10 **ABSTRACT:**

11 As human impacts and demands for ocean space increase (fisheries, aquaculture, marine reserves,
12 renewable energy), identification of marine habitats hosting sensitive biological assemblages has
13 become a priority. Epifaunal invertebrates, especially the structure-forming species, are an
14 increasing conservation concern as many traditional (bottom-contact fishing) and novel (marine
15 renewable energy) ocean uses have the potential to displace or otherwise impact these slow-
16 growing organisms. The differences in mega-invertebrate species assemblages between high-
17 relief rocks and low-relief sediments are well documented and likely hold for most marine
18 environments. In anticipation of potential development of marine renewable energy facilities off
19 Oregon and Washington (USA), a survey of the benthic invertebrate assemblages and habitats
20 was conducted on the continental shelf of the Pacific Northwest, using video footage collected
21 by ROV, to more finely characterize these assemblage-habitat associations. Four main
22 associations were found: pure mud/sand dominated by sea whips and burrowing brittle stars;
23 mixed mud-rock (which may be further divided based on size of mixed-in rocks) characterized

24 by various taxa at small densities; consolidated rocks characterized by high diversity and density
25 of sessile or motile mega-invertebrates; and rubble rocks showing less diversity and density than
26 the consolidated rocks, possibly due to the disturbance generated by movement of the
27 unconsolidated rocks. The results of this study will help classify and map the seafloor in a way
28 that represents benthic habitats reflective of biological species assemblage distributions, rather
29 than solely geological features, and support conservation and management planning.

33 **1. INTRODUCTION**

34 Although the oceans provide a variety of valuable goods and services, societies sometimes fail to
35 consider the damage that resource exploitation may cause to marine ecosystems over time
36 (Jackson et al. 2001). Examples of anthropogenic impacts and over-exploitations of these
37 ecosystems are numerous, and hard continental shelves and rocky reefs are among those most
38 impacted (Lotze et al. 2006; Halpern et al. 2008). Fisheries using bottom gear such as trawls and
39 dredges are by far the most damaging for the seafloor, acting like forest clear-cutting (Watling
40 and Norse 1998). Due to technological improvements during the last decades, bottom-fishing
41 gears are now used from polar to tropical waters on every type of seafloor; few places on the
42 world's continental shelves remaining non-affected (Watling and Norse 1998; Halpern et al.
43 2008). Other human uses of the oceans like aquaculture, mining or tourism activities threaten
44 continental shelf ecosystems (Rossi 2013) and their effects, both direct and indirect, can be
45 synergistic (Jackson et al. 2001; Kaplan et al. 2013). Human use changes such as marine
46 protected areas (MPAs) and marine renewable energy developments (MREs), like wave energy
47 or offshore wind farms, both may have some benefits for ecosystems by closing some areas to
48 fisheries (Sheehan et al. 2013). However, potential negative effects of marine renewable energy
49 developments arise from introducing hard structure to sedimentary seafloor habitats as well as
50 changing current and sediment flow patterns. The intensity and extent of such effects on seafloor
51 assemblages by MRE installations are as yet poorly characterized, mostly hypothesized from
52 studies of artificial reefs and oil platforms (see reviews in Boehlert and Gill 2010, Henkel et al.
53 2013, 2014). However, some hard-bottom (Keenan et al. 2011) and structure colonization studies
54 (Leonhard and Pendersen 2006, Wilhelmsson and Malm 2008, Langhamer et al. 2009) have been
55 conducted in relation to MRE installations in Europe (see also review by Leeney et al. 2014).

56 One of the major threats of seafloor exploitation to continental shelf ecosystems is a reduction of
57 habitat complexity and heterogeneity by damage to or smothering of slow-growing structure-
58 building organisms like sponges or gorgonians, which may create biogenic habitat (Watling and
59 Norse 1998; Kaiser et al. 2006; Sheehan et al. 2013) as well as damage to or sedimentation of
60 rocky outcrop or reefs themselves. Habitat heterogeneity can be a major driver of variability in
61 the abundance and diversity of marine species (Benedetti-Cecchi and Cinelli 1995; García-
62 Charton et al. 2004), supporting global species diversity by increasing niche availability and
63 community complexity and facilitating the formation of distinct species assemblages (Cerame-
64 Vivas and Gray 1966; García-Charton et al. 2004; McClain and Barry 2010).

