4. Introduction

4.1 Obesity and the central cholinergic system

Obesity is a multifactorial syndrome with serious medical sequelae and comorbidities, such as cardiovascular disease, cancer or metabolic syndrome, which poses major challenges for health care systems world-wide.¹ According to the World Health Organization (WHO) and the Global Burden of Disease Study more than 600 million adults worldwide are considered obese² underlining today's relevance in firmly approaching this health threat. Several factors have vast impact on obesity's etiology such as socioeconomic status, genetics, environmental circumstances and lack of physical activity combined with modern day diets, which consist of processed foods with high proportions of sugar and saturated fatty acids.^{3,4} Currently, surgical treatments such as sleeve gastrectomy are the most effective intervention for sustained weight loss but these procedures are associated with morbidity and mortality.⁵ Therefore the search for non-invasive treatment strategies as alternatives to surgical approaches to achieve sustainable weight loss represents a keystone in human obesity research. To identify putative pharmacological interventions, knowledge of the biological factors underlying obesity is essential. The precise role of neurotransmitter circuits involved in the regulation of eating behavior and obesity, however, still needs to be fully explored.

A well-known and highly interesting observation is that the cessation of smoking often leads to weight gain. Rupprecht et al.⁶ highlight that smoking cessation leads to an average increase of 10 pounds body weight within the first year. In general, increasing body weight is described to be greatest within first six months of smoking cessation due to decreased metabolic rate and enhanced food intake (Figure 1).⁷ McGovern et al. describe the enhanced food intake as "substitutable reinforcers" to compensate for the lack of reward through smoking as the source of substantial weight gain.⁷

Moderate smokers often have a lower BMI than non-smokers, but heavy, more frequent smokers often suffer from obesity as they seem to experience a reduced feeling of reward from smoking as well as from the ingestion of palatable food items.^{6,8} In another study, Kovacs et al. showed that young adult female smokers with the tendency to disinhibited eating behavior after being presented a food prime, would smoke more to compensate for their food craving.⁹

Figure 1: Association Between Smoking Cessation and Weight Gain

Increase of body weight is highest with continuous smoking cessation

On a behavioral level, individuals with obesity seem to have a tendency to immediately rewarding values or actions, irrespective of potential long-term negative outcomes.¹⁰ Furthermore, a great susceptibility to environmental food cues leading to habitual actions of eating in a stimulus-response paradigm points out to impairments in behavioral choice and alterations in traits of impulsivity.¹⁰ As such, individuals with obesity share neurobiological mechanisms similar to individuals that suffer from addiction.¹¹ This includes alterations of dopaminergic mesolimbic reward signaling as well as dysfunctional pathways of neuromodulation involved in the evaluation and value attribution of external stimuli. Understanding altered salience processing in obesity is therefore pivotal.

Interestingly, the particular computation of attentional as well as reward signaling involves cholinergic neuromodulation, through expression of nicotinic acetylcholine receptors (nAChRs).^{12,13} In rats, nicotinic stimulation increased the tendency to choose immediate yet smaller rewards in comparison to greater reinforcers.¹⁴ Preclinical findings in mice suggest that high-fat diets increase exploratory behavior and the density of nAChRs subtypes in brain areas like prefrontal cortex (PFC) or midbrain, which are associated with the regulation of impulsive behavior.¹⁵ This highlights the

potential involvement of cholinergic signaling in behavioral aspects of impulsive character traits affecting feeding behavior.

However, studies that investigate task-related cholinergic signaling in a baseline versus stimulus design in human obesity do not exist. To explore the relationship between cholinergic network modulation and its implications on eating behavior, this study will elucidate structural and functional characteristics of the $\alpha 4\beta 2$ nAChR in human obesity.

4.2 Cholinergic Neurotransmission

Neurotransmitters are chemicals that allow inter-neuronal communication throughout the body. There are a number of excitatory and inhibitory neurotransmitters used for different functions, including acetylcholine (ACh), glutamate, GABA, glycine, dopamine, norepinephrine, and serotonin.¹⁶ They coordinate brain activity at a molecular level and therefore regulate, e.g. emotional states, homeostasis, cognition and behavior.¹⁷ Imbalance of neurotransmitter homeostasis and therefore neuronal circuits can lead to several psychiatric disorders, such as schizophrenia¹⁸, depression¹⁹ or neurodegenerative diseases, such as Alzheimer's²⁰ or Parkinson's disease.²¹ Alterations in neurotransmitter signaling also maintain addiction²² and contribute to altered eating behavior.²³ Physiologically, neuronal signaling transmitted by ACh, which can also be referred to as cholinergic signaling, mediates pivotal cognitive processes²⁴ such as the generation of attention²⁵, working memory²⁶ or informational processing of salient cues²⁷, but it also has a central role in mesolimbic reward signaling.²⁸

There are two types of cholinergic receptors: the metabotropic, G-protein coupled muscarinic AChR (mAChR) and the cationic, nicotinic AChR (nAChR), each with individual functions in e.g. cognitive processing.²⁶ In the latter, both nicotine as well as ACh function as receptor agonists. ACh is synthesized by the enzyme choline acetyltransferase (ChAT). When an action potential arrives at the presynaptic neuron, neurotransmitters are released into the synaptic cleft by a presynaptic Ca^{2+} influx and the consecutive process called exocytosis. ACh binds as a ligand to the corresponding receptor situated at the postsynaptic neuron and either induces an influx of cations through a conformational receptor change (nAChR) or metabotropic, G-protein

coupled signaling cascade (mAChR). These processes in turn generate an action potential at the postsynaptic neuron and thus neuronal signaling is conveyed. When ACh is released from the postsynaptic receptor, it gets hydrolyzed by the enzyme acetylcholinesterase (AChE) into choline and acetate. Then, both molecules are transported back into the presynaptic neuron by the high-affinity choline transporter (CHT1)²⁰ (Figure 2).

4.3 Structure and Receptor Kinetics of nAChR

The nAChR are ligand-gated cation channels consisting of nine α - ($\alpha 2$ to $\alpha 10$) and three β -subunits ($\beta 2$ - $\beta 4$).²⁹ The nAChRs comprise five cylindrical, transmembrane subunits, arranged in heteromeric $\alpha\beta$ -combinations (e.g. $\alpha 3\beta 4^*$ containing nAChRs; the asterisk refers to one or more additional subunits that could be associated with the receptor), homomeric nAChRs ($\alpha 7$ - $\alpha 9$) and a heteromeric α -combination ($\alpha 9$ with $\alpha 10$), all adding to a broad nAChR landscape (Figure 3).³⁰ The accessory subunits influence the receptor characteristics, in terms of pharmacological and biophysical properties, as well as their response to allosteric modulation.²⁹ Different nAChRs with different amino acid sequences therefore react in a different manner to their ligand, each with distinct affinity, sensitization and cation permeability profiles.³¹ The $\alpha 4\beta 2$ nAChR is the most abundant in the mammalian brain, with the highest receptor density in the thalamus, followed by a rather intermediate density in cortical and caudate regions and finally lowest density in white matter.^{32,33}

Figure 3: Structure of nAChR

a – depicts the five transmembrane subunits with non-selective cation channels and two ACh binding-sites

b – examining the distribution of nAChR in the brain, one can find two most common types: the $\alpha 7^*$ homo-oligomer, characterized by a fast activation, a low affinity for ACh, and a high Ca^{2+} permeability, and the $\alpha 4\beta 2$ hetero-oligomer, typified by a high agonist affinity and slow desensitization and lower Ca^{2+} conductance³⁴

Adapted by permission from: Nature, Nature Reviews Neuroscience, Nicotine addiction and nicotinic receptors: Lessons from genetically modified mice, Changeux et al., © 2010

Graupner et al.²⁸ describe that the nAChR can be subdivided in four different functional states (Figure 4), according to e.g. abundance of receptor ligand and shifting timeframe from activated, desensitized state to resting state and thus being ready for receptor-ligand-interaction (Figure 4). They compile the four states to “the resting (closed) state (R), the open state (O), the fast-onset desensitized (closed) state (I), and the slow-onset desensitized (closed) state (D)[...].” Desensitization occurs after ligand binding and receptor activation. Although, ligand affinity is highest in the desensitized nAChR state compared to the activated one, the nAChR can only exert its excitatory function in the O state.^{28,35}

Figure 4: Essential nAChR Kinetics

Research in smokers showed that chronic tobacco smoking leads to a nicotine-induced upregulation of nAChR³⁶ as well as profound changes in conformational states. This results in desensitized nAChR disrupting endogenous ACh signaling, which is pivotal for computing environmental salient cues, e.g. visual food stimuli. Yet, studies that examine similar alterations in cholinergic signaling in human obesity and how this potentially affects eating behavior do not exist.

4.4 Topography of central nAChR

There are three main cholinergic projection points innervating numerous areas in our central nervous system (CNS): First, nuclei in the basal forebrain: namely the medial septal nucleus (MS), the nucleus basalis of Meynert (NBM) and the diagonal band (DB). These nuclei project to the hippocampus, most cortical regions as well as some subcortical nuclei. Second, the pedunculopontine-lateral dorsal tegmental nuclei from the brainstem, innervating the thalamus, midbrain and other regions in the brainstem and at last, striatal interneurons (Figure 5).³⁷

Figure 5: Central Cholinergic Projection Points

Table 1 gives an overview of distinct cholinergic topography. Here, cholinergic cell group Ch4 is especially notable, as the Nucleus basalis of Meynert (NBM) projects to almost the entire neocortex.²⁶

Table 1: Central Cholinergic Projection Points

System	Cholinergic cell group	Containing nuclei	Target
Basal forebrain	Ch1	Medial septum	Hippocampus
Basal forebrain	Ch2	Vertical limb of the diagonal band of Broca	Hippocampus
Basal forebrain	Ch3	Lateral part of horizontal limb of the diagonal band of Broca	Olfactory bulb
Basal forebrain	Ch4	Nucleus basalis magnocellularis (i.e., nucleus basalis of Meynert), Globus pallidus, neurons lateral to the vertical limb, and neurons in the medial part of the horizontal limb of the diagonal band of Broca	Neocortex, Basolateral amygdala
Brainstem	Ch5	Pedunculopontinus, cuneiform, parabrachial area	Thalamus, Basal ganglia
Brainstem	Ch6	Lateral tegmental nucleus	Thalamus, Basal ganglia

4.5 Cholinergic Neuromodulation

Picciotto et al.³⁸ define neuromodulation “as a change in the state of a neuron, or group of neurons, that alters its response to subsequent stimulation”. Neuromodulators alter neuronal excitability in the brain and thus change the state of neuronal networks and their response to new salient stimuli from a constantly changing environment. ACh acts as a neuromodulator on a broad spectrum of pre-, peri- and postsynaptic neurons, *en passant* synapses, as well as point-to-point synapses, enabling it to modulate various neurons of different neurotransmitter systems (Figure 6).²⁴ This leads to distinct neuromodulation processes: balancing out neuronal excitation, nAChRs can decrease neuronal excitation of high excitatory circuits. Nonetheless, it can also enhance neuronal excitation of low excitatory circuits.³⁹ Stimulation of nAChR also induces the release of other neurotransmitters, such as e.g. GABA, glutamate or dopamine³⁸, enhance synaptic plasticity⁴⁰ or even promote encoding in the hippocampus.⁴¹

