Sarcomas are a heterogeneous group of rare cancers of mesenchymal origin. In this study, we provide updated, world age-standardised incidence rate (ASR) and European age-standardised incidence rate for malignant soft tissue sarcoma (ICD-O-3 topographic code C47–C49) and bone sarcoma (C40, C41) in Italy, by area (north, centre, and south) and by cancer registry. We also assess morphology in relation to site and area and assess metastases at diagnosis. We analysed 1,112 cases, with incidence 2009–2012, provided by 15 cancer registries (CRs) affiliated to the Association of Italian Cancer Registries (AIRTUM). Overall, ASR was 1.7/100,000/year for soft tissue sarcoma and 0.7 for bone sarcoma. Central Italy had the highest (2.4) ASR and south Italy had the lowest (1.6) ASR for soft tissue sarcoma. Central Italy had the highest (1.1) ASR and north Italy had the lowest (0.7) ASR for bone sarcoma. By CR, ASRs ranged from 1.1 to 2.6 for soft tissue sarcoma and from 0 to 1.4 for bone sarcoma. The most

frequent soft tissue sarcomas were sarcoma not otherwise specified (NOS) (29.4%) and liposarcoma (22.2%); the most common bone sarcoma was chondrosarcoma (37.6%). Soft tissue sarcomas occurred most frequently (35.6%) in lower limb connective tissue; bone sarcomas arose mainly (68.8%) in long bones. The frequencies of morphologies arising at different sites varied considerably by Italian area; for example, 20% of hemangiosarcomas occurred in the head and neck in south Italy with 17% at this site in the centre and 6% in the north. For soft tissue sarcoma, the highest ASRs of 2.6 and 2.4 contrast with the lowest ASRs 1.1 and 1.3, suggesting high-risk hot spots that deserve further investigation. The marked variations in morphology distribution with site and geography suggest geographic variation in risk factors that may also repay further investigation particularly since sarcoma etiology is poorly understood.

1. Introduction

Sarcomas are a heterogeneous group of malignant neoplasms of mesenchymal origin. They are one of the major groups of rare cancers in Europe [1] accounting for around 1% of all cancers diagnosed [2]. The World Health Organization [3] recognises approximately 70 histotypes grouped into two main categories: soft tissue sarcoma and bone sarcoma. In Europe, soft tissue sarcomas are more frequent than bone sarcomas, with world age-standardised incidence rates (ASRs) of 1.5–3.0/100,000/year and 0.5–2.0/100,000/year, respectively. Both types of sarcoma are moderately more frequent males than females [4].

Soft tissue sarcomas constitute about 84% of the sarcomas diagnosed in Europe [5]. Accurate diagnosis of these entities is challenging in relation to their rarity and morphologic heterogeneity [6]. Nevertheless, site of origin tends to correlate with certain histotypes. For example, liposarcomas arise mainly in the thigh of young adults, and myxofibrosarcomas often arise in the superficial soft tissue of elderly patients [7]. The most common soft tissue sarcoma histotypes in Europe have been reported as leiomyosarcoma (19%), liposarcoma (16%), and sarcoma not otherwise specified (NOS, 14%) [8].

Bone sarcomas constitute around 14% of sarcomas diagnosed in Europe [5]. Osteosarcoma, the most frequent bone sarcoma overall (ASR 0.3), generally arises in long bones, but the proportion arising at an axial site increases with age [9]. Chondrosarcoma and Ewing's sarcoma are the most frequent bone sarcomas in adults, with ASRs of 0.2 and 0.3, respectively [9], followed by chordoma (ASR 0.5/million/year), which arises from persisting notochord [9]. Ewing's sarcoma mainly occurs in children and adolescents but is also seen in adults; it arises in long bones (about 50% of cases), followed by the pelvis, ribs, and vertebra.