65 The Pacific Northwest (PNW) continental shelf, especially in its northern part (i.e. off Oregon
66 and Washington), is mostly characterized by mud and gravel habitats, but rocky outcrops and
67 reefs occur in several areas (Romsos et al. 2007), supporting structure-building invertebrates that
68 increase the habitat complexity of the seafloor (Strom 2006). This region has a long history of
69 intense fisheries with a variety of fleets using bottom gears dedicated to benthic and / or
70 demersal species: groundfishes, demersal rockfishes, crabs and shrimps. Moreover, it is
71 becoming a focus for offshore wave and wind energy installations on the continental shelf and
72 slope, with an estimate of about 1000 TWh of just wave energy resource available per year for
73 the PNW continental shelf (EPRI 2011). However, despite the abundance (and some
74 documentation of) of invertebrate bycatch, little is known about mega-invertebrate assemblages
75 on this part of the continental shelf. Hixon and Tissot (2007) and Hannah et al. (2010, 2013)
76 compared trawled versus untrawled mud assemblages at two locations on the Oregon continental
77 shelf, and Tissot et al. (2007) described the invertebrate and fish assemblages at a single outer
78 continental shelf reef off Oregon. Only Strom (2006) has summarized the distribution of

79 structure-forming invertebrates at multiple sites along the continental margin off Oregon. On the
80 southern part of the eastern Pacific continental shelf (i.e. southern California), different
81 invertebrate assemblages have been distinguished based on the physical structure of the habitats:
82 habitats composed of high-relief rocks were associated with sessile and structure-forming mega-
83 invertebrates including sponges and gorgonians, while low-relief habitats composed of fine
84 sediments were associated with motile mega-invertebrates including sea stars, crustaceans,
85 bivalves, and sea cucumbers (Allen and Moore 1996; Allen et al. 1997; Stull et al. 1999; Tissot
86 et al. 2006). Large structure-forming mega-invertebrates such as sponges, corals, crinoids and
87 basket stars have been suggested to provide shelter and additional resources for fish and other
88 invertebrates by increasing the availability of microhabitats through their large surface area
89 (Tissot et al. 2006).

90 The differences in mega-invertebrate species assemblages between high-relief rocks and low-
91 relief unconsolidated sediment as described above likely hold for most marine environments.
92 However, the diversity of assemblage-habitat associations on the seafloor is more complicated
93 than this dual opposition and management decisions regarding protection or development of
94 seafloor habitats require a more detailed understanding of associated affected species. Thus the
95 objectives of this study were to distinguish finer differences in habitats based on substrata (and
96 depth if significant in the study range) and to characterize the diversity and composition of
97 mega-invertebrate assemblages in those habitats. The following substratum differentiations were
98 investigated. How mega-invertebrate assemblages found on pure sediment differ from
99 assemblages found on mud mixed with unconsolidated rocks (hereafter called mixed mud-rock),
100 which in turn differ from assemblages living in rocky habitats. Within rocky habitats, if the slope
101 of the rocks (i.e. flat rocks versus ridge rocks) and the cover of the rocks (i.e. a large

102 consolidated outcrop with a cover of unconsolidated smaller rocks, hereafter called rubble rocks;
103 rocks with a veneer of sediment; or bare rocks) affect the diversity and density of associated
104 epifauna. To test these hypotheses, underwater video footage from three different sampling sites
105 along the Washington (Grays Bank) and Oregon (Siltcoos Reef and Bandon-Arago outcrop)
106 coast were analyzed, to identify and enumerate the sessile and motile mega-invertebrates from
107 the images, and characterize the substrata encountered. These three sites were selected for this
108 study because they are located in areas of potential interest for the development of different
109 MRE projects and have been mapped with high-resolution multi-beam sonar.

110

111 **2. MATERIALS AND METHODS**

112 **2.1 Study sites**

113 In late August 2011 and September 2012, we used the remotely operated vehicle (ROV),
114 *Hammerhead*, a modified Deep-Ocean Engineering *Phantom* ROV customized and implemented
115 by Marine Applied Research & Exploration ([http://www.maregroup.org/the-hammerhead-](http://www.maregroup.org/the-hammerhead-rov.html)
116 [rov.html](http://www.maregroup.org/the-hammerhead-rov.html)), to survey habitats and mega-invertebrates at three sites on the Pacific Northwest
117 continental shelf (Fig. 1): Grays Bank (GB, 14 stations, off Grays Harbor, Washington) and
118 Siltcoos Reef (SC, 10 stations, off Charleston, Oregon) in 2011 and Bandon-Arago (BA, 12
119 stations, off Bandon, Oregon) in 2012. Each site was composed of several stations, themselves
120 composed of three transects, each approximately 250 meters long each separated by 250 meters
121 (Fig. 2). The ROV was kept at a regular speed ($\sim 0.5 \text{ m}\cdot\text{s}^{-1}$) and a regular height from the bottom
122 ($\sim 1 \text{ m}$) to provide images of good quality to identify and enumerate the mega-invertebrates. This
123 sampling plan was designed to maximize the number of bottom types surveyed at each study site.
124 The ROV *Hammerhead* was equipped with two color HD video cameras attached at the front of

125 the ROV: one facing downward and perpendicular to the sea surface, and the other facing
126 outward, angled roughly 30 degrees from the dorsal surface of the ROV. The ROV *Hammerhead*
127 was equipped with sizing lasers for each camera, a CTD that measured depth (meters),
128 temperature (Celsius), and salinity (PSU) continuously, and was integrated with a navigation
129 system that measured latitude and longitude every second.