Figure 6: Cholinergic signaling and its interaction with other neuronal groups
(such as GABAergic and glutamatergic neurons)

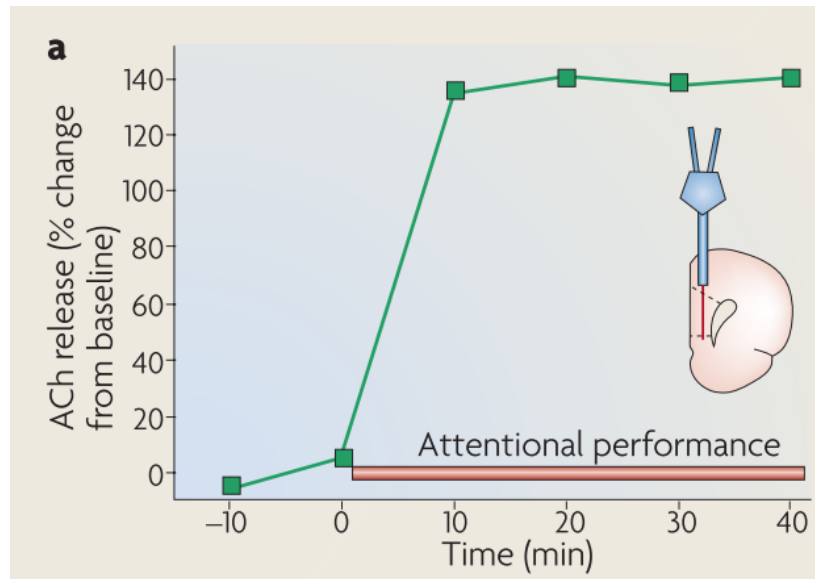

Reprinted from: Neuron, Volume 91, Ballinger et al., Basal Forebrain Cholinergic Circuits and Signaling in Cognition and Cognitive Decline, 1199-1218., © 2016, with permission from Elsevier

4.5.1 Cholinergic Neuromodulation and Cognitive Processes

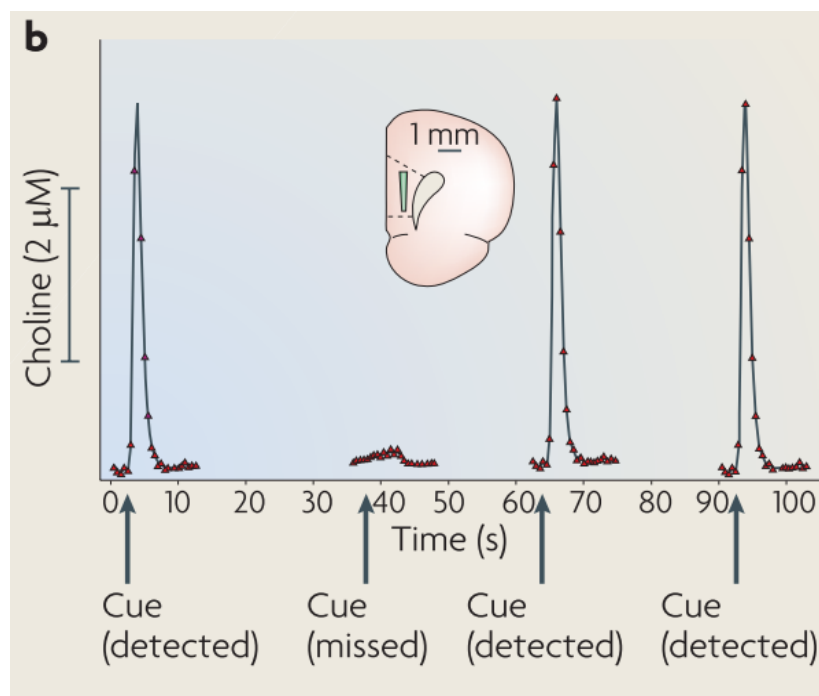

The cholinergic system as a pharmacological target is already broadly applied in modern day dementia treatment strategies to improve cognitive performance with cholinesterase inhibitors such as rivastigmine.⁴²

Interestingly, one crucial function of cholinergic signaling is the generation of attention and the detection of new salient sensory cues. Sarter et al. define cue detection as “a cognitive process that involves the incorporation of a cue into the ongoing cognitive and behavioral process and therefore allows the cue to control behavior”.²⁷ Due to its unique neuromodulation profile, cholinergic network modulation acts on different time scales: i.e. rather fast, transient (phasic) responses happening within a millisecond timeframe, as well as slower, longer lasting (tonic) modulatory effects.^{24,25,38} The phasic release of ACh into the prefrontal cortex (PFC) allows for the detection of the cue, while the longer lasting, tonic increase of ACh release represents a higher neuromodulation tone to enhance attentional performance (Figure 7).²⁷

Optogenetic stimulation of cholinergic transients in mice in a stimulus-response paradigm even increases invalid reporting of cues due to artificial dysregulation of phasic cholinergic signaling.⁴³ Parikh et al.¹³ describe the tonic release profile with changes in cholinergic activity that occur over minutes with higher tonic levels predicting greater amplitudes of phasic signals and enhanced cue detection. The tonic release profile therefore represents the classic understanding of cholinergic signaling as “arousal”-promoting. Paolone et al. highlighted improved attentional performance in mice in a sustained attention task (SAT) that had previously performed poorly, after the administration of partial $\alpha 4\beta 2$ nAChR agonist (ABT-089) in contrast to administration of amphetamine showing no improvement in attentional behavior.⁴⁴ Also, a substantial increase in extracellular prefrontal cholinergic activity showed a positive correlation with better results in the aforementioned SAT in comparison to mice with lower increase in prefrontal ACh levels.⁴⁴

Part a: prefrontal cortex microdialysis data *in vivo* of animals performing an attentional task: Tonic increase of ACh release compared to baseline enhances attentional performance on a scale of a few minutes through activation of thalamocortical circuits, eventually amplifying phasic ACh release.²⁷

Part b: phasic releases of ACh are essential for the detection of sensory cues.²⁷

Figure 7: ACh Release Profiles in Attentional Performance

Adapted by permission from: Nature, Nature Reviews Neuroscience, Phasic acetylcholine release and the volume transmission hypothesis: time to move on, Sarter et al., © 2009

On receptor dynamics level, cholinergic signaling enhances the signal-to-noise ratio, meaning the ability to differentiate between irrelevant and relevant sensory input, of new afferent information through distinct processes (Figure 8): through stimulation of nAChR it enhances afferent thalamocortical signaling, whereas it decreases cortical excitatory feedback connections and internal processing, as these processes would interfere with upcoming new information about environmental stimuli.^{45,46}

Figure 8: Cholinergic Neuromodulation of Cortical Attention Circuitry

The PFC is essential for task-relevant attentional shifts (also referred to as “top-down” regulation). Circuitries between the PFC, BFCN and sensory cortex eventually lead to enhanced cortical neuronal response reliability and cue detection through prefrontal, phasic ACh release^{24,47}

Abbreviations: PFC – prefrontal cortex; V/Au Ctx – visual / auditory cortex; BFCN – basal forebrain cholinergic neurons

Reprinted from Neuron, Volume 91, Ballinger et al., Basal Forebrain Cholinergic Circuits and Signaling in Cognition and Cognitive Decline, 1199-1218., © 2016, with permission from Elsevier

Bloem et al. precisely describe this process as a “combination of reduced lateral interactions and increased sensitivity to thalamic inputs [enhancing] the networks sensitivity to incoming information”.⁴⁸ Cholinergic signaling is therefore vital for the incorporation of newly detected stimuli in an individual’s behavior by promoting an enhanced arousal state as well as for the detection of salient cues themselves.

4.5.2 Cholinergic Neuromodulation and Reward

Obesity and addiction share similar features such as alterations in mesolimbic reward signaling in regards of the consumption of palatable food items or substances of abuse, respectively.²³ Here, cholinergic neuromodulation of dopaminergic projections plays a crucial role. The main neuronal mesolimbic pathways originate from the ventral tegmental area (VTA), which is situated in midbrain, to basal forebrain structures, most importantly the striatal nucleus accumbens (NAc).²³ Fast increases of dopamine release, triggered by drugs of abuse or other rewarding stimuli such as palatable food, are associated with the pleasant feeling, also referred to as “high”.²²

Cholinergic projections from the pedunculopontine-lateral dorsal tegmental nuclei from the brainstem innervate dopaminergic neurons in the VTA and predominantly change neuronal (dopaminergic) excitability, and coordinate the firing of these neurons (Figure 9).³⁸

Figure 9: Cholinergic Neuromodulation of the Mesolimbic Reward Pathway

Different nAChRs shape dopaminergic, mesolimbic signaling through interaction with other GABAergic and glutamatergic neurons

Abbreviations: NAc – nucleus accumbens; PFC – prefrontal cortex; PPTg - pedunculopontine-lateral dorsal tegmental nuclei; VTA – ventral tegmental area; LDTg – lateral dorsal tegmental group of neurons

Reprinted by permission from: Nature, Nature Reviews Neuroscience, Nicotine addiction and nicotinic receptors: Lessons from genetically modified mice, Changeux et al., © 2010

Mesolimbic dopaminergic neurons at resting state show a tonic (1-8Hz), low frequency firing pattern, whereas external stimuli lead to phasic (>15Hz) neuronal firing, which is essential for reward and goal motivated behavior signaling.²³

Both sucrose as well as nicotine increase dopaminergic firing activity in the mesolimbic reward system.⁴⁹ Here, the $\alpha 4\beta 2$ nAChR subunit seems to be notably essential for DA release.²³ Avena et al. showed that antagonizing the nAChR with mecamylamine substantially reduced dopamine release in the mesolimbic system after administration of cocaine.⁵⁰ Interestingly, in rats long-term diets high in sucrose lead to an increase of extracellular ACh, accumbal $\alpha 4\beta 2$ nAChR density as well as a decrease of dopamine in the NAc shell, pointing out to neurotransmitter imbalances as potential reasons for suffering from withdrawal symptoms or higher incentive salience value of food items or substances of abuse, respectively.^{51,52}

Individuals with obesity or substance abuse disorder both show a downregulation of dopamine D2 receptors (D2R) in the striatum and these D2R on cholinergic interneurons modulate the tonic-phasic firing patterns in response to salient cues, interacting with nAChR on presynaptic dopaminergic neurons.⁵³

Moreover, in rodents, higher levels of impulsivity are associated with D2R downregulation.²² Blendy et al.⁸ showed that smokers with obesity have lower rewarding effects from smoking cigarettes than non-obese participants.

In rats, intracranial self-stimulation (ICSS) with nicotine administration remarkably changed their sensitivity of their brain reward system, persisting for at least 36 days after administration.⁵⁴ Kenny and Markou et al.⁵⁴ proved that this aforementioned change could be antagonized by high-affinity nAChR antagonist dihydro- β -erythroidine (DH β E; 3 mg/kg), highlighting the receptor's relevance in this process. This so called "reward hypersensitivity" could substantially add to enhanced weight gain after smoking cessation using palatable food items as reward replacements instead of consuming nicotine.⁵⁴ In total, smoking, endogenous cholinergic signaling as well as distinct eating habits have great, longer lasting impact on mesolimbic reward signaling.

