolymers degrade in the human body and are devoid of any adverse effects, making them a feasible choice for medical use. Biopolymers have gained enormous recognition in recent years owing to their potential applications in biomedicine. Gelatin, for example, is a biopolymer commonly used in medicine for wound dressings, adhesives, and other purposes. In addition, simple porogen such as solvents or gases were used to make porous gelatin scaffolds and films. This procedure permits the scaffolds to contain medicine or nutrients that will be delivered to the wound to help it recover. Gums are used to encapsulate flavors, fragrances, phenolic compounds, antioxidants, and nutraceutical substances, among other things. The controlled drug release characteristic of gums enhances the targeted drug delivery mechanism. It is used to treat hypotension induced by surgical shock in the pharmaceutical business. It is also commonly employed in formulations as a tablet binder and emollient in cough drops and syrups (Yadav et al. 2015; Aggarwal et al. 2020).

In Drug Delivery

Synthetic polymers have long caught researchers' curiosity as encapsulating materials for a number of therapeutic chemicals. Despite the fact that they have better pharmacokinetics than small-molecule medications, the toxicity concern due to their buildup has caught enough attention (Schmaljohann 2006). The key challenge with the pharma industry's reorientation toward the custom utility of biopolymers is the choice of the appropriate compounds relying on the requirement and anticipated outcomes. It is critical that these biopolymer encapsulating agents safely deliver the active drug to the target effectively through oral or intravenous drug administration (George et al. 2019).

In the pharma manufacturing industry, alginate is arguably the most extensively utilized biopolymer, owing to its unique encapsulating and wound-patching properties. Alginate was initially utilized as an encapsulating agent in the treatment of diabetes to encapsulate pancreatic islet cells (Lim and Sun 1980), but alginate gels are too porous and cannot provide immunoprotection. Alginate gels must be treated with synthetic cationic polymers, namely, poly-L-lysine and poly-L-ornithine, which are utilized apart from glutaraldehyde, chitosan, PEG, and agarose.

The encapsulating ability of chitosan depends on crystalline nature, molecular weight, extent of deacetylation, and degree of ionization/free amino group. Chitosan prevents enzyme decomposition, controls discharge, and improves bioavailability when employed as a nanoparticle coating agent for nanoparticles utilized for brain disorders. It also affects tight junctions, which improves medication penetration across the blood–brain barrier (Yu et al. 2019). Furthermore, chitosan has high bioadhesive qualities and inhibits nasal drug release, and facilitates drug transport to the brain from the nasal cavity (Wang et al. 2008).

Agar derived from Rhodophyceae algae, is a long-chain biopolymer, constituting agarose and agaropectin (Mostafavi and Zaeim 2020). When agar functions as the

only encapsulating agent, the medication is released in two phases. The first and quicker phase results in the release of 10–20% of the medication depending on the extent of the agar content. The second phase is slower and lasts longer, and it gets slower as the disintegration progresses. The drug molecule remains on the surface and is present in the peripheral layer of the bead in the first phase, while in the second phase, the release is triggered by the solid core dissolution. The bigger the amount of agar in the beads when employed as an encapsulating agent, the matrix gets denser and it lowers drug molecule transport through the beads. Additionally, swift drug release occurs through beads with a lesser quantity of agar in formulation, resulting in large content of water (Rivadeneira et al. 2018).

As an encapsulating matrix, high crystallinity starch has been investigated. Starch can be altered to improve its mechanophysical properties, allowing it to be used more effectively in medicine delivery and other industries. Chemical, physical, enzymatic, and genetic mechanisms can all affect starch. Chemical processes are the most commonly employed since they are nondissolving and might potentially boost the functioning of the modified starch.

Carboxymethyl cellulose (CMC) remains one of the extensively utilized cellulose types owing to the properties being the most cost-effective and easy to spread. The presence of many hydroxyl groups in the structure of CMC creates hydrophilicity in the molecule that resists lipid oxidation and minimizes oxygen permeability. The metabolism of CMC in the digestive system limits its utility as probiotic encapsulation material. Biopolymer incorporation enhances the survivability of encapsulated anaerobic probiotics by 36% when combined with supplementary biopolymers like inulin, alginate, chitosan, gelatin, etc. (Zabihollahi et al. 2020).

Several constraints are still preventing the widespread application of biopolymers. First, most of the research has been done *in vitro*; consequently, additional biological testing in animals and humans is necessary to validate the therapeutic potential of biopolymers in diverse biomedical applications, particularly biocompatibility of drug delivery encapsulating materials (Zabihollahi et al. 2020). Studies are carried out by researchers to improve thermal resistance, mechanical properties, kinetics, and barrier properties to make materials that are equivalent to or superior to synthetic products. Some products, for example, have limited mechanical qualities, fast deterioration, and a high hydrophilic capacity, making them unsuitable for use in humid or unfavorable settings.

Extensive research in the area is required to make sustainable and permanent changes in the biomedical and pharma sector. Biopolymers have been shown to be successful as encapsulating materials in controlled drug delivery systems. Despite considerable improvement in biocompatibility, metabolic stability, and mechanothermal properties, the design of target selective carriers with diverse transport pathways and provide long-term release at the target site remains a hurdle (Udayakumar et al. 2021).

Despite present host restrictions, predominantly, the usage of polysaccharide-based polymers will continue to flourish in order to develop better drug interactions, biochemical and physiological transformations, and compatibility with target tissues. Although additional research is necessary to assess the complete potential of

polymers that are proved to be extremely useful for dispensing highly effective, biopotent, and safe small compounds.

In Tissue Engineering

Biocompatibility, biodegradability, non-immunogenic qualities, increased bodily fluid assimilation capacity, increased gel-forming ability, and antimicrobial and anticancer abilities are among the unique biophysical and biochemical properties of natural biopolymers. Such unique characteristics of biopolymers gave them an enviable stature in tissue engineering and other healthcare applications. Natural bone's outstanding mechanics are interconnected to its hierarchical pattern from the nano to the macro level, which can suitably arrange organic and inorganic components at the nanoscale level and periodically deposit collagenous substances during bone biomineralization. Hard and soft tissue engineering technology like cartilage restoration, regeneration of bone, and curing of wounds utilize a wide variety of biopolymers. Less mechanical, chemical, and structural qualities, as well as less biodegradation stability, are the key drawbacks of biopolymer tissue engineering. As a result, more research is required to change biopolymers in order to generate new flexible materials highly favored for tissue engineering applications. Currently, researchers are focused on constructing 3D scaffolds that may be used in tissue engineering applications to get superior results (Bedian et al. 2017; Babu et al. 2013; Chinga-Carrasco 2018).

Collagen is an important biopolymer that makes up 30% of the bulk of vertebrates. It is an adaptable biomaterial for neuronal repair and neural channel filling. Collagen hydrogels have proved to be a useful sciatic nerve repair material in rats. Collagen, when combined with proteins or other biopolymers, produces improved tissue regeneration results. The collagen-PGA tube has improved electrophysiological characteristics and is a promising material for nerve conduits in cats. The collagen framework enhances the rate of nerve repair by interlinking with laminin. Collagen remains the sole biopolymer that has been accepted for use in neuronal clinical examination (Cen et al. 2008).

Gelatin is an excellent denatured protein that is generated when animal collagen is hydrolyzed in an alkaline or acidic environment. Gelatin is a cheap, readily available sustainable biomaterial. Denatured gelatin shows lower antigenic properties than collagen, while the proliferation and variety of cell adhesion lead to the enhancement of biological qualities of the implanted polymeric device due to the changing chemical structure. The ideal biochemical, kinetic, and mechanical properties woven along with other synthetic and natural polymers are an integral part of functional frameworks. Gelatin nanoparticles are a sought-after biomaterial for neural tissue regeneration mainly due to their superior biocompatible nature. The acetate/PLA molecular framework support coated with gelatin nanoparticles exhibits higher cell viability than the uncoated materials. Development, cell adhesion, regeneration, and propagation of neurons are stimulation by gelatin–chitosan–PEDOT hybrid scaffolds. Regeneration, curing, and repair of damaged or infected tissues and

organs require a versatile biopolymeric material like collagen (Nikkhah et al. 2016; Salerno et al. 2018).

Flexibility, long-term stability, self-assembly, and interesting biological activity are the hallmarks of elastin. Apart from providing elasticity to tissues, it is also present in blood vessels, lungs, skin, and ligaments and has been found to be an important material for neurodegenerative diseases that can mend precise fragments of CNS (Ozsvar et al. 2015).

Hyaluronic acid (HA) consists of glycosaminoglycan derived from extracellular tissues in the human body, which plays a major role in lubricating and can be chemically manipulated apart from being biodegradable and biocompatible. The receptors present on the periphery of stem cells interact with HA and help in controlling various cellular activities like survival, motility, proliferation, intracellular signaling, as well as transduction and differentiation. Hence, HA-derived biopolymers have been extensively utilized in biological testing as injectable hydrogels and bioscaffolds, with promising results for tissue regeneration. HA hydrogels have the ability to boost the survival rate and neural precursor cell proliferation, which has significant implications for peripheral nerve regeneration treatments and CNS repair techniques owing to its versatile mechanical properties that can regulate neuronal networks and thus opening up a novel avenue for treating neurodegenerative illnesses (Makvandi et al. 2020; Hemshekhar et al. 2016).

Keratin is a polypeptide protein made up of a variety of nonpolar and polar amino acids linked together by both intra- and intermolecular molecular bonding. Keratin plays an integral role in facilitating cell proliferation and adhesion and is the primary biomaterial to be employed in neural tissue engineering that permits Schwann cells to infiltrate and proliferate more easily. Human hair-derived keratin hydrogels are efficient in treating fatal liver injury (Imam et al. 1999; Balasubramaniam and Chinnan 1997). Keratin's main disadvantages as a tissue engineering material are its low mechanical strength and complications encountered in handling high sulfur and protein content. The dissolution and abstraction of this biopolymer remain a huge challenge so far when compared to others in the same category (Lin et al. 2019; Rajabi et al. 2020; Shavandi et al. 2017).

Lower mechanical, chemical, and structural qualities, as well as less biodegradation stability, are the key drawbacks of biopolymer tissue engineering. As a result, tissue engineering research is essential to incorporate biopolymers to generate novel flexible materials better suited for tissue engineering applications. The current focus of researchers lies in constructing 3D scaffolds that may be used in tissue engineering applications to get superior results.

In Medical Implants

These biopolymeric materials are ideal candidates for implantable materials because of their biocompatibility, biodegradability, and lack of cytotoxicity. Implantable devices are designed to look like a bodily part and are used to substitute an injured organ or structure in order to maintain ordinary bodily functions. Medical implants

of important organs like the eye, heart, hips, etc., utilize ceramics, metals, and synthetic polymeric materials that are found to have several drawbacks, including immune system rejection arising from the biodegradability of synthetic polymers (Bhatt and Jaffe 2015). The metabolic processes like hydrolysis produce carbon dioxide, which in turn lowers the cellular pH, resulting in cellular necrosis (Liu et al. 2006). Biopolymers introduced as medical implants offer biodegradability and play a significant role in this arena.

PLA remains one of the potent biodegradable polymers possessing cost-effectiveness and mechanical properties similar to polypropylene (Mukherjee and Kao 2011). Furthermore, PLA is biocompatible, which is an added advantage when being used as implantable devices that will degrade, leaving no foreign body, which will circumvent the requirement for a second surgery to remove the device after its lifetime. PLA-incorporated biodegradable stents have shown great potential in preclinical and clinical studies (Hietala 2004). PLA-PGA copolymer-based devices are more beneficial than devices bearing respective copolymers and are employed as orthopedic implants to treat bone deformities and fractures. Framework building in the body to help cartilage construction also utilizes biopolymers (Rebelo et al. 2016).

Meinel and Kaplan (2012) utilized silk fibroin for scaffolding purposes in the musculoskeletal system with excellent mechanical competencies, exceptional stability, and precise delivery of protein and small-molecule drug molecules. Silk fibroin-derivatized scaffolds and their protein–drug bioconjugates help in fine-tuning the drug delivery through microneedles in mimicking biological processes. Forthcoming research results in the arena of biopolymers targeting skeletomuscular diseases are predicted to be prompted by potential developments in drug delivery/biomaterial interaction.

Chitin or poly-*N*-acetyl-*D*-glucosamine polycationic derivatives existing in microbial cell walls and envelope of crustaceans are generically known as chitosan. Implants derived from chitosan include stents, bone, cartilage, skin, liver, etc. The researchers have experimentally proved the ability of a combination of chitosan and heparin to rapidly increase the recuperation process in vivo in pigs post-stent replacement (Meng et al. 2009). Chitosan-derived films have also shown excellent mechanical stability when mixed with an alginate framework and have been reported to create an osteoconductive matrix (Chen et al. 2009; Li et al. 2005).

These biopolymers have intrinsic features, such as biodegradability and biocompatibility, offer significant benefits, and expand their potential usage in implantable medical applications. These advantageous features place them superior to their synthetic analogs, and it has to be noted that a combination of these biopolymers with synthetic counterparts has the potential to revolutionize the medical field.

In Wound-Healing Materials

The ability of biopolymers to absorb significant amounts of water while dry and donate water when hydrated is one of their most valuable characteristics. Medications impregnated with formulated biopolymers are both target-specific and controlled drug release and have been widely operational in tissue delivery and

rebuilding. Wound-healing dressings are classified according to their components to hydrocolloid, alginate, or hydrogel dressings in the reported literature. Alginate, being a hydrocolloid with the ability to create hydrogels, may plausibly fit into all three groups from a material standpoint. This ambiguity should not be misunderstood as wound-dressing classifications refer to the precise type of dressing used to treat certain types of wounds. Interactions of these biopolymers with the wound tissue, and stability and molecular mass of these biological polymers are not completely understood yet (Nyström 2016).

Collagen is recurrently employed as a hydrogel that aids wound healing by transporting anesthetics, growth factors, medications, etc. Integration is frequently successful as it is a substrate that thwarts rejection due to the fact that it is naturally occurring and cell attachment prefers it. Collagen creates hydrogels resembling skin and is very helpful in wound healing by transporting the mesenchymal stem cells to the wound (Ruszczak 2003).

The hemostatic character of gelatin coupled with other biopolymers is utilized as hydrocolloid wound dressings, and DuoDerm[®]/Granuflex[®] (ConvaTec) and Gelfoam are some of the trade names under which it is marketed. Despite having unique features that make it ideal for producing wound-healing dressings, gellan gum remains an underutilized polysaccharide. Gellan consists of a linear tetrasaccharide repeating unit that comprises two glucose units, rhamnose, and glucuronic acid, and is generated during aerobic fermentation of *Sphingomonas paucimobilis* (Smith et al. 2007; Sworn et al. 1995).

Another commonly exploited polysaccharide in wound healing is alginates. The calcium, sodium, magnesium, and alginic acid salts were isolated from seaweed (Phaeophyceae). The major purpose of employing an alginate dressing is to control wound exudate. When wound exudate comes into touch with alginate, the sodium ions in the exudate ion exchange with the calcium in the alginate, allowing the alginate to dissolve. This is because calcium is less tightly coupled to mannuronate than it is to guluronate, and thus solubilizes more rapidly. The development of drug-impregnated alginate wound dressings and composites with other biopolymers, resulting in multifunctional dressings, has been a focus of further advancements in alginate wound dressings (Jones 1999).

Biopolymers possess multifunctional activity and adaptability to various physical states, enabling them to be used in a broad range of types of wounds, from intertwined fibers that can help dry wounds by swelling when they interact with water-rich hydrogels. Physiologically receptive smart biopolymers are developed owing to their biocompatibility and drug delivery capacity when it comes in contact with varied physiological conditions. There exists a huge demand for a biomimetic and sustainable medicine approach to wound healing, in particular, it opens the door to the development of complex biopolymer products that combine medicines, wound-healing proteins, and cells. Furthermore, personalized medicine is the futuristic view amalgamated with the innovations in genomics, proteomics, and stem cell technologies. Potentially it transforms wound-healing treatments, and abundant advantages offered by biopolymers will almost certainly pave a way for the development and delivery of these treatments in the future (Boateng et al. 2008).

Outlook and Perspectives

Worldwide production of synthetic polymer crosses over 140 million tons per year. Synthetic polymers being very stable remain in biosphere for a very long time, creating various long-lasting environment pollution depending on their hydrophilic and hydrophobic nature. Water-soluble man-made polymers in wastewater and plastics have proven to dangerously interfere with food chain and result in biomagnification and are treated to be the major cause of extinction of certain species. Toxicity of these persistent organic pollutants is a grave issue that has been recognized by researchers across the globe. The natural polymeric materials and their derivatives have gained more priority owing to their biodegradable and nontoxic nature while not compromising on the effectiveness of their utility if not bettering the properties of synthetic polymers. Hence, current research is mainly centered on creating novel biodegradable polymers with enhanced applications. Most of the biopolymers are produced or formed during the life cycle of organisms involved in their production. Renewable materials as opposed to the nonrenewables have been in high demand due to various reasons discussed earlier in this chapter.

Plastics mainly utilized for packaging like styrofoam cause immense terrestrial and water pollution. This pollution is mainly linked to health problems in humans and animals, resulting in major life-threatening diseases and affecting the marine and terrestrial quality of life.

Scientists and technology experts are conscientiously creating innovative processes and novel biopolymers that can address the aforementioned disadvantages without compromising the quality. Such polymers have found their applications in different fields like agriculture, cosmetics, nutrition, healthcare and packaging, etc. Development of various biomaterials requires stringent research methodologies and analytical testing to evaluate the safety, effectiveness, toxicity, and environmental degradability. Once they cross this testing, they can replace synthetic polymers as a sustainable alternative and can be integrated into society for a healthier, safer lifestyle.

Researchers focus mainly on biodegradable characteristics while they develop novel biomaterials or biodegradable polymers apart from their antimicrobial potential. An array of biomaterials are being utilized to produce sustainable alternatives to polymers making use of various processes. For instance, fermentation of sustainable crops like corn and sugar beets yields biopolyesters like polylactic acid or PLA arising from the polymerization of lactic acid resulting from the fermentation process. Polymerization of ϵ -caprolactone is the raw material for another such polyester biomaterial PCL, which is also known as polycaprolactone with low viscosity, low melting point, and better thermal modulation. Stress resistance and adhesion properties are modulated by mixing PCL with other biopolymers. Polyhydroxy butyrate (PHB) and polyhydroxyalkanoates (PHA) are other examples of biopolymers frequently exploited for packaging of food.

A variety of techniques and materials are utilized to design and produce an assorted array of biodegradable and sustainable polymers unlike conventional

polymers that are mainly produced from volatile, toxic, and nondegradable petroleum resources. Newer biodegradable polymers ought to be fashioned with sustainable properties embedded in them so as to be used for biomedical operations, especially drug delivery vehicles/systems, tissue engineering porous 3D scaffolds, medical implants, and temporary prosthetics that cater to a variety of medicinal purposes like regenerative medicine, stimuli dependent hydrogels, etc.