130

131 **2.2 Video analyses**

132 Each video was watched a minimum of three times: one for substratum identification, one for
133 sessile mega-invertebrate identification and enumeration, one for motile mega-invertebrate
134 identification and enumeration. While two observers were used for classifying substrata, a single
135 observer identified all organisms to reduce potential observer-related differences in organism
136 detection or classification. Only benthic epifauna and some endofauna taxa showing
137 recognizable body parts above the sediment were recorded. Both the outward and downward
138 facing cameras were used to identify substratum patches and invertebrates. Since one camera
139 faced downward at a fixed angle from the vehicle, all footage viewed by the downward-facing
140 camera was considered “on-transect” and this view was used to count the invertebrates.

141 Generally, video analysis followed guidelines established by Tissot (2008). Each invertebrate
142 entry was accompanied with a time code that was used to determine in which substratum patch a
143 particular invertebrate was found.

144 *Substratum*: Substratum patches were identified based on the grain size class estimated from the
145 video footage and, for consolidated rocks, relief angle, with the start and end times of each
146 substratum patch recorded. Each substratum patch was coded with two letters; the first letter
147 indicated the primary substratum (comprising 50-80% of the duration of the patch) and the

148 second letter indicated the secondary substratum (comprising 20-50% of the duration of the
149 patch): R for ridge rock (angle $>30^\circ$), F for flat rock (angle $<30^\circ$), B for boulder (> 25.5 cm), C
150 for cobble (6.5 – 25.5 cm), P for pebble (2 – 6.5 cm), G for gravel (4 mm - 2 cm), and M for mud
151 (not distinguished from sand), refined from Stein et al. (1992). If a substratum patch was
152 comprised of two substrata in equal proportions, the patch was coded with the first letter
153 indicating the substratum with larger grain size. If a patch comprised over 80% of a single
154 substratum, the patch was coded with the same two letters (e.g. MM).

155 *Sessile mega-invertebrates*: Only sessile invertebrates taller than 5 cm were identified and
156 enumerated, as recommended by Riedl (1971) and Tissot et al. (2006) because smaller
157 individuals were difficult to see and identify on the images. Sponges and gorgonians, difficult to
158 identify on video, were characterized based on their morphology and sometimes color (e.g.,
159 branching sponge, shelf sponge, branching red gorgonian). Encrusting ascidians and bryozoans,
160 impossible to distinguish on video from encrusting sponges, were all gathered under the name
161 shelf sponge, while possible branching bryozoans were counted as branching sponges. These two
162 names thus describe a life form more than a systematic group and patches (shelf sponges) or tufts
163 (branching sponges) were counted as individuals.

164 *Motile mega-invertebrates*: Motile invertebrates taller than 5 cm were identified to the lowest
165 possible taxonomic level and enumerated. Some taxa were only identified to the family or genus
166 level, since many species in these families / genera have overlapping morphological features and
167 are difficult to distinguish without specimens to analyze. When the abundance of motile
168 invertebrates was high, one to three additional viewings were needed to identify and enumerate
169 all the individuals. In the Bandon-Arago footage, small orange brittle stars were too numerous to
170 be counted all along each transect and were only enumerated every 30 seconds.

171

172 **2.3 Substratum patch area and species density**

173 The ROV *Hammerhead* was equipped with a navigator beam that was used to calculate the
174 transect width and the approximate distance traveled every second. The area covered per second
175 was calculated based on the transect width and the distance the ROV traveled from the previous
176 second. Thus, the area of each different patch was calculated by adding all area entries from one
177 second after the start time of the patch to the end time of the patch. The density (individuals.m⁻²)
178 of each taxon for each patch was calculated by dividing the count for that taxon by the total area
179 of that patch covered by the ROV.

