Highlights

- A quantitative survey was completed by infertile patients and partners to patients
- Respondents waited an average of 3 years before receiving an infertility diagnosis
- Motivational coherence within couples was a key driver to seek fertility treatment
- Offerings of supportive services were positively correlated to treatment initiation
- Perceived cost was the most frequently reported barrier to fertility treatment

Barriers and factors associated with significant delays to initial consultation and treatment for infertile patients and partners to infertile patients.

Abstract

Research Question: What are the key drivers and barriers for infertile patients and their partners to see an infertility specialist and initiate treatment?

Design: An online, international, 30-minute quantitative survey collected data from 1,944 respondents from nine countries. Respondents were infertile patients (n=1,037) or partners to infertile patients (n=907; but not necessarily partners of the patient sample), at different stages of the treatment journey.

Results: The overall average times were 3.2 years to receiving a medical infertility diagnosis, 2.0 years attempting to achieve pregnancy without assistance before treatment, and 1.6 years of treatment before successful respondents achieved pregnancy.

The most common driver for considering treatment after a consultation (n=1,025) was an equal desire within the couple to have a child (40.8%). Of partners (n=356), 27.3% reported that transparency of information from healthcare professionals about treatment expectations was important. A significantly higher proportion of respondents seeking treatment reported that healthcare professionals offered supportive services (61.0%) and mental health services (62.0%) than the 207 respondents who did not seek treatment (32.0% and 37.0%, respectively; p<0.001).

Perceived cost was the most commonly reported barrier for respondents not seeking a consultation (37.5% of n=352) or treatment (42.0% of n=207). Of the 95 respondents who discontinued treatment, 34.7% discontinued due to financial impact.

Conclusion: Respondents reported significant delays to seeking treatment, likely negatively impacting chances of achieving pregnancy. Motivational coherence within couples was a key driver

and cost of treatment was the main barrier. Reported offerings of supportive services by healthcare professionals were highly positively correlated to treatment journey continuation.

Keywords: infertility treatment, patient perspective, partner perspective, treatment journey, treatment delay, survey.

Introduction

Approximately 8% to 12% of couples worldwide experience difficulties achieving pregnancy, and this rises to one in four couples in developing countries (Boivin et al., 2007; Kumar and Singh, 2015; World Health Organization, 2021). Some regions experience particularly high infertility prevalence, including areas of Europe, Asia and Africa (Inhorn and Patrizio, 2015). Infertility is defined as the failure to achieve a clinical pregnancy after at least 12 months of regular, unprotected sexual intercourse (Zegers-Hochschild et al., 2009). This condition is becoming increasingly common, likely in part due to the modern trend to pursue educational goals and economic stability prior to starting a family, therefore delaying pregnancy until older age (Molina-García et al., 2019)

Current literature has suggested that parenthood is considered to be central to the life plan of most adults (Boivin et al., 2018). Both men and women can feel an intense and profound desire for parenthood, indicating an emotional engagement acting as a driving force for patients to seek treatment for infertility (Hadley and Hanley, 2011; Langher et al., 2019). With the availability of reproductive technologies and treatment processes, it has been suggested that increased social pressure might be a significant driver to seek treatment and achieve pregnancy (Langher et al., 2019). A further important factor in determining patient treatment decisions is communication with the healthcare provider (HCP) team through infertility diagnosis, consultation and treatment, as quality of service influences the patients' experiences (Klitzman, 2018).

There are challenges encountered by both patients and their partners throughout the treatment journey, from the initial consultation to receiving treatment. Perhaps the most well established barrier to treatment for patients is the financial impact of the process, a particular issue in developing countries (Dyer and Patel, 2012; Eisenberg et al., 2010; Wu et al., 2013). Studies have demonstrated that wealthier patients, particularly those with a household income of over \$100,000, are more likely to utilise infertility services (Chandra et al., 2014; Smith et al., 2011). Therefore, cost can significantly impact on the accessibility, and use of, fertility treatments (Klitzman, 2017).

