## 1 Introduction

Finite-state automata are formalisms as old as computer science itself. By traversing an input structure while changing their internal state, they can solve a variety of computational tasks. Here, we are concerned with automata over infinite trees, which accept or reject a given tree based on its labels. A generalization of these automata with binary decisions are weighted automata. They do not just decide "yes" or "no", but rather compute a value from a given algebraic structure, e. g., a semiring or a lattice.

Because of their intimate connection with logical formalisms, automata working over infinite structures are valuable tools in many areas of theoretical computer science, such as model checking (using temporal logics, see [3, 9]) and description logics (see [1, 2]). The foundation of most of these applications is the reduction of the satisfiability problem of some logic to the emptiness problem for appropriate automata. Weighted automata can be used to compute priorities of different models or the most "desirable" model according to some specification.

When passing from unweighted to weighted formalisms, many problems can be translated accordingly. There are two basic approaches to lift an algorithm for an unweighted problem to a solution to the corresponding weighted problem. The black-box approach reduces the weighted problem to several applications of the unweighted problems and uses the existing algorithm to solve these. The glass-box approach takes the original algorithm and develops a completely new algorithm based on a generalization of the underlying ideas to the weighted formalism.

The purpose of this work is to determine the feasibility of solving the inclusion problem for automata on infinite trees and its generalization to weighted automata, the infimum aggregation problem. This is basically a sequel to [4, where the same problem has already been considered, albeit not very successful. The most difficult step of both the inclusion problem and the infimum aggregation problem is the complementation of automata. The inclusion problem can be reduced to complementation using polynomial-time constructions and a similar reduction can be done for the infimum aggregation problem. Hence there is a whole chapter in this work dedicated to complementation constructions for different automata models.

This work is structured as follows. After introducing the basic definitions in Chapter 2, we take a look at several problems and constructions for weighted and unweighted automata in Chapter 3. This chapter also contains a complexity analysis of the inclusion problem for Büchi tree automata. Following this, we take a look at the complementation problem for other kinds of tree automata in Chapter 4. This includes constructions for the complementation of unweighted and weighted tree automata with different acceptance conditions and comparisons of glass-box and black-box approaches. In Chapter 5 our findings are summarized and suggestions for future work in this area are made.

## 2 Preliminaries

In this section we first define some general conventions and afterwards introduce the basic notions about trees, lattices and automata.

For an infinite sequence $x:=\left(x_{n}\right)_{n \in \mathbb{N}}$ over an alphabet $\Sigma$,

$$
\operatorname{Inf}(x):=\left\{\alpha \in \Sigma \mid \exists^{\infty} n \in \mathbb{N}: x_{n}=\alpha\right\}
$$

denotes the set of symbols occurring infinitely often in $x$. For convenience, any sequence $x=\left(x_{n}\right)_{n \in \mathbb{N}}$ may at any time be used as the set $\left\{x_{n}\right\}_{n \in \mathbb{N}}$.
In order to shorten many expressions, we define the scope of quantifiers and big operators to always be as large as possible. For instance, in the expression

$$
\underset{y \in Y}{\forall} \underset{x \in X}{\exists}(f(x)=y \wedge g(x)=1)
$$

one may drop the outer parentheses.

### 2.1 Trees

Throughout all chapters, $k>0$ shall be some natural number and $K:=\{1, \ldots, k\}$. Our main object of study is the full $k$-ary tree $K^{*}$. The elements of $K^{*}$ are finite sequences over the alphabet $K$ and are called nodes or positions of the tree $K^{*}$. $\varepsilon$ denotes the empty sequence and is called the root node of $K^{*}$. For $i \in K$ and $u \in K^{*}$, ui is called the $i$-th successor of $u$ (see Figure 2.1). The full subtree of $K^{*}$ rooted at $u$ is the set $u\left[K^{*}\right]:=\left\{u v \mid v \in K^{*}\right\}$, whose root is $u$. It is easy to see that $\varepsilon\left[K^{*}\right]=K^{*}$. The depth $|v|$ of a node $v \in u\left[K^{*}\right]$ is the length of the sequence $v$ minus the length of $u$.
We can define a partial order on $K^{*}$ as follows: $u \leq w$ iff $w \in u\left[K^{*}\right]$, i. e., iff $u$ is a prefix of $w$. As usual, $u<w$ abbreviates $u \leq w$ with $u \neq w$. The fact $u \leq w$ is read as " $u$ is above $w$ ".

A subtree of $u\left[K^{*}\right]$ is a set $T \subseteq u\left[K^{*}\right]$ that is prefix-closed, i. e., if $v i \in T$ for $v \in u\left[K^{*}\right]$ and $i \in K$, then $v \in T$ must also hold. The maximal depth of $T$ is

$$
\mathbf{d}(T):=\left\{\begin{array}{ll}
-1 & \text { if } T=\emptyset \\
\max \{|v| \mid v \in T\} & \text { if } T \text { is finite } \\
\infty & \text { otherwise }
\end{array} .\right.
$$

A node $u \in T$ is called inner node of $T$ if all its successors $u i$ are also elements of $T$. A node $u \in T$ is called leaf of $T$ if it has no successors inside $T$. The set of all inner nodes of $T$ is called interior of $T$ and is denoted by $\operatorname{int}(T)$. The set of all leaves of $T$ is called

Figure 2.1: The full $k$-ary tree.
frontier of $T$ and is denoted by $\operatorname{fr}(T)$. A subtree $T$ is called closed if $T=\operatorname{int}(T) \cup \operatorname{fr}(T)$, i. e., every node of $T$ either has exactly $k$ successors in $T$ or none at all.

A path $p$ in $u\left[K^{*}\right]$ is a subtree that contains the root $u$ and for every $v \in p$ there is exactly one $i \in K$ with $v i \in p$. As an exception, there may be one node in $p$ that has no successor in $p$. If this is the case, the path $p$ is finite; otherwise, it is infinite.

The length of a path is its maximal depth. A path $p$ can be identified with the (finite or infinite) sequence of nodes that starts with $u$ and goes from each node $v \in p$ to its unique successor $v i \in p$, if it exists. For a natural number $0 \leq n \leq \mathbf{d}(p)$, the notation $p_{n}$ will be used to refer to the $(n+1)$-st node in this sequence, which is the unique node of depth $n$ in $p$. A path $p$ is maximal in a subtree $T$ if $p \subseteq T$ and $p$ is either infinite or its last node has no successor inside $T$. The set of maximal paths in a subtree $T$ will be denoted by $\mathcal{P} a t h(T)$. The set of paths of length $m \in \mathbb{N}$ inside $T$ will be denoted by $\mathcal{P a t h}(T, m)$.