4.5.3 Cholinergic Neuromodulation and Eating Behavior

Administration of nicotine as well as endogenous cholinergic signaling vastly influence central structures regulating appetite as well as body homeostasis. The hypothalamus plays a key role in body homeostasis regulation containing several neuronal areas, amongst others the ventromedial hypothalamus nuclei (VMH), responsible for appetite suppression, and the lateral hypothalamus nuclei (LHA), responsible for the stimulation of appetite.³⁰ Interestingly, within the VMH lie another group of nuclei, called the arcuate nuclei (ARC) which in turn contain central neurons mediating homeostasis: on the one hand, the anorexigenic, i.e. appetite-depressing, proopiomelanocortin (POMC) neurons and cocaine- and amphetamine-regulated transcript (CART) neurons. On the other hand, the ARC also contain the orexigenic, i.e. appetite-stimulating, neuropeptide Y (NPY) and agouti-related peptide (AgRP) neurons (Figure 10).³⁰

Figure 10: Homeostatic Appetite Regulation Signaling

Both orexigenic and anorexigenic group of neurons project to the melanocortin 3 and 4 (MC3R, MC4R) receptor. CART and POMC neurons do so by POMC cleavage product α -melanocyte-stimulating hormone (α MSH) and thereby activating MC4R, which leads to decreased food intake. On the contrary, orexigenic neurons inhibit MC4R, which in turn leads to increased food intake.⁵⁵ The nucleus tractus solitarii (NTS), devoid of a blood-brain-barrier (BBB), mediates peripheral homeostatic signals⁴⁹

Adapted by permission from: Nature, Nature Reviews Neuroscience, Common cellular and molecular mechanisms in obesity and drug addiction, Kenny et al., © 2011

Through activation of POMC neurons, nicotine decreases food intake and increases energy expenditure through stimulation of central β_4 nAChR.⁵⁶ Also, enhanced ACh levels in the NAc increase satiety. In rats, accumbal administration of neostigmine, which inhibits the AChE and therefore functions as a cholinergic agonist, dose-dependently decreases food intake compared to control rats.⁵⁰ Ablation of basal forebrain diagonal band of Broca (DBB) cholinergic neurons in mice through Cre-dependent14 adeno-associated virus (AAV), leads among other effects to higher average body fat, lean mass, and higher average insulin, leptin and blood cholesterol levels.⁵⁷

Moreover, in a fMRI study Kroemer et al.⁵⁸ showed that nicotine decreases functional coupling of homeostasis-regulating neurons in the hypothalamus and reward-mediating neurons in the basal forebrain during the reaction to palatable food cues, apparently reducing their incentive salience potential.

4.6. Positron Emission Tomography (PET) as a Molecular Imaging Technique for Measuring nAChR *In Vivo*

4.6.1 PET Imaging

PET is a molecular imaging technique applying radiotracers that are radioactive-labeled molecules for measuring receptor and cell function.⁵⁹

Tissue distribution of the tracer depends on variables such as cerebral blood flow, plasma clearance, as well as receptor affinity and quantity, therefore kinetic models are applied to analyze specific time-activity data.⁶⁰ Here, the outcome measure (or the receptor availability) is usually the binding potential (BP) representing an index of the relative number of unoccupied receptor sites.⁶¹ Interpretations of PET studies should consider that the BP can rise in case of an increase of receptors as well as a decrease of endogenous receptor ligands. To account for differences in tracer distribution, often the *Volume of distribution* (V_T) is applied: C_T / C_P (tissue (kBq·cm⁻³) / fraction of radiotracer in plasma at (pseudo-)equilibrium (kBq·mL⁻¹)).⁶²

Since PET data offers limited spatial resolution, additional or simultaneous magnetic resonance imaging (MRI) provides robust anatomical co-registration. Furthermore, the combination of PET and functional MRI (fMRI), allows *in vivo* imaging of the dynamics of central receptor signal transmission.¹⁷

4.6.2 Imaging of $\alpha 4\beta 2$ Nicotinic Acetylcholine Receptors

Receptor density of $\alpha 4\beta 2$ nAChR in human CNS is moderately low, making the production of a radiotracer with sufficient brain kinetics and acceptable binding potential quite demanding.⁶³ For many years [¹¹C]nicotine as the first radiotracer⁶⁴, and then 2-[¹⁸F]FA ((S)-3-(azetidin-2-ylmethoxy)-2-[¹⁸F]fluoropyridine) and 6-[¹⁸F]FA ((S)-3-(azetidin-2-ylmethoxy)-6-[¹⁸F]fluoropyridine) have been the commonly used radiotracers for imaging the nAChR (Figure 11).⁶⁵ Disadvantages with these tracers are e.g. high nonspecific binding while specific binding is low, and rapid metabolism for [¹¹C]nicotine. While showing good specific binding, further limitation included slow brain uptake and washout rates for 2-[¹⁸F]FA and 6-[¹⁸F]FA.⁶⁵ Hence, acquisition times of up to 6-7 hours are mandatory. Clinical applications are therefore in need of improvement. Nonetheless, due to the lack of better alternatives, imaging studies with 2-[¹⁸F]FA to examine the nAChR have still been conducted until recently.^{66,67}

Figure 11: Established Radiotracers for $\alpha 4\beta 2$ nAChR PET Imaging

Adapted by permission from: John Wiley & Sons, Journal of Labelled Compounds and Radiopharmaceuticals, Recent PET radioligands with optimal brain kinetics for imaging nicotinic acetylcholine receptors, Horti et al., © 2013

With the development of $[^{18}\text{F}]\text{nifene}$ and $[^{18}\text{F}]\text{AZAN}$ (Figure 12) two new radiotracers proved superiority compared to $2\text{-}[^{18}\text{F}]\text{FA}$ in terms of tracer kinetics and shorter time frames in scanning procedures in quantitative $\alpha 4\beta 2$ nAChR imaging.⁶⁵ $[^{18}\text{F}]\text{nifene}$ is an $\alpha 4\beta 2$ nAChR agonist with specific regional binding and fast kinetics, reaching transient equilibrium at approximately 30-45 minutes, and therefore 7-fold shorter compared to $2\text{-}[^{18}\text{F}]\text{FA}$. Preclinical baboon studies highlighted the suitability of $[^{18}\text{F}]\text{nifene}$ for human studies, even though one must mention the relatively high demands in radiosynthesis.⁶⁵

Figure 12: $[^{18}\text{F}]\text{AZAN}$ and $[^{18}\text{F}]\text{Nifene}$

Adapted by permission from: John Wiley & Sons, Journal of Labelled Compounds and Radiopharmaceuticals, Recent PET radioligands with optimal brain kinetics for imaging nicotinic acetylcholine receptors, Horti et al., © 2013

$[^{18}\text{F}]\text{AZAN}$, which is an $\alpha 4\beta 2$ nAChR antagonist, also demonstrates high non-displaceable binding potential (BP_{ND}) and V_{T} values as well as rapid brain kinetics, reaching steady-state within 90 minutes after injection time.³² Due to its lipophilic character $[^{18}\text{F}]\text{AZAN}$ efficiently penetrates the blood-brain barrier. Blocking studies with cystisine, an $\alpha 4\beta 2$ nAChR selective agonist, varenicline, a partial $\alpha 4\beta 2$ nAChR

agonist, as well as nicotine highlighted substantially lower brain uptake in baboon³² and human⁶³ brain due to competitive receptor binding. This also shows [¹⁸F]AZAN's sensitivity to a potential change in the endogenous ACh pool.

4.6.3 (-)-[¹⁸F]flubatine: a specific $\alpha 4\beta 2$ nAChR radiotracer

In this study, a new, second-generation radioligand for $\alpha 4\beta 2$ nAChR imaging was applied. (-)-[¹⁸F]flubatine which was earlier known as (-)-[¹⁸F]NCFHEB ((-)-[¹⁸F]norchloro-fluoro-homoepibatidine)⁶⁸, is a less noxious derivative of epibatidine. It was developed and clinically validated in Leipzig.^{68,69} There are two known enantiomers (+)-[¹⁸F]flubatine and (-)-[¹⁸F]flubatine (Figure 13).^{70,71}

Figure 13: Both (+)-[¹⁸F]flubatine and (-)-[¹⁸F]flubatine Enantiomers

^aAdapted by permission from: Springer Science+Business Media, European Journal of Nuclear Medicine and Molecular Imaging, (+)-[¹⁸F]Flubatine as a novel $\alpha 4\beta 2$ nicotinic acetylcholine receptor PET ligand-results of the first-in-human brain imaging application in patients with β -amyloid PET-confirmed Alzheimer's disease and healthy controls, Tiepolt et al. 2020, licensed under a Creative Commons Attribution 4.0 International License, <http://creativecommons.org/licenses/by/4.0/>

^bAdapted by permission from: John Wiley & Sons, Journal of Labelled Compounds and Radiopharmaceuticals, (-)-[¹⁸F]Flubatine: evaluation in rhesus monkeys and a report of the first fully automated radiosynthesis validated for clinical use, Hockley et al., © 2013

The improved tracer properties of newly developed (-)-[¹⁸F]flubatine with faster brain kinetics, high binding properties and preferable parent compound metabolism have been shown in several consecutive studies:

Firstly, Gallezot et al.⁷² preclinically proved a dose-dependent reduction in (-)-[¹⁸F]flubatine binding (V_T/f_p) in rhesus monkeys with two acetylcholinesterases (AChE), which leads to an increase of ACh, inhibiting its hydrolysis. This indicates the sensitivity of the radiotracer for measuring endogenous ACh changes (Figure 14).

Figure 14: (-)-[¹⁸F]flubatine’s Sensitivity to Endogenous ACh Changes

Dose-dependent reduction of radiotracer binding, induced by AChE in animal A and B (rhesus monkeys)

Adapted by permission from: John Wiley & Sons, Synapse, Evaluation of the sensitivity of the novel $\alpha 4\beta 2^*$ nicotinic acetylcholine receptor PET radioligand ¹⁸F-(⁻)-NCFHEB to increases in synaptic acetylcholine levels in rhesus monkeys, Gallezot et al., © 2014

Both AChE physostigmine and donepezil induced binding reduction effects in the aforementioned non-human primates: for physostigmine bolus plus infusion injection (0.06-0.28 mg/kg) with decreased binding of 18%–38% in thalamus, 22–43% in basal ganglia, and 15–33% in cortex; and for donepezil bolus injection (0.25 mg/kg), binding was reduced by 14% in the thalamus, 17–20% in the basal ganglia, 9–14% in the cortex, respectively.⁷² The heterogeneity in reduction most likely stems from known interactions of anesthetic agents (ketamine, isoflurane) with ACh release⁷² and was also reported in other studies.^{73,74}

Then, Sabri et al.⁶⁸ conducted the first-in-human application to proof the use of (-)-[¹⁸F]flubatine as an alternative for tracers with slow kinetics, such as 2-[¹⁸F]FA. This trial represents the successful translation from animal studies to application in humans. (-)-[¹⁸F]flubatine exhibits rapid kinetics, especially in cortical areas, as cortical tracer delivery rates are eminent and V_T can be estimated here within 30 minutes using a simple 1-tissue-compartment model (1TCM).⁶⁸ For all regions of interest (ROI), (for exemplary analysis, see 6. Materials and Methods), estimation of V_T can be achieved within a 90-minutes time frame. The radiotracer shows a very stable metabolism with high percentage of parent compound in blood plasma, as can be apprehended in Figure 15.