The causes of most sarcomas are unknown. A recent study on 1,162 patients over 15 years with histologically confirmed sarcoma found that 55% had an excess of pathogenic (and potentially aetiological) germline variants [10]. Several risk factors are well established, including advanced age, previous radiation treatment, previous cancer, and rare genetic conditions [11].

The rarity of sarcomas makes them difficult to study. Single institution reports of incidence, survival, and prevalence are unlikely to be reliable, and pooled data from population-based cancer registries are required to obtain representative data. The aim of the present study is to provide updated estimates of the incidence of malignant soft

tissue and bone sarcomas in Italy overall, by area (north, central, and south) and by cancer registry, using data from 15 population-based cancer registries affiliated to the Association of Italian Cancer Registries (AIRTUM) [12]. The presence of metastases at diagnosis and morphology in relation to site—which appears to not have been previously investigated in sarcomas diagnosed in Italy—were also assessed.

2. Materials and Methods

Italian cancer registries were asked to provide data on malignant soft tissue and bone sarcoma cases incidence between January 1, 2009, and December 31, 2012, that had at least five years of follow-up. Fifteen population-based cancer registries, all affiliated to AIRTUM, sent in data.

For each case, ICD-O-3 morphology, site (ICD-O-3 topography) [13], age at diagnosis, date of diagnosis, and vital status (with date and cause of death) were also ascertained. Cases were staged at diagnosis according to the 6th or 7th editions of the TNM [13, 14]. Sarcomas with organs as primary site were excluded, as were Kaposi's sarcoma and sarcomas of uncertain behaviour. NOS cases were included as this was a population-based study, and completeness was of interest, not simply morphological precision. The populations covered by each cancer registry, stratified by age and sex at January 1st of each study year, were obtained from the Italian Institute of Statistics (ISTAT) [15].

The cancer registries carried out passive and active follow-up of cases from date of diagnosis to the end of follow-up (December 31, 2017). For this study, north Italy was represented by the cancer registries of Val d'Aosta, Bolzano, Sondrio, Varese, Pavia, Genova, Reggio Emilia, Modena, and Parma. Central Italy was represented by the single registry of Firenze-Prato. South Italy was represented by the registries of Brindisi, Ragusa, Siracusa, Catania-Messina-Enna, and Nuoro. The results are presented overall, by area and by cancer registry. For metastases and morphology in relation to site, data are also presented by age class.

2.1. Statistical Methods. The analyses were descriptive and exploratory in nature. The chi-squared test was used to assess the significance of differences in distribution frequencies between sarcoma categories, using RStudio, version 3.2.5 [16]. Incidence rates (per 100,000 per year, unless otherwise stated) were age-standardised using direct methods and the world standard population 2000–2025 (ASRs) [17]. We also

present incidence rates age-standardised to the European population [18] to enable comparison with other European studies. Rates were estimated using SEER*Stat statistical software from Surveillance, Epidemiology, and End Results (SEER) [19].

3. Results

A total of 1,112 sarcoma cases were diagnosed in 2009–2012 in the areas covered by the 15 registries. There were 859 soft tissue sarcomas and 253 bone sarcomas; 55% of total cases were in males and 45% in females. Mean age at diagnosis was 57 years; 44.5% were of age 65 or more (Table 1).

3.1. Incidence. Overall ASRs were 1.7 for soft tissue sarcoma and 0.7 for bone sarcoma (Table 2). Incidence rates age-standardised to European population were 2.5 for soft tissue sarcoma and 0.8 for bone sarcoma. Incidence varied with geographic area (Table 3). For soft tissue sarcoma, ASRs were 2.4 in central Italy, 1.9 in the north, and 1.6 in the south. For bone sarcoma, ASRs were 1.1 in central Italy, 0.7 in the north, and 0.8 in the south.