For a labeling alphabet $\Sigma$, a ( $\Sigma$-) labeled tree is a mapping $K^{*} \rightarrow \Sigma$. As usual, the set of all such mappings is denoted by $\Sigma^{K^{*}}$. Similarly, (finite) ( $\Sigma$-)labeled subtrees are mappings $T \rightarrow \Sigma$ where $T$ is a (finite) subtree of $u\left[K^{*}\right]$ for some $u \in K^{*}$. For a given subtree $T$, the set of all $\Sigma$-labeled subtrees with domain $T$ is denoted by $\Sigma^{T}$.

### 2.2 Lattices

We now introduce some basic notions of lattice theory, which can also be found in any introductory book on the topic (see, e. g., [7]).

A lattice $(S, \oplus, \otimes)$ is an algebraic structure on the set $S$ that is equipped with two binary operations supremum $\oplus$ and infimum $\otimes$. These operations must be commutative and associative and the absorption laws $a \oplus(a \otimes b)=a=a \otimes(a \oplus b)$ must hold for any $a, b \in S$. From these axioms it follows that infimum and supremum are idempotent operations. The infimum of a finite subset $T \subseteq S$ (a finite family $\left(t_{i}\right)_{i \in I} \in S^{I}$ ) will be denoted by $\otimes T\left(\bigotimes_{i \in I} t_{i}\right)$, the supremum by $\bigoplus T\left(\bigoplus_{i \in I} t_{i}\right)$.

A partial order $\leq$ can be defined on a lattice as follows: $a \leq b: \Leftrightarrow a \oplus b=b \Leftrightarrow a \otimes b=a$ for $a, b \in S$. In fact, lattices can equivalently be defined as posets in which infimum and supremum of any two elements exist. The operations infimum and supremum are monotone in each component with respect to this partial order.

A lattic $\mathrm{D}^{1} S$ is called distributive if $a \oplus(b \otimes c)=(a \oplus b) \otimes(a \oplus c)$ and $a \otimes(b \oplus c)=$ $(a \otimes b) \oplus(a \otimes c)$ hold for every $a, b, c \in S$. We will usually deal with finite lattices, in which case distributivity is equivalent to complete distributivity. This property asserts that for all families $\left(a_{i, j}\right)_{i \in I, j \in J(i)}$ of elements of $S$ the equations

$$
\bigotimes_{i \in I} \bigoplus_{j \in J(i)} a_{i, j}=\bigoplus_{f \in \mathcal{F}} \bigotimes_{i \in I} a_{i, f(i)} \quad \text { and } \quad \bigoplus_{i \in I} \bigotimes_{j \in J(i)} a_{i, j}=\bigotimes_{f \in \mathcal{F}} \bigoplus_{i \in I} a_{i, f(i)}
$$

hold, where $\mathcal{F}$ is defined as the set of all mappings $f: I \rightarrow \bigcup_{i \in I} J(i)$ with $f(i) \in J(i)$ for all $i \in I$.

In a finite lattice $S$ we can also write $\bigoplus_{i \in I} t_{i}$ and $\bigotimes_{i \in I} t_{i}$ for supremum and infimum of an infinite family $\left(t_{i}\right)_{i \in I} \in S^{I}$. Furthermore, every finite lattice $S$ is bounded, i. e., it has a smallest element $0_{S}:=\bigotimes S$ and a largest element $1_{S}:=\bigoplus S$.

A bounded lattice $S$ is called complemented if for every $a \in S$, there exists a complement $b \in S$ with $a \otimes b=0_{S}$ and $a \oplus b=1_{S}$. If $S$ is distributive, then this complement is unique and we denote the complement of $a \in S$ by $\bar{a}$. A complemented distributive lattice is also called a Boolean lattice. Every Boolean lattice is isomorphic to a powerset lattice $(\mathcal{P}(X), \cup, \cap)$ for some set $X([7])$.
Example 2.1 The lattice $\mathbb{B}:=(\{0,1\}, \oplus, \otimes)$ with $0 \leq 1$ is a finite Boolean lattice. It is the smallest nontrivial lattice and is usually used for Boolean logics. In this case, 0 and 1 are interpreted as the truth values false and true, respectively. The infimum $\otimes$ is the binary conjunction of truth values and $\oplus$ is the disjunction. The expression "a implies b" can be represented as $a \leq b$ or equivalently as $\bar{a} \oplus b=1$ (see Lemma 2.2 a)).

In a Boolean lattice $S$, the equations $\overline{\bar{a}}=a, \overline{a \oplus b}=\bar{a} \otimes \bar{b}$ and $\overline{a \otimes b}=\bar{a} \oplus \bar{b}$ hold for all $a, b \in S$. We always have $a \leq b$ iff $\bar{b} \leq \bar{a}, \overline{1_{S}}=0_{S}$ and $\overline{0_{S}}=1_{S}$. In a finite Boolean lattice, the following equations hold for any family $\left(t_{i}\right)_{i \in I}$ of lattice elements:

$$
\overline{\bigotimes_{i \in I} t_{i}}=\bigoplus_{i \in I} \overline{t_{i}} \quad \text { and } \quad \overline{\bigoplus_{i \in I} t_{i}}=\bigotimes_{i \in I} \overline{t_{i}} .
$$

An element $p$ of a lattice $S$ is called meet prime if $a \otimes b \leq p$ always implies $a \leq p$ or $b \leq p$. The dual notion is that of a join prime element which is defined dually. In a distributive lattice, meet prime elements are exactly the meet irreducible elements. These are defined as elements $p \in S$ for which $a \otimes b=p$ always implies $a=p$ or $b=p$. Every element of a distributive lattice $S$ can uniquely be identified by the set of meet prime elements above it since

$$
a=\bigotimes\{p \in S \mid p \text { meet prime and } a \leq p\}
$$

holds for all $a \in S$. In a Boolean lattice $S$, the complement $\bar{a}$ of a meet prime element $a \in S$ is join prime and the other way around. If the Boolean lattice $S$ is isomorphic to the powerset lattice over some set $X$, then there are exactly $|X|$ meet prime and $|X|$ join prime elements in $S$, namely the co-atoms and the atoms, respectively.

In the following chapters we will mainly deal with finite Boolean lattices. We now prove a few useful facts about these structures.