Another arena wherein these biomaterials have found utility is their ability to be used as bioemulsifiers in food industry, which is estimated to be a 17.53 billion market in the next 5 years. Liposan is a well-known example derived from *Candida lipolytica*, which is utilized to improve the stability of vegetable oil-water emulsions.

Clearly, not all biopolymers are bona fide biopolymers. For engineering applications, it is typically a mix of oil-derived polymer and genuine biomass-derived polymer. The market is increasing, but at a rate that is about in pace with the broader plastics industry, implying that oil-derived products are not being displaced in any significant way. Biopolymer demand accounts for less than 1% of total global polymer demand. If biopolymers and those who make them are to have an impact on the environment, they must improve. Biopolymers are now being developed for usage in a plethora of industries, extending from simple uses to high-use applications such as medicine. Biopolymers are rapidly expanding in popularity due to their biodegradability, and these materials are being developed for a variety of uses. Biopolymers are being used in a varied array of applications, as evidenced by their market growth of over 23% per year since 2010. The market growth pattern is predicted to linger for a while, according to GBI Research. With the growing need for green energy and ecologically friendly materials, biopolymer manufacturing should increase, and the use of these materials should become more widespread to replace non-degradable polymers. Biodegradable biopolymers are expected to account for a bigger proportion of biopolymer manufacturing in the coming years. Manufacture is expected to rise almost twofold during the last 5 years (from 2.27 million tons in 2017 to 4.31 million tons in 2022), indicating the slow pace at which it travels in the journey of replacing petroleum products. Public demand and government policies create an impact on such a drive.

In many circumstances, the cost of bio-based products outweighs the cost of petrochemical ones. Biopolymers, on the other hand, have several drawbacks, including their hydrophilicity, which results in inferior mechanical characteristics in humid settings. As a result, we must find a solution to these issues. As a result, additional research is required to improve expertise in biopolymer engineering to develop new high biopolymer materials for specific applications and increased use. The nanofiller additions to these biopolymers, for example, can enhance the mechanical and barrier qualities of the biopolymer under study. This enhancement will aid in the expansion of numerous applications of biopolymers. The impending challenge of biopolymers is to completely substitute the use of petrochemical-based polymers in all industries as we come to the fag end of the “plastic era.”

Abstract

Recovery of wastewater has become a major concern owing to a decline in freshwater availability. Among the various methods available for the treatment of wastewater, the adsorption route is a simple, cost-effective, and efficient way to eliminate hazardous water contaminants from wastewater, increasing the availability of potable water. The present chapter introduces the readers to biopolymers-based nanocomposites as an adsorbent to remove various hazardous contaminants from the aqueous stream like dyes, phenols, pharmaceutical drugs, and pesticides. The chapter will attempt to convey to its readers the need for wastewater treatment and the use of biopolymers-based nanocomposites as sustainable and eco-friendly adsorbents. Throughout the chapter, chitosan, cellulose, starch, sodium alginate, and β -cyclodextrin-based nanocomposites for the removal of various organic contaminants will be introduced. The various adsorbate-adsorbent interactions responsible for the adsorption and effect of inorganic ions on the adsorption efficiency of biopolymer nanocomposites are also provided.

Introduction

Population and financial expansion have accelerated the pressure on water supplies. Consequently, 36% population of the global total currently resides in water-stressed areas. Urban development has caused a variety of water-related difficulties, notably in middle- and low-income nations, such as poor water quality and insufficient water supply facilities, especially in developing peri-urban and unorganized communities. Nations are launching major wastewater collection and treatment schemes to ameliorate the countries' wastewater issues (Elkady et al. 2020; Rodriguez et al. 2020). The area of the water supply has substantial investment requirements. As urbanization increases, there seems to be a chance to make expenditures most effectively and sustainably feasible. Prospective urban development will necessitate measures that reduce resource use while emphasizing resource recovery, in accordance with sustainability criteria. Wastewater is and should be seen as a precious commodity for extracting nutrients and energy, and a supplementary supply of water (Rodriguez et al. 2020). Wastewater may be processed to various quality levels to meet the needs of various industries, notably farming. It may be treated in an eco-friendly way and sometimes even repurposed as drinkable water. Treatment of wastewater frees up precious freshwater for alternative applications or conservation. Furthermore, treating wastewater effluent can be helpful for farming and power production, making wastewater treatment plants more ecologically and economically sound (Rodriguez et al. 2020). Polluted water is caused as a result of the presence of organic and inorganic contaminants that render the freshwater unfit for drinking and leave it with no further use (Thirunavukkarasu et al. 2020). To diagnose the polluted water, conventional chemical, biological, and physical methods were used. However, these approaches are most often regarded as being less effective in meeting water quality objectives. More specifically, these systems include drawbacks such as oxygen diffusive resistances, the building of stable lagoons, the discharge of waste containing harmful constituents, partial pollutants elimination, and lots of energy, cost, and time requirements for operation. The contaminated water has been diagnosed using the following methods, but each method has certain limitations (Table 1) (Li et al. 2020; Thirunavukkarasu et al. 2020). Wastewater contaminants can be into two classifications on the basis of their hazardous effect: (i) the black list: which includes harmful prioritized compounds that are chronic, extremely poisonous, or cause bioaccumulation and (ii) the grey list: which collects prioritized compounds that pose a severe environmental danger. These can be regrouped according to specific substances such as metals, phenols, nitro-compounds, or on the basis of the industrial sector such as metallurgy, food, pharmaceutical, dye, and agro-industries (Crini and Lichtfouse 2019; Li et al. 2020). Wastewater released from

Table 1 Methods for the treatment of the contaminated water

Method	Examples	Treatment
Primary treatment	Flootation, screening, centrifugal separation, filtration, coagulation, and sedimentation/gravity separation	Water is treated at the primary level, i.e., for the pretreatment of water before applying other purification
Secondary treatment	Biological methods such as aerobic and anaerobic treatment	Microbes that can transform contaminants into smaller and harmless compounds
Tertiary treatment	Ion exchange, electrolysis, oxidation, adsorption, reverse osmosis, electrodialysis, and precipitation	Includes chemical methods that have the potential to improve the quality of water to drinking water quality

the industrial sector can contain various contaminants according to their origin; the specific contaminants may need a different treatment.

Metal and organic contamination are among the most common environmental issues. They are nonbiodegradable and, in particular, have an elevated aqueous solubility, which facilitates their environmental mobilization by interacting with biotic and abiotic factors, such as adsorption onto organic colloids or buildup by life forms, posing a hazard to public health and ecological systems (Li et al. 2020; Lofrano et al. 2016). Hundreds organic contaminants, ranging from simplest to more intricately organized molecules, have been recognized as carcinogenic. Contaminations must be removed because they are hazardous to people and marine organisms when exposed to quantities over a certain threshold. Furthermore, the occurrence of these contaminants is unavoidable since these constituents are emitted by everyday items such as plastics, soaps, detergents, dyes, petroleum, and insecticides (Rout and Jena 2022; Thirunavukkarasu et al. 2020). In the presence of large quantities of organic contaminants, the dissolved oxygen in the water may be consumed at a faster pace than it could be replaced during the degradation/conversion of organic contaminants, resulting in oxygen deprivation and severe consequences for the organisms. Organically polluted wastewater comprises huge amounts of suspended matter, which restricts the amount of sunlight accessible to photosynthetic organisms making it undesirable for several creatures (Rashed 2013). Among several methods available for wastewater treatment such as ion exchange, reverse osmosis, photocatalytic degradation, adsorption, etc., adsorption is the simplest and most cost-effective. Ion exchange and reverse osmosis are often more appealing procedures since pollutant levels possibly be retrieved altogether with elimination from industrial effluent. But these methods require high investment and operational costs, and hence are not financially sustainable. Adsorption has the ability to be one of the most productive ways for the treatment and removal of organic pollutants in treating wastewater. Adsorption has an advantage over other technologies because of its simple design and cheap investment, making it economically sustainable (Feng et al. 2017; Mashile et al. 2020; Rashed 2013; Rout and Jena 2022). Biopolymers are lipopolysaccharides, glycolipids, proteins, and polysaccharides derived from biological sources such as microorganisms, plants, and animals. Biopolymers have additional benefits such as nontoxic nature, hydrophilicity, biocompatibility,

renewable nature, biodegradability, abundant functional groups, and availability (Heydari et al. 2018; Rout and Jena 2022; Sheen Mers et al. 2022). Furthermore, biopolymers are versatile and could be intercalated into complex configurations to enhance their characteristics or can be used as a matrix in which various other nanoscale materials can be reinforced to improve the characteristics of the existing biopolymers. They also have abundant reactive functional groups such as “–OH,” “–COOH,” “–SO₃H,” and “–NH₂” along with electron-withdrawing, hydrophilic, and hydrophobic sites, leading to varied porous polymeric networks. By adjusting the pK_a of the polymeric matrix, one can design the surface of a biopolymer with desired functional groups to eliminate particular contaminants. As a result, the biopolymer and its variants could be used to eliminate organic molecules (dyes, oils, phenols, etc.) and inorganic species (heavy metals), and other contaminants from wastewater effluents (Sheen Mers et al. 2022). Biopolymer-based nanocomposites have several inherent benefits against artificial polymer-based compounds, like being sustainable, biocompatible, biodegradable, physically resilient, and multifunctional (Sheen Mers et al. 2022; Xiong et al. 2018). Even though every one of these primary biopolymers has flexible and quasi-primary structures, secondary and tertiary organization of the biopolymers, as induced by complementary weak intramolecular and intermolecular bond formation, stowing, or knotting, is expected to present improved physical and functional efficiency for demanding applications (Xiong et al. 2018). Bio-based nanocomposites, because they symbiotically integrate the strength and functionality of individual components to yield new nanosystems with augmented utilities such as environmental sustainability, low toxicity, environmentally friendly, and processing biocompatibility, advanced bio-derived nanocomposites with advanced functionalities that open a promising pathway forward into producing the attributes essential to accommodate the changing demands of current technological advancements. These nanostructures’ improved biocompatibility makes these materials great prospects for a wide range of demanding human-technology advancements (Sheen Mers et al. 2022; Xiong et al. 2018). Thrown bio-nanocomposites break down rapidly to their lower basic components. As a consequence, the regenerative, biodegradable, and sustainable processing properties of biopolymeric materials have the potential to considerably cut CO₂ emissions and toxic waste. To obtain or improve on these environmental advantages, distinct functional nanocomponents with significant and complementary interactions with biopolymers should be included in the matrix material, to produce superior mechanical improvements or additional functions (Xiong et al. 2018).

Adsorption

Adsorption is a process in which pollutants from a liquid or gaseous carrier get deposited/concentrated on the surface of a solid known as an adsorbent, the constituents getting concentrated/deposited/adsorbed on the layer of the adsorbent are known as adsorbate. The phenomenon is known as adsorption (Nakhjiri et al. 2021). The adsorbate can form a single layer or it can form a multilayer on the adsorbents’ surface.

The adsorption performance is affected by many factors some of which are given below in brief.

Temperature: The removal efficiency of adsorbent may increase or decrease with varying temperatures depending upon the nature of the adsorption process. If the adsorption process is endothermic, then the removal of adsorbate gains heat from its surroundings, and an increase in the temperature will facilitate the adsorption of pollutants on the adsorbent. On the other hand, the contradiction is obtained if the adsorption process is exothermic (releases heat into the surroundings). The exothermic nature of the adsorption process leads to decreased removal efficiency of pollutants by the adsorbent. The majority of (nearly all) adsorption processes are exothermic as the adsorption of pollutants on the adsorbent surface decreases the energy of the adsorbent and hence excess energy is released in the form of heat.

pH: pH of the solution directly influences the adsorption performance depending upon the nature of the adsorbent and adsorbate. The variation in the pH of the solution can either protonate or deprotonate the surface of the adsorbent resulting in the generation of a cationic or anionic surface, which can improve or diminish the adsorption of pollutants depending upon the anionic or cationic nature of the pollutants.

Adsorbent amount: Increasing doses of the adsorbent leads to enhanced adsorption of pollutants. However, in selected cases, if the adsorbent is highly agglomerated, the adsorption may decrease with increasing adsorbent dose as a result of the decreased available active surface area and pores of the adsorbent.

Adsorbate (pollutant) amount: The dose of adsorbate may increase or decrease the removal of pollutants from the wastewater depending upon the saturation of active sites of adsorbent. After the saturation of active sites, increasing adsorbate content will decrease the % removal efficiency.

Contact time: The adsorption of the pollutants on the surface of the adsorbent increases until the equilibrium is established. The pollutants may get released from the surface of the adsorbent into the solution if the adsorbent is kept for a longer time in the solution.

Nature of adsorbate and adsorbent: The functionality, surface area, pore size, and surface charge of adsorbent on adsorbent influence the overall adsorption performance. The structural features (functionality and charge) can also influence the adsorption efficiency.

Dyes

Paper, textiles, leather, beauty products, food, and plastics are few of the industry sectors that use dyes (colored organic compounds) to color their products. Dye is an organic compound that may get attached to the surface of a material such as fabric or paper and impart color to that material. About 10–15% of all dyestuffs are lost directly to wastewater during dyeing procedures. The wastewater discharge containing dyes creates an eco-toxic threat and poses a risk of bioaccumulation

Fig. 1 Structure of a few cationic, anionic, and nonionic dyes

(Yeamin et al. 2021). The dyes can be classified into three major groups depending on their ionic charge (Fig. 1):

- (i) Anionic dyes: Consist of an organic moiety having a negative charge, hence produces organic negative ions when dissolved in water. Direct, reactive, and acidic dyes are anionic dyes. Because of anionic dyes' low degree of fixation owing to reactive group hydrolysis in water, releasing reactive dyes into the ecosystem causes severe hazardous effects (Kumar et al. 2019).

Examples: Methyl orange and Eriochrome Black T

- (ii) Cationic dyes: This group of dyes consists of a positive organic moiety that has a number of chemical structures based on their substituted aromatic groups. Wool, silk, nylon, and acrylic fabrics are majorly dyed using cationic dyes. Cationic dyes produce colored cation in water, and because of their ionic nature they are water soluble, and hence can badly influence the quality of water. The cationic dyes adversely affect health causing genetic disorders, cancer and dermatitis, and skin irritation. The Triarylmethane, azo, and anthraquinone dyes are cationic in nature (Kumar et al. 2019).

Examples: Methylene blue, crystal violet, and malachite green

- (iii) Nonionic dyes: The dyes included in this class does not possess charged ions in their structure.

Examples: Disperse Blue SBL

In humans, greater levels of these dyes cause cardiac problems, shock, vomiting, quadriplegia, tissue necrosis, and jaundice. The presence of pigments in the aquatic environment leads to the coloring of water and oxygen depletion, causing harm to animals as well as plants (Kumar et al. 2019). To overcome the environmental impact of dyes present in the wastewater, it is essential to remove the dyes from the wastewater. Biopolymer-based nanocomposites are extensively studied for the removal of dyes from wastewater.

Among the most substantially used biopolymers for synthesizing biopolymers-based nanocomposites included polysaccharides like starch, cellulose, chitosan, etc. Chitins' production originating from clam exo-skeletons is estimated to be just about equal to that of cellulose. Chitosan is produced by the deacetylation of chitin and is composed of β -(1-4) glycosidic bonds of D-glucosamine and N-acetyl-D-glucosamine. Cellulose is the most abundant polysaccharide followed by chitosan, which makes the nanocomposites based on cellulose and chitosan cheaper. Cellulose originating from vegetable sources such as grasses, stalks, woody plants, and reeds is made up of repetitive β -(1-4) D-glucose linked together by glycosidic linkage (Kanmani et al. 2017; Mashile et al. 2020; Sheen Mers et al. 2022). The low surface area, soft structure, and low mechanical strength limit the direct application of chitosan as an adsorbent. The hydroxyl and amine as well as hydroxyl functionality on the cellulose and chitosan, respectively, make their functional modifications possible for the adsorption of organic pollutants. However, when chitosan is dissolved in an acid medium, it agglomerates and gels, making it problematic to distribute/disperse and preventing -OH and -NH₂ groups to form chelated structures with cationic species (Fathy et al. 2020; Kanmani et al. 2017; Li et al. 2020). The three-dimensional (3D) porous structure enables easy and faster diffusion of adsorbate molecules on the adsorbent. Nanoclays are among the suitable adsorption materials owing to features such as swelling, layered microporous structure, large specific surface area, nanoscale size, capacity for cation exchange, and cheaper price compared to traditional adsorbents, i.e., activated carbon. Nanoclays are also appropriate for large-scale applications because of their high safety and stability. However, owing to the clays' solubility in water, inorganic clays are ineffective for the adsorption of lipophilic contaminants from water. Nevertheless, by intercalating alkyl linear chains or chemical bonding into the diffusion layer, the nature of the diffusion layer may be changed from hydrophilic to lipophilic, providing clay minerals with a diverse range of novel and fascinating adsorption characteristics. Because clays are biocompatible and biopolymers are biodegradable, their combination is an effective technique for the manufacture of bio-nanocomposites that may be utilized for pollutants removal (Orta et al. 2020). The synergy and control of interaction between biopolymers and clay in nanocomposite may help in producing novel smart composite material for the environmental applications. Hydrogel nanocomposites are 3D polymer frameworks that may be used independently in a wide

spectrum of uses as they retain a huge amount of water because of physical or chemical cross-linking among distinct polymer network, and they may soak huge amounts of water yet retain water insolubility (Bardajee et al. 2016). Salep, a hydrophilic, environment-friendly polysaccharide obtained from terrestrial orchids, possesses the ability to alter its swelling properties. Salep grafted by a polyacrylic acid hydrogel network reinforced with silver (Ag) nanoparticles follows a multilayered adsorption process for the adsorption of rhodamine cationic dye, indicating the potential of a physical adsorption mechanism. At 30 °C temperature, the highest adsorption capacity of the nanocomposite adsorbent was 92.59 mg g⁻¹. The presence of nanoscale Ag in the hydrogel establishes a coordination link with rhodamine's electron-rich groups, e.g., amine $\rightarrow\text{C-NH}_2$, and functional groups like C=NH_2^+ , O, and C-NH_2 interact with the hydroxyl (-OH) and carboxylic (-COOH) groups of the polymer matrix in the nanocomposite via hydrogen and polar interactions, promoting adsorption of dye. The presence of silver nanoparticles in the polymer network also enhances the porosity and free regions, resulting in significant swelling capability and dye adsorption (Bardajee et al. 2016). One of the most studied dyes for adsorption is methylene blue, excess amounts of methylene blue in an aqueous medium can cause skin and cardiovascular issues. On a long-term exposure, it is considered carcinogenic and is not easily degradable (Mahmoud et al. 2020). Several studies have focused to eliminate methylene blue from wastewater effluent using adsorption treatment utilizing biopolymer nanocomposites. Polyacrylic acid cross-linked chitosan reinforced with titania (TiO₂) shows increased swelling and adsorption capacity for methylene blue with increasing % TiO₂ content. The elevation in % TiO₂ concentration in the polymer matrix may decrease the density of cross-links in the resulting composite and increase the porosity of the nanocomposite material, and as a result more water may be absorbed due to free volume/space accessible in the polymeric network (Mahmoud et al. 2020). Montmorillonite is among the most widely utilized clays to reinforce the polymeric matrices. It is an aluminum phyllosilicate composed of aluminum oxide and silica layers arranged in an octahedral and tetrahedral geometry, respectively. The replacement of Al³⁺ ion present in octahedral sheet with isoelectronic Mg²⁺ results in the net negatively charged surface. This negatively charged surface is stabilized by exchangeable positively charged hydrated cations (Ca⁺² and Na⁺). Therefore, the clay has characteristics like swelling capability, cation exchange capacity can adsorb varying pollutants in its interlayer spacing, or electrostatic interaction with cationic charged polymer surfaces. The exfoliation of the clay sheets can enhance the specific surface area of the resulting nanocomposite. These properties enable clay-polymer-based nanocomposites a low-cost, more efficient, eco-friendly alternative to the conventional adsorbents. The varying amount of chitosan (reinforcing materials) from 50–300% of the cation exchange capacity of clay leads to the increased adsorption capacity of nanocomposite from 98–282.01 mg g⁻¹ for reactive violet 5 (an anionic dye) (da Silva et al. 2021). Natural clay modified with starch and MnFe₂O₄ nanofiller enhances the surface roughness and the active surface area of natural clay five times compare to pure clay without any modifications. The porosity is also an important factor in adsorption. The pore size of the resulting clay/starch/