However, cost is not always the main barrier to treatment; even in countries where fertility treatment is covered by national health policies, patients often fail to initiate treatment after a consultation or discontinue treatment before achieving their goals (Brandes et al., 2009; Jain and Hornstein, 2005). Further challenges to continuing the treatment journey include concerns about the emotional and physical impact of treatment (Eisenberg et al., 2010; Gameiro et al., 2012). In countries where the standard three-cycle treatment regimen is offered, a systematic literature review found that 22% of patients who do not achieve pregnancy do not complete all three cycles (Gameiro et al., 2013a). In circumstances where public funding is available for more than three cycles, discontinuation rates can reach 70% (Brandes et al., 2009).

There is increasing attention surrounding the time taken to achieve pregnancy for infertile couples and how best to incorporate the need for multiple cycles of treatment in patient consultations (Harrison et al., 2021; Sunkara et al., 2020). There is currently little research into the time taken to receive a medical infertility diagnosis, although it is understood that delays to receiving a medical diagnosis of infertility specifically caused by endometriosis are significant (Ballard et al., 2006; Santos et al., 2012). Therefore, there is a need to better understand the length and cause of delays throughout the treatment journey (Schmidt et al., 2012). Greater understanding would allow

deployment of interventions to minimise the delay, and therefore reduce the impact of age-related fertility decline on treatment outcomes (ASRM, 2012). This would ultimately allow the optimisation of time to pregnancy and potentially improve clinical and wellbeing outcomes. Additionally, the majority of research considers only female patients, neglecting to examine the perspectives of male patients or the partners of patients considering fertility treatment. The aim of this study was to describe the delays, key drivers and barriers to seeking a consultation and subsequently undergoing and continuing fertility treatment for patients and partners.

Materials and methods

Study design

This study used a quantitative questionnaire to explore the delays, drivers and barriers within the infertility journey for infertile patients and partners to infertile patients. A targeted literature review was conducted to explore understanding of fertility in addition to treatment choices and persistence for infertile couples. This informed the development of an international, 30-minute, online survey for this study. The survey was developed in English and translated to French, German, Italian, Spanish and Mandarin. Translations were validated by national linguists. Data were collected from 15th March to 17th May 2019 and responses were anonymised.

The target for recruitment was 1,980 respondents overall, including 110 infertile patients and 110 partners to infertile patients (but not necessarily partners to the patient sample) from each of the nine countries (United States, Canada, United Kingdom, France, Germany, Italy, Spain, Australia and China). Both men and women were recruited as patients and as partners to infertile patients.

All respondents who were included in this study were required to have directly received a medical infertility diagnosis at a medical consultation (patient) or to be a partner of someone who had

received a medical diagnosis of infertility (partner). Treatments for respondents who had received at least one treatment cycle included either assisted reproductive technology (ART), intrauterine insemination (IUI) or donor gametes. There were further sub-quotas to ensure the inclusion of respondents who received an infertility diagnosis at a medical consultation (self-reported), but did not explore a consultation, respondents who had attended a consultation to discuss treatment options but decided not to enroll in treatment, respondents who had been successful in fertility treatment and respondents who had been unsuccessful after at least two treatment cycles. This ensured that respondents were recruited from different stages of the treatment journey.

Respondents were identified through data collection partner M3 Global Research and were sent an email inviting them to participate in the survey. This alerted the respondent to the general topic of the survey, duration and honorarium amount, and provided additional guidance on what was required. Respondents were informed that responses were confidential and provided in aggregate. All email invitations complied with both ISO 20252 (Market Research Standards) and ISO 27001 (Information Security Standards) guidelines.

The respondent screener was incorporated at the start of the survey to ensure that only respondents who met the screening criteria were included. To be eligible, respondents needed to have received, or have a partner who had received, a medical infertility diagnosis whilst under the age of 50 and had received infertility treatment within the last five years (see supplementary materials for full respondent screener). An honorarium was provided to respondents who completed the full survey, compliant with relevant guidelines.