Figure 15: Metabolism of (-)-[¹⁸F]flubatine

Chromatographic analysis (radio-HPLC) highlights slow degradation and high proportion of parent compound in blood plasma

Reprinted from: NeuroImage, 118, Sabri et al., First-in-human PET quantification study of cerebral $\alpha_4\beta_2$ nicotinic acetylcholine receptors using the novel specific radioligand (-)-[¹⁸F]Flubatine, , 199-208, © 2015, with permission from Elsevier

The fast kinetics of (-)-[¹⁸F]flubatine are demonstrated in the plasma time-activity curves (TACs) (Figures 16 and 17) of the thalamus, frontal cortex and the reference region corpus callosum describing an early initial peak and slow tracer concentration decrease until 270 min.⁶⁹ In TACs the time (x-axis) is plotted against the measured tissue or plasma activity (y-axis).

Figure 16: TACs of (-)-[¹⁸F]flubatine (Blood Plasma, 0-90min)

Figure 17: TACs of (-)-[¹⁸F]flubatine (Blood Plasma, 0-270min)

Figure 16+17: Reprinted from: NeuroImage, 118, Sabri et al., First-in-human PET quantification study of cerebral $\alpha 4\beta 2^*$ nicotinic acetylcholine receptors using the novel specific radioligand (-)-[¹⁸F]Flubatine, 199-208, © 2015, with permission from Elsevier

Following the normal distribution of $\alpha 4\beta 2$ nAChR density (Figure 18) in the brain, V_T in the thalamus (27.44 ± 3.77) exhibits highest values, followed by midbrain, striatum and cerebellum (e.g., putamen: 12.70 ± 0.87), then cortical regions (e.g., frontal cortex: 10.02 ± 0.83), and lowest in the corpus callosum (6.31 ± 0.80).⁶⁸

Another important milestone in the development of imaging approaches with (-)-[¹⁸F]flubatine was the work of Hillmer and colleagues from Yale University, New Haven, CT. Hillmer et al. tested a bolus plus constant infusion protocol with (-)-[¹⁸F]flubatine administration as well as its sensitivity to endogenous ACh changes in humans with a physostigmine challenge.⁷⁵

Figure 19 describes the bolus plus constant infusion paradigm, illustrating an establishment of true equilibrium after approximately 120 min between radiotracer in tissue at receptor site and in plasma. One big advantage of studying receptor binding at true equilibrium in a single-scan (bolus-infusion) approach is the potential to observe slight changes in binding to eventually relate this to changes in neurophysiological processes, like enhanced endogenous neurotransmitter release. Changes in the TACs can then be referred to given stimuli (e.g. visual food cues). Taking regions under account that apparently do not reach true equilibrium after 120 minutes post injection, Hillmer et al. also suggested a *tissue clearance correction* (TCC).⁷⁶

Figure 19: Bolus Plus Infusion Protocol

Time (x-axis) is plotted against (-)-[¹⁸F]flubatine (y-axis) standard uptake value (SUV).

Abbreviations: SUV: describes the ratio of regional radiotracer compared to whole-body radioactivity concentration and is therefore a relative quantification measurement of specific radiotracer uptake.⁷⁷

Reprinted from NeuroImage, Vol. 141, Hillmer et al., Imaging of cerebral $\alpha 4\beta 2^*$ nicotinic acetylcholine receptors with (-)-[¹⁸F]Flubatine PET: Implementation of bolus plus constant infusion and sensitivity to acetylcholine in human brain., 71-80, © 2016, with permission from Elsevier

In the following, Hillmer et al. showed a stable metabolism in humans with high proportions of parent compound in plasma (Figure 20).

Figure 20: Parent Fraction of (-)-[¹⁸F]flubatine

After 90 min still almost 90% and after 210 min almost 80% remains of unchanged parent compound.

Reprinted from NeuroImage, Vol. 141, Hillmer et al., Imaging of cerebral $\alpha 4\beta 2$ nicotinic acetylcholine receptors with (-)-[¹⁸F]Flubatine PET: Implementation of bolus plus constant infusion and sensitivity to acetylcholine in human brain., 71-80, © 2016, with permission from Elsevier

To evaluate (-)-[¹⁸F]flubatine's sensitivity to changes in endogenous ACh levels, a physostigmine challenge in humans was conducted in a two-scan (bolus injection), as well as in a single-scan bolus-infusion paradigm, lead to small, but significant changes in V_T / f_P ⁷⁵, as depicted in Figure 21.

Figure 21: (-)-[¹⁸F]flubatine Physostigmine Challenge

Part A: Changes in (-)-[¹⁸F]flubatine: Physostigmine challenge (1.5mg) after 125 min lead to a decline in V_T/f_P in depicted brain areas (Striatum, Frontal Cx, Cerebellum), with stable parent compound metabolism in arterial plasma (blue dots)

Part B: Changes in (-)-[¹⁸F]flubatine binding from baseline (110-130 min) to post-challenge (200-220 min); voxel-wise (-)-[¹⁸F]flubatine V_T/f_P images⁷⁵

Abbreviations: Frontal Cx: Frontal Cortex; SUV: Standard Uptake Value

Reprinted from NeuroImage, Vol. 141, Hillmer et al., Imaging of cerebral $\alpha 4\beta 2^*$ nicotinic acetylcholine receptors with (-)-[¹⁸F]Flubatine PET: Implementation of bolus plus constant infusion and sensitivity to acetylcholine in human brain., 71-80, © 2016, with permission from Elsevier

To conclude, the work by Hillmer et al. provided evidence that the bolus-infusion administration protocol is suitable for quantification of V_T at fast kinetic rates (equilibrium at 120 min) and further highlights (-)-[¹⁸F]flubatine's sensitivity to changes in endogenous ACh levels.

4.7 Volumes of Interest (VOI)

According to recent literature we examined pivotal brain regions with cholinergic neuromodulation (Table 2) which are involved in reward and attentional signaling.

Table 2: Preselected Brain Regions with Neurophysiological Function

Volumes of Interest (VOI)	Neurophysiological function
Amygdala	Modulation of emotional and affective state as well as memory and attention ⁷⁸
Head of Caudate (Nc. Caud.)	Important region in goal-directed action selection circuitry as well as motor function ⁷⁹
Hypothalamus (HPT)	Regulation of body homeostasis e.g. in terms of feeding, which is critically modulated by cholinergic signaling ⁴⁹
Insula	Multifunctional structure including processing of salient cues, regulation of affective states as well as interoceptive awareness ⁸⁰
Nucleus Accumbens (NAc)	Plays a pivotal role in mesolimbic reward signaling, e.g. computing food reward stimuli whilst undergoing cholinergic neuromodulation ^{50,51}
Nucleus Basalis of Meynert (NBM)	Part of the basal forebrain, responsible for the majority of cholinergic innervation of almost the entire corticle mantle ³⁸
Orbitofrontal Cortex (OFC)	Assessment of reward value of sensory input as well as flexible behavioral adaptation in regards to stimulus-response paradigms ⁸¹
Prefrontal Cortex (PFC)	Executive control center responding to external and internal input with apt behavioral responses ⁸²
Thalamus	Encloses vast amount of nAChR ⁶⁸ ; crucial role in processing of sensory information as well as action-selection circuitry involving cholinergic neuromodulation responding to external cues ⁸³
Ventral Tegmental Area (VTA)	Plays a central role next to NAc in mesolimbic reward signaling, which is greatly modulated by cholinergic neurons ⁵⁰

5. Objective

Cholinergic modulation of basal forebrain, thalamocortical as well as mesolimbic networks has a pivotal role in cognitive function such as attention and information processing about salience and reward signaling. This implies that changes in ACh transmission may lead to altered cognitive control that augments altered eating behavior leading to obesity. The aim of the present study was therefore to investigate biological mechanisms of cholinergic neurotransmission, specifically the $\alpha 4\beta 2$ nAChR as a potential pharmacological target in obesity.

The $\alpha 4\beta 2$ nAChRs availability was quantified by means of PET and the highly $\alpha 4\beta 2$ nAChR-selective radioligand (-)-[^{18}F]flubatine under baseline and stimulus conditions (salient visual food stimuli) in order to assess changes of central cholinergic activity in individuals with obesity (OB) and normal weight (NW). Thereby, regional availability of $\alpha 4\beta 2$ nAChR was measured by applying VOI-based analyses to calculate V_T of (-)-[^{18}F]flubatine from PET data as the primary outcome measure.

- 1.) **The primary hypothesis** of the study is that **$\alpha 4\beta 2$ nAChR availability is higher in OB participants compared with NW controls** under baseline and stimulus conditions in brain regions important for:
 - cue detection, the generation of attention and motivational brain responses such as NBM, PFC, OFC, the head of the caudate and the thalamus
 - mesolimbic reward signaling such as the VTA and NAc
 - neuromodulation of affective states, interoceptive awareness as well as energy homeostasis such as the amygdala, insula and the HPT
- 2.) **The secondary hypothesis** is that changes in eating behavior scores on a **visual analogue scale (VAS)** are **correlated** with changes in **$\alpha 4\beta 2$ nAChR availability**. **The relationship differs** between **resting state and stimulus conditions** in both NW as well as OB.

These data together should provide hints towards an association between the $\alpha 4\beta 2$ nAChR availability and cognitive function such as attention, the processing of salience information and hedonic eating as neurobiological underpinnings of obesity. This will help to frame future intervention strategies in individuals with the propensity to develop obesity.

6. Materials and Methods

6.1 Ethics statement

This study was approved by the *Bundesamt für Strahlenschutz (BfS)* / Federal Office for Radiation Protection, local ethics committee of the Medical Faculty of the University of Leipzig (225/15-ek) and complies with the 1964 Declaration of Helsinki including current revisions. It follows the guideline for Good Clinical Practice (GCP) and is registered at the *Deutsches Register für klinische Studien (DRKS)* under DRKS00010927.

6.2 Study Design

The (-)-[¹⁸F]flubatine PET/MR imaging study was a prospective, open, proof-of-concept, monocentric phase 0/I study. Study participants completed three visits (Figure 22) including screening examination (Visit 0) and telephone follow-up (Visit 3).