Incidence also varied with cancer registry (Table 2). For the registries of Valle d'Aosta, Pavia, Brindisi, and Nuoro, ASRs for the two main histotypes varied "in harmony": 1.1, 2.6, 1.4, and 1.4 for soft tissue sarcoma; 0.7, 1.4, 1.0, and 0.4 for bone sarcoma. For other registries, a high incidence of soft tissue sarcoma did not correspond with a high incidence of bone sarcoma: Modena 1.5 for soft tissue sarcoma vs. 0.0 for bone sarcoma; Parma 1.6 for soft tissue sarcoma vs. 0.1 for bone sarcoma; and Ragusa 2.0 for soft tissue sarcoma vs. 0.7 for bone sarcoma. The registry of Pavia had the highest ASR of soft tissue sarcoma (2.6) and bone sarcoma (1.4), followed by Firenze-Prato (2.4 for soft tissue sarcoma and 1.1 for bone sarcoma).

3.2. Site and Morphology. As regards site, soft tissue sarcomas arose mainly in the lower extremities (35.6%) and trunk (33.6%), while 35.6% of bone sarcomas arose in the lower limb long bones, 33.2% arose in the upper limb long bones, and 21.3% in the trunk (Table 1).

Of the 859 soft tissue sarcomas diagnosed, 29.4% were sarcoma NOS, 22.2% were liposarcoma, 20.4% were fibrosarcoma, 16.1% were leiomyosarcoma, and 4.4% were rhabdomyosarcoma. Soft tissue sarcoma NOS also included other forms considered relatively aspecific: undifferentiated pleomorphic sarcoma, undifferentiated round cell sarcoma, spindle cell sarcoma, epithelioid sarcoma, and undifferentiated sarcoma NOS.

Among the 253 bone sarcomas diagnosed, 37.6% were chondrosarcoma—a high proportion related to the elderly population, 29.2% were osteosarcoma, 13% were Ewing's sarcoma, and 12.7% were other bone sarcoma morphologies.

The most frequent soft tissue sarcoma morphologies at each site and by geographic area are shown in Table 4. In the north, leiomyosarcoma was the most frequent morphology at head and neck (31%) and abdominal (26%) sites; liposarcoma was the most frequent morphology in the lower

limb (32%) and trunk (24%); and fibrosarcoma was the most common in the upper extremity (29%). In central Italy, sarcoma NOS was the most common (33%) at abdominal sites; leiomyosarcoma was the most common at the upper extremity (71%), head and neck (17%), and trunk (27%); and fibrosarcoma (29%) was the most common at the lower extremity and trunk (27%), while myxosarcoma (17%) was also common in the head and neck. In the south, leiomyosarcoma (30%) was the most common in the abdomen; liposarcoma (37%) was the most common in the lower limbs; fibrosarcoma was the most common in the upper limbs (25%) and trunk (22%); and hemangiosarcoma and fibrosarcoma were the most common in the head and neck (20% each).

The most frequent bone sarcoma morphologies at each site, by geographic area, are shown in Table 5. In the north, most bone sarcomas were chondrosarcoma (57% upper limb, 47% trunk, and 28% pelvic cases). The second most frequent bone sarcoma in the north was osteosarcoma (42% of lower extremity and 38% of head and neck cases). In central Italy, the commonest morphology was chordoma which constituted 50% of pelvic cases, whereas chondrosarcoma and Ewing's sarcoma accounted for 33% and 17%, respectively, of pelvic cases, followed by chondrosarcoma which constituted 89% of lower limb and 100% of upper limb cases (data not shown). Osteosarcoma constituted 60% of head and neck cases; 33% each of trunk cases were Ewing's sarcoma and chondrosarcoma. In the south, the commonest morphology was chondrosarcoma which formed 29% of pelvic cases, 90% of upper limb cases, 37% of facial bone cases, and 45% trunk bone cases, while 64% of lower limb cases were osteosarcoma.