Respondents were asked to record the time spent trying to achieve pregnancy without assistance before receiving an infertility diagnosis at a medical consultation, time spent trying to achieve pregnancy without assistance from receiving a medical infertility diagnosis to enrollment in treatment

and time spent receiving fertility treatment before pregnancy. Respondents completed time estimates up to the stage within the infertility journey from which they were recruited (after receiving a medical infertility diagnosis, after receiving a medical consultation to discuss treatment options or after receiving treatment). The next section of the survey captured information on reasons for respondents choosing to seek treatment, including interactions with their HCP team. Respondents were then asked to select barriers that they had experienced in seeking, and continuing with, treatment. When reporting drivers and barriers to treatment, respondents selected their responses from a list of prespecified answers.

Statistical analysis

Statistical analyses were performed on the data to explore potential relationships between responses to questions. The first of these was to explore any associations between drivers to seek treatment and between barriers to seeking consultation and treatment using Cramer's V analyses. Chi square tests were used to determine which responses were more often barriers than drivers and which were more often drivers than barriers. Finally, a Chi square analysis was used to explore differences between patients and partners in responses to drivers and barriers.

Results

Patient characteristics

A total of 1,944 respondents met the extensive screening criteria necessary to take part in the survey and be included in this study (see Table 1 and Table S1 in the supplementary information for baseline characteristics for all countries). Data were collected from 1,037 infertile patients and 907 partners to infertile patients (not necessarily partners of the patient sample). The number of respondents at each stage within the infertility journey can be seen in Figure 1.

For the overall respondent population, the average age was 35.8 years (standard deviation [SD]=9.7) and most were female (56.3%; n=1,095). Most respondents were heterosexual (91.2%; n=1,773), and over half were married (66.7% of those asked this question; n=1,119). Most patients were women and most partners were men. Medical infertility-related diagnoses that either respondents or their partners had received at a medical consultation are also reported. Treatment funding sources were investigated (Table 2), with the highest proportion of respondents reporting coverage by private health insurance (51.8%; n=387).

Average time to medical infertility diagnosis, treatment, pregnancy

All survey respondents (n=1,944) reported the time they spent trying to achieve pregnancy without assistance before receiving an infertility diagnosis at a medical consultation and the time spent trying to achieve pregnancy without assistance from receiving a medical infertility diagnosis to enrolment of treatment. Respondents who achieved pregnancy (n=591) also reported the time from treatment initiation to pregnancy. These outcomes are presented in Table 3 and Figure 2.

The overall average time spent trying to achieve pregnancy without assistance before receiving a medical infertility diagnosis for all respondents (n=1,944) was 38.6 months (SD=28.9). Analysis by country revealed that the longest average time to receiving a medical infertility diagnosis was reported by respondents in the United States (41.9 months; SD=32.8). Time to receiving a medical infertility diagnosis in European countries varied, from 41.6 months (SD=33.8) in France to 33.5 months (SD=21.3) in Spain. Respondents in China reported the lowest overall average time to receiving a medical infertility diagnosis (32.2 months; SD=22.2).

After receiving a medical infertility diagnosis, the average time spent trying to achieve pregnancy without assistance before initiation of fertility treatment for all respondents (n=1,944) was 23.6

months (SD=25.7). There were small variations by country. The shortest average time was observed in Spain (20.2 months; SD=19.8) and the longest average time was reported in Italy (28.8 months; SD=29.7).

After the initiation of treatment, 591 respondents reported the length of time for which they received treatment before they achieved pregnancy. The average time reported was 19.6 months (SD=16.3). Analysis by country showed that respondents in the United States reported the shortest average time (14.0 months; SD=11.6) and the longest average time was observed in France (26.7 months; SD=20.2).