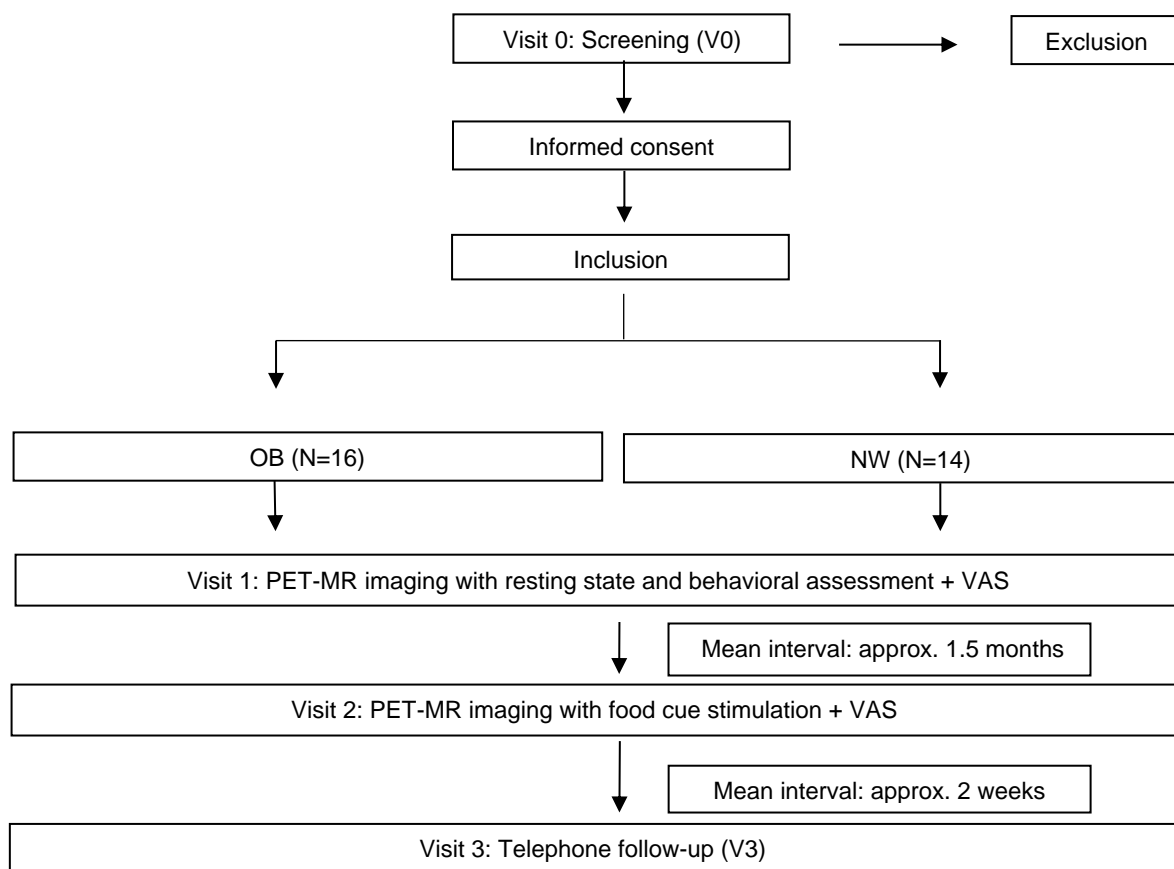

Figure 22: Study Design Flowchart

Abbreviations: OB: participants with obesity; NW: normal-weight participants; VAS: visual analogue scale assessing current state of emotions such as craving, hunger or sadness after each examination/visit

At screening visit (V0) information regarding personal data case history and concomitant diseases were received. Before each examination day (baseline and stimulus), brief clinical history and physical examination was conducted. To exclude eating disorders or manifest depression, we applied Beck Depression Inventory (BDI) and Eating Disorder Examination Questionnaire (EDE-Q8). Pregnancy was further excluded by β -hCG testing.

6.3 Study participants

Recruitment of participants included public postings and ecotrophological consulting meetings at the University Medical Center Leipzig (UKL). The whole study population consisted of 30 participants. Data acquisition was carried out in 14 NW (N=14; mean BMI 21.8 ± 1.90 kg/m²; 11 females; mean age 28.1 ± 7.58 years; ranging from 19-45 years) and 16 study participants with OB (N=16; mean BMI 37.8 ± 3.18 kg/m²; 10 females; mean age 40.6 ± 14.0 years; ranging from 20-62 years). All recruited individuals were non-smokers. Exclusion and inclusion criteria were applied to assess eligibility of study participants and a drug screening was conducted to ensure that no illicit substances that interfere with brain states and applied radiotracer were taken. Informed consent was obtained in each study participant. NW with TFEQ disinhibition score ≥ 8 were ruled out from study participation.^{84,85} Other inclusion and exclusion criteria comprised:

Inclusion Criteria

- OB BMI ≥ 30 kg/m²
- NW BMI ≤ 25 kg/m²
- Age: 18-65 years
- Sex: male and female
- Non-smoker
- Written informed consent
- Body shape to fit in MRI scanner

Exclusion Criteria

- Neurological / neuropsychiatric disorders stated in case history
- Neurosurgical operations in the past
- Structural brain lesions (stroke, trauma, etc.)
- Permanent use of psychotropic drugs
- Alcohol and substance abuse (checked through conducted drug screenings)
- Severe psychotic disorders and/or communicational deficits, that could affect informed consent
- Simultaneous participation in other clinical investigations
- General contraindications for nuclear medical examination, such as pregnancy or breastfeeding women, or for MRI (claustrophobia, heart pacemakers, ferromagnetic applications, etc.)
- Vegan nutrition habits

6.4 Visual Analogue Scale (VAS)

To obtain data on satiety state and hunger, feeling of disinhibition of eating, i.e. loss of control, or feelings of craving during the scans, the VAS was filled out after baseline and stimulus examination. The continuum at hand (Figure 23) was translated into numbers ranging from 0 (“not at all”) to 100 (“extremely”) and correlated with calculated V_T of (-)-[^{18}F]flubatine.

	Not at all	immensely
	0	100
1) Are you currently hungry?		
2) Are you currently craving for food?		
3) Are you currently experiencing a loss of control of your eating habits?		
4) Are you full, i.e. experiencing current state of satiety?		
5) Do you think food is tasty?		

Figure 23: Visual Analogue Scale

Self-assessment of current satiety state, cravings for food or loss of control

6.5 PET/MR Imaging

The $\alpha 4\beta 2$ nAChR radioligand (-)-[^{18}F]flubatine was applied twice on separate days, i.e. under baseline (resting state) and stimulus conditions, using the bolus-infusion protocol previously established by Hillmer et al.⁷⁵ (4.6.3 (-)-[^{18}F]flubatine: a specific $\alpha 4\beta 2$ nAChR radiotracer). Each scan was carried out with a truly simultaneous PET/MR imaging scanner (*Biograph mMR*; Siemens Healthineers, Erlangen). Radiotracer was synthesized using the synthesis module *TRACERlab FX FN* (General Electric Healthcare) under GMP conditions according to Patt el al..⁸⁶ Two intravenous cannulae were administered before each scan, one for the application of radiotracer, the other for intravenous blood sampling. The total scanning duration was 165 minutes, subdivided in two data acquisition time frames: from 0 to 60 minutes p.i. and, after having reached radiotracer equilibrium, from 120 to 165 minutes post injection. Before radiotracer application, MR imaging UTE (ultra-short echotime) sequence for attenuation correction was conducted.

In total, approximately 300 MBq of (-)-[^{18}F]flubatine was applied per scan. Each scan started with a 90-second bolus administration (10 ml; administered activity in NW, mean: 195 ± 26 MBq; in OB, mean: 202 ± 4 MBq), followed by constant tracer infusion (98 ml, infusion rate of 0.6 ml/min; NW, mean: 89 ± 14 MBq; OB, mean: 91 ± 1 MBq). During the first time frame of each visit, we carried out three-dimensional list mode acquisition for PET data and T1-weighted MP-RAGE (echo time: 2.53 ms, repetition time: 1900ms, inversion time: 900 ms) to obtain anatomical data for imaging data co-registration and to rule out neuroanatomical abnormalities. The acquired PET data were reconstructed into a 256×256 matrix (voxel size: $1.0 \times 1.0 \times 2.03$ mm³) using the built-in 3D ordered subset expectation maximization algorithm with 8 iterations, 21 subsets and a 3-mm Gaussian filter. Standard corrections for decay, scatter, dead time, and attenuation were performed.⁸⁷ Figure 24-26 depict radiotracer application according to the bolus-infusion protocol, starting with (-)-[^{18}F]flubatine bolus. After 60 minutes, study participants left the scanner while still receiving radiotracer infusion to reach radiotracer equilibrium after 120 minutes post injection.

Visit 1: Baseline Assessment (V1)

At 120 minutes p.i. fMR imaging data (EPI, echo-planar imaging) and structural MR imaging data (T1 MP-RAGE) together with three-dimensional list mode PET data acquisition was carried out (Figure 24). Scan ended at 165 minutes post injection.

Figure 24: Baseline Examination

Abbreviations: UTE: ultra short-time echo sequence for Attenuation Correction⁸⁸;
 MP-RAGE: magnetization prepared rapid gradient echo; EPI: echo-planar imaging

Figure 25: PET/MR Imaging Examination: (-)-[¹⁸F]flubatine Bolus Application

Visit 2: Visual Food Cue Stimulation (V2)

The whole visual stimulation task lasted 14.2 minutes, starting at 120 minutes p.i. when equilibrium was reached. A beamer projected the food items onto a screen at the back of the scanner. Placing a mirror onto the MR imaging head coil in front of the face, the participants were able to look at the displayed visual food cues (n= 80 items). During the stimulation scan, a standard set of salient food cues were presented in a randomized block design.

Each visual food cue was displayed for 3 seconds. After every presented item, the individuals had 1.9 seconds to rate the previously shown cue: being able to choose between four buttons in a single-piece apparatus in their hands, participants were asked to answer on a 4-point Likert scale ranging from very much (“sehr”) to not at all (“gar nicht”) how much they want to eat the presented food item at that certain moment (see Figure 27). Jitter between rating process and following presented item lasted between 1.8 and 7.8 seconds. Scan ended at 165 minutes post injection.

Figure 26: Stimulus Examination

Abbreviations: UTE: ultra short-time echo sequence for Attenuation Correction⁸⁸;
 MP-RAGE: magnetization prepared rapid gradient echo; EPI: echo-planar imaging

Visit 3: Telephone Follow-up (V3)

Approximately two weeks after V2, a telephone follow-up was conducted in order to control for any (severe) adverse events, changes in concurrent medication or concomitant diseases.

6.6 Imaging Data and Blood Plasma Analysis

Co-registration and motion-correction procedures of PET and MR imaging data were performed using SPM2-software (*Statistical Parametrical Mapping, Wellcome Trust Centre for Neuroimaging, University College London, UK*). VOIs in five consecutive transversal brain slices were manually drawn using PMOD software (*PMOD Technologies Ltd., Zurich, Switzerland*). Left and right VOIs (Figure 28, following page) of each hemisphere were later summed to their mean value to conduct statistical analyses (6.7 Statistical Analyses). Venous blood sampling was obtained for the calculation of our primary outcome measure V_T at 90, 105, 120, 135, 150, 165 minutes p.i. (Figure 27). This was based on the 120-165 minutes p.i. tracer concentration in tissue (C_{tissue}) at equilibrium divided by total radioactivity concentration in venous blood plasma (C_{plasma}), according to Innis et al.⁶² Each sampling included 4 serum tubes which contained 2 ml, adding up to a total of 48 ml. Figure 27 depicts a TAC of one healthy volunteer in the NAc.