3.3. Metastases. A total of 338/1,112 (30%) cases had information on stage at diagnosis, 136/338 (40%) of which had metastatic disease at diagnosis: 109/136 (80%) from soft tissue sarcoma and 27/136 (20%) from bone sarcoma. The commonest metastatic sites for soft tissue sarcoma were lung (38%) and bone (21%), with liver (15%) and pleura (6%) also fairly frequent; 4% had metastases to the central nervous system (Figure 1). The commonest metastatic sites for bone sarcoma were lung (58%), bone (18%), and pleura (6%) (Figure 2).

Figure 3 shows the most important metastasis sites by age for soft tissue sarcomas. The proportion of soft tissue sarcoma cases with lung metastases increased from 23.1% in the 0–19-year age class to 42.6% in the 50–69-year age class and declined to 34.4% in those of ≥ 70 years. The proportions with bone metastases reduced up to the 50–69-year age class to then increase in the oldest group. Metastases to liver increased from 7.7% in those of 0–19 years, peaked at 20.4% in the 50–59-year age class, and declined in the oldest group.

Figure 4 shows the most important metastasis sites by age for bone sarcomas: in the 0–19-year age class metastases involved lungs in 81.8% of cases and bone in 9.1%. Presentation with lung metastases declined in intermediate ages but increased again (to 57.1%) in patients ≥ 70 years. Pleural metastases became more frequent with increasing age to

peak at 25% in the 50–69-year age class and declined in patients ≥70 years.

4. Discussion

The 15 AIRTUM cancer registries that contributed data covered an annual mean of 8,183,639 persons over the four-

year study period, constituting 13.8% of the mean annual Italian population of 59,237,407 million during that period.

The data used in this study were checked for quality and completeness, by each cancer registry and by AIRTUM, using automated data checking procedures developed by the International Agency for Research on Cancer [20] and International Association of Cancer Registries, and described in Cancer Incidence in Five Continents Volume XI [21]. The

TABLE 2: Incidence rates (standardised to the age structure of the world population 2000–2025) of soft tissue and bone sarcoma per 100,000 per year by cancer registry.

Cancer registry	Soft tissue sarcoma				Bone sarcoma

proportion of microscopically verified cases, a major indicator of data quality, was 95.7% in our series.

4.1. Incidence. We estimated overall European age-standardised incidence rates of 2.5 for soft tissue sarcoma and 0.8 for bone sarcoma. These figures are similar to population-based estimates, for Europe as a whole, of 2.3 for soft tissue and 0.7 for bone sarcomas, cases diagnosed in 2000–2007 [22]. Our world age-standardised incidence rates (ASR) estimates of 1.7 for soft tissue and 0.7 for bone sarcoma (Table 2) are lower than and similar to, respectively, ASRs of 3.4 and 0.9 reported for US cases diagnosed in 2009–2012 [23].

It is noteworthy that ASRs varied between cancer registries (Table 2). For soft tissue sarcomas, ASR was highest in Pavia (north Italy) followed by Varese (north), Firenze-Prato (central), and Ragusa (south), with Parma (north) having the lowest ASR. For bone sarcomas, ASR was also highest in Pavia, followed by Firenze-Prato then Brindisi (south), with

no cases recorded in Modena (north). ASR variation between cancer registries is unlikely to be due to variation in completeness, since data quality controls were stringent [5]. They are more likely to be due to variation in sarcoma risk factors, particularly, for example, variation in proportion of persons given chemotherapy or radiotherapy for another cancer [24]. The area covered by the Pavia registry is characterized by high mesothelioma incidence [25]. Mesothelioma is known to be caused mainly by exposure to asbestos, leading us to speculate that the high ASRs for sarcomas in Pavia could be related to high levels of workplace or environmental carcinogens [26].