Drivers to seek consultation and treatment

Following the receipt of a medical infertility diagnosis, 63.4% of respondents (n=1,232) had a consultation to explore treatment options. There were 1,025 respondents who then had either begun treatment or planned to initiate treatment in the future. These respondents were asked to report their motivations for seeking treatment (see Table S2 in the supplementary information). The most frequent response was "My partner and I were equally keen to have a child by any means necessary", reported by 40.8% (n=418) of respondents. This statement was the most commonly reported driver across five of the nine countries (United States, United Kingdom, Canada, Australia and Germany). Respondents from the remaining countries most frequently reported "The timing was right", "I was determined to try anything to be a parent" and "[I/My partner] had great support from [my partner/me]". The second most common driver overall was "I was determined to try anything to be a parent", reported by 38.4% (n=394) of respondents. Cramer's V analyses showed that these responses were strongly associated and therefore often reported together (Cramer's V of 0.30).

The prespecified responses for drivers and barriers to consultation and treatment were approximate opposites. For example, the "equal" desire within a couple to achieve pregnancy could be selected as a driver ("My partner and I were equally keen to have a child by any means necessary") or a barrier ("My partner and I were not equally keen to have a child by any means necessary"). Chi square analyses explored the frequency with which responses were selected for both questions and found that the two most commonly reported drivers to seek treatment, "I was determined to try anything to be a parent" and "My partner and I were equally keen to have a child by any means necessary", were reported more frequently as drivers than barriers (p<0.0001).

Further Chi square analyses revealed that more patients reported "My partner and I were equally keen to have a child by any means necessary" and "I was determined to try anything to be a parent" than statistically calculated expected frequencies (p=0.01 and p=0.02, respectively). For partners to infertile patients, Chi square analyses showed that answers related to "support" in the relationship were more commonly selected as drivers than statistically calculated expected frequencies (p=0.03).

There were 472 respondents who decided to proceed with further fertility treatments after at least one failed attempt (see Table S3 in the supplementary information). The most common driver to continue was "My partner and I were equally keen to have a child by any means necessary", reported by 37.9% (n=179) of respondents. This statement was the most frequently reported statement in six of the nine countries and in both patient and partner subgroups.

Communication within relationships and with the HCP team

Respondents who had received a consultation (n=1,232) were asked to rank statements relating to treatment decisions and the role of the HCP team. The statement "I played an active role in [my/my partner's] treatment decisions" was the most highly ranked statement overall, and across four of the nine countries. Figure 3 shows the proportion of all respondents, patients and partners to infertile

patients reporting "agreement" or "strong agreement" with each statement (rankings of five to seven on the seven-point scale). The statement "I played an active role in [my/my partner's] treatment decisions" was agreed with most frequently amongst all respondents, followed by "[My/my partner's] healthcare professional team treated my partner and I like a couple (and not an individual)".

Patients and partners to infertile patients generally reported similar levels of agreement, although there was some variation in agreement with "I played an active role in [my/my partner's] treatment decisions", reported by 77.0% of patients and 68.0% of partners.

Further analysis showed variations in perceptions about the HCP team depending on treatment decisions (Figure 4). Respondents who sought treatment agreed more frequently (reporting five to seven on the seven-point scale) with all positive statements about their HCP team than those who chose not to seek treatment. The statement with which respondents most frequently agreed was "[My/my partner's] healthcare professional team treated my partner and I like a couple (and not an individual)", reported by 76.0% of respondents who sought treatment. The greatest difference in opinion was seen with "[My/my partner's] healthcare professional team offered resources, such as supportive services aimed specifically for [myself/my partner]", where 61.0% of respondents seeking treatment agreed compared to only 32.0% of those not seeking treatment.