[^0]Lemma 2.2 Let $S$ be a finite Boolean lattice.
a) For all $a, b \in S, \bar{a} \oplus b=1_{S}$ iff $a \leq b$.
b) For every index set $I$ and families $\left(f_{i}\right),\left(g_{i}\right) \in S^{I}$, the following holds:

$$
\left(\bigoplus_{i \in I} f_{i}\right) \otimes\left(\bigotimes_{j \in I} g_{j}\right) \leq \bigoplus_{i \in I}\left(f_{i} \otimes g_{i}\right)
$$

Proof:
a) If $a \leq b$, then $\bar{a} \oplus b \geq \bar{a} \oplus a=1_{S}$. Let now $\bar{a} \oplus b=1_{S}$ and $a \not \leq b$. Then $\bar{b} \not \leq \bar{a}$ and thus $\bar{b} \neq \bar{b} \otimes \bar{a}$. But $(\bar{b} \otimes \bar{a}) \otimes b=0_{S}$ and $(\bar{b} \otimes \bar{a}) \oplus b=\bar{a} \oplus b=1_{S}$, which means that $\bar{b} \otimes \bar{a}$ is another complement of $b$. This contradicts the fact that $S$ is uniquely complemented.
b) By distributivity of $S$, we have

$$
\left(\bigoplus_{i \in I} f_{i}\right) \otimes\left(\bigotimes_{j \in I} g_{j}\right)=\bigoplus_{i \in I}\left(f_{i} \otimes \bigotimes_{j \in I} g_{j}\right) \leq \bigoplus_{i \in I}\left(f_{i} \otimes g_{i}\right)
$$

For an alphabet $\Sigma$ and a lattice $S$, a formal tree series over $\Sigma$ and $S$ is a mapping $\Sigma^{K^{*}} \rightarrow S$. Each labeled tree is thus assigned a value from $S$. For a formal tree series $f: \Sigma^{K^{*}} \rightarrow S$, one usually writes $(f, t)$ for the image of a tree $t \in \Sigma^{K^{*}}$ under $f$ and calls this the coefficient of $f$ at $t$. The class of all formal tree series over $\Sigma$ and $S$ is denoted by $S\left\langle\left\langle\Sigma^{K^{*}}\right\rangle\right\rangle$.

For convenience, we define complex operations $f \oplus g, f \otimes g$ and $\bar{f}$ on tree series $f, g \in$ $S\left\langle\left\langle\Sigma^{K^{*}}\right\rangle\right\rangle$ as follows:

$$
\begin{aligned}
(f \oplus g, t) & :=(f, t) \oplus(g, t) \\
(f \otimes g, t) & :=(f, t) \otimes(g, t) \\
(\bar{f}, t) & :=\overline{(f, t)}
\end{aligned}
$$

### 2.3 Automata

We want to look at (non-deterministic) weighted tree automata that work on labeled trees $t \in \Sigma^{K^{*}}$ as input and output a value from some lattice $S$, i. e., they effectively compute a formal tree series over $\Sigma$ and $S$. These automata take the form of a 6 -tuple $\mathcal{A}=$ $(Q, \Sigma, S$, in, wt, $\mathfrak{F})$ where

- $Q$ is a finite set of states,
- $\Sigma$ is the input alphabet,
- $S$ is a lattice,
- in : $Q \rightarrow S$ is the initial distribution,
- wt : $Q \times \Sigma \times Q^{k} \rightarrow S$ is the transition weight function and
- $\mathfrak{F} \subseteq Q^{\mathbb{N}}$ is the acceptance condition, described as a predicate on infinite $Q$-sequences.

A run of this automaton is a $Q$-labeled tree $r \in Q^{K^{*}}$. Similarly, a subrun of $\mathcal{A}$ is a $Q$-labeled subtree $r \in Q^{T}$ for a node $u \in K^{*}$ and a subtree $T \subseteq u\left[K^{*}\right]$. Given a subrun $r \in Q^{T}$, an input tree $t \in \Sigma^{K^{*}}$ and an inner node $u$ of $T$, we define the transition of $r$ on $t$ at $u$ as the tuple $\overrightarrow{r(t, u)}:=(r(u), t(u), r(u i), \ldots, r(u k))$. The weight of $r$ (on $t$ ) is the value

$$
\mathrm{wt}(t, r):=\operatorname{in}(r(\varepsilon)) \otimes \bigotimes_{u \in \operatorname{int}(T)} \mathrm{wt}(\overrightarrow{r(t, u)})
$$

A run $r \in Q^{K^{*}}$ is called successful if for every path $p \in \mathcal{P a t h}\left(K^{*}\right)$ the sequence $\left(r\left(p_{n}\right)\right)_{n \in \mathbb{N}}$ is an element of $\mathfrak{F}$. The set of all successful runs of $\mathcal{A}$ is denoted by $\operatorname{succ}(\mathcal{A})$. The automaton $\mathcal{A}$ defines $\|\mathcal{A}\| \in S\left\langle\left\langle\Sigma^{K^{*}}\right\rangle\right\rangle$, the behavior of $\mathcal{A}$ (or tree series recognized by $\mathcal{A}$ ), by assigning each input tree $t \in \Sigma^{K^{*}}$ the value

$$
(\|\mathcal{A}\|, t):=\bigoplus_{r \in \operatorname{succ}(\mathcal{A})} \mathrm{wt}(t, r)
$$

This value is also called the behavior of $\mathcal{A}$ on $t$.
Since the images of in and wt are finite, the infima and suprema in the above definitions are restricted to a finitely generated (and thus finite, see [7]) sublattice. Thus, even if $S$ is an infinite lattice, the formal tree series $\|A\|$ has a finite image. In consequence, we may always restrict ourselves to finite lattices when reasoning about weighted tree automata.

Weihgted tree automata are classified by a sequence of several letters. Usually, this sequence has the form $W \alpha A$, where $\alpha$ describes the nature of the acceptance condition $\mathfrak{F}$ as follows:

- If $\mathfrak{F}=Q^{\mathbb{N}}$, which is equivalent to no restriction on the runs, then the automaton is called a weighted looping automaton (WLA). In this case, $\mathcal{A}$ is represented by the 5 -tuple ( $Q, \Sigma, S$, in, wt).
- If there is a set $F \subseteq Q$ of final states such that $\mathfrak{F}=\left\{q \in Q^{\mathbb{N}} \mid \operatorname{Inf}(q) \cap F \neq \emptyset\right\}$, then the automaton is called a weighted Büchi automaton (WBA). In the tuple representing the automaton, $\mathfrak{F}$ is then usually replaced by $F$.
A generalized Büchi condition is expressed by a family $\left(F_{i}\right)_{i \in I}$ of final state sets with a finite index set $I$. An infinite path $q \in Q^{\mathbb{N}}$ is then accepted if it is accepted by all of the Büchi conditions $F_{i}$. Such an automaton is called a $W G B A$.
- The co-Büchi condition is similarly defined based on a set $F \subseteq Q$ for which $\mathfrak{F}=\{q \in$ $\left.Q^{\mathbb{N}} \mid \operatorname{Inf}(q) \backslash F=\emptyset\right\}$. This yields a weighted co-Büchi automaton (WCA).
A generalized co-Büchi condition is determined by a family $\left(F_{i}\right)_{i \in I}$ of final state sets on a finite index set $I . q \in Q^{\mathbb{N}}$ is accepted if it is accepted by any of the co-Büchi conditions $F_{i}$. The resulting automaton is a $W G C A$.
- Another acceptance condition that is based on a set $F \subseteq Q$ is the weak Büchi condition, where $\mathfrak{F}=\left\{q \in Q^{\mathbb{N}} \mid q \cap F \neq \emptyset\right\}$. This type of automaton is expressed by the letters $W b A$.
- The weak co-Büchi condition is defined by a set $F \subseteq Q$ as $\mathfrak{F}=\left\{q \in Q^{\mathbb{N}} \mid q \backslash F=\emptyset\right\}$. Similar to the weak Büchi condition, these automata are called WcA.