MnFe₂O₄ nanocomposite was improved from 3.80–4.06 nm. The increased specific surface area and pore size of the nanocomposite allow dye molecules to penetrate more easily within the layers, resulting in 15% better adsorption performance of the clay/starch/MnFe₂O₄ nanocomposite than the clay for the adsorption of sunset yellow (anionic dye) and Nile blue (cationic dye) (Esvandi et al. 2020). Similarly, xanthan gum/Methionine-functionalized bentonite nanocomposite shows enhanced surface area than the bentonite clay. The composite exhibits a maximum capacity of 530.549 mg g⁻¹ for Congo red, a carcinogenic anionic dye (Ahmad and Mirza 2017). Sufficient interaction between biopolymer and nanofiller is of great importance for the performance of resulting nanocomposite. The polarity, large number of active functional groups, geometry, and aspect ratio are among the factors governing the interaction between matrices and fillers (Rouf and Kokini 2016). The adsorption capacity of nickel oxide (NiO)-reinforced chitin nanocomposites adsorb malachite green with a maximum adsorption capacity of 370.37 mg g⁻¹, which was not remarkable but the biodegradable nature of chitin in nanocomposite can provide a green alternative (Raval et al. 2016). TiO₂ nano-reinforced chitosan cross-linked with epichlorohydrin can adsorb reactive red 120 dye, an anionic azo dye (maximum adsorption capacity = 210 mg g⁻¹). The adsorption of reactive red azo dye on the nanocomposite could be the result of hydrogen bonding, electrostatic interactions, and/or π - π stacking (Jawad et al. 2020). The incorporation of magnetic nature in the biopolymer nanocomposite allows the easy separation of composite material after the adsorption treatment.

Graphene oxide (GO) is one of the most widely studied carbon nano-material-based adsorbents owing to its great chemical stability, large surface-to-volume ratio, surface functionality, and environmental friendliness.^[1] GO in an aqueous medium tends to agglomerate restricting their application as an adsorbent. Whereas GO has significant adsorption capabilities for a wide range of pollutants, its applicability is restricted as a result of the centrifugation force required after adsorption and GO's possible hazardous consequences. This limitation of GO can be avoided by reinforcing GO in matrices. Biopolymers might be employed to alleviate the constraints of GO in water pollutant removal (Feng et al. 2017; Heydari et al. 2018; Kanmani et al. 2017; Zaman et al. 2020). Natural biopolymers' large number of functional groups and stable macrostructure allows them to trap a variety of organic pollutants. Combining properties of biopolymers and GO in nanocomposite can provide an eco-friendly adsorbent with better performance, i.e., the presence of several -OH groups on cellulose (four portions) surface allows better dispersion of GO (one portion) in cellulose. The negative charge on the cellulose because of -OH functionality increases the interaction of the cationic dye with nanocomposite and the large surface area of GO can enhance the available active surface of nanocomposites resulting in better adsorption than the individual GO and cellulose material. The maximum adsorption of GO/cellulose nanocomposite for methylene blue adsorption was 751.88 mg g⁻¹. The GO/cellulose nanocomposite can be reused for up to seven cycles without major loss in the removal adsorption proficiency, after which a decline of up to 82.76% was observed on the tenth cycle. Loss of a small adsorbent amount during the regeneration could also appoint to some loss in the

removal efficiency during recycling (Zaman et al. 2020). In another study, the impregnation of aniline on the resulting chitosan/montmorillonite was achieved followed by polymerization to yield chitosan–montmorillonite/polyaniline nanocomposite for the removal of methylene blue. The maximum adsorption capacity was 111 mg g^{-1} , not great compared to other studies but yet higher than the individual components of the nanocomposite (chitosan = 28.1 mg g^{-1} ; polyaniline = 9.21 mg g^{-1} ; and montmorillonite = 64.4 mg g^{-1}) (Minisy et al. 2021).

Guesmi et al. (Guesmi et al. 2018) synthesized hydroxyapatite/sodium alginate nanocomposite with 5 and 10% sodium alginate content for the removal of methylene blue from the aqua medium. Polysaccharide sodium alginate, a linear polymer consisting of α -guluronic acid and 1,4- β -mannuronic acid, is a nontoxic, excellent adsorbent for organic contaminants, and biodegradable derived from alginic acid (found in the cell wall of marine algae) (Feng et al. 2017; Guesmi et al. 2018; Ragab et al. 2021). Sodium alginate has the ability to create a 3D framework hydrogel with strong hydrophobic nature owing to the abundance of -OH and -COOH groups that can cross-link with various divalent ions (i.e., Zn^{2+} , Ba^{2+} , Ca^{2+} , etc). As a result, sodium alginate may be used as a framework to create the composite hydrogel (Feng et al. 2017), the hydroxyapatite/sodium alginate nanocomposite with varying alginate content from 0 (surface area = $21.640 \text{ m}^2 \text{ g}^{-1}$; pore volume = $0.1620 \text{ cm}^3 \text{ g}^{-1}$; pore diameter = 300 \AA), 5 (surface area = $12.840 \text{ m}^2 \text{ g}^{-1}$; pore volume = $0.1147 \text{ cm}^3 \text{ g}^{-1}$; pore diameter = 357.3 \AA), and 10% (surface area = $3.390 \text{ m}^2 \text{ g}^{-1}$; pore volume = $0.02434 \text{ cm}^3 \text{ g}^{-1}$; pore diameter = 286.8 \AA). The filling of hydroxyapatite pores with alginate could be the reason for decreased surface area and pore volume of hydroxyapatite upon the incorporation of sodium alginate. The nanocomposite with 10% sodium alginate shows maximum adsorption (79.91% removal, $77.25 \text{ m}^2 \text{ g}^{-1}$ adsorption capacity) followed by 5% sodium alginate (75.25% removal, $72.69 \text{ m}^2 \text{ g}^{-1}$ adsorption capacity) and only hydroxyapatite (53.68% removal, $49.77 \text{ m}^2 \text{ g}^{-1}$ adsorption capacity). “N” of methylene blue could interact with “P-OH” functionality present on hydroxyapatite via H-bonding and “Ca-OH” group by electrostatic interaction, and as a result, methylene blue is adsorbed on the hydroxyapatite. Despite lowered surface and pore volume, the increased adsorption of methylene blue on hydroxyapatite/10% sodium alginate can be assigned to the interaction between the negative surface of COO^- present on sodium alginate in nanocomposite and positive charge on methylene blue. Adsorption of methylene blue on hydroxyapatite/sodium alginate is of exothermic nature, hence adsorption decreases with temperature rise. The plausible explanation is weakened interactions between active sites of hydroxyapatite/sodium alginate nanocomposite and methylene blue (Guesmi et al. 2018).

Xanthan gum cross-link poly(acrylic acid) hydrogel reinforced with oxidized multiwall carbon nanotubes (MWCNTs) can show potential adsorption capacity for the removal of cationic methylene blue dye. MWCNTs impart some valuable characteristics to the xanthan gum cross-link poly(acrylic acid) hydrogels such as short intraparticle distance, tunable pore size, and surface functionality, and enhanced specific surface area. In addition to that, the oxidation of MWCNTs creates more negative charge (COO^-) available on the surface of the nanocomposite,

eventuating in enhanced adsorption of cationic dyes. The negative surface on COO^- on the nanocomposite interacts with positively charge functionality on dye (i.e., $=\text{N}^+\text{H}^-$). Congo red, an anionic dye containing negative SO_3^- groups, can interact very poorly with xanthan gum cross-link poly(acrylic acid)/oxidized MWNTs, as a result the adsorption of anionic Congo red is poor compared to cationic methylene blue. Using xanthan gum cross-link poly(acrylic acid)/oxidized MWCNTs, the maximum adsorption capacity for methylene blue can reach 521.0 mg g^{-1} , which is higher than xanthan gum cross-link poly(acrylic acid) hydrogel without nanofiller (445.3 mg g^{-1}) because of the presence of more surface-active negative sites and increased specific surface area of hydrogel upon reinforcement of oxidized MWCNTs. The adsorption of methylene blue on xanthan gum cross-link poly(acrylic acid) was endothermic, i.e., removal efficiency increases with increasing temperature, but that on xanthan gum cross-link poly(acrylic acid)/o-MWCNTs changes to exothermic nature (Makhado et al. 2018).

Among transition metal oxide nanoparticles, zinc oxide (ZnO) is among the potential nanosize metal oxides favored owing to preferable biocompatibility, nontoxic property, high surface area, desirable adsorptive property, and high chemical stability. Filling nanosize ZnO within the matrix of biopolymers leads to increased reactive oxygen in the bio-nanocomposite material (Reghioia et al. 2021). The sodium alginate-based hydrogel nanocomposites can improve the adsorption of cation dyes from the wastewater, i.e., sodium alginate poly(acrylic acid) containing ZnO nanoparticles shows a maximum adsorption capacity of 1529.6 mg g^{-1} , higher than the hydrogel without nanofiller (1129 mg g^{-1}) for the adsorption of methylene blue (pH = 6, contact time = 40 minutes). The thermodynamics studies indicate the endothermic and exothermic nature of methylene blue adsorption on sodium alginate poly(acrylic acid)/ZnO and sodium alginate poly(acrylic acid) hydrogel, respectively. The authors studied the effect of sodium chloride (NaCl) salt on the adsorption performance of nanocomposite. When the competitive adsorption study using methylene blue and NaCl was carried out, it was found that the adsorption proficiency for methylene blue on sodium alginate/poly (acrylic acid) decreased slightly but decrement was high in the case of sodium alginate/poly(acrylic acid)/ZnO nanocomposite, indicating more adsorption of Na^+ on the negative surface of nanocomposite due to electrostatic interactions than methylene blue (Makhado et al. 2020).

Biocompatibility, nano-range size, high specific surface area, tunable functionality, and magnetic nature of magnetite (Fe_3O_4) have opened a new path to synthesizing nanocomposites with magnetic characteristics (Nakhjiri et al. 2021). These characteristics of Fe_3O_4 can be incorporated into chitosan along with ZnO nanomaterial to yield a hybrid magnetic nanocomposite with improved adsorption capacity toward anionic dyes. Chitosan cross-linked with benzil (a diketone)/ZnO/ Fe_3O_4 nanocomposite can improve the adsorption of Remazol Brilliant Blue R anionic dye up to 620.5 mg g^{-1} . This hybrid nanocomposite material can provide various active sites for adsorption because of the presence of three components in the nanocomposite. As a consequence, various adsorbent-adsorbate interactions like H-bonding, $n-\pi$, $\pi-\pi$ interactions, and electrostatic attraction can take place resulting in the higher adsorption of anionic dye. The positive charge ($\text{Zn}(\text{OH})^+$) and positive

functionality ($-\text{NH}_3^+$, $\text{C}=\text{NH}^+$, and $-\text{OH}_2^+$) on the chitosan/benzil/ZnO/Fe₃O₄ nanocomposite allow electronic attraction with Remazol Brilliant Blue R having a negative surface because of the presence of $-\text{SO}_3^-$ ion. The presence of free “H” on chitosan/benzil/ZnO/Fe₃O₄ nanocomposite allows H-bonding interaction with negative atoms (i.e., O and N) of Remazol Brilliant Blue R dye. Another type of H-bonding (Yoshida H-bonding) between aromatic moiety of dye and -OH functional groups of chitosan/benzil/ZnO/Fe₃O₄ is also possible. In addition to these, the π - π interaction between aromatic moieties of dye and chitosan/benzil/ZnO/Fe₃O₄ (from benzil and aromatic diketone) and n- π interaction between lone pairs of N and O and aromatic ring of dye make a possible enhancement in the adsorption of Remazol Brilliant Blue R on chitosan/benzil/ZnO/Fe₃O₄ compared to any of the individual constituents (Reghioua et al. 2021).

Guar gum-graft-poly(acrylamide)/silica nanocomposite impart a good adsorption capacity for anionic dyes such as reactive blue and Congo red. Intramolecular hydrogen bonding and the hydrophobic nature of Guar gum results in poor adsorption sites. The limitation can be solved by grafting polyacrylamide onto Guar gum, the grafting results in new hydrogel having more -OH functionality and an additional amide ($-\text{CONH}_2$) functionality resulting in better interaction with dye. Further addition of SiO₂ creates additional -OH functionality in the nanocomposite, improves hydrodynamic volume, and provides a larger active specific surface area for the adsorption. For reactive blue, a maximum adsorption capacity of 579.01 mg g⁻¹ was achieved within 40 minutes and in the case of Congo red, maximum adsorption of 233.24 mg g⁻¹ was achieved within 30 minutes. The zeta potential study indicates that the Guar gum-graft-poly(acrylamide)/silica nanocomposite has a positively charged surface (pH = 4.48). Hence, at pH below 4.48, the protonation of Guar gum-graft-poly(acrylamide)/silica nanocomposite takes place leading to a positive surface which may interact more efficiently with the negative surface ($-\text{SO}_3^-$) of dye because of opposite charges resulting in good adsorption of Guar gum-graft-poly(acrylamide)/silica nanocomposite toward anionic Congo red and reactive blue dyes. Formation of outer-sphere surface complex results in a decrement in the adsorption of anionic dyes with increasing ionic strength using salts, i.e., NaCl and Na₂SO₄. The complex formation is a result of the transfer of anions at the site of adsorption arising from hydrogen bonding within nanocomposite and anion of salt. Owing to the higher screening effect of SO_4^{2-} anion than Cl^- ion, the presence of SO_4^{2-} anion results in a greater decrement in the anionic dye adsorption (Pal et al. 2015).

Gum arabic (highly branched heteropolysaccharide obtained from acacia tree) cannot be utilized in a few applications in its original state due to flaws including unregulated hydration process and microbial contamination, loss in viscosity on stockpiling, and thickness; consequently, for most situations, it is bonded with other monomer units (i.e., acrylamide) to address these flaws. The main mechanism of adsorption on gum arabic nanocomposites is governed by pore diffusion, H-bonding, and electrostatic interactions. A comparative study on the removal efficiency of gum arabic cross-links poly(acrylamide)/ZnO nanocomposite shows that the nanocomposites exhibit greater adsorption for cationic dye (malachite green) than the anionic dye (methyl orange) owing to the additional electrostatic attraction between

gum arabic cross-link poly(acrylamide)/ZnO composite and malachite green. The competitive adsorption studies impart that removal efficiency for cationic dyes, i.e., methylene blue and malachite green can be reached >60%, double that for anionic dyes, i.e., methyl orange and Congo red (<30%), indicating preferential adsorption of cationic dyes over anionic dyes on gum arabic cross-link poly(acrylamide)/ZnO nanocomposite. In the mixture of five portions of cationic dye malachite green and one portion of anionic dye methyl orange, the maximum adsorption capacity of the gum arabic cross-link poly(acrylamide)/ZnO nanocomposite reach 766.52 mg g⁻¹. The regeneration study suggests that gum arabic cross-link poly(acrylamide)/ZnO nanocomposite can be used for up to seven cycles with no performance loss and after that mere 4% reduction in the adsorption performance was observed on the tenth reuse cycle. Because of the structural framework, gum arabic cross-link poly(acrylamide)/ZnO nanocomposite is immensely anionic at surface charge <pH owing to the numerous anionic binding sites (i.e., functionality like -COO⁻ and -OH) in gum arabic and hence there is a high probability for binding of cationic dyes than anionic dyes via electrostatic interactions (Scheme 1) and H-bonding with -OH groups present on the surface of ZnO nanofiller of the nanocomposite. The electrostatic attraction of cationic dye on nanocomposite can be confirmed by decreased adsorption of cationic dyes on the nanocomposite in the presence of cations like Ca²⁺ and Na⁺. The polar “N” atom of malachite green dye might result in hydrogen bonding with carboxyl group, but electrostatic interactions will dominate the H-bonding, and, therefore, H-bonding involvement would not impact much. The nanocomposite hydrogel possesses porous structure and hence diffusion of malachite green within the pores of composite

Scheme 1 Proposed mechanism for the adsorption of methylene blue onto gum arabic cross-link poly(acrylamide)/ZnO. (Reprinted by permission from [Mittal et al. 2020]; Springer; Journal of Polymers and the Environment; In Situ Synthesis of ZnO Nanoparticles Using Gum Arabic-Based Hydrogels as a Self-Template for Effective Malachite Green Dye Adsorption; Hemant Mittal et al. copyright [2020])

material could also possibly contribute to its adsorption on gum arabic cross-link poly (acrylamide)/ZnO (Mittal et al. 2020).

