AN ABSTRACT OF THE THESIS OF

<u>Frederick Kyle Herrera</u> for the degree of <u>Master of Science</u> in <u>Civil Engineering</u> presented on <u>March 16, 2022</u>.

Title: <u>Enhancing Detection of Marine Debris with Polarimetric Imagery</u>

Abstract approved: _____

Christopher E. Parrish

Marine debris is a chronic and increasingly pervasive problem for coastal regions around the world. Debris poses environmental risks, threats to wildlife, and degradation of the natural environment. Recent research has shown the advantages of uncrewed aircraft systems (UAS) for detection and recognition of marine debris, including the ability to efficiently collect data over large stretches of coast. To date, most UAS imagery acquisition is performed with red-green-blue ("natural color") imagery only. Polarimetric imaging, which captures information on the polarization state of electromagnetic radiation received at the camera, in addition to purely spectral information, has been shown beneficial in detection of human-made objects. This thesis investigates the ability to improve detection of marine debris using polarimetric imagery (PI). It is shown that PI bands increase the information content above and beyond spectral (RGB) bands and aid in visual detection and recognition of marine debris. Additionally, results of supervised classification revealed that classification accuracy improves through inclusion of image bands derived from the polarimetric information. While commercially available PI cameras are still very new and not quite operationally ready for installation on UAS, follow-on research using PI cameras on UAS is anticipated to greatly facilitate operational use of this new technology for marine debris mapping and management.

Enhancing Detection of Marine Debris with Polarimetric Imagery

1. Introduction

Marine debris accumulation plagues coastal areas worldwide and presents both immediate and long-term risks to humans and wildlife. The debris is any man-made, persistent solid material that either directly or indirectly ends up in the marine environment from land or ocean-based sources (Sheavly and Register, 2007; Pawar et al., 2016). Understanding spatial densities and distributions of marine debris in different regions, as well as the proportions of different debris types, and how these variables are changing over time is key to developing policies and directing resources for cleanup and mitigation efforts. To this end, NOAA's Office of Response and Restoration (OR&R) Marine Debris Program (MDP), the lead agency in the U.S. for addressing marine debris, maintains a Marine Debris Monitoring and Assessment Project (MDMAP), in which external partners and volunteers conduct periodic debris surveys (Opfer et al., 2012; Banford, 2013).

Marine debris surveys entail walking randomly-selected transects, searching for debris within a specified distance on either side of the transect centerline, and characterizing and recording debris items (Burgess et al., 2021). Recently, studies have documented the capability of uncrewed aircraft systems (UAS) to aid in marine debris detection and recognition (Brooke et al., 2015; Gonçalves et al., 2020; Taddia et al., 2021). Benefits of UAS for marine debris surveys include the ability to collect data rapidly, efficiently, and safely for large stretches of coast that might be inaccessible on foot. Additionally, automating the detection of debris items in UAS imagery may assist in reducing some of the subjectivity of the *in-situ* surveys and in providing contiguous data (sometimes called "wall-to-wall coverage"), in comparison to random transects.

To date, UAS data acquisition for marine debris projects has primarily included only red-green-blue (RGB) imagery. However, an emerging technology—namely, low-cost, commercially-available polarimetric imaging (PI) cameras—offers the promise of potentially improving detection and recognition of marine debris, due to its potential to distinguish between natural and human-made features. Polarization sensors reveal information about surface textures, shape, shading, and roughness, thus making it a valuable tool in both research and field applications (Tyo et al., 2006). Islam et al. (2019) found that unique signatures contained within polarimetric data reliably improved separation of man-made objects using supervised classification methods.

This study, however, did not utilize multiband combination of polarimetric and RGB data for analysis. Furthermore, Zhao et al. (2008) suggests that combining spectral and polarimetric information greatly enhances object detection and identification performance. They conclude that spectropolarimetric image analysis efficiently separates objects and background features. Though useful for determining surface characteristics, polarimetric sensor technology has rapidly evolved over the last three decades to fit an expansive scope of disciplines. Traditional employment of polarimetry ranges from atmospheric remote sensing to astronomy, to military target detection, and even biomedical diagnostics. It is a crucial technique for characterization of aerosol particles, discernment of circumstellar structures, detection of camouflaged military vehicles, and diagnostics for tissue measurements. The expansive list of applications includes agriculture, forensics, coastal management, robotic vision, and more as polarimetry's uses continue to develop each year (Snik et al. 2014).