180

181 **2.4 Statistical analyses**

182 The sample units considered here were the different patch types in a whole site: data from all the
183 same substratum patches were pooled at the site level. Only patch types observed longer than one
184 minute in total for a site were kept in the analyses. A matrix of Bray-Curtis similarities between
185 patch types was calculated on log-transformed density data. Nonmetric multidimensional scaling
186 (nMDS), analyses of similarities (ANOSIM), SIMPER, and DIVERSE were performed using
187 PRIMER 6th Edition (Clarke and Gorley 2006). The nMDS analysis plotted sample units (patch
188 types) on a two-dimensional ordination plane based on taxa composition similarities and
189 dissimilarities. Groups of patch types (hereafter ‘habitat types’) were discerned from the nMDS
190 plot and an ANOSIM was performed to test the strengths of similarities within and differences
191 between these habitat type groups, using permutation and randomization methods on the
192 resemblance matrix. SIMPER (Similarity of Percentage) was used to determine which taxa and
193 their densities contributed to defining each group and the percent contribution of each defining

194 taxon. DIVERSE was used to calculate the diversity indices (average number of taxa S , average
195 density N , Pielou's evenness J') on the untransformed abundances for each habitat group, and a
196 series of ANOVAs and Tukey HSD tests was performed in the open-source software R (R
197 Development Core Team 2013) to test whether or not the indices were significantly different
198 among habitat type groups. To test for a possible bathymetric structuring of the organisms, a
199 second set of nMDS was performed at the transect level on the density of taxa within a patch,
200 coded by the habitat type defined at the first round of analyses, using depth bin (sections 10
201 meters deep) as a factor. For this second set of nMDS, the sample units were the patch types
202 within a transect, that is all the patches of a same substratum type pooled at the transect level
203 because the depth range varied within a site but not so much along a transect. An ANOSIM was
204 also performed on the seven depth bins.

205

206 **3. RESULTS**

207 **3.1 Site characteristics**

208 The three sites showed slightly different physical characteristics (Table 1). Bandon-Arago (BA)
209 and Grays Bank (GB) were shallower than Siltcoos Reef (SC). The temperature was the coldest
210 at the northern stations (GB) and up to one degree Celsius warmer in 2012 at BA as compared to
211 SC in 2011. No bathymetric or latitudinal variation in salinity was noticed among the three sites.
212 A total of 28 different substrata (two-letter code combinations) were identified in the transects:
213 16 at SC, 20 at BA as well as GB. Eight substrata were discarded at GB, seven at SC, and two at
214 BA because of durations shorter than a minute, resulting in a grand total of 22 different substrata
215 (Fig. 3) that were analyzed and are discussed further. Substrata found in large proportion across
216 all sites were flat rock-mud (average = 23%), mud-mud (average = 20%), ridge rock-ridge rock

217 (average = 19%) and ridge rock-mud (average = 18%). A total of 85 taxa representing eight
218 phyla were found across all three sites (Table 2, Online Resource 1). The phyla Echinodermata,
219 Porifera and Cnidaria together comprised over 91% of all the invertebrates encountered in the
220 survey (Table 2). Porifera and Echinodermata were the most abundant at BA whereas Cnidaria
221 were the most abundant at GB and Echinodermata at SC (Fig. 4).

222

223 **3.2. Assemblage composition**

224 Six habitats (groups of patches hosting similar invertebrate taxa) were identified from the nMDS
225 ordination (Fig. 5). The habitat groups were mostly organized by substratum characteristics (e.g.
226 pure mud, mixed mud-rock, rock) and subsequently by sites. Unconsolidated sediment patches
227 from the sites split into three groups: group MM-GBSC consisted of pure mud patches from GB
228 and SC; group Mx-GBSC was made of mixed mud-rock patches from GB and SC; and group
229 Mx-BA gathered pure and mixed mud-rock patches from BA only. Rock-based patches clustered
230 into two main groups: cR made of consolidated rocks, both bare and covered with a veneer of
231 mud (BM, FM, RM, RR), from the three sites; and group rR made of rubble rocks (e.g. BC, FB,
232 RG) from the three sites. No distinction was observed between ridge rocks and flat rocks
233 meaning that the slope does not seem to matter. Group PG (pebble-gravel), was a patch type
234 found only at BA in a single transect and will not be discussed further. The ANOSIM performed
235 on the five remaining groups (MM-GBSC, Mx-GBSC, Mx-BA, cR and rR) demonstrated
236 significant overall differences in the compositions of assemblages between the habitats (Global R
237 statistic = 0.700, $p < 0.01$). In the pairwise test, comparisons were considered reliable when more
238 than ten permutations were possible. Nine of the ten possible pairwise comparisons showed
239 significant differences between groups (Table 3). The only non-significant pairwise comparison