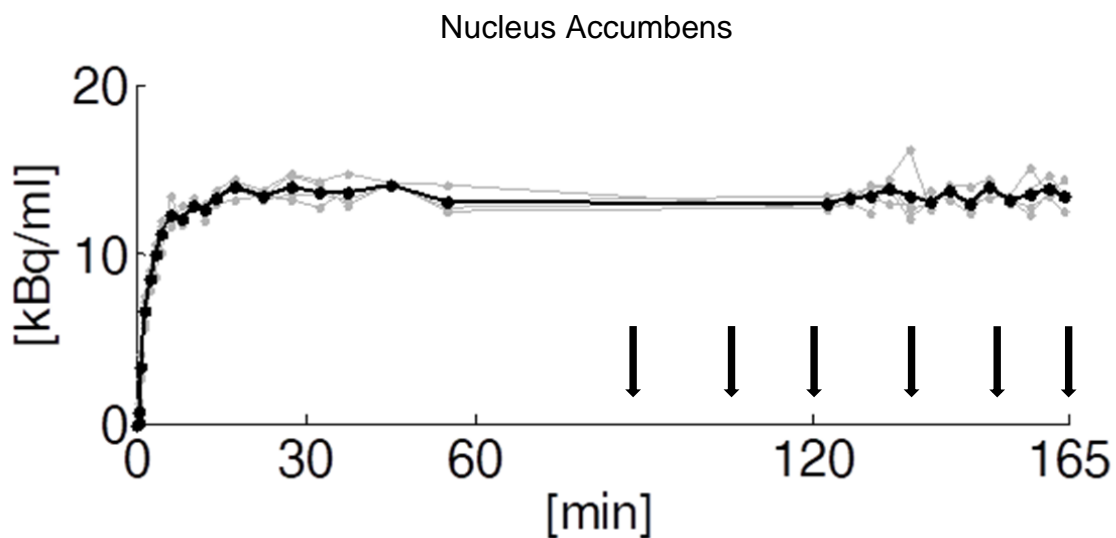

Figure 27: TAC of One Healthy NW Volunteer

Equilibrium is reached after latest 120 min p.i with bolus-infusion protocol in nucleus accumbens, according to Hillmer et al.⁷⁵. Schematic time frame of venous blood sampling for V_T calculation at 90, 105, 120, 135, 150 and 165 min p.i.

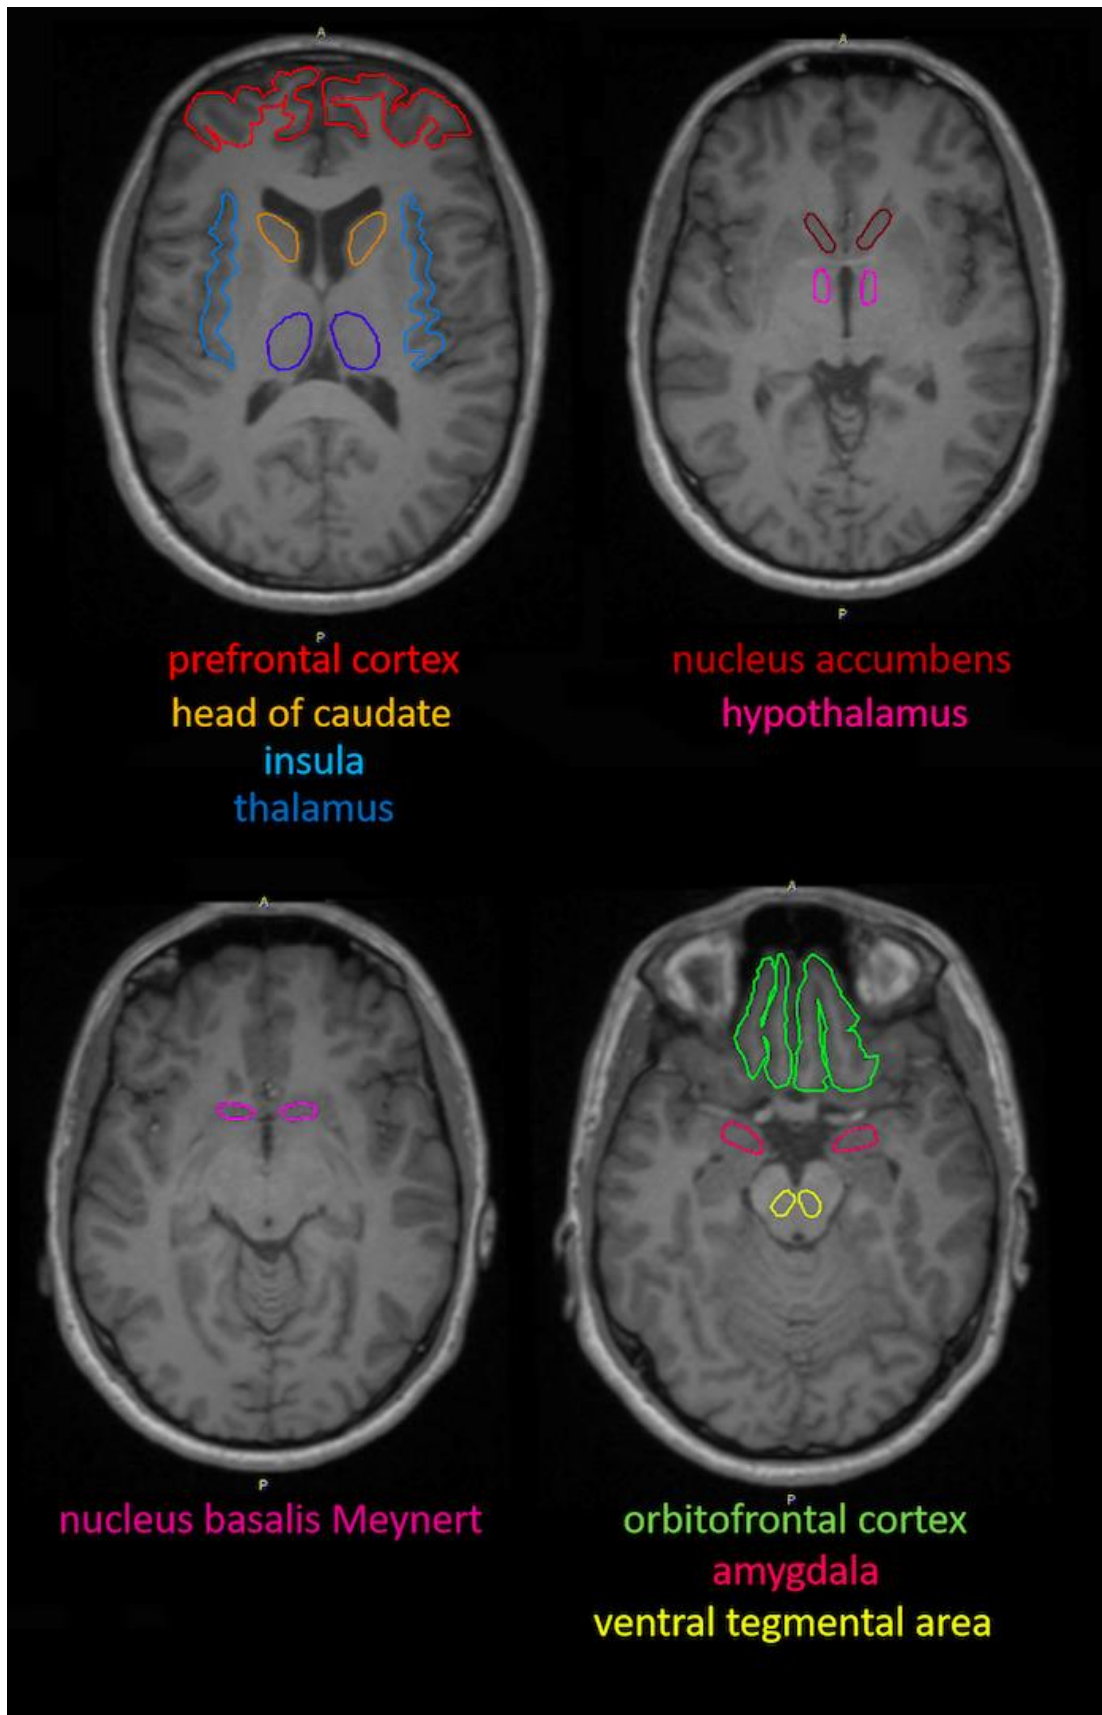

Figure 28: Volumes of Interest (VOI) of Preselected Brain Regions That Play a Crucial Role in Cholinergic Signaling

6.7 Statistical Analysis

Data analyses were carried out using *jamovi* (version 1.6, open source computer software). Applied Q-Q plots of our data showed distinct variation from normal distribution in some of our analyzed VOIs, making the follow-up Levene and Shapiro-Wilk tests to check for normal distribution and equality of variance redundant.

We therefore used non-parametrical Mann-Whitney-U test (MW-U) and to compare demographic parameters such as BMI, body weight, age as well as (-)-[¹⁸F]flubatine application dosage between normal weight and obese study group. We also used Fisher's Exact test to compare the gender of our two study groups. To evaluate V_T differences in each VOI we conducted ANCOVA (Analysis of Covariance) correcting for age (covariate age $p < 0.05$ between NW and OB). Intra-individual differences between rest and stimulus conditions were assessed using the non-parametrical Wilcoxon dependent samples analysis. To investigate the relationship between VAS scores and $\alpha_4\beta_2$ nAChR availability at resting state and stimulus conditions we applied Spearman rank correlation analyses. We also correlated changes between baseline and stimulus conditions via spearman rank correlation coefficients matrix of $\alpha_4\beta_2$ nAChR availability and VAS scores.

7. Results

7.1 Epidemiological Data

Table 3 shows demographics as well as applied radiotracer concentrations. Dropouts occurred due to dizziness, nausea or canceling of visits of our study participants.