Polarization is one key property of light along with intensity, wavelength, and coherence (Tyo et al., 2006). Light has five potential polarization states: natural (non-polarized), linearly polarized, partially polarized, circularly polarized, and elliptically polarized. Natural light becomes polarized when it reflects off a surface, and the resultant angle of polarization is parallel to that surface. The degree and orientation (angle) of polarization observed from object reflectance are affected by surface structure, texture, chemical composition, water content, and angle of incidence (Yan et al, 2020). Objects on land produce unique polarized signals during reflectance, and this idea forms the basis for evaluating the efficacy of polarimetry in marine debris detection.

PI cameras work by including sensors employing a combination of filters with different angular orientations. Specifically, chip sensors have been developed that are overlayed with specific filter orientations to capture both the degree and angle of polarization. A combination of pixel filters, arranged at angles of 0, 45, 90, and 135 degrees, are typically overlayed atop the sensor in repeating 2-pixel blocks as shown in Fig. 1. This combination of 2×2-pixel filter blocks is then extrapolated for the full sensor size. To characterize the polarization of light, measurements from all four angles of polarization are required. To achieve this for each pixel on the sensor requires an interpolation process where data from adjacent pixels is combined. This procedure is analogous to how data from adjacent red, green, and blue pixels is combined on color sensors to

produce RGB values for each pixel via a Bayer filter. Modern sensors, such as the Sony IMX250MZR used in this study, provide unique opportunities with a total payload of less than 100 grams, opening the door to UAS platform integration.
Figure 1: Polarizing filters overlaid on sensor in repeating pixel blocks (adapted from FLIR, 2021).

Despite the potential benefits of UAS-mounted polarimetric imaging cameras for marine debris detection and recognition, because affordable, commercially-available PI cameras are so new, this topic has not yet been studied. To that end, the goal of this thesis is to investigate and quantify potential improvement in marine debris detection and recognition using polarimetric imagery. The study utilized PI collected at four field sites and includes both visual and quantitative analysis. The visual analysis consists of viewing standard RGB imagery along with PI-derived image information to test whether the PI information improves detection of debris. Meanwhile the quantitative analysis includes both image band distance metrics (with the PI information treated as additional image bands) and supervised image classification, both with and without PI information included. The results indicate that PI information can, in fact, improve the detection of marine debris.

2. Methods

2.1. Equipment

Selection of a PI camera and development of the processing procedures were critical initial tasks in this study. The following sections detail the equipment and procedures.

The FLIR Blackfly S USB3 5-megapixel polarimetric camera was selected for use in this study to evaluate the efficacy of marine debris detection. It was paired with a Fujinon 12.5-mm focal length C-mount lens (Figure 2). The FLIR camera was secured to an extendable pole in all fieldwork scenarios to achieve the desired height above ground level. Two different poles were utilized, both outfitted with a 6.35-mm (¼") camera adapter for the FLIR to maintain nadir perspective. The first pole type was a plastic, extendable painter pole which secured to a weighted stand. The second was an extendable, metal survey rover pole which provided ample rigidity when extended to heights greater than 3.5m. This rigid configuration was essential for image quality when subjected to movement and wind gusts, which are common in many coastal locations. The pole was then either held by a crew member over debris object(s) or fixed in a weighted stand (Figure 3). The reason for operating the camera from a pole mount, rather than a UAS, in this research was that the lack of autonomous camera function meant that computer software was essential for not only saving images, but also adjusting the camera parameters. The camera required constant hardwired connection to the field laptop via a 5-m USB3.0 cable to perform any live parameter adjustments on the SpinView GUI (Teledyne Inc.) software, making it a two-person operation. The exposure settings were determined to be imperative for polarimetric quality, but needed to be changed frequently with changing illumination conditions (e.g. sun angle, clouds, shadows, etc.). These factors led to the need for meticulous manual adjusting of the PI camera parameters during acquisition.

Figure 3. (a-b) Camera configurations used in fieldwork scenarios. (a) fixed setup used at O.H. Hinsdale Wave Research Lab (left); (b) mobile setup used in Corpus Christi TX (right).