## 2 Preliminaries

- A weighted Rabin automaton (WRA) is a weighted tree automaton whose acceptance condition $\mathfrak{F}$ is described by a set of pairs $\mathcal{F}=\left\{\left(E_{i}, F_{i}\right) \mid i \in I\right\}$ for some finite index set $I$. A sequence $q \in Q^{\mathbb{N}}$ is then in $\mathfrak{F} \operatorname{iff} \operatorname{Inf}(q) \cap F_{i} \neq \emptyset$ and $\operatorname{Inf}(q) \cap E_{i}=\emptyset$ for some $i \in I$.
- A Rabin chain condition is a Rabin condition $\left\{\left(E_{1}, F_{1}\right), \ldots,\left(E_{n}, F_{n}\right)\right\}(n \in \mathbb{N})$ for which the strict inclusions $E_{1} \subsetneq F_{1} \subsetneq E_{2} \subsetneq F_{2} \subsetneq \ldots \subsetneq E_{n} \subsetneq F_{n}$ hold. These automata are called WRCA.
- The Streett condition is also defined by a set of pairs $\mathcal{F}=\left\{\left(E_{i}, F_{i}\right) \mid i \in I\right\}$ for a finite set $I$. $q \in Q^{\mathbb{N}}$ is accepted $\operatorname{iff} \operatorname{Inf}(q) \cap F_{i}=\emptyset$ or $\operatorname{Inf}(q) \cap E_{i} \neq \emptyset$ for all $i \in I$. The letters WSA indicate this kind of acceptance condition.
- A Muller condition is given by a set $\mathcal{F} \subseteq \mathcal{P}(Q)$ of state sets. Then $q \in \mathfrak{F}$ iff $\operatorname{Inf}(q) \in \mathcal{F}$. This is indicated by the letters $W M A$.
- The acceptance condition of a weighted parity automaton (WPA) is defined by a function $\pi: Q \rightarrow \mathbb{N}$ assigning a priority to each state. Based on this, $\mathfrak{F}$ is described as the set $\left\{q \in Q^{\mathbb{N}} \mid \min \operatorname{Inf}(\pi(q))\right.$ is even $\}$.
The relationships between these acceptance conditions are depicted in Figure 2.2. In this diagram the different conditions are ordered by expressiveness, i.e., the inclusion of the respective classes of recognized tree series. Most of these inclusions are easy consequences of the above definitions. See [13] for the equivalence of Rabin, Streett, Muller, and parity conditions.

Figure 2.2: The hierarchy of acceptance conditions for weighted tree automata
Example 2.3 We want to illustrate these relationships by a few examples.
Let $Q$ be a state set and $F \subseteq Q$ the final state set of a Büchi acceptance condition. An equivalent parity condition is defined by the mapping

$$
\pi(q):=\left\{\begin{array}{ll}
1 & \text { if } q \notin F \\
0 & \text { if } q \in F
\end{array} .\right.
$$

For a parity condition given by $\pi: Q \rightarrow \mathbb{N}$, an equivalent Streett condition consists of the pairs

$$
\left(\pi^{-1}(\{0, \ldots, 2 k\}), \pi^{-1}(2 k+1)\right)
$$

for all $k \in \mathbb{N}$ with $0 \leq 2 k \leq \max \pi(Q)$. Thus the number of Streett pairs is roughly half the number of priorities.

Example 2.4 Now we want to show that Rabin chain conditions and parity conditions determine equivalent classes of automata (see [13, Definition 6.4]).

Similarly to the previous example, any parity condition $\pi: Q \rightarrow \mathbb{N}$ on a state set $Q$ can be expressed as a Rabin chain condition using the pairs

$$
\left(\pi^{-1}(\{0, \ldots, 2 k-1\}), \pi^{-1}(\{0, \ldots, 2 k\})\right)
$$

for all $k \in \mathbb{N}$ with $0 \leq 2 k \leq \max \pi(Q)$.
The converse is also true, since for a Rabin chain condition $E_{1} \subsetneq F_{1} \subsetneq \ldots \subsetneq E_{n} \subsetneq F_{n}$ we find an equivalent parity condition with the priority function

$$
\pi(q):=\left\{\begin{array}{ll}
2 k & \text { if } q \in F_{k} \backslash E_{k} \text { for some } k \\
2 k+1 & \text { if } q \in E_{k+1} \backslash F_{k} \text { for some } k
\end{array},\right.
$$

if we define $F_{0}:=\emptyset$ and $E_{n+1}:=Q$.
Again, the difference between the number of priorities and the number of pairs is only a constant factor of 2 .

There are a few other important classes of automata that arise from the following restrictions.

If $S=\mathbb{B}$, the automaton is called (unweighted) tree automaton and the letter $W$ is dropped out of the classification. In this case, $S=\mathbb{B}$ is usually left out of the tuple describing the automaton. The tree series recognized by $\mathcal{A}$ can then be interpreted as the set

$$
\mathcal{L}(\mathcal{A}):=\left\{t \in \Sigma^{K^{*}} \mid(\|\mathcal{A}\|, t)=1\right\}
$$

called the tree language recognized by $\mathcal{A}$. If $t \in \mathcal{L}(\mathcal{A})$, then we say that the tree $t$ is accepted by $\mathcal{A}$. The functions in and wt are usually replaced by the initial state set $I \subseteq Q$ and the transition relation $\Delta \subseteq Q \times \Sigma \times Q^{k}$, respectively.

In addition, any classification may be prefixed by the letter $D$, indicating that the automaton is deterministic, i.e., there is exactly one $q \in Q$ for which $\operatorname{in}(q)>0_{S}$ and for every $q \in Q$ and $\alpha \in \Sigma$ there is exactly one tuple $\left(q_{1}, \ldots, q_{k}\right) \in Q^{k}$ such that $\operatorname{wt}\left(q, \alpha, q_{1}, \ldots, q_{k}\right)>0_{S}$. This implies that for each input tree $t \in \Sigma^{K^{*}}$ there is exactly one run $r \in Q^{K^{*}}$ with $\mathrm{wt}(t, r)>0_{S}$.