The adsorption of cationic dyes methyl violet and crystal violet can significantly improve by using β -cyclodextrin-based nanocomposites. β -cyclodextrin is composed of seven glucopyranose units arranged in a cyclic structure via glycosidic bonds. The arrangement of these glucopyranose units gives β -cyclodextrin a cone shape appearance in which the outer part acts as a hydrophilic and the inner part as a hydrophobic site. Hence, β -cyclodextrins' inner cavity has the capability to act as a host for various organic molecules (Heydari et al. 2018; Rout and Jena 2022). Therefore, the addition of β -cyclodextrin to various polymeric macromolecules results in increased adsorption of the material, i.e., hydroxypropyl- β -cyclodextrin–polyurethane nanoconjugates containing magnetic Fe_3O_4 nanofiller have a maximum adsorption capacity of 1667 and 1269 mg g^{-1} for cationic dyes methyl violet and crystal violet, respectively. Hydroxypropyl- β -cyclodextrin–polyurethane adsorbent demonstrated great adsorption efficiency for the removal of both methyl violet as well as crystal violet from the synthetic waste aqueous solution and therefore has a great potential to act as a promising adsorbent material for the proficient adsorption of cationic dyes in an aqueous medium (Nasiri and Alizadeh 2019). Another potential adsorbent for high adsorption of methylene blue is sodium alginate cross-link polyacrylic acid hydrogel reinforced by TiO_2 . It has a very high maximum adsorption capacity for methylene blue, 2257.36 mg g^{-1} . The content variation in TiO_2 nano-reinforcement suggests improved adsorption efficiency of the nanocomposite for the methylene blue. The plausible explanation is that increased TiO_2 content results in increased surface-active site and increased negative charge on the surface allows more interaction between the nanocomposite and the cationic dye. The growth in absorption of methylene blue may be attributable to charge-repulsive force inside the gels' cross-link framework. The negative surface of the TiO_2 pushes away the $-\text{COO}^-$ ion because of similar charge. This leads to increased available surface-to-volume ratio of nanocomposite on which the positively charged methylene blue can attach itself. The 80% removal efficiency (for methylene blue) of sodium alginate cross-link polyacrylic acid gel was increased to 99.4% by reinforcement of a mere 2% TiO_2 . The effect of enhanced adsorption of methylene blue on nanocomposite with only 2% TiO_2 could have been observed because of the large specific surface area (186 $\text{m}^2 \text{g}^{-1}$) of TiO_2 than other inorganic clay nanofillers. The mechanism of adsorption was governed by electrostatic attraction between the positive surface of methylene blue and the negative surface of composite owing to $-\text{COO}^-$ and H-bonding between imine of methylene blue and $-\text{OH}$ of nanocomposite (from TiO_2 surface) (Thakur et al. 2016).

Pesticides

Pesticides are substances that are used in the agro sector to exterminate, expel, or suppress pests such as fungus, rats, bugs, and grasses. If allowed to thrive unchecked in agricultural land masses, these pests could be damaging or cause postharvest

losses. As a result, pesticides are popular for disposing of or controlling pests in agricultural regions, enhancing agricultural output, and, as a result, raising the global public's livelihood. Annually, almost two million tonnes of pesticides are used to combat insects, parasites, and unnecessary vegetation across the world. Pesticides are categorized as rodenticides, fungicides, insecticides, herbicides, and so on, depending on the specific target that is required to be eliminated. Herbicides and insecticides are the most well-known and commonly used pesticides, accounting for 29.5% and 47.5% of overall pesticide usage, respectively (Rana et al. 2021). The growing human population requires more resources to sustain life leading to increasing demands for agricultural products. In addition to that, the storage of such food also requires the elimination of pests to reduce agricultural loss. Therefore, the use of pesticides is continuously increasing. Pesticides can easily become a part of the food chain through soil or water. Pesticides are hazardous and cannot be easily degraded. Therefore, it is a necessity to eliminate pesticides from the water through proper treatment. The following are some types of pesticides classified according to their application type:

Herbicides: Used to prevent unnecessary vegetation in the crop, i.e., the unwanted weeds in the crop may compete with the crop for nutrients leading to decreased crop yield, e.g., atrazin, butachlor, simazine, ametryn, etc.

Fungicides: Inhibits fungi growth, e.g., chloranil, dichloran, hexachlorobenzene, captofol, etc.

Insecticides: Eliminates/Control insects, e.g., toxaphene, parathion, phenylpyrazole, etc.

Rodenticides – To eliminate rats and mice, e.g., warfarin, sodium fluoroacetate, α -naphthylthiourea, etc.

Butachlor, N-(butoxymethyl)-2-chloroN-(2,6-diethylphenyl) acetamide is among the most widely used herbicides in Asia during rice and wheat production to reduce undesired vegetation and periodic grasses with a yearly consumption rate of 45 thousand tonnes because of its minimal cost and diverse efficacy. It suppresses the lengthening of the chain fatty acids and key enzymes in geranylgeranyl pyrophosphate cyclization. Butachlor's unregulated use has resulted in environmental concerns due to erosion, weathering, and drainage of water, posing a threat to public health and marine life forms. It has already been found in surface water, soil, and groundwater, with remnant quantities ranging from 100–1400 ng L⁻¹ in fresh water, and 29,500–74,000 ng kg⁻¹ in soil because of agricultural usage. Owing to its lipophilic nature, it is nonresponsive to natural deterioration and tends to accumulate in the body of aquatic creatures, creating a variety of hazardous consequences. Butachlor was found to be a potential carcinogenic in toxicology investigations on many marine creatures, causing anatomical defects, inhibiting egg development, and causing considerable fatality in zebrafish *Danio rerio*. It has the tendency to create oxidative toxicity and cytotoxicity in fish by inhibiting the glutathione detoxification system in the kidney, as well as affecting zebrafish's reproductive function. Butachlor has been shown to be mutagenic to frogs, a development suppressant in earthworms, and a possible tumor enhancer with cancerous effects in mice livers.

Butachlor lacks the functional group having the capability to hydrolyze and, therefore, it cannot be hydrolyzed naturally (Kaur et al. 2021).

Chitosan/Poly(vinyl alcohol) hydrogel reinforced with Ag nanoparticles has a capacity to adsorb butachlor from the aqueous medium. Ag nanoparticle deposition in the polymer matrices improves the density of cross-linking leading to a larger surface-to-volume ratio and the formation of nanoscale pores in the composite material, i.e., the specific surface area of chitosan/poly(acrylic acid) gel increases from 6.579–8.316 m² g⁻¹, pore volume increases from 0.011–0.016 cm³ g⁻¹, and pore diameter increases from 1.98–2.33 nm upon nanofilling of polymer matrix with Ag nanoparticles. The actual surface area of the gel could potentially be higher than these values for the powdered sample because of swelling. The enhanced textural parameters of chitosan/poly(acrylic acid)/Ag nanocomposites impart a potential for better adsorption than chitosan/poly(acrylic acid) gel. The adsorption studies suggest that the maximum adsorption capacity of butachlor on chitosan/poly(acrylic acid)/Ag nanocomposites was 23.81 mg g⁻¹, slightly higher than chitosan/poly(acrylic acid), suggesting a possible contribution of Ag in the adsorption performance. The mechanism contributing significantly to butachlor sorption is thought to involve electrostatic attraction (H-bonding) and pi-pi interaction. The mechanism contributing significantly to butachlor sorption is thought to involve π - π (between chitosan and the aromatic moiety of butachlor) and electrostatic interactions. At lower pH, -NHCO- functional group in chitosan/poly(acrylic acid)/Ag is protonated and, therefore, the number of sites for H-bonding is increased. On the other hand, an increase in pH does not allow the protonation of “-NHCO-” group leading to a decrement in sites for H-bonding on the surface of the nanocomposites, consequently the adsorption of butachlor is reduced. The removal efficiency of chitosan/poly(acrylic acid) was reduced to 71.06% between the first and fifth reusability cycle and that of chitosan/poly(acrylic acid)/Ag nanocomposites were reduced to 79.32%, suggesting good adsorption efficiency of nanocomposites after the fifth cycle compares to hydrogel without nanofilling. This reduction in sorption is most likely attributable to the saturation of active adsorption sites owing to the difficulty of butachlor to desorb from these sites (Kaur et al. 2021).

Exposure to methyl parathion pesticide, a frequent contaminant found in farming untreated wastewater, causes organophosphate poisoning along with lethal conditions characterized by confusion, sweating, migraine, diarrhea, convulsions, etc., hence it is required to dispose water into the streams after proper treatment. The maximum methyl parathion pesticide adsorption capacities achieved with bentonite incorporated in chitosan and (chitosan and 2-hydroxyethyl methacrylate/methyl methacrylate) polymers are 634.5 and 868.5 mg g⁻¹, respectively, against 287.3 mg g⁻¹ maximum adsorption capacity of bentonite clay alone. The better performance of bentonite/chitosan than bentonite/(chitosan and 2-hydroxyethyl methacrylate/methyl methacrylate) could be due to a larger surface area and smaller pore diameter of the latter (e.g., surface area and pore volume of bentonite/chitosan was 106.4 m² g⁻¹ and 14.6 nm, respectively; for bentonite/(chitosan and 2-hydroxyethyl methacrylate/methyl methacrylate) surface area was 118.2 m² g⁻¹ and pore diameter was 12.6 nm). This may have been connected to polymeric

networks' participation in the formation of secondary microspores, which increase the porosity and surface area of the formations. As bioadsorbents for methyl parathion pesticide, all compositions, i.e., bentonite, bentonite/(chitosan and 2-hydroxyethyl methacrylate/methyl methacrylate), and bentonite/chitosan have a high recovery and recycling efficiency. The bentonite can remove >86 and > 81% of pesticide after the third and fifth recycle periods. The nanocomposite bentonite/chitosan was able to maintain a 100% adsorption efficiency for the second cycle and slightly declined to 95% in the fifth recycle period. The bentonite/(chitosan and 2-hydroxyethyl methacrylate/methyl methacrylate) adsorbent shows a decline in removal percentage to 97% after the fifth cycle, suggesting potential recyclability capabilities for commercial usage of the biopolymer nanocomposites as an adsorbent for methyl parathion pesticide removal from wastewater (Abukhadra et al. 2021).

The pesticides containing wastewater discharge do not only have a single pollutant in them. The presence of other pollutants could influence the adsorption capacity of the adsorbent in real applications. The most common ions are ammonium (NH_4^+) and phosphate (PO_4^{3-}) because of their use as fertilizers. A study of adsorption of methyl parathion pesticide in the presence of PO_4^{3-} , NH_4^+ , Mn^{2+} , and Pb^{2+} was carried out by Abukhadra et al. (Abukhadra et al. 2021). The adsorption of methyl parathion on bentonite significantly declined to ~50% in the presence of Mn^{2+} ions and between 27 and 34% in the presence of NH_4^+ , Pb^{2+} , and PO_4^{3-} ions. The substantial decline in pristine bentonites' selectivity for methyl parathion in the presence of these ions was reasonable owing to bentonites' high cation exchange characteristics and preference for inorganic cations over organic pesticides. The adsorption affinities of both bentonite/chitosan and bentonite/(chitosan and 2-hydroxyethyl methacrylate/methyl methacrylate) for methyl parathion were considerably declined with the presence of PO_4^{3-} and Pb^{2+} ions and marginally influenced by the presence of NH_4^+ and Mn^{2+} ions, still the modified nanocomposite adsorbent manages to provide good adsorption for methyl parathion (Table 2). This can be attributed to the transformation of clay into an adsorbent with preferential adsorption of organic moiety over inorganic ions during the intercalation. Therefore, the biopolymer addition in bentonite clay improves the adsorption efficiency as well as selectivity for the adsorption of methyl parathion from the synthetic wastewater.

Three mechanisms influence the adsorption reactions of adsorbents: (i) electrostatic interaction, (ii) ion exchange, and (iii) chemical complexation. In

Table 2 Effect of various ions on the removal efficiency of clay-biopolymer-based nanocomposite for methyl parathion pesticide (data obtained from [Abukhadra et al. 2021])

Adsorbent	% removal of methyl parathion on adsorbent in the presence of ions			
	NH_4^+	PO_4^{3-}	Mn^{2+}	Pb^{2+}
Bentonite	33.4	27.8	50.3	30.6
Bentonite/Chitosan	80.3	56.5	86.7	64.8
Bentonite/(Chitosan and 2- hydroxyethyl methacrylate/ methyl methacrylate)	78.6	53.5	84.3	57.2

nanocomposites, hydroxyl attached to Al and Si in clay minerals facilitates electrostatic interaction and complex formation (Abukhadra et al. 2021).

Other chitosan-based nanocomposites filled with zeolite provide the composite with efficient active surface functionality, increased stability and reactivity, and biodegradability along with enhanced adsorption for organic compounds. Mostafa et al. studied the adsorption of chitosan/zeolite nanocomposite to explore its possible adsorption for three organophosphorous pesticides, namely methyl parathion, acephate, and omthosate (Mostafa et al. 2021). The eco-friendly chitosan/zeolite nanocomposites display an excellent adsorption capacity for all three pesticides. The adsorption capacity for methyl parathion, acephate, and omthosate can be reached 560.8, 650.7, and 506.7 mg g⁻¹, respectively, owing to increased surface functionality, specific surface area, and pore volume in chitosan/zeolite nanocomposite (446.7 m² g⁻¹ surface area, 23.6 nm pore diameter, and 0.412 cm³ g⁻¹ pore volume) than zeolite alone (423.0 m² g⁻¹ surface area, 11.6 nm pore diameter, and 0.382 cm³ g⁻¹ pore volume) (Mostafa et al. 2021).

The competitive adsorption studies of these pesticides in the presence of ions like Cd²⁺, Zn²⁺, Pb²⁺, PO₄³⁻, and NO₃⁻ are given in Table 3 (Mostafa et al. 2021). Although the removal efficiency of chitosan/zeolite for pesticides declined greatly, the decline in the removal efficiency was higher in the presence of PO₄³⁻ among PO₄³⁻ and NO₃⁻ anions. That might be due to the great preferences of adsorbents for PO₄³⁻ ion to make a variety of combinations with the -OH of both zeolite and chitosan as well as their interchangeable characteristics with the ionic constituents of clay. The least effect was observed in the presence of Cd²⁺, indicating the preferential adsorption of organic pesticides over Cd²⁺ on chitosan/zeolite nanocomposite (Mostafa et al. 2021). The application of the chitosan/zeolite composite in real wastewater may further decline the adsorption as other pollutants among themselves for the active adsorption sites of the adsorbent.

The chitosan/zeolite adsorbent can be used for up to five recycle periods with minimum loss in the removal efficiency, i.e., ~95% for methyl parathion, 95% for acephate, and ~92% for omthosate (Mostafa et al. 2021).

Unlike dyes, the adsorption of pesticides is not highly efficient. However, some adsorbent may adsorb pesticides more preferentially over dyes, i.e., cadmium sulfide (Cds) reinforced with silanized cellulose nanofibers can preferentially adsorb

Table 3 Competitive adsorption of methyl parathion, acetaphate, and omthosate pesticides on chitosan/zeolite nanocomposites in the presence of anions and cations (data obtained from [Mostafa et al. 2021])

Ions	Removal efficiency (%)		
	Methyl parathion	Acephate	Omthosate
Cd ²⁺	80.7	83.4	77.8
Zn ²⁺	61.3	67.5	55.7
NO ₃ ⁻	52.4	60.3	48.7
PO ₄ ³⁻	46.2	52.7	34.7
Pb ²⁺	45.8	47.3	40.2

chlorpyrifos pesticide (86.96 mg g^{-1}) over coloring pigments methylene blue (26.66 mg g^{-1}) and safranin-O (17.86 mg g^{-1}). Adsorbent performance is greatly attributed to the increased silanized cellulose nanofibers content, with peak adsorption reaching for Cds incorporated with 10% silanized cellulose nanofibers, and then a decrement in adsorption characteristics was noticed, attributed to increased constraint for efficacious CdS nucleation and altered responsiveness of effective surface area for contaminant species. This is a financially viable and commercially exploitable substance for pollutants removal due to its uncomplicated method for synthesis, bio-based fruitful adaptation, and accelerated sorption attributes (Komal et al. 2020).

In recent years, triazine herbicides have been frequently utilized to suppress weeds in a range of agricultural crops. Such pesticides are essential in the production of grains like rice and maize. Their remnants, on the other hand, are becoming a major cause of pollutants in the environment. Triazine herbicides may potentially pose a risk to humans, including birth abnormalities, disruption of hormone systems, and cancer. The variations between the six triazine insecticides adsorbed by the cellulose/reduced GO nanocomposite must be exploited by comprehending how the adsorbates interact with the nanocomposite. The triazine insecticides' strong bonding structure, as well as the electron releasing properties of the O, N, and S atoms, can help with adsorption. All six triazine insecticides are structurally related and contain nearly the same number of nitrogen atoms. As a result, most pesticides' π -bonding networks are remarkably similar. As a result, the discrepancies might be due to the O, Cl, and S atoms, as well as van der Waals interactions. Comparing the structure of ametryn, prometryn, and simeton, the "O" atom in simeton differs from the "S" atoms in ametryn and prometryn in addition to the additional branch in ametryn and prometryn (Fig. 2). Ametryn has a higher potential for contributing electrons since it includes a "S" which has a lower electronegativity compared to "O" atom. Therefore, the adsorption of ametryn on cellulose/reduced GO adsorbent is higher. On the other hand, despite the presence of "S," prometryn contains an extra branched structure that impairs van der Waals interactions between adsorbent and

Fig. 2 Structure of triazin pesticides

prometryn, making it the least adsorptive of the triazine insecticides. The “Cl” atoms of atrazine and simazine are electron-withdrawing because of high electronegativity. “Cl” atoms may provide an acidic π -system that quickly forms complexes with the π -system with no derivative and hence aids the adsorption. Surface studies implicate rough and wrinkled surfaces with a lamellar structure which is a favorable situation and significantly boosts the adsorption of the nanocomposite. The proposed nanocomposites could be recycled with 85% adsorption efficiency up to the sixth cycle (Zhang et al. 2015).

Neonicotinoid pesticides (e.g., imidacloprid, acetamiprid, dinotefuran, etc.) are a type of diverse fast insecticides that have been used worldwide to eradicate bugs. They are indeed the main substitutes for carbamates and organophosphorus. As a result, neonicotinoid pesticides serve an important part in the preservation of a wide range of crops, including rice, fruits, maize, and vegetables. Neonicotinoid contaminants can contaminate natural waterways, vegetables/fruits, and soil as a consequence of their widespread usage and buildup over time, posing significant health and ecological concerns (Liu et al. 2017). In nanocomposites, a highly porous network of cross-linked polymers can provide better removal efficiency for both organic and inorganic pollutants. The porous polymeric structure based on a metal-organic framework includes a strong bridging/chelating between a metal ion and an organic moiety. Metal-organic framework based on magnetic $\text{Fe}_3\text{O}_4/\text{GO}/\beta\text{-CD}$ nanocomposite core and Cu-benzene-1,3,5-tricarboxylate with high specific surface area ($250.33 \text{ m}^2 \text{ g}^{-1}$) and pore volume ($0.826 \text{ cm}^3 \text{ g}^{-1}$) could adsorb neonicotinoid from the aqua medium. The nanocomposites-based porous metal-organic framework has a maximum adsorption capacity ranging between 1.77 and 3.11 mg g^{-1} for a variety of neonicotinoids. The findings indicate that the established metal-organic framework was a simple and suitable adsorbent for removing neonicotinoid pesticides from the aquatic ecosystem (Liu et al. 2017).