2.2. <u>Processing Procedures</u>

The first step in processing the data from the PI camera was to compute the Stokes parameters (Stokes, 1852), which describe the complete or partial polarization state of light. The Stokes vector, Eq. 1, consists of four parameters with three of them being mutually independent (Yan et al., 2020). The nature of these parameters is particularly well suited for the analysis of partially polarized light which is almost always observed in an outdoor environment (Snik et al., 2014). The four Stokes parameters, defined in Eq. 1, form the basis of all results generated in this study and serve as input to the calculations of the degree of linear polarization (DoLP) and the angle of linear polarization (AoLP). This four-dimensional vector can describe the status of any polarization state and degree (Yan et al., 2020):

$$S = \begin{bmatrix} S_0 \\ S_1 \\ S_2 \\ S_3^2 \end{bmatrix} = \begin{bmatrix} \langle \tilde{E}_x^2(t) \rangle + \langle \tilde{E}_y^2(t) \rangle \\ \langle \tilde{E}_x^2(t) \rangle - \langle \tilde{E}_y^2(t) \rangle \\ \langle 2\tilde{E}_x(t)\tilde{E}_y(t)cos\delta \rangle \\ \langle 2\tilde{E}_x(t)\tilde{E}_y(t)sin\delta \rangle \end{bmatrix} = \begin{bmatrix} I0 + I90 \\ I0 - I90 \\ I45 - I135 \\ 1 - (S1^2 + S2^2) \end{bmatrix} \tag{1}$$

where $\tilde{E}x$ and $\tilde{E}y$ are components of the electrical field vector along x, y in the selected coordinate system, δ is the phase differences between two vibration components, and $\langle \rangle$ denotes time-averaging.

The individual components of the Stokes vector are computed as shown in Eq. 2-6. First, intensity of non-polarized light, alternately denoted S_0 or I, is given by Eq. 2 and has a pixel value range of $0 \leq S_0 \leq 512$.

$$S_0 = I0 + I90 \tag{2}$$

The difference between horizontal and vertical polarized pixels is represented as S_1 (Eq. 3). Positive values are horizontally linearly polarized and negative values are vertically linearly polarized. The pixel value range associated is $-255 \leq S_1 \leq 255$.

$$S_1 = I0 - I90 \tag{3}$$

The 45-degree component is represented by S_2 (Eq 4) where positive values are 45° linearly polarized and negative ones are 135° linearly polarized. The pixel value range is similarly $-255 \leq S_2 \leq 255$.

$$S_2 = I45 - I135 \tag{4}$$

The final parameter, S_3, is the circular polarization component and is not measured by the IMX250MZR used in this study. S_3 is assumed to be zero because sunlight is unpolarized and its reflection only imparts linear polarization. However, in environments with controlled illumination it is possible to eliminate unpolarized light and characterize the circular component using Eq 5 (FLIR, 2021).

$$S_3^2 = 1 - (S_1^2 + S_2^2) \tag{5}$$

After computing the Stokes parameters, the next step is to compute the degree of linear polarization (DoLP) and angle of linear polarization (AoLP). DoLP is the primary means of interpreting polarization state and is represented by the proportion of light that is polarized at a given pixel. A completely unpolarized light source will have a DoLP of 0% while a perfectly polarized source would be 100%. This measure of intensity is represented by saturation level on a scale of zero to one, from white to black. DoLP is computed via Eq. 6 (Conte et al., 2021).

$$DoLP = P = \frac{\sqrt{S_1^2 + S_2^2}}{S_0} \tag{6}$$

The second component that describes the polarization status of light is the orientation or the angle of linear polarization (AoLP). In the AoLP calculation, Eq. 7, Ψ represents the azimuth angle of an eclipse based on the Stokes vector. The angle of polarization is often represented using a color wheel to denote specific orientation within a scene.

$$AoLP = \psi = \frac{1}{2} \arctan\left(\frac{S_1}{S_2}\right) \tag{7}$$

Bivariate color maps can often display the association between two variables more effectively than a side-by-side comparison of the two individually (Trumbo, 1981). For visualization purposes, DoLP and AoLP are combined into a bivariate image which describes the polarization state in terms of hue and saturation, as shown in Fig. 4. Greater saturation (x-axis) corresponds to increasing degree of linear polarization while hue (y-axis) represents the angle of polarization at any given pixel.
Figure 4. Illustration of bivariate image created from DoLP and AoLP. On the left is a bivariate DoLP/AoLP image of a pole in a walkway blocking vehicle traffic generated from imagery acquired with the camera used in this study. The plots on the right show how intensity, hue, and saturation are used to visually depict the degree and angle of linear polarization within the bivariate DoLP/AoLP image.