240 was MM-GBSC vs. Mx-GBSC ($p=0.067$). This was not surprising because of the low number of
241 permutations possible for this pairwise comparison. The SIMPER analysis showed large
242 dissimilarities for each pairwise comparison, ranging from 70.81% to 99.47% of difference in the
243 taxonomic composition of the groups (Table 4). Differences also were found among habitats
244 based on the univariate analyses of number of taxa S , density N and evenness J' (Fig. 6).
245 Pure mud at GB and SC (33 % similar) showed a medium number of taxa and a high density of
246 individuals with a significantly lower Pielou's evenness than all other habitats. Pure mud habitat
247 at these sites was characterized by high density of burrowing brittle stars and Subselliflorae (sea
248 whips) (Table 5). Mixed mud-rock habitats at GB and SC were characterized by medium to high
249 density of anemones and low density of sponges with the lowest within group similarity (16 %;
250 Table 5); they also showed lower number of taxa and density of individuals than the same
251 habitats at BA. Mixed mud-rock habitats at BA (which included pure mud at this site; patches
252 46 % similar) showed a medium number of taxa, a low density of individuals and were
253 characterized by many of the same taxa as the consolidated rocks (minus the anemones and squat
254 lobsters) but in much lower densities (Table 5). What made the two mixed mud-rock groups
255 93.18% dissimilar was the higher density of several echinoderm species (brittle stars, sea stars
256 and sea cucumbers), sponges, branching gorgonians and tunicates at BA than GB and SC, and a
257 higher density of sea anemones at GB and SC than BA (Online Resource 2).
258 Consolidated rocks showed 37 % within-group similarity, supported the highest number of taxa
259 and density of individuals (Fig. 6), and were characterized by high density of sponges, branching
260 gorgonians, giant plumose anemones, echinoderms (brittle stars, sea cucumbers and sea stars)
261 and squat lobsters (Table 5). In contrast, rubble rocks supported significantly fewer taxa (three-
262 fold) and much smaller densities of individuals (88-fold) and were characterized by low density

263 of sponges and sea cucumbers with nearly 36 % within-group similarity (Table 5). What made
264 the consolidated rock group 90.47 % different than the rubble rock group was higher density and
265 diversity of sponges, gorgonians, echinoderms (brittle stars, basket stars, sea stars, sea
266 cucumbers), anemones, squat lobsters and tunicates on the consolidated rock (Online Resource
267 2).

268 There appeared to be some distinction of groups by depth; however separation on the ordination
269 plane was dominated by habitat (Fig. 7) and the ANOSIM performed on the seven depth bins did
270 not demonstrate significant overall differences in the compositions of assemblages between
271 depth (Global R statistic = 0.193, $p < 0.01$). Based on taxa densities pure mud transects at GB and
272 SC clustered together in the top right section of the graph with further separation by depth bin;
273 mixed mud-rock transects at GB and SC (50-79 m) clustered in the bottom right. Mixed mud-
274 rock at BA (50-69 m) and consolidated rocks (50-119 m) from the three sites mixed together on
275 the left side of the two-dimensional plot with rubble rocks (50-119 m) in the lower left. Clearer
276 distinctions among the three habitat groups appeared on the three-dimensional plot (results not
277 shown).

278

279 **4. DISCUSSION**

280 This study aimed to distinguish finer resolution in benthic habitats that support distinct epifaunal
281 invertebrate assemblages on temperate continental shelves. Specifically, groups of benthic mega-
282 invertebrate epifauna were described from three rocky reefs and the surrounding soft sediments
283 off the Oregon and Washington coast and associated with the substrata on which they were
284 observed. In addition to building an understanding of the diversity, density, and taxa various
285 habitats support, this study provides data on benthic mega-invertebrate abundances and

286 distributions on the Pacific Northwest continental shelf at a specific time point, which may be
287 compared to future similar surveys for assessments of the effects of global warming, fisheries
288 management and marine renewable energy development on the distribution of such taxa.
289 Hundreds of thousands of sessile and motile individuals were identified and enumerated, as well
290 as the characteristics of the substratum. However, several identifications were not able to reach
291 the species level without actual specimens to check and dissect for diagnostic morphological
292 characters. For example, the different species of the sea star genera *Henricia* and *Solaster* are
293 impossible to differentiate without a check of the aboral plates, the adambulacral spines and the
294 pedicellariae (Lambert 2000; C. Mah, pers. comm.); similarly, species identification via images
295 is nearly impossible for organisms like sponges, which are usually identified on the structure of
296 their spicules. All branching and encrusting organisms (trickier to enumerate and discriminate)
297 were gathered as functional groups under the names “branching sponge” and “shelf sponges”
298 respectively, even if these groups included more than just sponge taxa (e.g. bryozoans or colonial
299 ascidians). Since different species use different ecological niches and suitable habitats, a full
300 understanding of which taxa might be most susceptible to small habitat changes would require
301 sampling these organisms, particularly the sessile invertebrates, and identifying them to species.
302 Despite these taxonomic limitations, the review of the video footage and the statistical analyses
303 performed on taxa densities allowed the discrimination of different assemblages on particular
304 substrata based on their taxonomic composition. Like previous studies (Allen and Moore 1996;
305 Allen et al. 1997; Stull et al. 1999; Tissot et al. 2006), differences were observed between
306 habitats composed of higher-relief rocks (greater densities of sessile and structure-forming mega-
307 invertebrates and greater diversity) versus low-relief habitats composed of fine sediments (more
308 motile mega-invertebrates). However, finer distinction was also characterized within both low-