Pharmaceutical Drugs

Medications have been regarded as emergent contaminants in the marine ecosystem over the past few decades owing to their long persistence, limited degradability, and negative impacts on animal and human health as well as marine life. Medical drug companies, sanitary items, health care effluent, and excretion via feces/urine are all major sources of pollution in water. While the quantity of pharmacological untreated wastewater discharged into the environment is small, the discharge of this sort of contaminant into the environment may happen and represent a long-term hazardous danger to freshwater bodies and life forms. The antibiotics are most frequently used therapeutically active drugs. The increased use of these antibiotics has led to their accumulation in fresh water, contaminating the water (Gor and Dave 2020; H. Ragab et al. 2021; Karimi-Maleh et al. 2021; Luo et al. 2019). Third-generation fluoroquinolones drug ciprofloxacin is antibacterial with a water solubility of 11.48 g L^{-1} . Ciprofloxacin concentrations in hospital discharge range between 0.7×10^{-6} and $1.24 \times 10^{-4} \text{ g L}^{-1}$ and it is hazardous to some microbes at extremely

low concentrations. As a result, ciprofloxacin elimination from untreated water is critical. Nickel ferrite (NiFe_2O_4), a magnetic nanomaterial that can be reinforced into modified gum ghatti cross-link poly(acrylamide) hydrogel can effectively remove ciprofloxacin with a maximum adsorption capacity of 274.84 mg g^{-1} (Gor and Dave 2020). The hydrophobic interaction (antibiotic and the oxygen-containing moiety of nanocomposites), $n-\pi$ interactions, and H-bonding are all involved in gum ghatti/poly(acrylamide)/ NiFe_2O_4 nanocomposites' removal of ciprofloxacin (Gor and Dave 2020).

Tylosin is a common animal health antimicrobial drug that has been shown to facilitate the development in animals and is extensively used as a pharmacotherapeutic medicine in the diagnosis of mycoplasmosis in livestock and poultry. Aggregated tylosin might cause gene problems, raise bacterial resistance to antibiotics, and adversely affect human and aquatic life forms (Luo et al. 2019). Porous charcoal derived from carbon-containing sources can contribute significantly to adsorption, i.e., polymeric matrix may be benefited from its broad and regulated pore structure and size, large surface-to-volume ratio, excellent stability, and adsorption efficiency. Moreover, highly porous charcoal may be produced using less expensive resources such as biomass waste (Mashile et al. 2020). Activated charcoal reinforced into chitosan/cellulose matrix shows potential for the removal of tylosin having a maximum adsorption capacity of 59.26 mg g^{-1} . The adsorption of tylosin on the nanocomposite is controlled by $\pi-\pi$ and electrostatic interactions (repulsion between protonated tylosin and the positive surface of adsorbent at $\text{pH} < 7.2$), H-bonding (between surface $-\text{OH}$ and $-\text{COOH}$ groups of nanocomposite and tylosins), internal diffusion, and size exclusion impact. The study of kinetics revealed that tylosin sorption on chitosan/cellulose/activated charcoal is a sluggish phenomenon. The 23.844 nm pore size of the nanocomposite suggests a mesoporous adsorbent. Tylosin has a flexible structure and hence can diffuse into the adsorbents' pores. As a result, the size exclusion effect affects tylosin adsorption by nanocomposite (Luo et al. 2019).

The specific substance having a magnetic property may be simply retrieved by an outer magnetic force positioned on the exterior of the vessel after the adsorption process is completed, with no extra centrifugation or filtering of the specimen. As a result, magnetic separation is straightforward, a less expensive, and faster way of separating such tiny nanocomposite particles than a laborious filtration procedure (Nakhjiri et al. 2021; Nezhadali et al. 2021). The nanoparticles tend to be agglomerated and as a consequence, the adsorption of the magnetic nanomaterial is reduced. The reinforcement of magnetic nanomaterials not only enhances the dispersion and stabilized these nanomaterials, but also enhances surface functionality, which is a very critical parameter to decide adsorbents' performance (Feng et al. 2017; Nezhadali et al. 2021). Carbamazepine (treatment of nerve pain and epilepsy) is persistent in the environment. Carbamazepine can be removed from the industrial effluents using polypyrrole-chitosan/ Fe_3O_4 magnetic nanocomposite. The maximum adsorption capacity of polypyrrole-chitosan/ Fe_3O_4 was 121.95 mg g^{-1} with a slight loss in performance ($<5\%$) after recycling and reusing it for the fifth cycle. The polypyrrole-chitosan/ Fe_3O_4 can remove 94.5% carbamazepine from the

aqueous medium within 25 minutes. In addition to that the presence of magnetic characteristics makes its separation from aqueous solution a lot more efficient. Hence, polypyrrole–chitosan/ Fe_3O_4 is a better nanocomposite that can be used with enhanced adsorption compared to only Fe_3O_4 nanoparticles (64% removal efficiency) for carbamazepine adsorption. Carbamazepines' pKa value (~ 13.9) suggests it possesses a neutral structure between 2 and 9 pH value. In a similar range, polypyrrole moiety of nanocomposite may have a cationic charge, but as carbamazepine do not possess any charge in the pH range in which polypyrrole-chitosan/ Fe_3O_4 has a charged structure, therefore, there are no electrostatic interactions between adsorbate and adsorbent. H-bonding, dipole-dipole, and π - π interactions between adsorbate and adsorbent governs the adsorption of carbamazepine on polypyrrole–chitosan/ Fe_3O_4 nanocomposite (Nezhadali et al. 2021).

The most frequent endocrine disruptive substances are steroids. Among the most potent endocrine-disrupting chemicals is estradiol. Estradiol and its metabolites are commonly discovered in marine ecosystems and can cause serious harm (Li et al. 2020). Chitosan reinforced with hybrid Al_2O_3 -hydroxyapatite (chitosan/ Al_2O_3 -hydroxyapatite) can efficiently remove estradiol from water. The chitosans' low surface area ($0.908 \text{ m}^2 \text{ g}^{-1}$) and pore volume ($0.003 \text{ cm}^3 \text{ g}^{-1}$) result in its lower adsorption of estradiol on chitosan (maximum adsorption capacity = 29.04 mg g^{-1}) despite the presence of a large number of active functional groups on its surface ($-\text{NH}_2$, $-\text{OH}$). Improvement in the textural property of chitosan by producing chitosan/ Al_2O_3 -hydroxyapatite resulted in increased adsorption of chitosan toward estradiol, i.e., the resulting chitosan/ Al_2O_3 -hydroxyapatite composite possesses improved adsorption capacity (39.78 mg g^{-1}) for estradiol owing to the increased surface $-\text{OH}$ groups, surface area ($94.823 \text{ m}^2 \text{ g}^{-1}$), and pore volume ($0.2000 \text{ cm}^3 \text{ g}^{-1}$). In addition to that, the chitosan/ Al_2O_3 -hydroxyapatite adsorbent is quite selective toward only organic pollutants. The presence of inorganic constituents did not alter the adsorption of estradiol on the nanocomposite. However, the presence of organic contaminants does affect the adsorption of estradiol (Li et al. 2020). Chitosan/ Al_2O_3 -hydroxyapatite can be used to successfully remove estradiol in the wastewater in the presence of high inorganic ion concentrations.

Because of amoxicillin's excellent resistance to pathogens and broad spectrum against a variety of pathogens, it is among the most extensively used commercialized penicillins. It is prevalent in effluents from the pharma sector and clinics, where it induces skin problems and bacterial resistance in pathogenic microorganisms. Between 30 and 90% of the total amoxicillin is emitted into the water via human and animal feces. Another drug, nonsteroidal anti-inflammatory drug, diclofenac is widely used across the globe. It is well known to get discharged into waterways in the form of potassium or sodium salt (H. Ragab et al. 2021). Limestone-activated carbon-sodium alginate shows prominent adsorption for both amoxicillin and diclofenac with a maximum removal capacity of 249 and 246 mg g^{-1} , respectively. The effect of pH suggests an electrostatic interaction must have influenced the adsorption of both drugs on nanocomposite, i.e., at lower pH (acidic pH = ~ 2), the negatively charged drugs must be attracted to protonated positive sites of the nanocomposite adsorbent, leading to an increased removal percentage of amoxicillin

(99.6%) and diclofenac (98.4%). The same can be concluded from the large decline in the removal efficiency of the nanocomposite in basic conditions because the deprotonated negative surface of drugs and limestone-activated carbon-sodium alginate repel each other (H. Ragab et al. 2021).

Mashile et al. (Mashile et al. 2020) reported the adsorption of three fluoroquinolones (antibacterial drugs), namely enrofloxacin, levofloxacin, and danofloxacin on a biodegradable magnetic mesoporous carbon/ β -cyclodextrin-chitosan. The insertion of magnetic nanoparticles into mesoporous carbon eases separation, and functionalizing the material allows a decrease in its hydrophobicity, i.e., the starch-based mesoporous carbon was having a very high specific surface area and pore volume of $1181 \text{ m}^2 \text{ g}^{-1}$ and $2.54 \text{ cm}^3 \text{ g}^{-1}$, respectively. The reinforcement of this mesoporous carbon led to magnetic-carbon/ β -cyclodextrin-chitosan nanocomposite having an excellent specific surface area and pore volume of $1264 \text{ m}^2 \text{ g}^{-1}$ and $4.65 \text{ cm}^3 \text{ g}^{-1}$, respectively. The removal of all three fluoroquinolones drugs by the magnetic-carbon/ β -cyclodextrin-chitosan nanocomposite was governed by surface adsorption as well as intramolecular diffusion of drugs within the nanocomposite. For enrofloxacin, levofloxacin, and danofloxacin the nanocomposite shows maximum adsorption of 195, 165, and 130 mg g^{-1} , respectively. These capacities were reduced to 122, 116, and 88 mg g^{-1} , respectively, on the eight regeneration-reuse cycles, imparting prominent adsorption of magnetic-carbon/ β -cyclodextrin-chitosan nanocomposite after so many reuse cycles (Mashile et al. 2020).

Phenols

Phenol manufacturing businesses, like pesticides, fertilizer, dye manufacturing, petroleum refineries, and so on, produce phenol constituents in their wastes. Phenols exert substantial negative impacts on health including pancreatic, protein, harm kidney and liver, cause tissue deterioration, as well as paralyze the nervous system. Migraines, vision discomfort, and high blood pressure are all side effects of phenol exposure (Fathy et al. 2020; Guo et al. 2019; Nakhjiri et al. 2021). The creation of biocompatible and hydrophilic (3D) reduced graphene oxide (rGO) hybrid hydrogels can effectively avoid rGO sheet aggregation and restacking while also broadening the spectrum of rGO-based composites in potential implementation. Reinforcement of rGO sheets into sodium alginate can help to reduce the aggregation of rGO as well as modify rGOs' hydrophilicity (Feng et al. 2017). The use of rGO/sodium alginate composition shows more adsorption for phenol (adsorption capacity = 26.126 mg g^{-1}) than bisphenol-A (adsorption capacity = 14.123 mg g^{-1}), which is quite low compared to other composite materials despite the large specific surface area of rGO ($2630 \text{ m}^2 \text{ g}^{-1}$), but better than sodium alginate which merely shows capability for phenol adsorption. The π - π interaction and H-bonding are thought to be responsible for the adsorption of the phenolic compound on rGO/sodium alginate (Feng et al. 2017).

The utilization of epichlorohydrin cross-linked β -CD polymer reinforced with GO can remove the α -naphthol and β -naphthol with a removal efficiency ranging

between 50 and 60% for the former and 60 and 70% for later. This was quite high compared to β -CD/GOs' adsorption efficiency for phenol 15–20%. The adsorption was plausibly a combined effect of both components in β -CD/GO nanocomposite. The removal efficiency of β -CD/GO for phenols was lower than GO but higher than β -CD, indicating reinforcement of GO has benefited β -CD's adsorption efficiency for phenols. The same can be verified by the fact that increasing GO content from 0–2.4 results in increased adsorption. The adsorption mechanism consists of β -CD that can interact via guest-host interaction and GO can interact with phenol via π - π interactions. It has the potential to be used as an adsorbent for naphthols because of its low cost and environmental friendliness (Heydari et al. 2018).

Another study employing rGO/epichlorohydrin cross-linked β -CD (Rout and Jena 2022) shows the adsorption of three phenolic compounds (phenol, 2-chlorophenol, and 2,4-dichlorophenol) from aqueous solutions. The maximum uptake for phenol, 2-chlorophenol, and 2,4-chlorophenol was 659.475, 674.155, and 702.853 mg g⁻¹, respectively. A removal efficiency of 78% was observed for phenol from the industrial waste within 60 minutes. The reactivity of phenolic compounds with disinfectant chlorine produces chlorophenols. Primary contaminants include chlorophenols such as o-chlorophenol and 2,4-dichlorophenol antioxidants. Paper, petrochemicals, dyes, wood preservatives, plastics, insecticides, and trash disposal contain these contaminants. Furthermore, it is created as a side product of chlorine bleaching of pulp and chlorination treatment of potable water. The presence of chlorine groups in o-chlorophenol and 2,4-dichlorophenol makes it extremely harmful in the environment, even at a low dosage (Rout and Jena 2022). The adsorption mechanism is mainly controlled by H-bonding between adsorbent-adsorbate and electrostatic interactions because of charged surface of nanocomposite and π - π interaction between π electron cloud of phenolic ring and oxygen-containing functionality on rGO/ β -CD nanocomposite. During adsorption, the phenol rings as electron-gaining moiety and the rGO/ β -CD nanocomposite's π electron-dense areas operate as electron-releasing sites. As a result, the dispersive interaction of π cloud electrons controls the adsorption of phenolic chemicals onto the composite (Scheme 2). Furthermore, van der Waals forces and hydrogen bonds generate a guest-host inclusion complex between phenolic chemicals and β -CD. As a consequence, additional phenolic molecules are drawn to the surface of the adsorbent, accelerating the removal of phenols from the aqueous medium. Because the interaction between the composite and phenolic compound takes place over the whole rGO/ β -CD nanocomposite surface, the adsorbed phenolic molecules are dispersed evenly on the adsorbent surface. Two distinct electron acceptor–donor interactions occur during the removal of phenolic contaminants: (i) the engagement of the rGO/ β -CD's electron donor -COOH and -OH groups with the electron-acceptor phenyl ring of the phenolic molecule and (ii) the interaction of the rGO/ β -CD's electron-rich -NH₂ with the aromatic ring of the phenol. During the adsorption process, the interaction between the donor and acceptor of the adsorbent and phenolic compounds is determined by the dipole moment of the different functionality available on the basal plane (Scheme 2) (Rout and Jena 2022).

Scheme 2 Schematic diagram for proposed phenolic compound removal mechanism. (Reprinted by permission from [Rout and Jena 2022]; Springer; Environment science and Pollution Research; Synthesis of novel epichlorohydrin cross-linked β -cyclodextrin functionalized with reduced graphene oxide composite adsorbent for treatment of phenolic wastewater; Rout, D.R., and Jena, H.M. copyright [2022])

The removal efficiency of phenol can be improved by using collagen-based double-network composite material. Collagen (extracellular proteins) is a biopolymer that has been found to be significantly preserved among organisms. It is the most common extracellular component of most tissues in mammals, accounting for one-third of all protein found within tissues. Collagen-(2-acrylamido-2-methylpropane sulfonic acid- methacrylic acid/acrylamide)- $\text{Fe}_3\text{O}_4@ \text{SiO}_2$ magnetic double-network nanocomposite hydrogel synthesized via in situ ultrasound-assisted approach can remove 77% phenol and 83% p-nitrophenol from the wastewater. The maximum adsorption capacity of double-network nanocomposite hydrogel was

16.527 mg g⁻¹ and 19.201 mg g⁻¹ for phenol and p-nitrophenol, respectively. The proportion of phenol removal percentage rose as the pH grew from 2–9. Adsorption, in reality, is primarily governed by the ion exchange process. In acidic pH, the removal efficiency is minimally attributed to very weak ionization (or perhaps the absence of ionization) and the development of strong H-bonds throughout the chains. Furthermore, at acidic pH, the adsorbent surface is often protected by “H⁺” ions, preventing adsorbent-adsorbate contact. The adsorbent surface is negative in alkaline conditions due to a decrease in the proportion of H⁺ ions and an increase in the number of OH⁻ ions. As a result of the repulsion of -OH ions as well as adsorbent anionic functions, the greatest % removal efficiency was obtained at higher pH (below 11). At pH 11 or higher, deprotonation of phenol led to the formation of phenoxide anion which results in repulsion between phenol and adsorbent leading to decreased adsorption (Nakhjiri et al. 2021). The presence of nitro (-NO₂) at the para position of phenol leads to increased H-bonding interactions between active functional groups of double-network nanocomposite and hence the removal efficiency of adsorbent p-nitrophenol is higher than phenol.

Chitosans' maximum adsorption capacity for phenol (61.69 mg g⁻¹) can be improved to 89.96 mg g⁻¹ with the addition of MWCNTs to form covalently linked chitosan/MWCNTs nanocomposite (Guo et al. 2019). Further, the use of chitosan/mesoporous silica nanocomposite can remove phenol from aqua solution with a maximum adsorption capacity of 149.25 mg g⁻¹, higher than that of collagen, β-CD, and sodium alginate-based nanocomposites because of its mesoporous structure (Fathy et al. 2020; Feng et al. 2017; Heydari et al. 2018; Nakhjiri et al. 2021). Silica (MCM-48) is a well-known mesoporous silica product with an interlaced and branching porous structure that is ideal for entrapping phenol from water solution due to its consistent porous structure, vast specific surface area, and customizable pore diameter (Fathy et al. 2020). The reusability study suggests a sharp decline in removal percent of phenol on chitosan/mesoporous silica nanocomposite from 92.94–48.13% throughout six reuse cycles owing to adsorbent mass loss. Nevertheless, the adsorbent can still be used up to seven cycles (Fathy et al. 2020).

Conclusions and Future Outlooks

To conclude, water scarcity has become a global concern because of the increasing global human population. This is a high time to restore the contaminant water and store it for the future era. The eco-friendly, cost-effective, and sustainable way is to use biopolymer-based compositions for wastewater treatment. Biodegradability and biocompatibility of the natural polymers can be modified into other better performing composite materials. The tertiary treatment of water using the adsorption approach can be utilized for various agro and industrial sectors, freeing up fresh water for potable purposes. Modified biopolymer-based nanocomposites containing chitosan, sodium alginate, cellulose, β-CD, starch, collagen, etc. as a reinforcing material or matrix have the potential to provide cheaper, environment-friendly, sustainable adsorbent with enhanced removal efficiency. As opposed to their fully

synthetic polymers, biopolymer-based compositions do not accumulate in the environment causing secondary pollution after or during adsorption. Especially use of magnetic biopolymer nanocomposite is a very efficient and less energy-consuming way to retrieve adsorbent after application. Despite good adsorption capacity, compared to hybrid semisynthetic biopolymers, the nanocomposite containing only biopolymer and nanofiller lacks a large specific surface area and high adsorption capacity. The biopolymer-based nanocomposites' adsorption can easily get disturbed by the presence of other contaminants than the target molecules, and hence the enhancement of biopolymer nanocomposites for selective adsorption is still yet to be fully developed. The combined techniques for wastewater treatment can pave the way for future water recycling.

Abstract

Chitin is a biopolymer widely distributed in nature, and it is the second most abundant polysaccharide after cellulose. Due to its biological activities and usefulness in industry, chitosan and its oligosaccharides have recently attracted a lot of interest. Chitosan is a nontoxic biopolymer made by deacetylating chitin. Chitin, chitosan, and its derivatives are often employed in food science, tissue engineering, and wound healing. Easy techniques for making chitin and chitosan nanofibers have recently been established, and research on the biological uses of chitin and chitosan nanofibers is continuing. This chapter aims to analyze the recent advances in biomedical applications of chitin and its derivatives.