After computing the Stokes vector components and DoLP and AoLP, the next step was to bandstack the imagery to create multi-band images that included this additional PI-derived information as image bands. It should be noted here that there is no theoretical basis for treating $S0$, $S1$, $S2$, and $S3$ or DoLP and AoLP as "spectral" bands, and, in fact, they do not provide spectral information. However, treating the PI-derived information as additional bands enabled us to employ readily-available image analysis and classification routines and, thereby, to easily assess the potential improvement in marine debris detection and classification afforded by polarimetric information. The multi-band generation was performed in ArcGIS Pro v2.8.3 (Esri, Inc.). The analyses and classifications performed in this study utilized the polarimetric bands, $S0$, $S1$, $S2$, DoLP and AoLP, as additional spectral bands combined with standard RGB. This resulted in 8-band (R/G/B/S0/S1/S2/DoLP/AoLP) composite images for assessment purposes as portrayed in Fig. 5. There will naturally be some correlation between these bands, since, for example, DoLP and AoLP are computed from S0, S1, and S2. Hence, assessing band correlations and separability were part of the analysis.

Transformed Divergence (TD) is a prominent separability index in classification routines, representing the statistical difference between two multivariate, Gaussian distributed signatures (Chauhan, 2016). Idol et al. (2008), found that texture features extracted from polarization data greatly improved separability between land cover classes and overall classification accuracy. The Divergence (D) between two classes is shown in Eq. 9 and is used to compute the Transformed Divergence. TD has a value range of 0 to 2000, with 2000 being maximum spectral separability between classes, and is calculated as shown in Eq. 10. Mausel et al. (1990) concluded that TD is an excellent separability measurement for multi-band image classification and determining the best channel combinations.

$$D_{ij} = \frac{1}{2}tr[(C_i - C_j)(C_j^{-1} - C_j^{-1}) + \frac{1}{2}tr[(C_i^{-1} + C_j^{-1})(M_i - M_j)(M_i - M_j)^T] \quad (9)$$

where C is the class covariance matrix, M is the mean vector, and T is the transpose of the matrices.

$$TD_{ij} = 2000 \left[1 - \exp\left(-\frac{D_{ij}}{8}\right)\right] \tag{10}$$

Band Correlation Matrices were also generated using ArcGIS Pro and used to assess the correlation between different image bands.

As the final step in the analysis, a supervised image classification was performed in MultiSpec (Biehl, 2002), both with and without the PI-derived bands included.

3. Experiment

3.1. Study Sites

PI imagery was acquired at a total of four different field locations, including a simulated beach at the O.H. Hinsdale Wave Laboratory on the Oregon State University campus (Figure 3a), Neptune State Scenic Area on the Oregon coast (Figure 5), and two areas on the Texas coast: Padre Island and San José Island, Figure 6. These sites were selected to achieve sufficient variability in not only material type and size, but also substrate and object state. Light sand, dark rock, and coastal vegetation are the foundation upon which many objects are typically found. Debris was encountered buried in, lying on top, or nestled within the various substrate types.