7.2 Baseline and Stimulus V_T Calculations

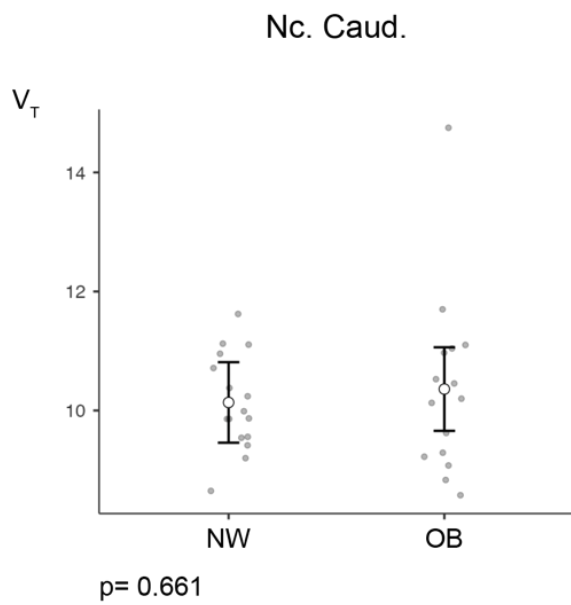

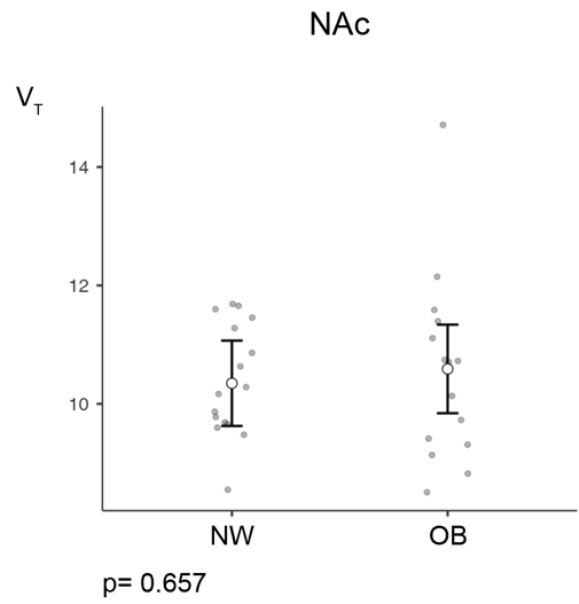

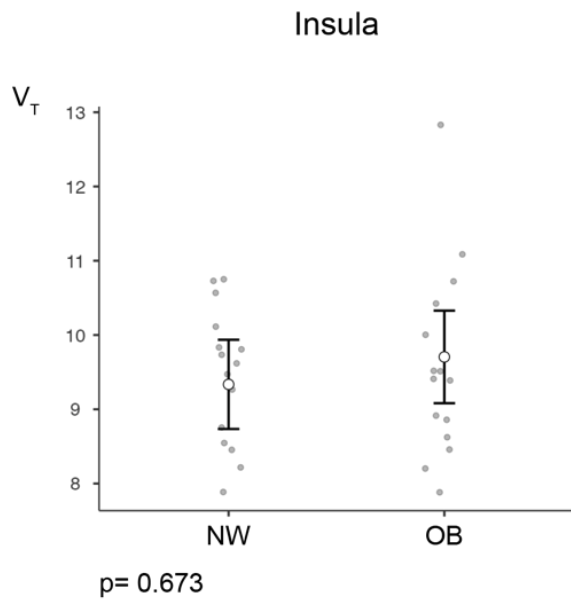

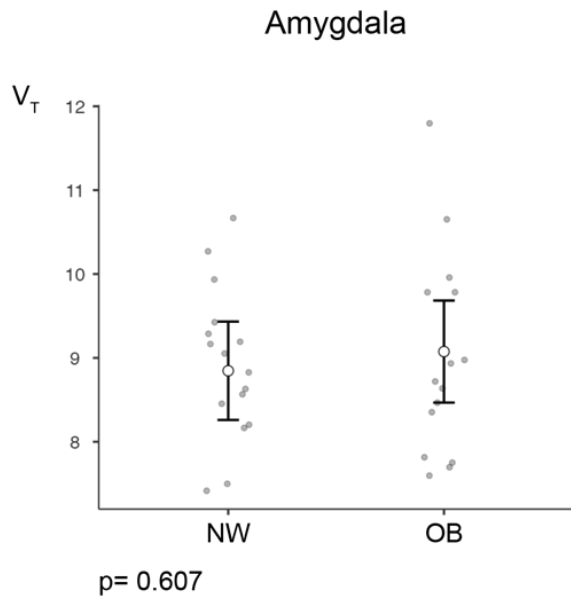

To evaluate V_T differences in each VOI between NW and OB, we conducted ANCOVA correcting for age in both baseline and stimulus conditions. Table 4 and Figure 29 indicate the data distribution and statistics of calculated V_T under baseline conditions. OB tend to show lower V_T in the NBM and higher V_T in the thalamus although, overall, no statistically significant differences in V_T between our two groups under baseline conditions were found.

Baseline Scan (Visit 1)

Table 4: Distribution Volumes (V_T) in NW and OB Under Baseline Conditions (ANCOVA Correcting for Age)

Baseline (Visit 1)	Mean V_T NW	Mean V_T OB	Mean difference	p value	Effect Size (η_p^2)

7.3 Intra-individual V_T Assessment Between Baseline and Stimulus Conditions

We intra-individually assessed differences in V_T in a paired samples analysis in each study group between baseline and stimulus conditions, looking for changes in V_T that are caused by the presentation of visual food cues. In both paired samples analyses (comparison NW and OB: baseline and stimulus scan, respectively) no statistically significant differences in V_T were found (Table 6, Table 7). However, OB showed greater intra-individual mean differences in V_T between resting state and stimulus conditions (Figure 31) and a tendency to smaller p values compared with NW (e.g. VTA NW: mean difference 0.02, $p=1.00$; OB: mean difference -0.686; $p=0.11$)

Table 6: Baseline Versus Stimulus V_T Assessment in NW Participants

VOIs (NW)	Baseline; mean V_T	Stimulus; mean V_T	Mean difference	p value	Effect size

7.4 Correlational Analyses of VAS Versus V_T

Figure 33 shows the correlation between regional V_T and obtained VAS scores of NW. NW present statistically significant negative correlation coefficients between VAS Score “craving” and several VOIs such as VTA ($r= -0.61$), NAc ($r= -0.58$), OFC ($r= -0.52$), and insula ($r= -0.55$) as well as thalamus ($r= -0.74$). Interestingly, these significant negative correlations seem to disappear under stimulus conditions.

Figure 34 depicts the correlation between V_T and VAS scores of OB. This analysis revealed a statistically significant negative correlation between VAS Score “disinhibition” and distinct VOIs such as NBM ($r = -0.54$), thalamus ($r = -0.64$), VTA ($r = -0.58$), NAc ($r = -0.56$), OFC ($r = -0.52$), PFC ($r = -0.59$). No further significant correlations under stimulus conditions were found. Figure 35 and Figure 36 highlight group-specific differences in correlational analyses.

8. Discussion

This is a prospective, open, monocentric phase 0/I, proof-of-concept PET/MR imaging on cholinergic neuromodulation in obesity and its role in processing the effects of salient food stimuli. Dynamic PET data were obtained using the $\alpha 4\beta 2$ nAChR specific radiotracer (-)-[^{18}F]flubatine. We specifically elucidated nAChR with (-)-[^{18}F]flubatine in an *in vivo* human baseline versus stimulus experimental design not only investigating resting state but also task-related cholinergic signaling in human obesity. Final outcome measures were differences in (-)-[^{18}F]flubatine V_T between NW and OB in resting state and stimulus conditions in unpaired as well as paired samples analyses. Secondary, we explored whether changes in eating behavior measured by VAS (visual analogue scores) are correlated with changes in $\alpha 4\beta 2$ nAChR availability.

Baseline V_T Calculations

In an independent samples analysis we compared $\alpha 4\beta 2$ nAChR availability between NW and OB under baseline conditions. Correcting for age, we did not find statistically significant differences in V_T between our two study groups. Yet, we did observe a tendency to lower OB V_T in NBM compared with NW. The NBM is the central basal forebrain area of cholinergic transmission that innervates the amygdala as well as almost the entire cortical mantle.²⁶ Changes in nAChR availability in this region can therefore be assumed to affect widespread neuronal circuits computing sensory stimuli. Bentley et al.⁸⁹ describe neuronal network activation as a function of ACh levels which can be depicted in an inverted U-shape, similar to the Yerkes-Dodson law highlighting non-linear relationships between arousal, cognitive activation and task performance.⁹⁰ Thereby, Bentley et al. compared a so called relative hypocholenergic state to cigarette-deprived smokers and sufficient cholinergic tone to non-smokers. As mentioned above, overstimulation of nAChR can lead to receptor desensitization. Quick et al.⁹¹ define the process of desensitization as a decrease or loss of biological response following prolonged or repetitive stimulation.

The tendency to lower baseline V_T of OB could potentially indicate a state of food stimuli deprivation during the scan represented by nAChR desensitization, similar to nicotine-deprived smokers. Contradicting this argument Graupner et al.²⁸ pointed out that nAChR have their highest affinity to its ligand while being desensitized. An interesting approach to disentangle this phenomenon would be to differ between fast-

onset and slow-onset desensitized receptor state in our study group, as both differ in their ligand affinity.²⁸ Limited temporal resolution of PET examinations however might not be able to detect changes in nAChR conformation as this happens in a millisecond to minutes timeframe versus temporal resolution in neuroreceptor PET ranging from 0.5 min – 10 min.^{17,28,35}

Interestingly, Picciotto et al. pointed out that nicotinic stimulation of nAChR leads to a shift from tonic to phasic firing of DA neurons, potentially increasing the salience of sensory cues as inhibitory GABA release is rapidly decreased due to presynaptic nAChR desensitization.³⁵ These mesolimbic feedback loops affected by cholinergic neuromodulation could therefore enhance the detection of cues associated with reward, such as food.

Also, studies in rats showed that nAChR desensitization following nicotine exposure lead to a long lasting increase in reward sensitivity, which was mediated by nAChR upregulation.⁵⁴ As this increase in reward sensitivity could also be transferred to other substances of abuse, the sequence of cholinergic stimuli leading to desensitization and lastly nAChR upregulation to recover from desensitization, could explain a potential pathway to enter a state of “reward hyperexcitability”.⁵⁴

Simulating a state of nAChR desensitization through ablation of cholinergic neurons using a Cre-dependent14 adeno-associated virus (AAV) in the BF in rodents, lead to hyperphagia and substantial weight-gain compared to their control group.⁵⁷ Also, nicotinic stimulation of anorexigenic neurons in the hypothalamus induces satiety.⁵⁶ Mitigated cholinergic signaling of NBM in our OB study group, could therefore impair satiety pathways, eventually leading to prolonged appetite. Conversely, Dezfuli et al. showed that prolonged nAChR desensitization in mice through application of β 2-selective agonist sazetidine-A (SAZ-A) lead to decreased body weight and food intake.⁹² Lastly, the precise role of nAChR desensitization affecting eating behavior thus remains somewhat elusive.

Stimulus V_T Calculations

Our two-tailed independent samples analysis under stimulus conditions showed significantly higher α 4 β 2 nAChR availability in the thalamus region in OB compared to NW. Correcting for age, these findings robustly endured ($p=0.028$; $\eta^2p=0.167$). The thalamus plays a pivotal role in the processing of sensory information as well as action-selection circuitry involving cholinergic neuromodulation responding to external cues.⁸³

It is also the brain region with the highest density of $\alpha 4\beta 2$ nAChR, according to Sabri's et al. *in vivo* data.⁶⁸ Functional aberrations in cholinergic signaling could therefore play an important role in shaping pathological (eating) behavior.

Rodent research showed that activation of thalamic nAChR increased the firing probability of excitatory neurons conveying auditory, sensory signals through thalamocortical pathways.⁹³ Interestingly, this nicotinic enhancement could be reversed by applying the high-affinity nicotinic receptor antagonist dihydro- β -erythroidine (Dh β E).

One possible mechanism that underlie cholinergic importance in thalamocortical signaling could be that stimulation of thalamic nAChR induces an excitatory glutamate release onto PFC neurons, which in turn regulate processes like attention or cortical arousal.⁹⁴ Also, optical recording studies in mice showed that ACh as a neuromodulator serves to weaken intercortical circuitry and strengthens bottom-up sensory information processing through enhanced thalamocortical signaling.⁹⁵ Boswell et al.⁹⁶ compile in a meta-analysis insights from food cue reactivity research with OB study participants, summarizing similar reactivity levels comparing actual food cues with visual ones, and higher effects comparing visual to olfactory cues. Interestingly, cigarette-deprived smokers show similar thalamic fMR imaging activation patterns due to stimulation by visual smoking cues.⁹⁷ Halassa et al.⁹⁸ furthermore highlight the importance of thalamic nuclei, namely the pulvinar and the mediodorsal nucleus, in the regulation of inter- as well as intracortical functional connectivity to adapt to external stimuli, such as visual cues. Augmented thalamic gating of sensory information (through cholinergic signaling) could therefore create an attentional bias, eventually leading to overeating.