4.2. Site and Morphology

4.2.1. Soft Tissue Site. Soft tissue sarcomas develop mainly on the extremities. Hui [24] reported that 28% of US cases developed on lower extremities and 12% on upper extremities. The 2005 review of Clark et al. [27], which

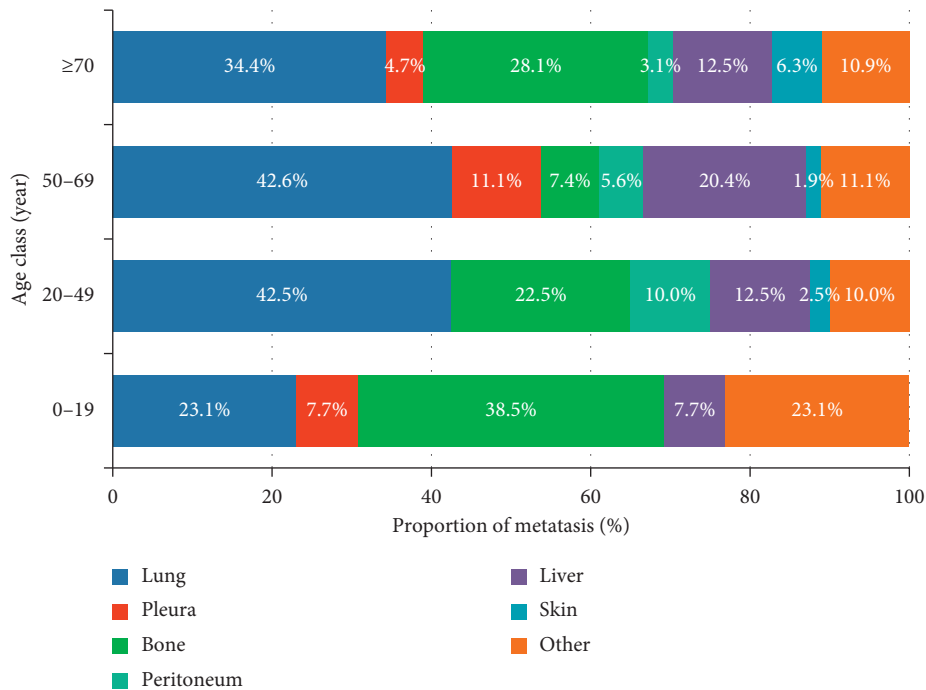

FIGURE 3: Most important metastasis sites according to age for soft tissue sarcomas diagnosed in 2009–2012 in 15 Italian population-based cancer registries.

FIGURE 4: Most important metastasis sites according to age for bone sarcomas diagnosed in 2009–2012 in 15 Italian population-based cancer registries.

considered only adult soft tissue cases, reported that 40% arose on a lower limb or girdle and 20% arose on an upper limb or girdle. Our findings (35.6% on a lower limb and 19.3% on an upper limb) are in line with the proportions reported by Clark et al. [27]. A 2015 survey of soft tissue sarcomas in France [28] found that in 60% of cases the disease occurred peripherally (49% on a limb and 11% head and neck), while the remaining 40% of cases were truncal

(17% thoracic, 9% retroperitoneal, 8% pelvic, and 6% abdominal). This difference in site distribution compared to our findings could be due to the fact that the French study included sarcomas of uncertain behaviour as well as those that were frankly malignant.

4.2.2. Bone Site. We found that 35.6% of bone sarcomas arose in a lower extremity, 33.2% in an upper extremity

(predominantly long bone involvement), 21.3% in trunk, and 9.9% at other sites. This site distribution is consistent with the morphology distribution (chondrosarcoma 37.6%, osteosarcoma 29.2%, and Ewing's sarcoma 13%) in our ageing population.

To our knowledge, data on the subsite distribution of bone sarcomas have not been published previously, so we consider published subsite distributions according to morphology. As regards chondrosarcomas, these arise principally in long bones but can also develop in axial bones (pelvis, ribs, and scapula). Thus, in a population-based series from the Netherlands [29], 50.8% of chondrosarcoma arose in long bones and 49.2% in axial bones. In a SEER study, 44.5% arose in extremities, 31.1% in axial bones, 14.9% other bone site, and 9.6% in soft tissues [30].