Barriers to seeking consultation and treatment

Respondents who discontinued their treatment journey after receiving a medical infertility diagnosis, consultation or initiation of treatment were asked to report the reasons for their decision (see Table S4, Table S5 and Table S6 in the supplementary information). Of those who decided against seeking a consultation to explore treatment options (18.1%; n=352), the most common barrier was "Fertility treatments are costly", reported by 37.5% (n=132) of respondents. Cramer's V analyses showed that this barrier had a strong association with "[I/my partner] was determined to conceive a child

naturally", and "[I/my partner] could no longer afford the cost of fertility treatments" (Cramer's V for both associations=0.28), indicating that they were frequently reported together. Chi square analyses of the frequency with which statements were selected as drivers and barriers revealed that the cost of treatment was more often reported as a barrier than a driver (p<0.0001), as were concerns about the time investment (p<0.01) and emotional strain (p<0.05).

Of the 1,232 respondents who sought a consultation, 207 did not subsequently initiate treatment. The most commonly reported reason for this was "Fertility treatments are costly", selected by 42.0% (n=87) of all respondents. The second most frequently reported barrier was "[I/my partner] was determined to conceive a child naturally", reported by 30.9% (n=64) of respondents. Like previous results, there was a strong association between these two statements (Cramer's V=0.27), and between "Fertility treatments are costly" and "[I/my partner] could no longer afford the cost of fertility treatments" (Cramer's V=0.28).

Analysis by patient and partner subgroups revealed similar results for respondents who chose not to seek a consultation and respondents who chose not to initiate treatment. In both populations, a higher proportion of patients were concerned about the cost of fertility treatments (42.3%; n=52 and 48.5%; n=50, respectively) than partners to infertile patients (34.9%; n=80 and 35.6%; n=37, respectively), although cost remained the most commonly reported barrier overall.

The greatest disparity between patient and partner responses for respondents who did not seek a consultation was in the statement "[I/my partner] was worried about the physical strain of undergoing treatment", reported by 23.6% of patients (n=29) and only 10.9% of partners (n=25). Chi square analyses revealed that this statement was selected more frequently by patients than statistically calculated expected frequencies (p<0.01). The greatest disparity in patient and partner responses amongst those who did not initiate treatment was in agreement with "[I/my partner] was concerned

about the side effects of fertility treatments", reported by 40.8% of patients (n=42) and 18.3% of partners (n=19).

"Fertility treatments are costly" was the greatest barrier to consultation across seven of the nine countries and to treatment initiation in five countries. This statement was reported more frequently by females (43.8%; n=96) than males (27.1%; n=36).

There were 95 respondents who discontinued treatment for reasons other than achieve pregnancy. The most frequently reported reason was "Fertility treatments are costly" (by 34.7% of respondents; n=33), with little variation across patient and partner subgroups. Of respondents in Canada, 77.8% (n=7) reported cost as a barrier to continuation of treatment compared to only 9.1% (n=1) of respondents in Italy.

Discussion

Overall, respondents delayed fertility treatment for years, which can significantly reduce the chances of achieving pregnancy. Motivational coherence within the couple and offers of support from the HCP team were significant determinants of infertility journey continuation. Cost was the main barrier to treatment. These results highlight the importance of support for patients and partners seeking treatment, financial planning and awareness of the impact of delays on treatment outcome.

Average time to medical infertility diagnosis, treatment, pregnancy

Respondents took longer than clinically recommended before seeking medical attention and treatment for infertility. There is little research documenting the time to milestones within the infertility journey, but this study suggests significant delays for patients and partners, particularly to receiving a medical infertility diagnosis. Despite the definition of infertility as the failure to achieve pregnancy after one year (12 months) of regular, unprotected sexual intercourse, respondents

reported an average of 3.2 years (38.6 months) of trying to achieve pregnancy without assistance before receiving a medical infertility diagnosis (Zegers-Hochschild et al., 2009). The subsequent average 2.0 years (23.6 months) spent trying to achieve pregnancy without assistance before treatment and 1.6 years (19.6 months) receiving treatment before pregnancy resulted in an average overall treatment journey length of 6.8 years.