Introduction

Chitin is a biopolymer widely distributed in nature, and it is the second most abundant polysaccharide after cellulose. The use of chitin emerged as a suitable alternative for the synthetic polymers, which ruled the society after the World War 11. Chitin occurs in nature as crystalline microfibrils, and due to its crystalline nature, it is found to be less soluble in most of the solvents. This low solubility often restricts the use of chitin in various applications (Roy et al. 2017). The deacetylated form of chitin, chitosan, is found to be soluble in many solvents including acids. Chitin is a polysaccharide consisting of a higher percentage of the acetylated form, while chitosan contains a higher degree of the deacetylated form. Chitosan can be prepared from chitin by (i) partial deacetylation in the presence of concentrated NaOH or (ii) enzymatic hydrolysis using the enzyme chitin deacetylase. Although the main commercial source of chitin comes from crabs and shrimps, it is also found in insects, the cell walls of nematodes, fungi, and yeast (Rouhani Shirvan et al. 2019). In addition to their easy availability, chitin and chitosan are biodegradable, biocompatible, antimicrobial, and are found to be less toxic. Additionally, both of these are in the list of environmentally degradable plastics (EDP). It is due to these advantageous properties, particularly its abundance, that makes chitin and its derivative a suitable polymer for various applications such as biomedical, food and cosmetics, pharmaceuticals, and tissue engineering (Kaczmarek et al. 2019). Chitin is made up of poly β -(1 \rightarrow 4)-*N*-acetyl-D-glucosamine units linked by glycosidic linkages. Abundant hydroxyl, amino, and acetyl groups in chitin and chitosan will provide a tendency for inter- and intramolecular hydrogen bonding, which may increase the crystallinity of these polymers (Fig. 1).

Chitin occurs in different crystalline polymorphic forms such as α , β , and γ . The outer skeleton of crab and shrimp consists of the α -chitin, which is the most dominant form, while β form is seen in the proteins in squid pen and γ in the cocoon of moth. α -chitin has an antiparallel arrangement of individual chains,

Fig. 1 Structure of chitin and chitosan

which makes it possible for maximum hydrogen bonding between the chains and results in high crystallinity. β -chitin has a parallel alignment of units and a larger distance between the molecules, which makes it more flexible and soluble in solvents (Tamura and Furuike 2014). In γ chitin, we can see a combination of α and β forms. Due to the strong intermolecular interactional forces existing between the molecules in chitin, it is very difficult to utilize chitin for various modifications using organic solvents. For this reason, chitin is often converted to its different derivative forms such as chitosan, carboxymethyl chitin, fluorinated chitin, (diethylamino) ethyl chitin, phosphoryl chitin, mercapto chitin, and chitin carbamates. These chemically modified forms are used in various fields such as cosmetic, food, and textile industries, water treatment, plant protection, and pharmaceutical fields. Chitin and its derivatives have important applications in biomedicine. This chapter is intended to summarize the various biomedical applications of chitin and chitosan (Li et al. 2020; Daraghmeah et al. 2011).

Sources of Chitin

After cellulose, chitin is the polysaccharide that occurs in nature in the greatest abundance. It is extensively dispersed across the animal and plant kingdoms and is a significant renewable resource (Fig. 2). One of the primary sources of chitin and chitosan is an invertebrate group known as the crustaceans, which include crabs, lobsters, and shrimps; it is also a part of the exoskeletons of insects and mollusks, and it occurs in combination with other substances such as lipids, calcium carbonate, proteins, and pigments (Tamura and Furuike 2014; Daraghmeah et al. 2011). Every year, roughly 6.1 million tonnes of crustaceans are harvested from interior and coastal waterways with the goal of producing chitin and chitosan. In addition to this, chitin accounts for around 40% of the remaining wastes created by marine food,

Fig. 2 Different sources of Chitin

the majority of which are environmental pollutants. A few types of fungus naturally contain chitin, and these fungal biopolymers offer a number of advantages over those extracted from processed seafood. Not all fungus species' cell walls contain chitin and chitosan (Rinaudo 2006). It is known that the fungi belonging to the classifications Basidiomycetes, Ascomycetes, Zygomycetes, and Deuteromycetes have chitin and chitosan in their cell walls. Before stepping up production, it is important to optimize the quantity and characteristics of fungal biopolymers, as they are influenced by a variety of parameters.

In nature, chitin is found in three different crystalline polymorphic forms. They are α -chitin, β -chitin, and γ -chitin. Different orientations of the microfibrils exist within each form; antiparallel chains that make up the α -form, which is widely present and responsible for the polymer backbone's rigidity (strong hydrogen bonding, two per unit cell), are found in the prawn, crab, and lobster shells, as well as beetle shells and fungal cell walls, which are examples of crustacean shells (Shukla et al. 2013; Lizardi-Mendoza et al. 2016). However, β -chitin is composed of parallel chains that create monocyclic crystals with both intramolecular (hydrogen bonds, one per unit cell) and intermolecular interactions. A somewhat more complex arrangement of the chitin chains and crystalline structure may be seen in γ -chitin, which consists of three chitin chains and alternately aligned parallel and antiparallel polymer chains. The presence of γ -chitin is less frequent than that of α - and ∞ -chitin, and it has only been suggested in a small number of studies that beetle cocoon fibers contain it (Velásquez and Pirela 2016) (Fig. 3).

For example, the fungal, insect cocoons, and yeast includes a variety of parallel and antiparallel chains (α -chitin and β -chitin), and the squid pens, pogonophoran tubes, and diatom spines contains only β -form of chitin. The chitinous materials extracted from crustaceans, invertebrates, and arthropods, especially those with hard outer shells, are often shaped like an α -form. This is because the chains are antiparallel, making the arrangement comparatively compact as a result of stronger and more stable hydrogen bonding. In insect cocoons, which feature two parallel threads and one antiparallel string, chitin with the γ -form is most common. The α -form can be converted into the β -form, but not the other way around. Chitin separated from different sources has different crystallization, purity, and polymer chain compositions depending on the source and the amount of chitin that is naturally present there.

Fig. 3 Three different polymorphic forms of chitin

Extraction of Chitin

There are always new sources of crustacean chitin being found after decades of discovery. Now a number of ways to acquire chitin are available in the literature, including chemical, biological, and even a mix of the two to produce an even more efficient procedure. Whatever method is used, the objective is the same: remove all proteins, minerals, lipids, and colors until just the desired substance is left. Due to its efficiency and usefulness, the chemical approach is currently the most used method in industrial production; however, other methods of generating chitin are generally accessible and extremely useful (Hou et al. 2021).

Strong acids and bases are used in the chitin extraction process, which has negative effects on the process such as high material costs, the creation of chemical waste, and low purity levels in the finished product. Biological processes are becoming more and more appealing since they have cheap production costs, do not create high-risk pollutants (unlike chemical processes), and produce high-quality final goods (Younes and Rinaudo 2015). The goal of every procedure described in the literature is to get chitin by removing the minerals and proteins from the source material. In addition to having significant biotechnological utility, chitin produces by-products (like chitosan) that are equally valuable and even more pertinent (Fig. 4).

Fishing sector waste, mostly the shell of prawns, crabs, and lobsters, is the primary industrial source utilized to extract the biopolymer. To eliminate any organic matter adhered to their surface, the crustacean shells are crushed to the proper size (often a few mm) and thoroughly cleansed. In the deprotonation stage, the washed sample was treated with a diluted NaOH solution at an elevated temperature of 60–100 °C for around 30 min. Depending on the treatment, the reaction might

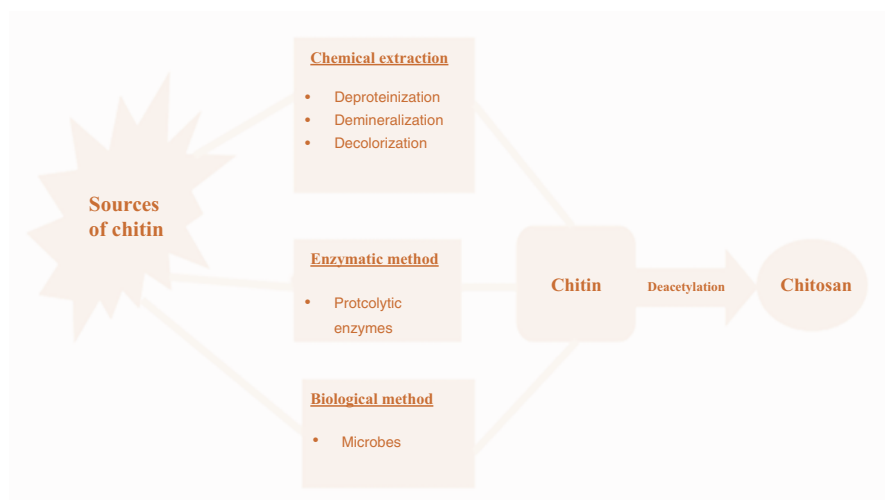

Fig. 4 Standard protocols for chitin and chitosan extraction

continue for up to 4 days. KOH, K₂CO₃, Na₂CO₃, NaHCO₃, Ca(OH)₂, Na₃PO₄, Na₂S, Na₂SO₃, and NaHSO₃ were also used as reagent for the above process of deprotonation. After this stage, the pH of the solution is adjusted to the isoelectronic point to obtain precipitate (Percot et al. 2003; el Knidri et al. 2018). The protein obtained can be utilized as an additive for cattle livestock. The deproteinization methods involving enzyme extracts or isolated enzymes and biological fermentations have shown some success, since they reduce the chemical breakdown of chitin and provide cleaner operations. The problem with enzymatic/microbiological treatments is that they take time and leave the material with 1–7% of residual protein.

In the demineralization stage, the calcium carbonate present in the shells can be eliminated via treating with dilute hydrochloric acid. The stoichiometric ratio of acid has a crucial role in the demineralization stage so as to control the depolymerization and deacetylation of chitin. The process follows the below equation:

To minimize thermal degradation, high temperature treatments must also be avoided. Use of the complexing agent EDTA (ethylenediamine tetra acetic acid) in basic solutions is an alternate treatment for demineralization (Acosta et al. 1993).

The staining is a reliable sign of the material's contaminants. This is achieved through the depigmentation process. The presence of pigments such as astaxanthin, canthaxanthin, astacene, lutein, and -carotene is primarily responsible for the color of crab shells. These pigments are often extracted at room temperature with acetone, chloroform, ether, ethanol, ethyl acetate, or a combination of solvents (Percot et al. 2003; el Knidri et al. 2018).

Application of Chitin and Its Derivatives

Pharmaceutical and Biomedical Application of Chitin and Chitosan

Chitin and its derivatives are excellent biomaterials with a wide range of applications despite all of their distinctive qualities. Because of its biocompatibility, biodegradability, and low toxicity, chitosan is a particularly beneficial polymer for biomedical applications. Chitin is also known to be biocompatible and biodegradable, and it has been used for a variety of things including suture threads, bandages for treating wounds, and sponges. However, because of its insolubility in water and mild reactivity, it has often gotten less attention than chitosan. With its hierarchical structure, multifunctionality, excellent light management, and exceptional mechanical capabilities, chitin offers a wealth of opportunities for us to employ it as a cutting-edge material (Azuma et al. 2014).

In Drug Delivery

Chemical modifications possible in chitin and chitosan, together with their additional qualities like easy bioadhesion, crosslink formation with other polymers, different

kinds of gel formation, and antimicrobial activity, enable researchers in using these polysaccharides in drug delivery. Chitin nanofibrils were integrated with alginate-based microspheres by Lin et al., and they found an increase in storage modulus and loss modulus which confirms the fibril reinforcing function (Parhi 2020). Thus, prepared composite microspheres showed a smooth surface morphology, suggesting an enhancement in structural integrity by the addition of nanofibrils. The encapsulation efficiency of these composite microspheres was tested using theophylline, and it was found that more than 55% encapsulation was achieved by the 3D network of the nanofibrils, which helped in the controlled drug release. Chitosan and alginate-based porous composite hydrogels mixed with bioceramic powders as a dispersed phase were developed and used in drug delivery and tissue engineering. Carboxymethyl chitin (CMC) nanoparticles were used as potential cancer drug delivery systems. A hydrophobic cancer drug, 5-fluorouracil (5-fu), was loaded into the CMC nanoparticles and the drug release studies showed a sustained release at the pH 6.8. Additionally, the prepared nanoparticles showed antibacterial and ferromagnetic behavior, which makes them useful in drug tracking system. O-carboxymethyl chitosan (O-CMCS) hydrogel beads were prepared with several modifications, and their pH-sensitive characteristics were investigated. The drug entrapment efficiency was tested and was found that chitosan-coated calcium-O-CMCS hydrogel beads showed higher entrapment efficiency and proper protein release properties. Thus, it was concluded that these hydrogel beads form promising protein drug carrier for the site-specific release in the intestine. Chitosan/carboxymethyl cellulose polyelectrolyte complexes were synthesized by Luppi et al. as vaginal inserts for the local delivery of chlorhexidine digluconate. O-CMCS microspheres were also used as a potential drug carrier (Das et al. 2022; Rivas et al. 2022). Several other modified CMC derivatives also presents promising results in the field of drug delivery. Carboxymethyl chitin microspheres (CMCH-Ms) were prepared through cross-linking in an aqueous two-phase system by increasing temperature without using organic solvents, surfactants, or cross-linking agents. Naproxen and ropivacaine hydrochloride were used as model drugs for drug loading by using solid-in-water (S/W) immersion in aqueous system. The CMCH microspheres and the drug loading microspheres were embedded in the hydroxypropyl chitin (HPCH) hydrogels to form CMCH-Ms/HPCH gel composite scaffolds. These scaffolds showed good biodegradability and biocompatibility and less burst drug release with a sustained drug release.

Drug release kinetics of some model drug systems including, curcumin, progesterone, and mesalamine, for 24 h in physiological conditions were investigated in pectin-chitosan hydrogels as drug carriers. Chitosan film was developed using pectin or hydroxypropylmethyl cellulose, and a model drug, miconazole nitrate, was loaded into the films. These films of chitosan-hydroxypropylmethyl cellulose were found to be the most suitable as drug carriers. Chitin nanocrystals were synthesized and cross-linked with glutaraldehyde, and these cross-linked crystal were used as scaffolds. Curcumin was used as the model drug, and the drug release profile showed promising results. Cytotoxicity studies were also done, which affirm the potential of the synthesized nanocrystals in drug delivery and tissue engineering. Chitosan films

were prepared with varying molecular weight and acetylation degree chitosan-depolymerization-products and were applied as drug delivery materials. It was found that by varying the molecular weight and acetylation degree of chitosan depolymerization products, several properties like water resistance, mechanical, and antibacterial properties were changed to a considerable extent. In vitro ciprofloxacin (CFX)-release behavior was also studied on these films after cross-linking using glutaraldehyde. These cross-linked CFX-loaded films showed increased water resistance, optical, tensile strength, and thermal properties to the unloaded films. A thermosensitive chitosan-based hydrogel was prepared for the sustained release of latanoprost, which is used to control ocular hypertension. This was found to be biocompatible with a sustained drug release and was proposed as an alternative to traditional eye drops for the treatment of glaucoma (Nayak et al. 2022).

In Tissue Engineering

The inadequacy of the engineered tissue structures to endure the mechanical stress that may occur under in vivo settings at the moment of implantation is a challenge in tissue engineering and regenerative medicine research. Additionally, the scarcity of suitable biomaterials as temporary matrix is also a major challenge in this area. However, chitosan, by virtue of its properties like biocompatibility, cell adhesion, differentiation, and proliferation, is used widely in the field of tissue engineering. It finds its application in bone tissue engineering, cartilage regeneration, and nerve and liver tissue engineering (Yang 2011). Nowadays, much attention has been given by the researchers to the development of polymer nanofibers with various diameters ranging from several micrometers to nanometers using electrospinning. Biodegradable and biocompatible hydrogels were derived from chitosan and hyaluronan through metal-free click chemistry, and it was found that these could be used as an injectable scaffold for adipose tissue engineering. On account of their structural similarities with glycosaminoglycans and mechanical and morphological properties with collagen, chitosan derivatives are excellent substitutes in tissue engineering. Chitosan derivatives are effectively used in skin tissue engineering (Jayakumar et al. 2011; Wan and Tai 2013). A bilayered chitosan hydrogel was prepared for the treatment of burns in pig models. It was found that efficient reconstruction of dermal-epidermal junction and dermis as well as the re-epithelialization of wound could be attained. Various chitosan composites with collagen and elastin were extensively used as scaffolds in skin regeneration to increase the tensile strength and flexibility of the prepared scaffolds. A polyelectrolyte gelatin-chitosan hydrogel was prepared for 3D bioprinting in skin tissue engineering (Soroush et al. 2022). Electrospinning was found to be an efficient synthesis of the scaffolds in tissue engineering. Poly (L-lactic acid)/collagen nanofiber that was coated with chitosan was synthesized and tested for sustained release of aloe vera (AV) gel. It was shown that these nanofibers had an enhanced effect on mouse fibroblast attachment, with improved viability and proliferation. The composites of chitosan and hydroxyapatite hydrogels were reported to show a wider scope in bone tissue engineering. HVP functionalized with chitosan was tested for osteoblast proliferation, differentiation, and bioadhesion, and it showed best results compared to the Chit-RGD. Chitosan-collagen composite films have been shown to produce promising

results in osteoblast proliferation, differentiation, and matrix mineralization in MC3T3-E1 cells. Chitosan-gelatin composites were also reported as better scaffolds, and these composites when incorporated with hydroxyapatite, remarkably improved cell attachment and growth on chitosan-gelatin matrices. Many synthetic polymers, such as polylactic acid, poly-methyl methacrylate (PMMA), poly-caprolactone, and polyethylene glycol, are blended with chitosan to show enhanced mechanical properties, and these polymer composites were found to be biocompatible as well (Bi et al. 2021). An in situ-forming hydrogel was prepared from chitosan, gelatin, and bioactive glass. This is an injectable hydrogel and is stimulated by body temperature. This hydrogel can be administered as a fluid using a syringe and a needle, making it a unique thermosensitive, lowly invasive system. Graphene and graphene oxide have been successfully combined with chitosan for applications in bone tissue engineering. These composites reinforce organic-inorganic hybrid scaffolds because of their superb mechanical properties, and due to the presence of free π electrons, they possess antibacterial properties in addition to cell adhesion, proliferation, and differentiation. Chitosan and cellulose nanofiber-based injectable suspensions were developed for intervertebral disc (IVD) repair and its regeneration through the augmentation of one of its regions, the nucleus pulposus. Efficient promising transparent injectable solution was developed for IVD regeneration, which offers an alternate for open surgery (Croisier and Jérôme 2013). This is a biocompatible and nontoxic chitosan-based hydrogel. It shows a constant storage modulus over a wide range of strains, which resembles the IVD ECM structure and makes it a suitable scaffold for cells of IVD and regeneration. Vascular layer-by-layer patches have been developed in which the layered deposition improved attachment and proliferation of cells. Different layers are built up from oppositely charged components. Vascular tissue engineering scaffolds were developed using chitosan-immobilized polyethylene terephthalate and chitosan-PVA films, which showed improved cell adhesion, morphology, and growth. Chitosan-PVA combination showed improved cell attachment while maintaining the physical properties of the scaffold. A blood vessel tube with blended PLLA-chitosan-collagen electrospun fiber was developed by electrospinning, which generated blood vessels with high surface area-to-volume ratios. These prepared blood vessels showed improved cell viability and hemocompatibility, good tensile strength, and good burst pressure. Periodontal disease causes irreversible loss of periodontal tissues and ultimate tooth loss (Liu et al. 2011). Chitosan was combined with different organic and inorganic materials in the biodental field. Incorporation of DNA into a chitosan and collagen matrix was found to regenerate periodontal tissue. This chitosan/collagen matrix was porous which embedded chitosan/plasmid DNA nanoparticles encoding platelet-derived growth factor. Due to its porous structure, the DNA was released in a steady manner for about 6 weeks. Analysis was continued for 2 weeks, and it was revealed that the material was capable of initiating protein at high levels. Moreover, it also developed periodontal connective tissue-like structures. Alginate microspheres were prepared by electrospraying and then incorporated into previously formed chitosan gels. They were tested for controlled delivery of bone morphogenetic protein-6 (BMP-6), which was the major growth factor for promoting the periodontal tissue regeneration (Bi et al. 2021).