The classes of tree series recognized by a specific type of automata are defined as

$$
S^{\tau}\left\langle\left\langle\Sigma^{K^{*}}\right\rangle\right\rangle:=\{\|\mathcal{A}\| \mid \mathcal{A} \text { is a weighted tree automaton over } S \text { and } \Sigma \text { of type } \tau\} .
$$

In the next chapter we will take a closer look at some of these automata models. We will consider several tasks for weighted tree automata and try to solve them.

## 3 Weighted Tree Automata

In this chapter we want to introduce the main problem that we try to solve subsequently. The main focus of this work lies on weighted Büchi automata (WBA), because for this relatively simple acceptance condition there are efficient algorithms that solve a number of fundamental problems.

The next section gives an overview over the basic tasks for Büchi automata. Afterwards we will introduce the main problem and prove a complexity result.

### 3.1 Basic Results

In this section we will take a look at various closure properties of the class $S^{\mathrm{WBA}}\left\langle\left\langle\Sigma^{K^{*}}\right\rangle\right\rangle$. We will later use these to give algorithms for more complex problems by reducing them to a very simple problem - the emptiness problem for Büchi automata. The name of this problem suggests the domain of unweighted automata.

## Task (Emptiness Problem)

Given a BA $\mathcal{A}$, decide whether $\mathcal{L}(\mathcal{A})=\emptyset$.
This can be decided in quadratic time in the size of the input automaton ([11]). The generalization of this problem to weighted automata is as follows.

## Task (Behavior Computation)

Given a WBA $\mathcal{A}$ over a singleton alphabet, compute $\|\mathcal{A}\|$.
This can be solved by lifting the unweighted algorithm to the weighted case. In [2] this algorithm was developed and it was shown that its complexity is polynomial in the size of the input automaton and the underlying lattice if the lattice is finite and distributive. In the remainder of this work, $S$ is assumed to be finite and distributive unless specified otherwise.

By reduction to the emptiness problem, several other problems can be shown to be of polynomial complexity.

## Task (Infimum Computation)

Given two WBA $\mathcal{A}_{1}, \mathcal{A}_{2}$, compute $\left\|\mathcal{A}_{1}\right\| \otimes\left\|\mathcal{A}_{2}\right\|$.

## Task (Supremum Computation)

Given two WBA $\mathcal{A}_{1}, \mathcal{A}_{2}$, compute $\left\|\mathcal{A}_{1}\right\| \oplus\left\|\mathcal{A}_{2}\right\|$.
These problems were solved in [4 by constructing a third WBA $\mathcal{A}$ with $\|\mathcal{A}\|=\left\|\mathcal{A}_{1}\right\| \otimes$ $\left\|\mathcal{A}_{2}\right\|$ (or $\left\|\mathcal{A}_{1}\right\| \oplus\left\|\mathcal{A}_{2}\right\|$ ) whose behavior could then be computed using the algorithm from [2]. The construction of $\mathcal{A}$ is of polynomial complexity in both cases.

Another result concerning generalized Büchi automata is of interest here. It turns out that $S^{\mathrm{WGBA}}\left\langle\left\langle\Sigma^{K^{*}}\right\rangle\right\rangle=S^{\mathrm{WBA}}\left\langle\left\langle\Sigma^{K^{*}}\right\rangle\right\rangle$.
Lemma 3.1 Let $\mathcal{A}$ be a $W G B A$. Then there is a WBA $\mathcal{A}^{\prime}$ with $\left\|\mathcal{A}^{\prime}\right\|=\|\mathcal{A}\|$ which is of size polynomial in the size of $\mathcal{A}$.
Proof: For automata over a singleton alphabet $\Sigma=\{\star\}$, this was proven in 2 by giving an explicit construction for $\mathcal{A}^{\prime}$. The construction and the proof were lifted to arbitrary weighted automata in [4].

A result that will be useful later is that to compute the behavior of a weighted automaton over a finite lattice $S$ on a given input tree $t$ it suffices to consider a finite subtree of $K^{*}$. We prove a more general result.
Lemma 3.2 Let $S$ be a finite lattice, $\Sigma$ an input alphabet, $t \in \Sigma^{K^{*}}$ an input tree, $Q$ a state set and $P: K^{*} \times\left(Q \times \Sigma \times Q^{k}\right) \rightarrow S$ a function that assigns a lattice element to each pair $(u, y)$ consisting of a node and a transition. There is a closed, finite subtree $T \subseteq K^{*}$ such that for every run $r \in Q^{K^{*}}$ we have

$$
\bigotimes_{u \in K^{*}} P(u, \overrightarrow{r(t, u)})=\bigotimes_{u \in \operatorname{int}(T)} P(u, \overrightarrow{r(t, u)})
$$

Proof: We first construct the infinite tree $R$ of all finite subruns. The root of $R$ is labeled by the empty subrun $r: \emptyset \rightarrow Q$ and its direct successors are labeled with all subruns $r:\{\varepsilon\} \rightarrow Q$ of depth 0 . For each node of $R$ of depth $n$ that is labeled with a subrun $r$ of depth $n-1$, its successors are labeled with all extensions of $r$ to subruns $r^{\prime}$ of depth $n$. Since $r$ has $k^{n-1}$ leaves, there are $k^{n-1}|Q|^{k}$ such extensions. Thus, $R$ is finitely branching.

The tree $R^{\prime}$ is now constructed from $R$ by pruning it as follows. We traverse $R$ depth-first and check the label $r \in Q^{T}$ of each node. If there is an extension of $r$ to a finite subrun $r^{\prime} \in Q^{T^{\prime}}$ with

$$
\bigotimes_{u \in \operatorname{int}(T)} P(u, \overrightarrow{r(t, u)})>_{S} \bigotimes_{u \in \operatorname{int}\left(T^{\prime}\right)} P\left(u, \overrightarrow{r^{\prime}(t, u)}\right)
$$

then we continue. Otherwise, we remove all nodes below the current node.
Since $S$ is finite, for every run $r \in Q^{K^{*}}$ the expression $P(u, \overrightarrow{r(t, u)})$ can only yield finitely many different values. Thus, there must be a depth below which the value of the infimum of all $P(u, \overrightarrow{r(t, u)})$ is not changed anymore. Since every infinite path in $R$ uniquely corresponds to a run $r \in Q^{K^{*}}$, this path must have been pruned in the construction of $R^{\prime}$, and thus $R^{\prime}$ can have no infinite paths.

Since $R^{\prime}$ is still finitely branching, by König's Lemma, $R^{\prime}$ must be finite and thus have a maximal depth $m$. Now it is easily seen that the tree $T:=\bigcup_{n=0}^{m} K^{n}$ has the desired property.