There are likely multiple factors contributing to the length of time before receiving a medical infertility diagnosis, including the established lack of infertility awareness, education level, negative beliefs about the cost, accessibility and safety of treatment, and a fear of receiving a medical infertility diagnosis and being stigmatised (Bunting et al., 2007; Costa et al., 2013; Daumler et al., 2016; García et al., 2016). In addition, higher educational level is linked to a higher possibility of recognising fertility problems (Pedro et al., 2018). It is well established that fertility declines with age especially in women, for whom chances of achieving pregnancy decline substantially at around the age of 35 (ASRM, 2012). Therefore, the large delays recorded by respondents will likely negatively impact chances of treatment success as a result of older age at treatment initiation. The significance of age-related fertility decline necessitates a greater public awareness of the benefits of childbearing at a younger age (ASRM, 2012).

The differences between countries in time to receiving a medical infertility diagnosis may be a reflection of differences in healthcare systems and treatment funding offered. The longest time to receiving a medical infertility diagnosis was reported by respondents in the United States, which could result from healthcare system inefficiencies or financial concerns in a country where there is no federal mandate for infertility coverage. In states where coverage is mandated, higher treatment expenditures via treatment plans or employers are reported, indicating a greater usage of fertility services compared to states without a mandate (Boulet et al., 2019). By contrast, the shortest average

delays to receiving a medical infertility diagnosis were often reported in Australia and European countries like Italy where infertility services are provided by the government (Calhaz-Jorge et al., 2020; Morshed-Behbahani et al., 2020). Therefore, further research should be conducted to explore the impact of different medical cultures and health systems on the time taken to achieve pregnancy.

Drivers to seek consultation and treatment

Motivational coherence within couples is important for seeking medical advice. Analysis of the drivers for respondents to seek treatment and then continue after failures to achieve parenthood with medical assistance showed that an equal desire within the couple to achieve pregnancy was important across patient and partner subgroups and most countries. This suggests that motivational coherence within couples is significant when making treatment decisions and in determining continuation in the infertility journey. Previous literature supports this idea as it has been shown that disagreements about fertility treatment within couples can impact on relationships and may influence their motivation to seek and continue with treatment (Brandes et al., 2009; Klitzman, 2017).

Current literature suggests that the financial impact of fertility treatment represents a large barrier to female patients, and this study supports these findings. However, patients reported cost as a barrier more often than partners to infertile patients. This could suggest that patients are better informed about the fertility treatment journey and its implications than partners and therefore partners may benefit from the HCP team taking a more couple-oriented approach to treatment. Further research is required into the perspectives of partners to explore this.

Communication with the HCP team

Communication remains an important aspect of patient-centered care. The transparency of the HCP team and the effectiveness of their communication with respondents were important drivers for

respondents to seek treatment. Previous research has also established the importance of communication with the HCP team during treatment (Dancet et al., 2012; Klitzman, 2018). Studies regarding patient-centered care for infertility have shown the emotional support and information provided by the HCP, in addition to their competence and accessibility, are important factors for infertile patients (Dancet et al., 2012). In Europe, provision of information regarding infertility is a top priority (Dancet et al., 2012). These factors have been positively associated with patient wellbeing, suggesting that the HCP team can influence a patient's infertility experience and quality of life (Dancet et al., 2012; Gameiro et al., 2013b; Harzif et al., 2020).

The results of this study support these findings. Respondents who initiated treatment more frequently agreed with positive statements regarding the communication and helpfulness of the HCP team and their propensity to treat respondents as a couple rather than an individual than those who did not seek treatment. These respondents also more frequently reported that their HCPs offered support services, mental health support and resources. This highlighted the significance of the HCP team in determining treatment journey continuation. HCP teams should therefore maintain a focus on good communication with infertile couples, provide them with information about their medical infertility diagnoses and consider whether they would benefit from additional emotional support. These results also highlight the importance of the inclusion of the partner, indicating the need for a more couple-centered approach to fertility treatment.