In Wound Healing

Since the early 1980s, chitosan and its derivatives have been used to treat skin and wounds. Beschitin, a chitin material, was used for dressing skin and nasal wounds. Faster wound healing was observed with chitin and its derivatives where they improve the hemostasis by the production of collagen in fibroblasts. It also helps in the formation of coagulum, with red blood cells responsible for the blood coagulation (Khor and Lim 2003). *N*-acetylglucosamine, which is an extracellular macromolecule crucial to wound healing, is the monomeric unit of chitin, often found in hyaluronic acid. For uses ranging from straightforward wound dressings to complex artificial skin matrices, chitin can be used since it ought to have properties that encourage quick dermal regeneration and expedited wound healing. Basic fibroblast growth factor (bFGF) infusion enhanced the pace of healing, and hence chitosan was an effective substance for wound healing (Mizuno et al. 2003). A step crucial for rapid wound healing in polymorphonuclear (PMN) cell infiltration at the incision site was facilitated by chitosan in the form of chitosan-cotton, which augmented wound healing. For use in healing process, a composite material made of α -chitin and nanosilver were developed (Ueno et al. 1999). These α -chitin/nanosilver composite materials were found to have potent antibacterial activity against *S. aureus* and *E. coli*, as well as a strong blood clotting capacity (Mathew et al. 2010). It has been suggested that burn dressings be made with electrospun nanofibrous materials based on chitosan. For burns of degrees IIIa and IIIb, chitosan nanofiber mats were produced and tested as wound dressings. The study revealed that chitosan nanofiber dressings effectively sucked up secretions, oxygenated the area, were designed to protect from infections, and initiated the function of skin tissue regeneration. Damage to the wound from mechanical action during removal was averted by the degradation of these materials (Cai et al. 2010). A crucial component for the physiological activities of freshly created tissue is vascularization. In growing tissue, the polysaccharides actively contribute to neovascularization. By implanting chitosan in the cornea, researchers were able to show that it can encourage neovascularization. Chitosan is said not to cause any further inflammatory reactions. According to recent clinical research, modified chitosans that include amino acid moieties and substituents at the N-atom are helpful in the healing of wounds. The development of vascularized, nonrefractive tissues with well-oriented collagen is often induced by these factors. Capsular tissue development is inhibited by modified chitosans. Due to chitosan's angiogenic properties, some cartilaginous tissues may also be healed (Singh and Ray 2000).

In Artificial Kidney Membrane

It has been suggested that chitosan membranes, which have great mechanical strength and urea and creatinine permeability, might be used as prosthetic kidney membranes. Serum proteins are not able to pass through these membranes. In order to give improved selectivity and higher dialysis rates for medium- and large-size molecules like uric acid and the like, it is necessary to improve hemodialysis membranes. To fulfill the needs of dialysis applications, either the modification of preexisting polymeric membranes or the synthesis of novel polymeric membranes

are being developed (Nakatsuka and Andradý 1992). The pH-dependent permeability coefficients of a membrane consisting of chitosan and PVA, cross-linked with different concentrations of glutaraldehyde, riboflavin, and insulin, were identified (order of $106\text{--}107\text{ cm}^2/\text{s}$). Additionally, the impact of chitosan cross-linking and blending with PVA on the permeability of vitamin B-12 was investigated. The partition coefficients for the membrane under study were essentially constant ($K = 0.4$), supporting the idea that vitamin B-12 is transported by “pore-type” processes (Chandy and Sharma 1992). It has been reported on a number of membranes made by mixing chitosan and PVA and immobilizing bioactive molecules like prostaglandin E1 (PGE1) on heparin. These membranes have strong small molecule permeability and significantly reduce platelet attachment (Blair et al. 1987). Chitosan can be altered to have dialysis capabilities via graft copolymerization and blending with water-soluble polymers. Chitosan and polyvinyl acetate (PVA) combine to create a transparent, uniform blend with a tensile strength that is higher than the sum of the component parts, as was proved in a study by Srinivasa et al. In order to study the active transport of the halide ions over the chitosan/PVA membrane, created a cross-linked chitosan/PVA blend were created with a set proportion of the cross-linking agent. In a heavily cross-linked membrane, Reinhart and Peppas investigated the diffusion of bovine serum albumin (Reinhart and Peppas 1984). The transport of alkali metal ions and smaller molecular weight solutes via various polymeric membranes made from chitosan derivatives was proposed in other research. Chitosan and its derivatives were used to create a variety of membranes (Hirano 1978) and the membranes demonstrated better dialysis characteristics. In order to improve blood compatibility and permeability, vinyl monomers were added to chitosan membranes using ^{60}Co γ -ray irradiation (Singh and Ray 1999). According to certain researchers, albumin-blended chitosan membranes had better permeability qualities for smaller molecules than the conventional cellulose membranes and demonstrated the greatest reduction in platelet adherence in comparison to other membranes. The permeability of KCl and sucrose was examined in a glycol-chitosan membrane modified with thiol groups. The study demonstrated that permeation control may be accomplished by adjusting the cross-linking agent’s concentration.

In Cancer Therapy

In the world, cancer accounts for 13% of fatalities, and its prevalence is rising. By 2030, 12 million individuals are predicted to develop cancer, with lung, prostate, colorectal, and breast cancer being the most frequent forms (Shanmuganathan et al. 2019). It is essential to utilize drug carriers that are secure and capable of effectively delivering the medications to the malignant tissue without endangering healthy cells as part of anti-cancer therapy. In chemotherapy, chitosan and chitin have been utilized as drug delivery vehicles. 5-fluorouracil (5-Fu), an anticancer medication, was loaded onto carboxymethyl chitin (CMC) nanoparticles, which are soluble in water and created by cross-linking with CaCl_2 and FeCl_3 (Jayakumar et al. 2010a). It has been demonstrated that chitin and chitosan’s chemical alteration significantly affects their physiological characteristics, biodegradability, and interaction with other molecules (Jayakumar et al. 2010b).

Therefore, in order to make use of chitin and chitosan, it is crucial to identify methods that may increase their solubility in typical solvents. Chitin carboxymethylation has previously been demonstrated to improve chitin's water solubility while maintaining biocompatibility and preventing the development of antibodies (Jimtaisong and Saewan 2014). They are created by a condensation reaction between monochloroacetic acid and chitin powder using isopropyl alcohol as the solvent. In a mouse model, it was found that the medication was delivered in a regulated and sustained manner and that the nanoparticles were not harmful to normal fibroblast cells. CMC nanoparticles have shown antibacterial activity and ferromagnetic qualities that can be employed to distribute medications utilizing tracking devices. Due to its beneficial characteristics, carboxymethyl chitin may also be utilized as a material for wound dressings, but it must be cross-linked to keep its integrity (Jayakumar et al. 2010b). Chitosan polymers have been utilized to deliver medications in the treatment of several cancer types in a number of forms, including hydrogels, nanoparticles, and nanofibers. Chitosan polymers are excellent candidates for chemotherapeutic target therapy because of their diverse characteristics. By altering the surface moieties, other properties can be obtained, such as membrane-penetrating peptides, monoclonal antibodies, or surface receptors that target certain cancer cells. Chitin is extracted from shrimp shells to stabilize silver nanoparticles (AgNP) and treat human hepatocellular carcinoma in an endeavor to develop appropriate carriers for cancer therapy (Vijayakumar et al. 2020). Because they are harmful to human cells, Ag nanoparticles have been employed in the therapy of cancer. Their disadvantage is that they may also harm healthy bodily cells. As a result, using a carrier that can only access cancer cells is necessary when using AgNP to treat cancer. Both chitin and chitosan, which are considered to be safe biological sources, have been demonstrated to have anti-proliferative effects in various human malignancies, including colon and lung cancers, two of the most prevalent cancers in the world (Kurishima et al. 2017). Applications for tumor-targeted medication delivery using nanoparticles made of chitosan are shown in Fig. 5.

Fig. 5 Applications of chitosan-based nanoparticles in the delivery of drugs to tumors

In Artificial Skin

Chitosan that resembles glycosaminoglycans structurally may be used in the creation of artificial skin. A nonantigenic membrane that serves as a biodegradable template for neodermal tissue was designed for artificial skin that is suitable for long-term chronic usage (Dagalakis et al. 1980). A material for covering wounds has been created using polyelectrolyte complexes of chitosan and sulfonated chitosan. Oligomers of chitosan that have been broken down by tissue enzymes have been found to speed up wound healing and to be effective in regenerating skin tissue around wounds. An artificial skin made of chitosan-collagen composite is produced by a pharmaceutical company called Katakurachikarin in Hokkaido, Japan, and appears to speed up the healing of surgical wounds or burns. Chitosan and gelatin were combined to create a novel absorbable framework for artificial skin that was explored using freezing and lyophilizing techniques. The chitosan-gelatin cross-linked scaffolds were made, and an artificial bilayer skin was created by co-culturing fibroblasts and keratinocytes. The artificial skin created was elastic and had good mechanical characteristics. Additionally, it was discovered that when implanted under the skin of rabbits, it did not cause any unfavorable inflammatory reactions. The *in vitro* cell culture test revealed no contraction, and the scaffolds were biocompatible and biodegradable after implantation (Islam et al. 2017).

In Stem Cell Technology

Embryonic stem cells, post-natural or adult stem cells, and induced pluripotent stem cells are the three main categories of stem cells (Wu and Hochedlinger 2011). Biological materials, such as chitin and its compounds, can assist in realizing stem cells' enormous potential in regenerative medicine using cells. Chitin was used for the *in vitro* growth of programmable stem cells (Lu et al. 2012). The first chitin that was water soluble utilized to create an interfacial combination with alginate acid that encapsulates cells in fibers. There are two ways to spool these fibers: around a flat surface or tangled to create structures for the long-term culturing of cells, which is unique to water-soluble chitin and suited for encapsulating cells. Complex polyelectrolyte chitin and alginate fibers assisted the process of self-renewal. Comprising two induced pluripotent stem cells and two embryonic stem cells' lines for at least ten *in vitro* passages, whereas cells kept their karyotype constant. This use of chitin is due to the creation of a 3D hydrogel environment in which the stem cells multiplied into aggregates without adhering to the cells.

In Ophthalmology

Chitosan, a polycationic biopolymer made from chitin that was alkaline deacetylated, was selected as the carrier for ophthalmic formulations because it possesses a number of beneficial biological characteristics, including biodegradability, nontoxicity, and biocompatibility. It has become necessary to develop pharmaceutical formulations that provide sustained release, increased bioavailability, and decreased frequency of administration due to the occurrence of diseases like glaucoma, age-related macular degeneration, diabetic macular edema, diabetic

retinopathy, or dry eye syndrome, which require drug delivery for a prolonged period of time. Overcoming ocular obstacles without inflicting lasting tissue damage is a major hurdle in reaching this aim. Chitosan became commercially available in 1990, and various studies were conducted to explore its potential as a pharmaceutical excipient. It is a good choice for ocular formulations because of its mucoadhesiveness, biodegradability, biocompatibility, and nontoxic nature. Chitosan solutions do not disrupt the precorneal tear film due to their pseudoplastic and visco-electric qualities.

For the treatment of glaucoma, ocular inserts made of chitosan have been developed as an alternative to those that release brimonidine tartrate. Analytical characterization of inserts was carried out utilizing FTIR, SEM, and DSC. Additionally investigated on Muller cells were swelling capacity, active substrate release profile, and in vitro bioavailability. Brimonidine tartrate was physically diffused across the polymer chains, according to the study's findings. For 30 days, the inserts release the active ingredient without causing any harm. They furthermore have the benefit of not containing preservatives (de Souza et al. 2016). Chitosan formulations with a prolonged precorneal residence period were tried because of its mucoadhesive properties as well as its capacity to improve solution viscosity properties. In fact, an ionic interaction with the negative charges of the sialic acid residues in the mucus has been hypothesized as a mechanism of mucoadhesion due to its positive charges at neutral pH. For longer precorneal medication residence durations, the mucoadhesive polysaccharide chitosan was examined as a possible ingredient in ophthalmic gels. This cationic carrier was predicted to slow down medication excretion through the lacryme by increasing the viscosity of the solution and reacting with the mucus' negative charges (Felt 1999).

Due to their biocompatibility and transparency, hydrogels are typically used to make soft contact lenses. When using contact lenses, hydration is necessary because it helps oxygen reach the cornea. It is advised to wear contact lenses together with eye drops since dehydration causes dry eye syndrome. Dexamethasone might be made more readily available to the eye by being mixed with chitosan nanoparticles and then imprinted on pHEMA hydrogel contact lenses, according to a study by Behl et al. In vitro release experiments were also researched. The lens was clear, with an average transmittance of 95–98%, and the dexamethasone release rate was 55.75 percent in 22 days. The study found that within the first 10 days, dexamethasone had a 72% higher bioavailability than eye drops. According to the study's findings, using contact lenses containing dexamethasone-infused chitosan nanoparticles has beneficial therapeutic effects (Tashakori-Sabzevar and Mohajeri 2015; Behl et al. 2016). When chitosan is used in ophthalmic delivery systems like nanoparticles, nanomicelles, nanosuspensions, liposomes, microemulsions, microspheres, in situ gels, inserts, contact lenses, or mini-tablets, the active ingredient is retained for longer at the eye level while also having its bioavailability increased. As a result, the dosage will need to be given less frequently, and the patient will be more compliant, which will enhance his quality of life. These chitosan-based products do not harm tissues, change ocular barriers permanently, or obstruct tear production (Popa et al. 2018).

Other Miscellaneous Applications

In Wastewater Treatment

Currently, the primary commercial use of chitosan is in the treatment of industrial effluent. As chitosan has a limited beneficial effect, It is simpler to remove metal ions from waste streams or contaminated areas when an agent has a positive charge and binds to metal ions. The commercial chitosan from shrimp and crab waste shell and synthetic polyelectrolyte used in turbidity reduction were shown to be equal to or superior in terms of usage for recovering organic compounds in wastewater. The physical chemistry and mechanistic properties of chitin and chitosan, which encompass the electrostatic interactional behavior (Nechita 2017) of functional groups, clearly define their potential as scavengers for the removal of target metal ions in contaminated water.

Chitosan appears to be more efficient than other polymers in these particular uses, including synthetic resins, activated charcoal, and even chitin itself. Additionally, the amino group in chitosan is a powerful functional group that may be chemically changed to produce various chitinous derivatives with particular advantageous properties as powerful absorptive agents. In addition to the crucial role played by electrostatic interactions, the high hydrophilicity of chitosan owing to hydroxyl groups and primary amino groups on the surface is accounted for by the noticeable biosorption behavior of chitosan for heavy metal removal (Hubert Ribeiro and dos Santos 2019). Additionally, chitosan contains a flexible polymer chain in that may be configured in a way that facilitates the biosorption phenomena.

Cu (II) ion-containing wastewater was treated using sodium alginate and chitosan, according to research by Qin et al. (0975–0991 (Online); 0971-457X (Print)). They looked at how various factors affected this ion removal (Qin et al. 2007). According to the findings, chitosan and sodium alginate worked better together than they did separately. Hexavalent chromium (Cr (VI)) removal from wastewater using FeO-nanoparticles-chitosan composite beads (CSNZVI beads) was examined by Liu et al. The thermodynamics investigation revealed that the endothermic and spontaneous removal of Cr (VI) by CS-NZVI beads was due to the sorbent's high affinity for Cr (VI) ions and the increase in randomness at the solid-solution interface during the adsorption process (Liu et al. 2012). In the successful application, this finding will be extremely helpful to comprehend the impacts of NZVI on heavy metal Cr (VI) removal from wastewater. Pesticide removal from wastewater was explored by Dwivedi et al. (Ueno et al. 1999) using hydrogel beads made of chitosan and gold nanoparticles. The collected findings demonstrated that the synthetic sorbent had high pesticide removal capacity (Dwivedi et al. 2014). The efficacy of chitosan as waste treatment agents varies depending on their physical properties, such as molecular weight, crystallinity, deacetylation, particle size, and hydrophilicity. The scientific community is quite interested in determining which biosorbent is best for eliminating pollutants, though. Consequently, well-organized research is being done in a variety of fields throughout the world (Sarode et al. 2019).

Agricultural Applications

Biocontrol employing natural substances like chitin, a carbohydrate chain polymer, and its derivatives is a viable method as the need for sustainable agriculture grows more urgent. Plants' built-in defense systems are induced or strengthened by chitin and its derivatives. They are acknowledged as growth regulators, growth promoters, and inducers of secondary metabolite formation in plants. As fertilizers, soil conditioners, plant disease preventatives, antitranspirants, ripening inhibitors, and seed and fruit coatings, they have positive benefits. Chitin and chitosan are powerful inhibitors of bacterial and fungal plant disease development, which causes higher plants to mount defense responses (Shamshina et al. 2019).

The majority of synthetic plant protection chemicals are poisonous, bioaccumulative, persistent in the environment, and dangerous to both people and animals. Recently, there has been a lot of interest in using chitin polymer as an environmentally acceptable natural alternative to synthetic herbicides to manage plant diseases and control plant growth. Chitin is a substance that is used in agriculture to make fertilizers and is regarded as a "nitrogen type" "organic" fertilizer. A C:N ratio of around 25–30 is maintained by effective fertilizers. More than a 25:1 carbon-to-nitrogen ratio with excess carbon often indicates that fertilizer will breakdown slowly. Contrarily, if there is a surplus of nitrogen and the C:N ratio is too low, this might result in the soil losing its ability to hold onto plant nutrients. For completely deacetylated chitosan, the C:N ratio of chitin and chitosan ranges from around 6 to 7 for chitin. The amount of nitrogen (N), phosphorus (P), and potassium (K) that the product contains is another crucial ratio; this is typically denoted on fertilizer labels as the "N-P-K ratio"; chitin contains neither phosphorus nor potassium (Shamshina et al. 2020). According to the mode of action, chitin or chitosan has a fertilizer impact by either biodegrading into ammonia-derived compounds in the soil, which have a fertilizer effect on their own owing to the presence of amino groups, or by encouraging the development of certain microbes.