309 relief (between pure mud and mixed mud-rock) and higher-relief (among rock types) habitats as
310 described in the following sections. Although the goal was to describe habitats that were
311 generalizable across sites, some differences among sites were observed. However, this did not
312 seem to be driven by latitudinal or depth differences, which might be suspected to affect species
313 distributions. Siltcoos Reef was more similar to Grays Bank, which is ~500 km north, than to
314 Bandon-Arago, which is only 50 km south (Fig. 1), and Grays Bank and Bandon-Arago had
315 overlapping depth ranges, while Siltcoos was deeper. Thus, observed differences likely stem
316 from differences in the geologic history of the sites such that the assemblage-habitat associations
317 are not unique to a site *per se* but rather are based on characteristics of the substratum. The major
318 habitat types discerned across this ROV survey are described here below.

319

320 *Pure mud*

321 Not surprisingly, the assemblages found along patches of pure mud (not distinguished from sand)
322 were very different from the assemblages found in other types of habitats. The diversity and
323 evenness of taxa living on the mud or partially burrowed in it were quite low while the
324 abundance of some of these taxa numbered in the hundreds. The pure mud community was thus
325 largely dominated by a very few taxa, like Subselliflorae sea whips and burrowing brittle stars
326 with occasional sea anemones and sponges. This dominance of sea whips on mud communities
327 previously has been noted along the Oregon coast (Hixon and Tissot 2007; Hannah et al. 2010,
328 2013), as well as on the southern California shelf (Tissot et al. 2006; de Marniac et al. 2009),
329 the Gulf of Alaska and the Bering Sea (Malecha and Stone 2009). This type of mega-invertebrate
330 can live in dense populations and provides structure and habitat heterogeneity for other
331 invertebrates in this otherwise non-complex environment (Tissot et al. 2006; Malecha and Stone

332 2009). However, Subselliflorae are adapted to life in very homogeneous and stable habitats and
333 are more vulnerable to habitat alteration (e.g. from bottom-fishing gears) than benthic
334 communities found in less consolidated coarse sediments like the mixed mud-rock (Collie et al.
335 2000; Malecha and Stone 2009). Nonetheless, despite the high number of shrimp-trawl records
336 in the vicinity of Siltcoos Reef (R. Hannah, pers. comm.), the observed high abundance of
337 Subselliflorae indicates that the populations observed on the video transects might be in areas
338 around the reef not really accessible to bottom-trawling and could act as source populations to
339 refill the impacted ones nearby. Burrowing brittle stars were also identified in de Marignac et al.
340 (2009) as dominant taxa along what they called the ‘recovering transects’ in central California.
341 In contrast to Siltcoos Reef and Grays Bank, the pure mud patches at Bandon-Arago were not
342 differentiated in their benthic assemblages from the mixed mud-rock patches at the same site and
343 were comprised of very few to no Subselliflorae and burrowing brittle stars. Bandon-Arago is a
344 large and old rock outcrop on the mid Oregon shelf (Romsos et al. 2007) and the pure mud and
345 mixed mud-rock patches were found within the reef itself (Fig. 2). In contrast, Siltcoos Reef and
346 Grays Bank are smaller rock outcrops and pure mud was mostly found around the reefs. The
347 ‘pure mud’ at Bandon-Arago might rather be a thin layer of mud on the bedrock, not really stable
348 and not suitable enough for the species characteristic of pure mud communities to settle in.

349

350 *Mixed mud-rock*

351 Mixed mud-rock habitats were made of mud (or sand) more or less assorted with coarser
352 sediments like gravel, pebble, cobble or even boulder. These unconsolidated rocks act as
353 physical supports for sessile organisms. The taxa inhabiting the mixed mud-rock at Bandon-
354 Arago were sessile organisms like sponges (both shelf and branching) and gorgonians, known as

355 structure-forming mega-invertebrates. They add complexity and heterogeneity to this habitat and
356 supply support, shelter, or food to motile invertebrates like sea stars, sea cucumbers and
357 nudibranchs. However, some of the most abundant motile taxa in this habitat were partially
358 burrowing organisms such as the sea cucumbers *Cucumaria* spp. or the small orange brittle stars
359 that live with the body hidden in tiny cracks in the mud or between small rocks and the arms
360 extending out. At Siltcoos Reef and Grays Bank, in addition to the structure-forming sessile
361 organisms (gorgonians and sponges), the taxa inhabiting the mixed mud-rock habitats were
362 mostly sea anemones and a few motile species like sea stars.