Figure 6. Neptune State Scenic Viewpoint AOI on the Oregon Coast.
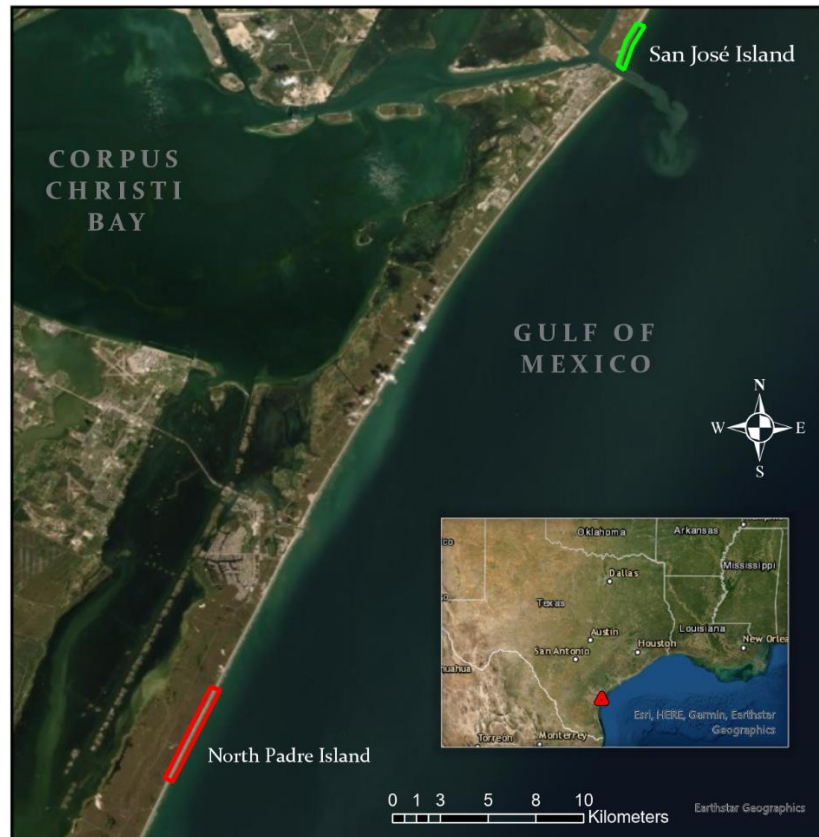

Figure 7. Corpus Christi Texas field sites.

The O.H. Hinsdale Wave Research Lab location contained sandy substrate (sourced from the Oregon coast) with direct sun exposure, making it a great scenario for initial camera testing and imagery acquisition. Debris utilized here consisted mostly of household debris objects, due to limited availability of actual shoreline debris. The round of testing conducted at this site served primarily as a proof of concept and provided a first look into polarimetric results. It was here that camera and software settings were tested and optimized, and above ground heights were explored.

The Neptune State Scenic Viewpoint located in coastal Oregon provided the first shoreline scenario for polarimetric image acquisition. It was here that procedures developed at the wave lab were translated to an actual beach. Due to the pristine nature of Oregon coastlines, the only *in-situ* debris readily observed are minimal microplastic fragments. Apart from storm events and select hotspots, weathered marine debris was surprisingly difficult to source. Oregon Parks and Recreation Department (OPRD) assisted in the gathering of actual debris objects that had

accumulated over time. This debris was transported by the OSU research team and hand-seeded along Neptune beach to simulate a debris-dense shoreline for polarimetric image acquisition.

The barrier islands east of Corpus Christi, located on the Texas Gulf Coast, featured a variety of *in-situ* macro debris objects, and included two sites well suited for validating the classification procedure. The beaches were flat, wide swaths of sand, about forty meters from the waterline to the backing dunes, with dense vegetation on the landward side. Site A, Padre Island, had debris focused along the seaward dune edge with debris objects partially buried in sand, due to the high wind conditions. Site B, San José Island, afforded substantial macro debris objects because of its remoteness and difficulty to clean. The debris here had a wider distribution along the beach width, ranging from the backside vegetation all the way to the waterline. Large storm events in previous years had washed ashore large objects such as vessels and metal mooring buoys. Most debris encountered between these two sites had been significantly weathered, making them excellent locations for evaluating operational capabilities under the challenging types of conditions encountered in marine debris surveys.

This experiment also investigated the potential applications for polarimetric sensors integrated on UAS platforms for marine debris management. With assistance from the US Coast Guard, the research team was able to simulate UAS altitudes to evaluate the camera performance by way of helicopter. Two tracks were flown over both study sites near Corpus Christi, TX. The camera was secured to a 1-m pole and held by hand outside of the cabin door, positioned nadir over the shoreline debris as shown in Figure 7. The first flight acquired imagery at 45-m altitude while the second achieved a 90-m flying height. The MH-65 helicopter maintained a speed of roughly 8 m/s and each flight strip produced 100 polarimetric images. The camera consistently captured quality imagery despite aircraft vibration and wind conditions. Objects on the ground exhibited valuable polarimetric returns from the elevations achieved, opening potential avenues for full UAS integration and debris management efforts.