Barriers to seeking consultation and treatment

Despite gender differences, the cost of treatment remained the most significant overall barrier to consultation, initiating treatment and continuing with treatment. It is important to note that the 'cost of treatment' encompasses both the cost of fertility medications and the context of affordability of these treatments to patients and partners. Respondents from the United States cited cost as a barrier to

both consultation and treatment more frequently than any other country, which is likely a reflection of the significantly higher costs and lack of nationwide publicly funded fertility treatments in the United States in contrast to most other developed countries (Morshed-Behbahani et al., 2020; Mossialos and Wenzl, 2016). Results from Italy and France conversely reported consistently low concerns about the cost of treatment. However, the consistency with which respondents reported cost as a barrier throughout the treatment journey indicates that it is a significant issue, particularly in countries where fertility treatments are not publicly funded. Therefore, it is possible that the introduction of country-wide subsidised programs similar to those in other countries could alleviate the concerns of a substantial proportion of infertile patients and their partners and significantly improve accessibility of treatment. Previous research has demonstrated that investment in assisted reproductive technology is both clinically and economically valuable, as the lifetime taxes paid by a child represent a return on investment (Connolly et al., 2008; Matorras et al., 2015; Wei et al., 2021). However, it should be noted that there were many respondents for whom cost of treatment was not an issue, and that 87.1% of those who received treatment reported some level of public or private coverage or funding.

Another mindset frequently reported as a barrier throughout the infertility journey was a determination to achieve pregnancy without assistance. This indicates the need for greater education for patients and partners regarding the lower chances of achieving pregnancy without assistance after years of trying and resultant older age (ASRM, 2012). The value of improved education has been demonstrated in a recent randomised controlled trial which found that this accelerated births amongst partnered individuals (Maeda et al., 2018). The physical effect of treatment was also a significant issue for respondents, corroborating previous findings in infertile patients (Gameiro et al., 2012). It is possible that improved patient support services would alleviate some of these negative perceptions

and enable them to continue in their treatment journey. Variations between patient and partner responses indicate the need for further research into partner-reported barriers to fertility treatment.

Strengths and limitations

This study corroborated findings already established in the literature regarding drivers and barriers to treatment and the importance of interaction with the HCP team and generated new data on delays in the treatment journey. Additionally, this study explored the previously under-researched perspectives of partners to infertile patients and male patients and partners. This allowed the comparison of male and female, and patient and partner responses to highlight differences in the perceived barriers to fertility treatment. The study was designed to include a large sample size of 1,944 respondents and had broad inclusion criteria.

A limitation of this study is that the anonymous questionnaire did not allow for response validation, for example with verification of infertility diagnoses by medical professionals. Respondents were unable to ask clarifying questions. There was little constriction on the recall period, allowing for long periods of time to have passed since the respondents received a medical infertility diagnosis, which could reduce the validity of some responses. Furthermore, recruitment of individual respondents into patient and partner subgroups meant that there were no sub-analyses of patient-partner pairs, and the cross-sectional nature of the study meant that causality cannot be proven. Additionally, it is possible that some of the surveyed patients and partners were part of the same couple. Respondents who had received treatment received only ART, IUI or donor gametes. Other fertility treatments are available and therefore all fertility treatment options were not captured in this study.

Conclusion

This study highlights the significant delays to receiving a medical infertility diagnosis, indicating the need for better education surrounding treatment and the lower chances of success with longer delays and resultant older age. Motivational coherence within couples in the desire for a child was a key driver, and perceived supportive service offerings of the HCP team were important determinants of treatment journey continuation. These results are indicative of the need for support both within the couple and within the patient-provider relationship and suggest that HCP teams should maintain an emphasis on open communication with patients and partners. Financial concerns were an important barrier to treatment and country differences indicated the need for improved accessibility to treatments.

The analysis of subgroups showed that males and partners to infertile patients have different experiences and perceptions of the fertility treatment journey than those of the female patient population already established in the literature. This indicates the requirement for further research to investigate the effects on these under-researched groups to improve care for both male and female patients and partners.