Note that this does not only hold for the infimum of the values $P(u, \overrightarrow{r(t, u)})$. Using the same arguments, an analogous result can be proven where $\otimes$ is substituted by $\bigoplus$.
Corollary 3.3 For every weighted tree automaton $\mathcal{A}=(Q, \Sigma, S$, in, wt, $\mathfrak{F})$ with finite $S$ and every input tree $t \in \Sigma^{K^{*}}$, there is a closed, finite subtree $T \subseteq K^{*}$ with the property that

$$
\left.(\|\mathcal{A}\|, t)=\left(\|\mathcal{A}\|_{T}, t\right):=\bigotimes_{r \in \operatorname{succ}(\mathcal{A})} \operatorname{in}(r(\varepsilon)) \otimes \bigotimes_{u \in \operatorname{int}(T)} \mathrm{wt}(\overrightarrow{r(t, u})\right)
$$

Proof: Apply Lemma 3.2 with $P(u, y):=\mathrm{wt}(y)$ for every $u \in K^{*}$ and $y \in Q \times \Sigma \times Q^{k}$.
This means that the computation of $(\|\mathcal{A}\|, t)$ for a given $t$ can be carried out in a finite amount of time, which is of course due to the finiteness of $S$. We now reformulate the above results for unweighted automata.
Corollary 3.4 Let $\Sigma$ be an input alphabet, $t \in \Sigma^{K^{*}}$ an input tree, $Q$ a state set and $P \subseteq K^{*} \times\left(Q \times \Sigma \times Q^{k}\right)$ a predicate on pairs $(u, y)$ of nodes and transitions. There is a closed, finite subtree $T \subseteq K^{*}$ such that for every run $r \in Q^{K^{*}}$ we have

$$
\forall_{u \in K^{*}} P(u, \overrightarrow{r(t, u)}) \Longleftrightarrow \forall_{u \in \operatorname{int}(T)}^{\forall} P(u, \overrightarrow{r(t, u)})
$$

Corollary 3.5 For every unweighted tree automaton $\mathcal{A}=(Q, \Sigma, I, \Delta, \mathfrak{F})$ and every input tree $t \in \Sigma^{K^{*}}$, there is a closed, finite subtree $T \subseteq K^{*}$ with the property that

$$
t \in \mathcal{L}(\mathcal{A}) \Longleftrightarrow \underset{r \in \operatorname{succ}(\mathcal{A})}{\exists} r(\varepsilon) \in I \wedge \underset{u \in \operatorname{int}(T)}{\forall} \overrightarrow{r(t, u)} \in \Delta
$$

### 3.2 Inclusion

In the remainder of this work, we are concerned with solving the following task.

## Task (Infimum Aggregation)

Given two WBA $\mathcal{A}$ and $\mathcal{A}^{\prime}$, compute $\bigotimes_{t \in \Sigma^{K^{*}}}(\|\mathcal{A}\|, t) \oplus \overline{\left(\left\|\mathcal{A}^{\prime}\right\|, t\right)}$.
This can be seen as a generalization of another task, where both automata are unweighted.

## Task (Inclusion Problem)

Given two BA $\mathcal{A}$ and $\mathcal{A}^{\prime}$, decide whether $\mathcal{L}\left(\mathcal{A}^{\prime}\right) \subseteq \mathcal{L}(\mathcal{A})$.
Deciding this inclusion is problematic, because one usually checks emptiness of the intersection $\overline{\mathcal{L}\left(\mathcal{A}^{\prime}\right)} \cap \mathcal{L}(\mathcal{A})$. However, the class $\mathbb{B}^{\mathrm{BA}}\left\langle\left\langle\Sigma^{K^{*}}\right\rangle\right\rangle$ is not closed under complement ([13]), so this approach does not work when one works only with Büchi tree automata. Luckily, the class $\mathbb{B}^{\mathrm{PA}}\left\langle\left\langle\Sigma^{K^{*}}\right\rangle\right\rangle$ of all tree languages recognized by unweighted parity automata is closed under complement and intersection ([13]), so we can decide the inclusion problem by viewing $\mathcal{A}$ and $\mathcal{A}^{\prime}$ as parity automata (see Example 2.3). We will now look at the complexity of this approach.

### 3.2.1 Complexity of Inclusion

To prepare the ground for the complexity analysis of the inclusion test for unweighted Büchi automata, we need to introduce several new automata models. Since these are only needed in this section, we define them only for the unweighted case.

Definition 3.6 An automaton on finite trees is a tuple $\mathcal{A}=(Q, \Sigma, I, \Delta)$, where $Q, \Sigma, I$ and $\Delta$ are defined as for automata on infinite trees. Input trees for these automata are all finite $\Sigma$-labeled subtrees. Such a subtree $t \in \Sigma^{T}$ is accepted if there is a finite subrun $r \in Q^{T}$ with $r(\varepsilon) \in I$ and $\overrightarrow{r(t, u)} \in \Delta$ for every $u \in \operatorname{int}(T)$. The language recognized by $\mathcal{A}$ is $\mathcal{L}(\mathcal{A}):=\left\{t \in \Sigma^{T}\right.$ finite labeled subtree $\mid \mathcal{A}$ accepts $\left.t\right\}$.

Definition 3.7 An alternating tree automaton is a tuple $\mathcal{A}=(Q, \Sigma, I, \delta, \mathfrak{F})$, where $Q, \Sigma$, $I$ and $\mathfrak{F}$ are defined as for non-deterministic unweighted tree automata. The transition function $\delta: Q \times \Sigma \rightarrow \mathcal{F}(Q \times K)$ maps each state and input symbol to a monotone Boolean formula over $Q \times K$.

Intuitively, an atomic formula $(q, i)$ means that the automaton goes to state $q$ at the $i$-th successor of the current node. Conjunction $\wedge$ means that the automaton splits up into several copies which each pursues the directions given by the conjuncts. Disjunction $\checkmark$ means that the automaton can make a non-deterministic choice as to which disjunct to follow.

Starting from the root and an initial state, from one starting automaton many copies can be generated, depending on the non-deterministic choices. Basically, each of these copies consists of a path taken through $K^{*}$ and an associated sequence of states. An input tree is accepted if it is possible to make each of the non-deterministic choices in such a way that the state sequences generated by the resulting copies are all accepted by $\mathfrak{F}$.

Alternating tree automata are designated by the prefix $A$ to the classification, e. g., ABA stands for the class of all alternating automata with a Büchi acceptance condition.

Example 3.8 A non-deterministic unweighted tree automaton $(Q, \Sigma, I, \Delta, \mathfrak{F})$ can easily be transformed into an alternating one by replacing $\Delta$ with the function

$$
\delta(q, \alpha):=\bigvee_{\left(q, \alpha, q_{1}, \ldots, q_{k}\right) \in \Delta} \bigwedge_{i \in K}\left(q_{i}, i\right),
$$

i. e., the automaton non-deterministically chooses a transition to take and then sends one copy in every direction.