The ingestion of a high-fat diet (HFD) in mice lead to augmented levels of impulsivity and this was associated with higher prefrontal $\alpha 4\beta 2$ nAChR density, as again nicotinic antagonization lead to behavior normalization.¹⁵ Mean BMI of our OB study group was 37.8 kg/m² (± 3.18 SD), making the regular consumption of a HFD with similar long-lasting neurobiological effects for them highly probable.

Common phenomena in obesity research include higher degrees of impulsivity and loss of inhibitory control in individuals eating behavior due to alterations in several neurotransmitter signaling pathways.^{11,23,99} Our data suggest that these could also be, in part, due to enhanced (cholinergic) thalamocortical signaling in OB participants compared to NW. However, this is a pilot study and data should be considered as

preliminary. Yet, findings of our study are highly relevant and should stipulate validation studies by increasing sample size.

Intra-individual V_T Assessment Between Baseline and Stimulus Conditions

The two-tailed paired samples analyses (Wilcoxon rank) investigated baseline versus stimulus $\alpha 4\beta 2$ nAChR availability in NW and OB. Here, we did not find statistically significant differences in intra-individual $\alpha 4\beta 2$ nAChR availability.

However, we did observe a tendency for greater V_T mean differences in OB participants compared to NW. The increase in thalamic as well as cerebellar V_T in OB between baseline and stimulus conditions was not observed in NW, where V_T remained stable. Hence, the presentation of salient food items created robust V_T differences in OB compared with NW.

As described in recent research^{27,100} cholinergic signaling functions in phasic as well as tonic ACh release patterns. Phasic signaling happens in milliseconds, potentially leading to rapid neuromodulation, which is a lot faster than the temporal resolution of a PET examination can offer.¹⁷ An interesting approach to enhance temporal resolution could be applying seed-based fMR imaging analyses to further disentangle the role of phasic signaling in the processing of sensory cues, such as food items.

Correlational Analyses of VAS Versus V_T

To investigate the relationship between cholinergic neuromodulation and eating behavior, we correlated regional $\alpha 4\beta 2$ nAChR availability with VAS scores. Here, NW showed statistically significant negative correlations between different brain regions responsible for mesolimbic reward signaling (VTA and NAc), reward value attribution (OFC), interoceptive awareness (Insula) and VAS score “craving” under baseline conditions. OB demonstrated negative correlations between several brain regions relevant for reward signaling (VTA, NAc), interoceptive awareness (Insula), or cholinergic signaling (NBM, Thalamus) and VAS score “disinhibition” under baseline conditions. Less significant correlations for both study groups under stimulus conditions were found. The fact that our two study groups present different correlation profiles under baseline and stimulus conditions could highlight that altered eating behavior assessed by VAS scores can be associated with contrasting cholinergic signaling profiles.

However, the interpretation of the exact nature of our correlations is rather challenging as upregulation or desensitization of nAChR can occur³⁵ and this would have an impact on investigated V_T and hence correlational analyses.

We also saw differences between our study groups examining the correlation of changes in $\alpha 4\beta 2$ nAChR availability and VAS Scores between baseline and stimulus conditions. While we see a significant positive correlation between HPT and “satiety” in our NW study group, a significant negative correlation between NAc and “disinhibition” in OB could be found. The first could indicate a physiological, hypothalamic energy homeostasis in NW involving cholinergic signaling.¹⁰¹ The latter could once again point out to group differences in cholinergic neuromodulation influencing accumbal mesolimbic reward signaling. Paolone et al. point out that in obesity, cholinergic modulation of top down, attentional control seems to be altered in individuals who attribute high incentive salience to rewarding cues.⁴⁴ Taken together, these associations might be a further hint for disturbed hedonic pathways in obesity with reduced top-down control of mesolimbic centers towards rewarding food cues mediated by $\alpha 4\beta 2$ nAChR.

Limitations

Being an exploratory analysis, we allow ourselves to look and interpret tendencies in V_T differences ($p= 0.05 - 0.15$) while we did not conduct a Bonferroni correction, either. Moreover, as in other neuroimaging studies number of study participants is limited and that might impact the statistical power of our analysis ($n= 30$ in total, baseline and stimulus examination completed $n= 27$). The relatively small effect size may be due to the current small sample size, as previous case number estimates indicated a participant number of at least $n= 60$ to achieve statistically significant group differences. The estimate was based on results (SD, mean V_T) from analogous exploratory receptor availability studies.^{102,103}

It was especially challenging to recruit eligible participants with obesity due to the following reasons: they all had to be mentally healthy, non-smokers and without any neuropsychiatric medication or concomitant diseases. Yet, a lot of potential participants were suffering from mental disorders, also underlining the important association between obesity and mental disorders. Total bore size measures 60cm,

resulting in closely fitted OB examination conditions. Some potential participants even had to be ruled out due to lack of eligible body shape to fit in the scanner.

Another factor that should be discussed is the partial volume effect. One of the key regions of cholinergic signaling is the NBM. As it is a relatively small region, manually drawn VOIs of that region could therefore be vulnerable to partial volume effect errors (PVE). We used manually drawn VOIs to account for physiological alterations in individual neuroanatomy. Thomas et al. also established a toolbox to compensate for PVE in PET imaging studies, which could be a promising next step to increase neuroimaging accuracy.¹⁰⁴

The calculation of primary outcome measure V_T was based on the 120-165 minutes p.i. tracer concentration in tissue (C_{tissue}) at equilibrium divided by total radioactivity concentration in venous blood plasma (C_{plasma}). Own pilot data using arterial input function without metabolite correction generated about 10% lower V_T for all regions, without important biasing effect on V_T .⁶⁸ Also, the relative standard deviation of V_T was even lower with input functions without metabolite correction. Mathematical correction for metabolization was therefore not conducted as focus of this study was the examination of baseline versus stimulus examination.

Outlook

The study is currently with extension of study participants, thus further data will be gathered to draw a specific picture of the neurobiological mechanism of cholinergic signaling in human obesity. We will also subdivide our participants in low (LD) and high disinhibition (HD) eating characteristics, according to the TFEQ¹⁰⁵ and investigate $\alpha 4\beta 2$ nAChR availability differences between LD and HD. Next to recruitment of more study participants (N=60 in total), we will apply seed-based fMR imaging analyses to examine $\alpha 4\beta 2$ nAChR availability, functional connectivity and the potential implications of these joint data analyses on neurobiological computation of salient food cues. Another next step in phase 0/I studies could include a pharmacological challenge applying partial $\alpha 4\beta 2$ nAChR agonist varenicline for the examination of $\alpha 4\beta 2$ nAChR occupancy and adequate dose adjustment in human clinical trials. This is in line with prior studies applying varenicline. Here, decreased sugar intake in mice⁵¹ as well as dampened mesolimbic dopamine release in nicotine-dependent humans could be proven.¹⁰⁶

Conclusion

To conclude, this study was the first in-human analysis investigating cholinergic signaling in regards to eating behavior applying specific radiotracer (-)-[¹⁸F]flubatine. Our data indicate differences in $\alpha 4\beta 2$ nAChR availability in OB compared to NW, especially in key regions such as the NBM and the thalamus. Specifically, higher thalamic V_T in OB can be assumed. This should lead to enhanced thalamocortical processing of sensory information and could offer a quantitative neurobiological framework for increased attentional shifts towards food cues in overweight individuals. Correlational analyses further revealed distinct group- and region-specific differences comparing VAS scores for eating behavior and $\alpha 4\beta 2$ nAChR availability. Yet, due to the small sample size and heterogeneity of our study group, interpretation of these analyses requires further confirmation. If confirmed, the $\alpha 4\beta 2$ nAChR represents a prospective pharmacological target for novel non-invasive treatment strategies combating the obesity epidemic.

9. Summary

Introduction: Cholinergic network modulation is carried out through the neurotransmitter acetylcholine (ACh) and expression of $\alpha 4\beta 2$ nicotinic acetylcholine receptors (nAChRs) in central brain regions responsible for the detection of external sensory stimuli through thalamic and basal forebrain circuits but also within mesolimbic reward signaling. Alterations in $\alpha 4\beta 2$ availability could therefore contribute to pathologically increased eating behavior leading to obesity. Investigations of task-related cholinergic neurotransmission *in vivo* in human obesity comparing baseline versus stimulus conditions have yet to be established.

Objective: Aim of this exploratory study was to investigate the neurobiological mechanisms of cholinergic signaling and its ramifications on eating behavior to possibly identify $\alpha 4\beta 2$ as a pharmacological target in obesity therapy approaches. Primary outcome measure was the distribution volume calculated from PET data by VOI-based analyses. We compared $\alpha 4\beta 2$ nAChR availability in OB (participants with obesity) with NW (normal weight participants) under baseline and stimulus conditions. Secondary, we explored whether changes in eating behavior measured by VAS (visual analogue scores) are correlated with changes in $\alpha 4\beta 2$ nAChR availability. We also hypothesized that this relationship differs between resting state and stimulus conditions in both NW as well as OB.

Materials and Methods: Study population consisted of 16 study participants with OB (N=16; mean BMI 37.8 ± 3.18 kg/m²; 10 females; mean age 40.6 ± 14.0 ; range from 20-62 years) and 14 NW (N=14; mean BMI 21.8 ± 1.90 kg/m²; 11 females; mean age 28.1 ± 7.58 ; range from 19-45 years), all mentally healthy and non-smokers. Every participant underwent simultaneous PET-MR imaging (mMR Siemens) under baseline and stimulus conditions, applying a standard set of salient food items. Calculations of V_T was based on the bolus-infusion protocol. This includes investigation of V_T as the ratio between mean (-)-[¹⁸F]flubatine in brain tissue and mean plasma (-)-[¹⁸F]flubatine in venous blood samples at 120 until 165 minutes post injection. During each visit VAS data were obtained.

Results: No significant group differences in V_T between NW and OB under baseline conditions were found, while OB showed a trend towards lower V_T in the Nucleus basalis of Meynert (NBM; NW: mean V_T = 11.6; OB: mean V_T =10.2; mean difference= 1.35; p = 0.119). Under stimulus conditions, OB demonstrate higher thalamic V_T (Thalamus; NW: mean V_T = 25.1; OB: mean V_T = 28.8; mean difference: - 3.63; p = 0.028). Additionally, OB showed a tendency to greater V_T mean differences between resting state and stimulus conditions compared with NW. Correlational analyses revealed statistically significant positive correlation (r = 0.61) between HPT and VAS “satiety” in NW and a significant negative correlation (r = -0.59) between NAc and VAS “disinhibition” in OB.

Conclusion: These first in-human data suggest substantial changes in cholinergic signaling in brain circuits that process external sensory stimuli with high-incentive properties such as visual food cues in obesity. If confirmed in an extended population with larger sample size and including seed-based fMR imaging investigations, the $\alpha_4\beta_2$ nAChR represent a promising target for pharmacological intervention as a non-invasive alternative to surgical procedures to combat the obesity epidemic.