Table 1 outlines fieldwork and data collection dates along with the objectives associated with each.

Figure 8. Polarimetric camera acquiring aerial imagery of debris at UAS altitudes onboard USCG helicopter.

3.2. Data Collection

Table 1. Description of the data collected at each of the study sites.

Date(s)	Location	Equipment	Data collection objectives
10/28/2020	O.H. Hinsdale Wave Lab	Fixed PI setup (2.1m AGL)	Obtain preliminary polarimetric results, test camera parameters
12/2/2020	O.H. Hinsdale Wave Lab	Fixed PI camera setup (3m AGL)	Test different material types and new sensor height
10/30-10/31/2021	O.H. Hinsdale Wave Lab	Fixed PI camera setup (3.7m AGL)	Test using actual marine debris sourced from Oregon coast at new sensor height, generate georeferenced orthomosaic
5/4/2021	Neptune State Scenic Viewpoint	Mobile PI setup (3m AGL)	Acquire polarimetric imagery of marine debris seeded on sandy shoreline
7/8/2021	Neptune State Scenic Viewpoint	Mobile PI setup (3.7m AGL)	Acquire polarimetric imagery of higher quality debris scene debris scene on mix of substrates (sand, cobble, rocky outcrop)
12/10/2021	Padre Island, TX	Mobile PI setup (4.4m AGL) w/ belt mount	Acquire polarimetric imagery of in-situ debris objects between 3 sections of shoreline

12/12/2021	San José Island, TX	Mobile PI setup (4.4m AGL) w/ belt mount	Setup robust debris field using debris sourced from 1km^2 area to create large orthomosaic analysis
12/14/2021	San José Island, TX	Mobile PI setup (5m AGL) w/ belt mount	Setup another debris field featuring different types of local debris objects for orthomosaic analysis
12/15/2021	Padre Island & San José Island, TX	FLIR attached to 1m pole, held out of cabin door	Fly over both Texas field sites with USCG support to test camera capabilities at UAS altitudes (45-90m AGL)

Of the data collection activities listed above, the data in the debris fields on San José Island, Texas, served as the primary data set for this research.

This study site was located within first couple kilometers north of the north Port Aransas jetty. The site contained a range of debris extending from water line up to the dune. The composition was mostly plastics, especially near the water, with some larger objects sprinkled up towards the dune line. The polarimetric imagery acquired in the site included a mix of singular frames with interesting/multiple objects as well as a constructed conglomerate scene using a substantial number of objects from several different classes.

The project team aggregated debris from a 1km^2 area to form two different debris fields, each containing different material types and distributions. The larger field was organized into a 38×8 m scene to achieve high quality polarimetric data of the native debris items (Fig. 8). The scene included mostly plastic objects ranging from water bottle size up to some larger gas jugs/barrel fragments. The next most populated classes in the scene were ropes (~12) and wood (~12). The ropes varied in length, diameter, and color, as did the wood samples. The smaller debris field accounted for alternate debris classes and allowed for rigorous analysis of rubber (tire fragments/flip flops), glass, wood, buoys/foam, and aluminum. This scene was more compact with an area of 6×2.5 m and is shown in Figure 10. These seven classes (plastic, rope/line/net, wood, rubber, glass, buoys/foam, and aluminum) had substantial sample size for robust testing to determine whether inclusion of polarimetric bands improved detection/classification of these types.
Figure 9. Debris Field 2 on San José Island.

Figure 10. Polarimetric imagery acquisition at San José debris field 2 on 12/12/2021.