We are now ready to show the EXPTIME-completeness of the inclusion problem.
Theorem 3.9 The inclusion problem is EXPTIME-complete. $T$
Proof: We show EXPTIME-hardness by reduction of the inclusion problem for finite trees, i. e., given two automata $\mathcal{A}$ and $\mathcal{A}^{\prime}$ on finite trees, decide whether $\mathcal{L}\left(\mathcal{A}^{\prime}\right) \subseteq \mathcal{L}(\mathcal{A})$. It was shown in [12, Theorem 2.1] that this problem is EXPTIME-complete.

The reduction employs a straightforward translation of automata on finite trees to Büchi automata. Given an automaton $\mathcal{A}=(Q, \Sigma, I, \Delta)$ on finite trees, the equivalent Büchi automaton $\mathcal{B}=\left(Q^{\prime}, \Sigma^{\prime}, I, \Delta^{\prime}, F\right)$ is constructed as follows:

- $\Sigma^{\prime}:=\Sigma \cup\{\star\}$, where $\star$ is a new symbol
- $Q^{\prime}:=Q \cup\left\{q_{\star}\right\}$, where $q_{\star}$ is a new state
- $\Delta^{\prime}:=\Delta \cup\left\{\left(q, \star, q_{\star}, \ldots, q_{\star}\right) \mid q \in Q^{\prime}\right\}$
- $F:=\left\{q_{\star}\right\}$

[^1]In this construction every finite tree $t \in \Sigma^{T}$ is uniquely represented by an infinite tree $t^{\prime} \in \Sigma^{\prime K^{*}}$ with $t^{\prime}(u)=\star$ for every $u \in K^{*} \backslash T$ and $\mathcal{B}$ accepts only those infinite trees that represent a finite tree in this way. It is easy to see that $\mathcal{L}\left(\mathcal{A}^{\prime}\right) \subseteq \mathcal{L}(\mathcal{A})$ holds for two automata on finite trees iff $\mathcal{L}\left(\mathcal{B}^{\prime}\right) \subseteq \mathcal{L}(\mathcal{B})$ holds for their corresponding Büchi automata.

We will now give an algorithm that decides $\mathcal{L}\left(\mathcal{A}^{\prime}\right) \subseteq \mathcal{L}(\mathcal{A})$ in time exponential in the size of the Büchi automata $\mathcal{A}$ and $\mathcal{A}^{\prime}$. Let $n$ and $n^{\prime}$ be the number of states of $\mathcal{A}$ and $\mathcal{A}^{\prime}$, respectively.

1) We translate $\mathcal{A}$ into an equivalent $\operatorname{APA} \mathcal{B}$. The transition function $\delta$ of this automaton can be determined as in Example 3.8, the equivalent parity condition as in Example 2.3. This construction yields an automaton with $n$ states and 2 priorities.
2) We use [16, Lemma 6.8] to construct an equivalent PA $\mathcal{B}^{\prime}{ }^{2}$ This non-deterministic automaton has a number of states exponential in $n$ and a number of priorities polynomial in $n$. Let $2^{p(n)}$ be a bound on the number of states and $p^{\prime}(n)$ be a bound on the number of priorities of $\mathcal{B}^{\prime}$ for suitable polynomials $p$ and $p^{\prime}$.
3) Now we have to construct an automaton $\mathcal{C}$ recognizing the intersection of $\mathcal{L}\left(\mathcal{B}^{\prime}\right)$ and $\mathcal{L}\left(\mathcal{A}^{\prime}\right)$. To do this, we use a standard product construction on the automata, where the acceptance conditions have first been rewritten as Streett conditions. For $\mathcal{B}^{\prime}$, the equivalent Streett condition has at most $p^{\prime}(n)$ pairs and for $\mathcal{A}^{\prime}$ we only need one pair (see Example 2.3). The product automaton then has as acceptance condition the conjunction of these two Streett conditions, which is again a Streett condition with at most $p^{\prime}(n)+1$ pairs. The number of states of $\mathcal{C}$ is bounded by $n^{\prime} 2^{p(n)}$.
4) We rewrite the SA $\mathcal{C}$ again as a PA $\mathcal{C}^{\prime}$. For this we use the construction in [5, Theorem 7]. This construction takes a finite-state Streett game and constructs an equivalent Rabin chain game. Unweighted automata can be interpreted as special finite-state games, so this result also holds for Strett automata and Rabin chain automata (see, e.g., [13]). Rabin chain conditions can equivalently be expressed as parity conditions of the same size (see Example 2.4).
We arrive at a PA with $O\left(n^{\prime} 2^{p(n)}\left(p^{\prime}(n)+1\right)!\right)$ states and $O\left(p^{\prime}(n)+1\right)$ priorities. Thus, the number of states is bounded by $n^{\prime} 2^{r(n)}$ and the number of priorities by $r^{\prime}(n)$ for polynomials $r$ and $r^{\prime} .3$
5) By testing emptiness of $\mathcal{L}\left(\mathcal{C}^{\prime}\right)$, we effectively decide the inclusion problem for $\mathcal{A}$ and $\mathcal{A}^{\prime}$. It was shown in [8, Theorem 5.1 (1)] that emptiness of the parity automaton $\mathcal{C}^{\prime}$ is decidable in time $O\left(\left(n^{\prime} 2^{r(n)}\right)^{r^{\prime}(n)}\right)$, i. e., exponential in the number of states of $\mathcal{A}$ and thus also exponential in the size of both $\mathcal{A}$ and $\mathcal{A}^{\prime}$.

### 3.2.2 From Inclusion to Infimum Aggregation

There are two approaches to get an algorithm for the infimum aggregation problem based on an inlcusion test algorithm. These are general methods that can be used when one is given an unweighted algorithm and wants to transform it into a weighted one.

[^2]
## Glass-box Approach

The so-called glass-box approach uses the specifics of the unweighted algorithm and transforms them piece by piece into a weighted version of the algorithm. This is a rather laborious approach which usually only works if the unweighted algorithm is constructive in the first place, i. e., does not prove a complexity result without giving an explicit construction.

Since the inclusion test from the previous section is rather complicated, this cannot easily be applied to our current case. However, we will later use this approach to show that the complement of a WLA-recognizable tree series is recognizable by a WbA (see Section 4.2). For this, we use a rewritten version of the infimum aggregation value:

$$
\bigotimes_{t \in \Sigma^{K^{*}}}(\|\mathcal{A}\|, t) \oplus \overline{\left(\left\|\mathcal{A}^{\prime}\right\|, t\right)}=\overline{\bigoplus_{t \in \Sigma^{K^{*}}} \overline{(\|\mathcal{A}\|, t)} \otimes\left(\left\|\mathcal{A}^{\prime}\right\|, t\right)}
$$

One can see that infimum aggregation can also be done directly by complementing the automaton $\mathcal{A}$ and computing the supremum aggregation of the resulting two automata. The supremum aggregation problem for WBA was shown to be solvable by a polynomial construction in [4]. We have thus reduced the infimum aggregation to complementation of WBA, similar to the reduction of the inclusion test to the complementation problem for BA.