Authors' roles

AD, RV, MD, MC, EV, JB and BC contributed to the study conception and study design. JG was responsible for survey design and data collection. ER, CS and MM were responsible for data analysis. JG, MM, AD, RV, MD, MC, EV, JB, CS and BC contributed to the writing of the manuscript. All authors reviewed and approved the final version of the manuscript.

Acknowledgments

The authors would like to thank the researchers at W2O Group who developed the survey and collected the results for analysis and Adelphi Group for editorial assistance with the manuscript.

Funding

This study was funded by Ferring Pharmaceuticals Ltd.

Data availability

The data underlying this article will not be shared publicly.

Conflict of interest

AD has received fees from Ferring Pharmaceuticals during the conduct of the study and fees from Ferring Pharmaceuticals, Merck, Abbott and Nestlé outside of the submitted work.

21

MC has received grants from Ferring Pharmaceuticals during the conduct of the study.

BC is currently employed by RESOLVE: The National Infertility Association.

MM has received personal fees from Ferring Pharmaceuticals, outside of the study.

CS is the owner of Outcomes Analytica AS and has received funding from Ferring Pharmaceuticals.

JG is currently employed by W2O Group, which received professional fees to complete the research.

ER has received personal fees from Ferring Pharmaceuticals during the conduct of the study.

JB has received a grant from Merck Serono Ltd and personal fees from Ferring International, Theramex and the Office of Health Economics outside of the submitted work.

Alice D. Domar, Ph.D, is the executive director of the Domar Centers for Mind/Body Health, director of integrative care at Boston IVF, and associate professor of obstetrics, gynecology, and reproductive biology, part-time, Harvard Medical School. She is the author of seven books and co-creator of the apps FertiCalm and FertiStrong.

Key message: An average three-year wait before infertility diagnosis indicates reduced chances of success due to older age. Patient-provider relationships and supportive service offerings were significantly associated with treatment initiation, highlighting the importance of communication and service quality. Partners showed a high concurrence with patients regarding the significance of supportive service offerings.

Tables

Table 1. Baseline characteristics of overall respondents, patients and partners

	Patient characteristic	All (n=1,944)	Patient (n=1,037)	Partner (n=907) ^a
Age	./0			
Average years (SD)		35.8 (9.7)	35.0 (8.7)	36.6 (10.6)
Sex				
Male	10	43.6%	33.8%	54.7%
Female		56.3%	66.1%	45.2%
Marital status	9			

Patient characteristic	All (n=1,944)	Patient (n=1,037)	Partner (n=907) ^a		
Single	22.5%	18.3%	26.6%		
Married	66.7%	72.0%	61.6%		
Divorced	4.4%	4.1%	4.6%		
Widowed	1.1%	0.9%	1.3%		
Other	5.4%	4.7%	6.0%		
Sexual preference					
Heterosexual	91.2%	90.5%	92.1%		
Homosexual	5.9%	6.6%	5.1%		
Other	2.9%	3.0%	2.9%		

^aPartners were not necessarily partners of the patient sample.

SD = standard deviation.

Treatment coverage / funding through health insurance	Overall respondents (n=747)	Patient (n=490)	Partner (n=257) ^c
[My/my partner's] treatment(s) were covered / funded through private health insurance	51.8%	51.8%	51.8%

[My/my partner's] treatment(s) were covered / funded through public health insurance	35.3%	36.3%	33.5%
[My/my partner's] treatment(s) were NOT covered / funded through health insurance	20.1%	18.8%	22.6%
Unknown/unsure	1.1%	0.6%	2.0%

Table 2. Treatment coverage / funding through health insurance for overall respondents, patients and partners who chose to undergo treatment a,b

^aRespondents were able to report both public and private coverage and thus the columns in the table do not sum to 100%.

^bRespondents who reported coverage / funding through health insurance did not necessarily have 100% coverage.

^cPartners were not necessarily partners of the patient sample.