As regards osteosarcomas, according to Savage and Mirabello [31], around 80% of them occur in lower long bones, whereas in a SEER series, 20.8% occurred on an extremity, 39.3% in axial bones (pelvis, spine, and ribs), and 19.3% at another location (mandible, skull, etc.) [32]. It has been reported that axial bone involvement becomes more frequent with advancing age [33]. A Japanese population-based study reported that 48.9% of osteosarcomas arose on a lower extremity, 36.9% on the trunk, and 10.1% on an upper extremity [34].

As regards Ewing's sarcoma, a SEER study [9] reported the most common primary sites as extremity bones (50%) followed by pelvis, ribs, and vertebra, although any bone can be affected. Bernstein et al. [35] reported that 26% of Ewing's sarcomas arose in pelvis, 20% in femur, 16% in chest wall, 10% in tibia, 6% in humerus, and 2% in skull. A population-based study from the Netherlands [29] reported that 56.9% of Ewing's sarcomas occurred in axial bones and 43.1% in long bones.

4.2.3. Soft Tissue Morphology. We found that 29.4% of soft tissue sarcomas were NOS, followed by liposarcoma (22.2%), fibrosarcoma (20.4%), leiomyosarcoma (16.1%), rhabdomyosarcoma (4.4%), and hemangiosarcoma (4.2%). The study of Stiller et al. [4] on EUROCARE 5 cases diagnosed in 2000–2007 from 29 European countries reported that the proportion of NOS sarcomas (likely mainly soft tissue sarcomas) varied from 37% in Croatia to 4% in Slovenia, with an overall figure of 13%. Wibmer et al. [36] analysed soft tissue sarcomas diagnosed in 1984–2004 in the Austrian National Cancer Registry, finding that 36% were NOS. Interestingly, in a RARECARE study [5], 18% were sarcoma NOS, and 79% of these soft tissue sarcomas were confirmed as NOS after revision, indicating that even experienced pathologists diagnose sarcoma NOS in a substantial proportion of cases.

We found that morphology distribution by site varied with geographic area in that 20% of hemangiosarcomas occurred in the head and neck in south Italy (Table 4), compared to 6% (data not shown) in the north, suggesting geographic variation in the distribution of soft tissue sarcoma risk factors.

4.2.4. Bone Morphology. The most frequent bone sarcoma in our series was chondrosarcoma (37.6%), which is generally reported as most common bone sarcoma in adults: it is typically low grade and often originated from preexisting benign bone lesions [30]. The 2016 UK guidelines for bone sarcoma management [37] noted chondrosarcoma as the most common bone sarcoma in the ageing UK population. Our population is also ageing (44.5% \geq 65 years), and our high proportion of chondrosarcomas is consistent with UK findings. The second most frequent bone sarcoma was osteosarcoma (29.2%). This mainly affects people in the first three decades of life [31]. However, a recent study noted a second incidence peak in persons over 50 years [33], and this is consistent with the high relative proportion of osteosarcomas in our ageing Italian population.

Ewing's sarcoma, the third most common (13.0%) bone sarcoma in our population, is an aggressive yet highly treatable tumour that mainly affects adolescents and young adults. [38]. Genetically Ewing's sarcoma is characterized by balanced chromosomal translocations in which a member of the FET gene family fuses with an ETS transcription factor [38]. As regards geographic variations of site and morphology of bone sarcomas (Table 5), we found that in central Italy proportionately more chordomas arose in the pelvic (sacral) region. A large (400 cases) SEER study of chordomas reported that 32% of chordomas were cranial, 32.8% spinal, and 29.2% sacral [39], suggesting that subsite occurrence within the axial skeleton is in fact more uniform than indicated by our limited data.

In another SEER study [30], 44.5% of chondrosarcomas arose in upper and lower extremities—similar to the proportion we found in north Italy, but lower than in south Italy. However, comparison is complicated by the fact that 14.9% of SEER cases had location not specified, while in our study all cases had specified locations.