363 Mixed mud-rock has not been described as a major benthic habitat type on the PNW continental
364 shelf in previous studies. On other temperate continental shelves like the Bay of Biscay or the
365 English Channel, mixed mud-rock habitat is described and is further divided into different
366 categories, depending on the size and abundance of the unconsolidated rocks involved, with
367 different assemblages (Brind'Amour et al. 2014). Within this study, the differences between
368 mixed mud-rock at Bandon-Arago versus the other two sites similarly may be related to the
369 difference of the size and abundance of the unconsolidated rocks. At Siltcoos Reef and Grays
370 Bank, the mud was mixed with gravel and occasionally pebbles (small rocks). At Bandon-Arago
371 the mixed mud also included cobbles and boulders. It is thus not certain whether the differences
372 observed between the two mixed mud-rock assemblages here described are locally-induced
373 differences from a general mixed mud-rock habitat, or two distinct habitats differentiated by the
374 characteristics of the mixed-in rocks which support different assemblages. More occurrences of
375 each substratum across sites might have helped highlight differences in benthic assemblages
376 related to the size of the unconsolidated rocks mixed in the mud. Given these findings, 'mixed
377 mud-rock' should be mapped as a distinct habitat characterized by low densities of a diversity of

378 taxa, particularly sponges, gorgonians, anemones, and burrowing echinoderms. Since
379 Brind'Amour et al. (2014) have shown that this habitat can be divided in several categories,
380 future studies should be designed to obtain thorough coverage of transition areas between
381 consolidated rock and mud habitats to discern whether the different sizes of the interstitial rocks
382 in the transition zone support distinct mega-invertebrate assemblages.

383

384 *Consolidated rocks*

385 Most of the species diversity and individual densities were associated with consolidated rocks,
386 which include boulders, flat rocks and ridge rocks with a veneer of mud as well as bare ridge
387 rocks. Across all sites, this habitat had the highest abundance of sessile and structure-forming
388 invertebrates such as sponges, gorgonians, giant plumose anemones, sometimes in very dense
389 aggregations, and other sea anemones. The motile mega-invertebrates were very diverse, with an
390 average of forty taxa, including a variety of crabs, echinoderms (basket stars, brittle stars, feather
391 stars, sea cucumbers and sea stars), nudibranchs, octopuses, scallops and squat lobsters. This
392 diversity can be attributed to the physical complexity of higher-relief substrata where there may
393 be greater variation in depth, temperature, current direction and velocity, nutrient transport, and
394 the substrata may be composed of different elements (Taylor & Wilson 2003). Furthermore, the
395 large diversity of structure-forming sessile and motile invertebrates (e.g. basket stars and feather
396 stars) further increases the habitat complexity and heterogeneity and provides a variety of
397 shelters, refuges, spawning grounds and ecological niches for both invertebrates and fishes
398 (Cerame-Vivas and Gray 1966; Benedetti-Cecchi and Cinelli 1995; Tissot et al. 2006).

399

400 *Rubble rocks*

401 On the other hand, although some of the major species were the same, the substrata composed of
402 rubble rocks (flat or ridge rocks with a cover of unconsolidated rocks) showed very different
403 assemblages. Despite these substrata being rock-based, they did not support the greater densities
404 of sessile and structure-forming mega-invertebrates and greater diversity generally attributed to
405 high-relief rocks (Allen and Moore 1996; Allen et al. 1997; Stull et al. 1999; Tissot et al. 2006).
406 This habitat had the lowest diversity (an average of only ten different species) and densities. This
407 difference might be due to the weak stability of the unconsolidated rocks on a high-relief
408 substratum, probably engendered by hydrodynamic movements due to the strong currents found
409 on the Oregon continental shelf (Kurapov et al. 2003; Osborne et al. 2014). This instability of the
410 substratum may result in frequent disturbance not suitable for the establishment of dense
411 populations of structure-forming organisms able to attract a variety of motile invertebrates. The
412 role of natural disturbance in structuring marine communities has been well described in the
413 intertidal (Dayton 1971; Lubchenco and Menge 1978; Sousa 1979, 1984; Paine and Levin 1981)
414 and shallow subtidal, especially for algae (Airoldi et al. 1996; Airoldi 1998; Scheibling et al.
415 2008). Disturbance due to the movement of rubble rocks might similarly affect the recruitment
416 and persistence of mega-invertebrates in this habitat. Mapping efforts have not yet distinguished
417 this habitat from consolidated rocks and will be challenging to differentiate from complex, yet
418 still consolidated rocks using sonar. However, it should be classified as a separate habitat since it
419 certainly supports a different species assemblage and lower abundances than consolidated rocks
420 without associated rubble.