Any poison that kills a living thing is considered to be a biocide, which includes fungicides that are active against fungi, oomycetocides that are active against oomycetes, bactericides that are active against bacteria, antivirals that are active against viruses, nematocides that are active against nematodes, and insecticides that are active against insects (Malerba and Cerana 2019). Since chitosan is an antibacterial agent on its own, chitosan derivatives showed strong "direct" antifungal activity; however, chitin does not have much in the way of "direct" antibacterial activities since it lacks free amino groups. According to research, chitosan's "direct" antibacterial action is directly related to DA, or the quantity of free amino groups. Chitosan's antibacterial activities increased with the amount of protonated amino groups present, whereas a low DA was associated with the absence of such characteristics (Sharp 2013).

Chitin naturally serves as scaffold material in insects; hence, it is not anticipated to have pesticide capabilities. But chitin derivatives work as antivirals, or something that can kill a virus. According to reports, chitosan can boost a plant's immune system and prevent the growth of viruses. Chitosan's ability to inactivate viruses is not explained, and there has been no research on how underivatized chitin affects

viruses. According to one theory, chitosan's efficacy against plant viruses is caused by altering the plants' reaction to infection and preventing the spread of viral particles (Pospieszny et al. 1991). Despite the fact that chitin lacks "direct" antibacterial action, it is frequently employed as a fungicide because of the polymer's eliciting activity and indirect suppression of the pathogens brought on by chitin breakdown by-products. Chitin's fungicidal efficacy is influenced by the molecular mass of the substance. Furthermore, soil fumigation, irrigation, or the addition of chitin-containing mixes to the soil are other ways that chitin is used as a plant nematicide. Chitin has been demonstrated to provide a physical barrier that stops pathogens from entering healthy plant tissues and enhances the lignification of injured leaves. It is a solitary seed treatment that is applicable. Chitin is used as a postharvest biocontrol treatment and to strengthen the resistance of fruits to disease in food postharvest applications (Shamshina et al. 2020; Malerba and Cerana 2019; Milholland 1973).

In Food Industry

It is well recognized that chitin and its derivatives offer a wide range of biological activities, such as antioxidant and antibacterial effects, as well as many other qualities that might be employed in the food market to enhance food quality, safety, and shelf life. The food sector can employ chitin and its derivatives as food preservatives (Sayed-Elahl et al. 2019). They can shield food from microbial degradation owing to their antibacterial activities. The positive charges of chitinous materials have been shown to interact with the negative charges of bacterial cell walls, causing leakage of the internal molecules of microorganisms. This interaction has been connected to the antibacterial activity of chitinous materials. Chitosan is a substance that is added to food to prevent the growth of bacteria, hence preventing bad looks, off tastes, and financial losses. El-Diasty, Nesreen, and Hoda (2012) discovered that cheese's mycological quality was enhanced by the addition of chitosan. Shelf life was increased, and mold and yeast development were prevented (Hamed et al. 2016).

Chitosan's antibacterial qualities have also been applied to active edible packaging. Chitosan has been used to create biofilms that enable long-term food storage. Vegetables, fruits, cereals, and fish that have an antimicrobial coating prevent microbial invasion because chitosan serves as a protective barrier to improve the food's flavor and nutritional value. Edible biopolymer films can be employed as carriers of bioactive substances to improve food quality in addition to serving as a protective barrier. Dietary fiber has been obtained from chitosan and its low-molecular-weight derivative. They are regarded as functional foods because digestive enzymes cannot break them down, allowing them to act as prebiotics. They encourage the growth of advantageous microorganisms in the digestive system. They can also serve as stabilizers and thickeners (Manigandan et al. 2018).

In Textile Industry

Chitosan has been used in the textile industry as an eco-friendly finishing agent for more efficient materials. Textiles provide attached bacteria food and a place to live,

which can damage human health and spread illness. Antibacterial treatment of textiles is crucial to preventing this (Qamar et al. 2020). *Staphylococcus aureus*, *Escherichia coli*, and *Bacillus subtilis* are among the microorganisms that chitosan exhibits broad-spectrum antibacterial action against. Chitosan is primarily used in two methods to create antibacterial materials. The first method involves applying chitosan to the fabric's finish. In order to graft chitosan onto cotton textiles under UV irradiation, Aloson et al. employed citric acid as a cross-linking agent and sodium dihydrogen phosphate as a catalyst. This provided the textiles with good antibacterial capabilities (Moattari et al. 2018; Lee et al. 2017).

Textile items are less attractive and comfortable because of their tendency to wrinkle and undergo permanent deformation due to their relatively poor elastic properties. Fiber alteration can enhance the fabric's anti-wrinkle efficacy. A simple and efficient method to raise the fabric's anti-wrinkle effectiveness is to finish with chitosan. Typically, chitosan is first dissolved in 1% w/v acetic acid to create a chitosan solution. The cloth is then completed in the chitosan solution using a standard dipping-rolling-baking method. After drying, the water-insoluble protective layer created by the chitosan solution forms on the fabric's surface, strengthening and lessening the fabric's ability to distort. Additionally, chitosan macromolecules fill in the fiber micropores, where a significant number of intermolecular hydrogen bonds are generated between the hydroxyl and amino groups of chitosan and the polar residues of the fiber molecules. This makes the amorphous areas of the fibers stronger and less mobile, giving the fabric wrinkle resistance (Xiao 2018).

Chitosan was initially utilized in the textile industry as a dye-deepening agent. Chitosan is regarded as the best fixing agent for anionic dyes since it is a cationic polymer. Chitosan may be used to color without adding salt, along with a few other additions. In the textile business, antistatic fabric finishing is growing in popularity. The chitosan-finished fibers have an ion-conducting activity in water and may swiftly leak the static charges produced by friction because NH_3^+ is present in the molecular structure of chitosan (Ifuku 2014). When the charge on the chitosan molecule is in opposition to the surface charge on the fiber, electrical neutralization is created. Additionally, the chitosan molecules are extremely hygroscopic and produce a continuous water layer on the surface of the fiber due to the presence of several strong polar groups, such as hydroxyl groups and amino groups. Chitosan may be mixed with traditional textile fibers like wool, cotton, silk, and polyester with ease and with strong interactions thanks to its structural features. Chitosan can be used as a finishing agent or fiber modification to create functional textiles with antibacterial, anti-wrinkle, coloring, and antistatic qualities. The use of chitosan in the textile industry not only enhances the functionality and value of textiles but also encourages the effective utilization of natural resources (Vellingiri et al. 2013; Zhou et al. 2019).

In Cosmetic and Dermatological Applications

Chitosan is frequently used in cosmetic and skin care products because it supports the extracellular matrix, treats acne, maintains skin hydration, tones skin, and enhances the skin's natural barrier function. Chitosan is a natural stimulant

that promotes good histoarchitectural tissue organization and optimal collagen structure throughout the skin regeneration and wound healing processes. This makes it a perfect component for antiaging skincare products and wound healing (Aranaz et al. 2018). Chitosan has excellent film-forming capabilities and a bioadhesive nature. Therefore, it can serve as the active component or act as a delivery system, extending the time an active agent is in touch with the dermis and boosting the penetration of active substances in a long-term, regulated way. These are its two major roles in cosmetic and cosmeceutical applications. Essential oils and active substances, including vitamins, antioxidants, and enzymes, can be found in cosmeceutical products made using chitosan (Abo Elsoud and el Kady 2019).

Chitosan and chitosan films can be utilized as sunscreens since their UV spectra show absorption below 400 nm. It has been observed that chitosan gel has an *in vitro* SPF of 0.89. When comparing two chitosan films, the shrimp chitosan film had a higher transmittance for UVA-UVB (300–250 nm) than the mushroom chitosan film did. This finding suggests that the UV resistance of mushroom chitosan extract was superior to shrimp chitosan film. The purpose of skin-conditioning products is to keep the skin in excellent condition. The only chitosan derivative recognized as a skin-cleansing agent is chitosan argininamide. Many chitosan compounds as well as certain chitin derivatives have been categorized as skin conditioning agents. Cosmetics known as humectants are used to enhance the water content of the skin's outer layers. Cationic humectants absorb to the skin's surface, changing it adversely. Chitosan and pyrrolidone carboxylic acid (PCA) were mixed to create a humectant that forms films (Morin-Crini et al. 2019a). To enhance the chitosan's humectant characteristics, acyl and alkylated chitosan derivatives were created. Using moisturizing lotions keeps the skin supple and smooth by increasing its water content. By oxidative degradation with H_2O_2 , many chitosan samples with varying molecular weight were created. The molecular weight and level of acetylation of the resultant chitosan affected their ability to absorb and retain moisture (Morin-Crini et al. 2019b).

A wide range of hair products, including shampoos, rinses, permanent wave agents, hair colorants, styling lotions, hair sprays, and hair tonics, include chitosan and its derivatives. In order to create clear, elastic films over the hair fibers, chitosan and its cationic derivatives interact with keratin. These films strengthen and soften hair while preventing breakage. Hyaluronic acid, collagen, and chitosan were combined, and the resulting films on hair were examined. The thickening of hair and improvement of its mechanical qualities as well as the hair's overall look and conditioning were caused by covering. In place of synthetic resins, alkyl-hydroxypropyl-substituted chitosan derivatives were added to hairsprays to prevent prolonged drying times, sticky hair, and helmet development (Aranaz et al. 2018). Chitosan's binding and film-forming abilities enable antioxidants to be administered to the skin gradually and steadily, improving the therapeutic efficacy of the resulting skincare formulation. As a result, chitosan serves as a dynamic agent for facilitating the delivery of medicinal chemicals and substances, such as nutrients, oxygen, antioxidants, and other substances, to the skin.

In Aquaculture

In recent years, the aquaculture sector has employed chitin and chitosan as feed supplements in the diets of fish and shellfish. Numerous studies have been done to determine how well chitin and chitosan work in the aquaculture industry. The scientific community is looking for safer and more environmentally friendly options to treat aquatic species due to the escalating limits on the use of antibiotics and other chemotherapeutics (Alishahi and Aider 2012). Utilizing immunostimulants to reduce aquatic creature illnesses is such a sustainable alternative strategy.

Chitin could be beneficial as a constituent of fish feed that has been specially prepared. There is proof that the gut bacterial population of fish and other aquatic animals differs noticeably from that found in the environment or in food. It has been discovered that adding chitin to feed for growing organisms enhances growth and feed conversion as well as stimulating the immune system by raising serum lysozyme levels, which also lowers production costs. However, significant fat accumulation in the liver, heart, and carcass occurs in some fish species due to chitin oversupplies (Ahmed et al. 2019). While chitosan, a deacetylated chitin derivative, was considered to be a more intriguing and effective bioactive polymer during the culture of particular farmed organisms, it was also examined as encapsulating bioactive chemicals. Vitamin C is better released while retaining its bioavailability when it is encapsulated in chitosan. Chitosan can encapsulate antigens for vaccinations and the virus that causes white spot syndrome, but how well they work depends on the infection. Additionally, chitosan has qualities that might help to enhance the quality of aquaculture effluent. The use of chitin and chitosan in aquaculture raises a number of unanswered concerns, including the stability of chitosan-encapsulated substances and the appropriate chitin content for each cultivated species, among others (Iber et al. 2021).

The research findings also suggest that the species being tested, the dose of chitin and chitosan, the time of administration, and the size of the chitin particle all have an impact on the immunostimulatory effects of these substances. Therefore, it is crucial to optimize the circumstances for the application of chitin and chitosan in order to both reap the most advantages and avoid any potential drawbacks, such as immune system suppression and growth retardation. The methods by which chitin and chitosan trigger immunological responses in fish and shellfish need to be better understood (Kamilya and Khan 2020).

In Fuel Cells

As a well-known source of clean next-generation energy, fuel cells draw interest. Solid fuel cells are one of them that are gaining popularity due to its mobility and stability. Therefore, it is necessary to discover novel fuel cell electrolytes that are inexpensive and have minimal environmental impact during the manufacturing process. Chitosan is an effective and ecologically friendly biopolymer that has recently undergone substantial research as a new material for use in fuel cells. Various fuel cells, including alkaline polymer electrolyte fuel cells, direct methanol fuel cells, and biofuel cells, can employ this biopolymer as both a membrane electrolyte and an electrode (Ma and Sahai 2013). Tissue-derived biomaterials

have recently attracted our attention as a fuel cell electrolyte due to their low cost and abundance in nature. Since chitosan's backbone contains free amine and hydroxyl functional groups, it can be chemically modified to suit a variety of needs. So, it can be used in fuel cell applications, pervaporation, ultrafiltration, electro-ultrafiltration, and polymer electrolyte membranes for the separation of metal ions, amino acids, and protein by adsorption.

Chitosan has a number of advantages for use as a polymer electrolyte membrane, including affordability and environmental friendliness, hydrophilicity, a useful quality for use in high temperature and low relative humidity environments, and low methanol permeability. Chitosan's main strength is that it has specific functional groups that enable chemical modification to tailor its properties (Shaari and Kamarudin 2015). Chitin functions as the fuel cell's electrolyte and transforms into a proton conductor. The quantity of water molecules grows along with the proton conductivity. In addition, the examination of proton conductivity in sheets and strongly oriented specimens revealed that chitin had anisotropic conductivity. It is discovered that the proton conductivity increases more along the chitin fiber direction than it does perpendicularly. The presence of proton conductivity in chitin is due to the proton transfer via the water network established between the chitin and water molecules, which is connected with the side chain of chitin along the direction of the chitin fiber (Muhmed et al. 2020). Numerous anionic and cationic chitosan-based membranes have undergone significant testing for use in fuel cells. In terms of proton conductivity, these chitosan-based membranes often do not provide appreciable benefits over conventional Nafion membranes, and as a result, the corresponding power density of associated fuel cells is likewise lower than that of Nafion-based ones. Therefore, for fuel cell applications, the inherent ionic conductivity of chitosan-based membranes needs to be further enhanced. Additionally, there is a need to improve the mechanical durability and shelf life of chitosan, which have not received much attention. Improvements to the chitosan membrane's qualities have been accomplished through chemical modification, the creation of chitosan blends, and composite materials. These techniques enhance some chitosan features while maintaining or enhancing others (Wan et al. 2006).

Other Applications

The excellent sorption capabilities of natural chitin and chitosan have been well documented in the literature. The creation of supports for chromatographic separation was a logical outcome of the sorption experiments. As chitin and chitosan are organic, renewing biopolymers with the additional advantages of being nontoxic, mechanically stable, and chemically inert, they have a great deal of promise for usage in industrial-scale separation processes. Due to the presence of a number of functional groups in the polymer chain unit, including an amine group at the C2 position, -CH₃ moieties in the acetamido group at the C2 position, and -OH groups at the C3 and C6 locations, they have been easily employed in liquid chromatography as a stationary phase. The primary method used in studies of chitin and chitosan was column chromatography, while studies of thin layer chromatography were rather few (only as chitosan-Fe for phenolic compound separation). A fascinating

alternative to column chromatography is membrane chromatography. This method is still in the early stages of research, but given how easily it can be scaled up for large-scale commercial separations with low pressure drop and high flow rates and simple membrane fabrication (Morin-Crini et al. 2019b).

The uses of chitosan in veterinary medicine, such as bone regeneration, analgesic and antibacterial properties, and wound healing, were previously discussed by different scientists. They explained well how chitosan may be used as a food additive and for the administration of drugs and vaccines to veterinary species. The delivery of chemotherapeutics like antibiotics, antiparasitic drugs, anesthetics, painkillers, and growth promoters to the mucosal epithelium for absorption for local or systemic activity, as well as the delivery of immunomodulatory agents to the mucosal associated lymphoid tissue for induction, are the veterinary drug delivery areas most likely to benefit from chitosan given the restrictions imposed by financial and animal restraint considerations (Gerdts et al. 2013).

Chitosan can be used in the wine-making process to clarify, deacidify, stabilize, and remove ochratoxin A, enzymes, and other unwanted compounds, such as metals and pesticides. Chitosan is also employed as a natural flocculant for the clarity of beer and an eco-friendly coagulant for the clarifying of passion fruit. Outlined recent chitosan-based matrices used for clarification, preservation, encapsulation, and active and intelligent packaging of various beverage types, including alcoholic, dairy-based, and nonalcoholic beverages, including fruit juices, nectars, concentrated fruit juices, tea, coffee, and tisanes (Galiano et al. 2018; Escudero et al. 2019). The most recent literature suggests that there is still a strong interest in using chitin-based materials, primarily chitosan, as a promising enzyme immobilization support for a variety of applications, ranging from the wine, sugar, and fish industries to sophisticated biosensors for both in situ measurements of environmental pollutants and metabolite control in artificial organs. These applications range from the removal of organic contaminants from wastewaters to the wine, sugar, and fish industries (Krajewska 2004).

In the papermaking sector, chitosan was first used in 1936, according to a report. The primary purpose was to increase the paper's moist strength. In order to build a cohesive, rupture-resistant film, chitosan functions as a substance that can interact with cellulose pulp to create paper. To help with compliance with environmental requirements, this biopolymer is also nontoxic, biodegradable, and environmentally friendly. In order to remove lignin, color, and unwanted pollutants from pulp and paper wastewaters as well as reduce total organic carbon and chemical oxygen demand, chitosan is also utilized in this process. The use of nanoparticles and nanostructured materials in papermaking has recently been studied. The chitosan market is anticipated to expand quickly as a result of rising usage in a variety of industries, including water treatment, the beverage sector, nutrition, and cosmetics. Indeed, the markets for nutraceuticals and cosmeceuticals are expanding (Gassara et al. 2015). Chitosan is also in higher demand in developing nations. Products that are therapeutic and biomedical are also anticipated to positively affect the industry. It is significant to note that chitosan applications in the biomedical field are still limited, despite the fact that numerous papers and patents have been reported over

the past 20 years. This is primarily because it is extremely challenging to access the biopolymer with sufficient purity and dependability at its source.

Conclusions

Chitin and chitosan are miraculous natural biopolymers found in the cell walls of fungus, the exoskeletons of insects and mollusks, and the shells of crustaceans. They are manufactured commercially from crab shells and have several uses in agriculture, medicine, and other fields.

It is a strong chemical of interest, because it is a naturally biodegradable, environmentally friendly, biocompatible, and nontoxic substance. To various degrees, chitin is deacetylated to create chitosan. Chitin can be produced via chemical or biological processes. Chitosan, on the other hand, is a substance with several potential uses. Almost all biological disciplines can benefit from the use of chitosan. Since chitosan has strong antibacterial qualities, it may be used to make antimicrobial compounds for use in food, farming, and medical procedures. Chitosan has a number of incredibly intriguing qualities, such as biocompatibility and antibacterial activity, but its use in the biomedical field is still rather restricted. This is mostly because it is exceedingly challenging to get enough purity and source reliability for the biopolymer.