After the bandstacking operation performed in ArcGIS to generate 8-band individual frame images, these images were then processed in Agisoft Metashape to generate georeferenced orthomosaics. The debris field orthomosaics served as input to the k-nearest neighbors (KNN) algorithm for supervised classification in MultiSpec. KNN was selected as the classification routine due to the simple yet effective employment in discriminant analysis (Silverman and Jones, 1989). To enable the comparison between the imagery with and without the PI-derived information included, the original three-band (RGB) images were also processed in Metashape to generate a separate set of orthomosaics. Objects within each scene were split into training and test fields, and each class contained 12-30 fields for evaluation. Objects were selected, based on the goals of having roughly equal numbers of each type and condition (weathered/new, partial/whole, color, size) of object in the training and test data sets. The model tested on the same samples it used for training, making the training accuracy improvement also noteworthy. The nearest K Neighbor value was set to 5 and the total run time was about 150 hours for the three scenes. Training and test accuracies as well as kappa statistics improved with inclusion of the polarimetric data stacked as additional spectral bands.

Figure 11. Object class sample fields selected in MultiSpec for supervised classification of San José orthomosaic 1.

4. Results

4.1. Visual Assessment

The first part of the analysis was to visually assess the PI camera outputs to see if they improved visual detection and recognition of debris over what is achievable with RGB imagery only. This visual representation was achieved using the bivariate display consisting of DoLP and AoLP measurements. It was found that PI is visually rich in the instance of like-color substrate and objects, dark scenes, structural perception, and material type distinction. Dark objects with distinct angular features are better perceived in the polarimetric display. Similarly, dark scenes where the object surfaces visually blend into the substrate are more easily distinguished in the polarimetric imagery. In instances of homogenous backgrounds such as fine sand, PI helps to highlight the shape of objects and allow for easier visual inference (natural vs man-made). As the substrate becomes more complex, including items such as shells, rocks, and vegetation, the visual quality of polarimetric imagery is diminished. At high elevations, man-made objects are still easily discernible in the polarimetric imagery when surrounded by sand or minimal vegetation. These observations are all represented in Figures 11-15 as well as Appendix A.

Material type and surface textures can be observed in Figure 11 with smooth, reflective objects (i.e., undamaged plastics and coated metal bars) showing the strongest polarimetric returns. Objects with granular surface textures, such as the bike tire, exhibited less specular reflectance (indicated by a "shiny" appearance in the RGB imagery) and had a lower degree of polarization. Against the dark rock backdrop, however, the circular tire shape is still visually discernable. Figure 12 displays *in-situ* examples of weathered and partially buried debris objects encountered at San José Island TX. Defining object characteristics, such as shape or texture, are readily observed in the bivariate display for the bucket, tire fragment, and rope despite the natural deformation to object state. The influence from complex substrate type can be seen in Figs 11-14 where rocks, shells, wood, and vegetation draw significant visual attention. Smooth sand has a uniform, dull appearance in the bivariate polarimetric imagery, allowing debris objects to readily stand out against a sand background. For example, in Fig. 13, man-made objects are readily discernable from natural sand in the imagery acquired over San José debris field 2 from 45-m altitude in the USCG helicopter.

Figure 15. Partially buried fences @ 90m altitude, San José TX.
Figure 16. San José debris field 2 @ 45m altitude.

4.2. Quantitative Analysis

The classification results are expressed using training and test accuracies (per class), training and test accuracies (overall), as well as the kappa statistic. Overall accuracy is a popular classification measure that is calculated by dividing the total correct pixels (sum of the diagonal) by the total number in the error matrix. The individual class performance is measured using producer's and user's accuracies. Producer's accuracy refers to the probability of a reference pixel being correctly classified while the user's accuracy indicates the probability that a pixel on the image actually represents that class on the ground (Congalton, 1991). Kappa represents the proportion between actual agreement and the agreement expected by chance (Cohen, 1960).

$$K = \frac{(p_o - p_c)}{(1 - p_c)} \tag{11}$$

where p_o is the proportion of units in which the model agreed, and p_c is the proportion of units for which agreement is expected by chance.

The results of the band correlation analysis are shown in Tables 2, 5, and 8 for the scenes shown in Figs. 16-18. The results of the KNN classification routines are shown in Tables 3, 4, 6, 7, 9, and 10.