421
422 Rocky reefs in the PNW continental shelf were highly targeted by fishing activities due to the
423 high diversity of associated rockfish species. Repeated contacts of bottom-trawls on the reefs

424 have damaged or even eradicated slow-growing structure-forming sessile invertebrates and the
425 motile species they attract (Watling and Norse 1998; Kaiser et al. 2006; Sheehan et al. 2013).
426 Nevertheless, because of the decline in rockfish stocks along the PNW coast at the end of the
427 20th century (see review in NRC 2002), the Pacific Fishery Management Council established in
428 the early 2000's new regulations leading to a drastic decrease of the fishing pressure on part of
429 the rocky reefs particularly on the outer continental shelf (Hannah 2003; Bellman et al. 2005;
430 Bellman and Heppell 2007). Since that time, some studies have focused on the recovery of
431 rockfish populations on reefs (Bellman et al. 2005; Bellman and Heppell 2007) or invertebrate
432 populations on mud substrata (de Marignac et al. 2009; Hannah et al. 2010, 2013) after fishing
433 closures, but much remains to be done on the recovery of structure-forming invertebrate species
434 on rocky reefs. The three reefs in our study are not included in the Essential Fish Habitat
435 conservation areas (NMFS 2013) and are thus still open to bottom-trawling, as evidenced by
436 fishing gear debris seen on the video footage at Grays Bank and Siltcoos Reef. Although the
437 fishing pressure is not too high on these three inner shelf reefs (R. Hannah, W. Wakefield, pers.
438 comm.), it is not the case for all the non-protected rocky reefs on the PNW continental shelf, and
439 a comprehensive description of the benthic assemblages is needed to understand the effect of
440 bottom-contact ocean-use activities (e.g. fishing, renewable energy development) and integrate
441 this benthic component into the conservation and management plans. The present results could
442 encourage the design of a video survey on rocky reefs now protected from fishing activities to
443 compare the mega-invertebrate assemblages of reefs now recovering from bottom-gear
444 disturbance to those of reefs clearly still impacted by bottom-fishing activities.

445

446 **5. CONCLUSIONS**

447 Before management decisions can be made about the ocean (for example where to close to
448 fishing practices, where to allow renewable energy installations) it is useful to know what is
449 being protected from potential impacts. While biological communities are shaped by a variety of
450 bottom-up and top-down processes, and species interactions, a major driver structuring benthic
451 mega-invertebrate communities is substratum. Thus, more precise habitat mapping is necessary.
452 This study identified at least four habitats for mega-invertebrate assemblages: (1) Pure mud (not
453 distinguished from sand on the video footage) dominated by sea whips and burrowing brittle
454 stars; (2) Mixed mud-rock (which may be further divided based on size of mixed-in rocks)
455 characterized by medium diversity of species in low density; (3) Consolidated rocks (big rocks
456 with or without a veneer of sediment) characterized by high diversity and density of sessile and
457 motile taxa; and (4) Rubble rocks (big rocks with a cover of unconsolidated rocks) showing less
458 diversity and density than the consolidated rocks, probably due to the disturbance generated by
459 the unconsolidated rocks. These four habitats were consistent across the sites, even if some
460 differences were observed between the mixed mud-rock habitats at BA versus GB and SC,
461 probably due to the different geologic history of the reefs. It may be possible to map mixed mud-
462 rock separately from other unconsolidated sediment with existing data. Future survey methods
463 should attempt to distinguish rubble-rock from consolidated rock.

464

465 **6. ACKNOWLEDGEMENTS**

466 The authors would like to thank K. Politano and T.S. Lee for their participation in the ROV
467 survey cruises and video review. The authors acknowledge funding from the Bureau of Ocean
468 Energy Management via a Cooperative Agreement to SKH, which supported both TSL and LGH,

469 and Hatfield Marine Science Center's Mamie Markham Research Award to TSL. We
470 acknowledge C. Goldfinger (OSU College of Earth, Ocean, and Atmospheric Sciences) for
471 providing high-resolution maps for survey areas. We thank Marine Applied Research and
472 Exploration (MARE) and the crew of the R/V *Pacific Storm* for the completion of ROV surveys
473 in 2011 and the *Derek M. Baylis* for vessel support in 2012. We also thank B. Tissot
474 (Washington State University Vancouver) for assistance in study design and for providing
475 patience, enthusiasm, and thorough guidance during the substratum type and invertebrate
476 classification training. We finally thank W. Austin (Khoyatan Marine Laboratory) and C. Mah
477 and D. Pawson (Smithsonian Institution) for their help on identifying some tricky sponges, sea
478 stars and sea cucumbers on the video footage, as well as W. Wakefield (NOAA Fisheries,
479 Northwest Fisheries Science Center) and R. Hannah (Oregon Department of Fisheries and
480 Wildlife) for their help to understand the fishing rules along the Pacific Northwest coast. We are
481 grateful to the three anonymous reviewers whose comments greatly helped to improve the
482 manuscript.