4.3. Metastasis. Only 30% of our cases had stage information at diagnosis, 40% of which were metastatic. In a population-based study [8] of malignant adult soft tissue sarcomas diagnosed in Germany in 2003–2012, only 18.2% had stage information at diagnosis, 36% of which had metastases at diagnosis. Several US SEER-based studies have been published. In one [40] on cases of primary soft-tissue sarcoma occurring on an upper extremity and diagnosed in 1973–1998, only 10.7% had no stage information, and 4.7% of the whole population were metastatic at diagnosis. In two more recent SEER studies [41, 42] on pediatric soft-tissue sarcomas, all cases had stage information (local, regional, or distant), 15% of which were metastatic at diagnosis. Clearly, SEER data on pediatric cases are more complete in terms of stage information than European data. According to the follow-up study of Patel et al. [43], disease dissemination in sarcomas occurs mainly by hematogenous as opposed to lymphatic spread (<5%); metastases primarily occur in lung, but also bone, liver, regional lymph nodes, peritoneum, distant subcutaneous tissue, and brain, although the preferred metastatic site varies with subtype [44]. We found that

the main metastatic sites for both soft tissue and bone sarcomas were lung, bone, and pleura; liver was also a frequent metastatic site for soft tissue sarcoma (Figures 3 and 4). Nevertheless, liver was the most common site in adults in the 50–69-year age class, and peritoneum was the most common site in the 20–49-year age class. Our findings are broadly similar to those of Patel et al. [43] and also to those of Shweikeh et al. [45] and Marchiori et al. [46].

5. Strengths and Limitations

The main strength of our study is that we used data from AIRTUM cancer registries characterized by high quality (95.7% of cases microscopically verified) and high completeness. However, the data were not perfect. The large proportions of NOS reflect the difficulties of histopathologic, and increasingly, molecular diagnosis and suggest that sarcoma diagnoses should be routinely reviewed by a pathologist specialised in sarcomas. However, this is not often possible. Another problem is that sarcoma patients are normally treated at specialist centres available outside the cancer registry area and data from centres outside registry areas are not routinely available to cancer registries. AIRTUM is working to ensure that cases treated outside registry areas are not lost to cancer registries.

A second study strength is that we excluded visceral and Kaposi's sarcomas, thereby avoiding the misclassification that is common in sarcomas arising in organs. We emphasize that our cases were population-based, thereby avoiding selection bias, and that we analysed a relatively large number of cases so that our findings are likely to be reliable. Nevertheless, there were low numbers of cases in some soft tissue and bone sarcoma categories, and in these cases, findings should be interpreted cautiously. As a limitation, we note that stage at diagnosis and details of treatment were largely lacking: such information if present would likely have provided additional insights into these rare cancers. In addition, only a few Italian cancer registries use software to automatically generate case data from the data sources (now mostly electronic databases). Automatically generated cases are subjected to checking procedures, and flagged cases undergo manual (operator) checking. Most cancer registries, however, still generate cases manually from clinical records and various electronic databases.

6. Conclusions

High sarcoma incidence rates in the cancer registry areas of Pavia and Firenze-Prato suggest that these may be high-risk hot-spots deserving further investigation. Marked variations of morphology distribution with site between Italian areas suggest a more general geographic variation in risk factors that may also repay further investigation, particularly since sarcoma etiology is poorly understood. We are planning an analysis of survival for bone and soft tissue sarcomas archived in the cancer registries that participated in the present study. For this, we will collect information (treatment comorbidities) from clinical records (not available in

registry records) to enable us to better interpret survival variations.

Data Availability

The data on sarcoma cases used in this study were provided by cancer registries affiliated to AIRTUM and cannot be made freely available.

Conflicts of Interest

The authors declare that there are no conflicts of interest.

Acknowledgments

The authors thank Don Ward for his help with the English language and for critically reading the manuscript. The authors thank Eli Lilly Italia SpA for the unconditioned support to the study.