5. Discussion

Beyond the overall accuracy assessment results, the transformed divergence (TD) values were found to provide insight into the improvement attainable by adding the PI information. The TD values substantially increased, indicating that polarimetric inclusion benefits separability of marine debris classes. This is likely attributed to the added information about surface texture features such as roughness, shape, and shading. The TD results revealed that red-green-blue were not always the best 3-band combination for debris separability within these scenes. For the SJ ortho 1, the best 3-band combination was green-blue-S0 with an average TD value of 1175 (versus 1081 RGB). For SJ ortho 2, the best combination was red-blue-S0 at 1366 (versus 1213 for RGB). The wavelab ortho best 3-band combination was indeed red-green-blue with an average TD value of 1219. As a specific example, if we consider the SJ Ortho 2 and the separability of plastic vs. rope, the TD value when using only the RGB bands is 560, which is considered very poor (inseparable). However, by adding the PI-derived bands, the TD jumps to 1546. Similarly, if we consider wood vs. rope for the same orthomosaic, the TD value for RGB only was 662, but increased to 1561 after adding the PI-derived bands. These results are particularly interesting for future studies in evaluating the ideal data combinations in debris classification procedures.

On the USCG helicopter, the FLIR camera performed well at altitudes of up to 90 meters and speeds of 8 m/s once the exposure was adjusted accordingly. The quality of the aerial imagery obtained showed promise for implementing this type of technology in debris survey and response efforts. Future efforts could benefit from use of a Raspberry Pi onboard system to increase autonomous camera function and allow full UAS integration. Polarimetric sensor technology of this size has only been released to market within the last decade and is certain to be further developed as its field applications continue to grow.

The investigations performed in this study identified practical challenges and technological limitations of the system employed. The lack of camera autonomy, primarily due to the new sensors, meant that the acquisition process was quite manual and tedious. The camera required consistent cable connection to a field laptop where images were individually captured, and parameters often adjusted. Exposure level and weather conditions were key for polarimetric imaging quality. Time of day/incidence angle substantially affected polarimetric state observed

on many objects tested where the same object resulted in different reflectance signatures between scenes. Atmospheric conditions also significantly affected the polarized light state observed. Yan et al. (2020) found that dense or even partial cloud cover induced a light scattering phenomenon which decreases quality of both DoLP and AoLP. Shoreline and substrate conditions also heavily influenced debris detection and classification. Objects nestled in dense vegetation or submerged in complex substrate (i.e. rocks/shells/sand) were not easily identifiable in the polarimetric imagery. Wet sand and compacted features, such as footprints and car tracks, also showed polarimetric returns and added noise to some scenes.

6. Conclusion

This study provided strong indication that polarimetric imaging is a useful asset in detection and classification of marine debris objects across seven material classes. Overall, the polarimetric information displayed visually rich object characteristics and improved both the visual identification and automated classification of debris. In particular, polarimetric imaging enhanced information about surface textures, shape, shading, and roughness that spectral bands otherwise could not.

A major logistical challenge was sourcing sufficient debris accumulations of various material types. Most scenes and debris encountered consisted of primarily plastic objects, followed by processed wood, buoys/foam, glass, rubber, ropes/nets, and aluminum cans. Due to the practical limitations of the field study (particularly, the number and types of debris items available and amount of area that could realistically be covered using the pole-mounted camera), the sampling strategy and numbers of items sampled within each class did not adhere to the stringent guidelines often employed in remote sensing for classification accuracy assessment (e.g., Congalton and Green, 2019). For this reason, the accuracy values in Tables 3, 6 and 9 may overestimate the accuracies that could be achieved in an operational marine debris mapping project. However, what is important in these tables is the *improvement* in accuracy, based on adding the PI-derived bands.

Future endeavors can build on this work by experimenting with different material types and machine learning algorithms. One recommended extension is to investigate other machine learning algorithms, beyond KNN, for auto-classification of debris in the imagery. For example, convolutional neural networks could be investigated for classification of marine debris in polarimetric imagery, where much larger training data sets are available. It would also be advantageous to acquire imagery at variable incidence angles and sky conditions to investigate optimal acquisition conditions and parameters.

Integration of polarimetric sensors on UAS platforms would greatly expand operational capabilities and could easily be employed for coastal response teams such as NOAA's Marine Debris Program. Hence, future efforts should focus on integrating the PI camera onto a UAS, leveraging the work done in this study acquiring imagery from the helicopter. Lastly, it would be of interest to investigate additional methods of processing the PI data for both enhanced visual

analysis and use in the automated classification routines. Through this ongoing work, PI cameras are anticipated to become increasingly valuable for the application of marine debris detection and classification.