However, there is still the problem that BA are not closed under complementation, and thus neither are WBA. We will later circumvent this problem by considering other classes of automata for which the complement is a Büchi automaton (see Chapter 4).

## Black-box Approach

The black-box approach, on the other hand, does not need to know anything about how the unweighted algorithm works. It reduces the weighted problem to one or more problems of the unweighted type and solves these using the "black-box" that is the unweighted algorithm.

In 44 a black-box algorithm for the infimum aggregation was described, which is based on an approach from [6]. For every meet prime element $p$ of the finite Boolean lattice $S$, one can decide whether $\bigotimes_{t \in \Sigma^{K^{*}}}(\|\mathcal{A}\|, t) \oplus\left(\left\|\mathcal{A}^{\prime}\right\|, t\right) \leq p$ holds by using the inclusion test on two unweighted automata that are generated from $\mathcal{A}$ and $\mathcal{A}^{\prime}$. The solution to the infimum aggregation problem is then easily computed as the infimum of all those $p$ for which that test succeeded. We will now describe this procedure in more detail.

For given WBA $\mathcal{A}=(Q, \Sigma, S$, in, wt,$F)$ and $\mathcal{A}^{\prime}=\left(Q^{\prime}, \Sigma, S, \mathrm{in}^{\prime}, \mathrm{wt}^{\prime}, F^{\prime}\right)$ and a meet prime element $p \in S$, the cropped automata $\mathcal{A}_{p}$ and $\mathcal{A}_{\bar{p}}^{\prime}$ are defined as the BA $(Q, \Sigma, I, \Delta, F)$ and ( $Q^{\prime}, \Sigma, I^{\prime}, \Delta^{\prime}, F^{\prime}$ ), respectively, where the new initial state sets and transition relations are defined as follows:

- $I:=\{q \in Q \mid \operatorname{in}(q) \nsubseteq p\}$
- $\Delta:=\left\{y \in Q \times \Sigma \times Q^{k} \mid \mathrm{wt}(y) \not \leq p\right\}$
- $I^{\prime}:=\left\{q^{\prime} \in Q^{\prime} \mid \mathrm{in}^{\prime}\left(q^{\prime}\right) \geq \bar{p}\right\}$
- $\Delta^{\prime}:=\left\{y^{\prime} \in Q^{\prime} \times \Sigma \times Q^{\prime k} \mid \mathrm{wt}^{\prime}\left(y^{\prime}\right) \geq \bar{p}\right\}$

The transitions allowed in $\mathcal{A}_{p}\left(\mathcal{A}_{\bar{p}}^{\prime}\right)$ are exactly those transitions having weight $\not \leq p(\geq \bar{p})$ in $\mathcal{A}\left(\mathcal{A}^{\prime}\right)$. This property is transferred to the behavior of the weighted automata as follows. For any input tree $t \in \Sigma^{K^{*}}$, we have

$$
\begin{aligned}
(\|\mathcal{A}\|, t) \leq p & \Leftrightarrow \forall_{r \in \operatorname{succ}(\mathcal{A})}^{\forall} \operatorname{wt}(t, r) \leq p \\
& \Leftrightarrow \underset{r \in \operatorname{succ}(\mathcal{A})}{\forall} \operatorname{in}(r(\varepsilon)) \leq p \vee \underset{u \in K^{*}}{\exists} \operatorname{wt}(\overrightarrow{r(t, u)}) \leq p \\
& \Leftrightarrow t \notin \mathcal{L}\left(\mathcal{A}_{p}\right)
\end{aligned}
$$

and similarly, $\left(\left\|\mathcal{A}^{\prime}\right\|, t\right) \geq \bar{p} \Leftrightarrow t \in \mathcal{L}\left(\mathcal{A}_{\bar{p}}^{\prime}\right)$. Thus,

$$
\begin{aligned}
\bigotimes_{t \in \Sigma^{K^{*}}}(\|\mathcal{A}\|, t) \oplus \overline{\left(\left\|\mathcal{A}^{\prime}\right\|, t\right)} \leq p & \Leftrightarrow \underset{t \in \Sigma^{K^{*}}}{\exists}(\|\mathcal{A}\|, t) \leq p \wedge\left(\left\|\mathcal{A}^{\prime}\right\|, t\right) \geq \bar{p} \\
& \Leftrightarrow \underset{t \in \Sigma^{K^{*}}}{\exists} t \notin \mathcal{L}\left(\mathcal{A}_{p}\right) \wedge t \in \mathcal{L}\left(\mathcal{A}_{\bar{p}}^{\prime}\right) \\
& \Leftrightarrow \mathcal{L}\left(\mathcal{A}_{\bar{p}}^{\prime}\right) \nsubseteq \mathcal{L}\left(\mathcal{A}_{p}\right) .
\end{aligned}
$$

This involves all meet-prime elements of the Boolean lattice $S$, and their number is the same as the size of a generating set of $S$. Thus, this black-box approach will only add a linear factor to the exponential complexity of the unweighted inclusion test. Also note that the construction did not use the acceptance condition of the automata $\mathcal{A}$ and $\mathcal{A}^{\prime}$, i. e., the same method works for any kind of weighted automata for which the corresponding inclusion problem can be decided.

## 4 Complementation

We now want to consider a modified infimum aggregation problem, where we leave the acceptance condition of one automaton unspecified (represented by $X$ ).

## Task (Infimum Aggregation with WXA)

Given a WXA $\mathcal{A}$ and a WBA $\mathcal{A}^{\prime}$, compute $\bigotimes_{t \in \Sigma^{K^{*}}}(\|\mathcal{A}\|, t) \oplus \overline{\left(\left\|\mathcal{A}^{\prime}\right\|, t\right)}$.
This task can be approached in two ways, which are both based on a complementation procedure that takes an (unweighted) XA $\mathcal{A}$ and yields a BA $\overline{\mathcal{A}}$ with $\mathcal{L}(\overline{\mathcal{A}})=\overline{\mathcal{L}(\mathcal{A})}$. The first approach is to use this for a decision procedure for the inclusion problem with XA and then use the black-box algorithm from the previous section to lift this to a solution of the infimum aggregation problem with WXA.

The second possibility is a glass-box approach that yields a complementation procedure for WXA to WBA. This can then be used to solve the infimum aggregation problem, as detailed in the previous section.

In this chapter we will present several solutions to the following task and compare the complexity of black-box and glass-box approaches based on them.

## Task (Complementation for XA)

Given an XA $\mathcal{A}$, construct a BA $\overline{\mathcal{A}}$ with $\mathcal{L}(\overline{\mathcal{A}})=\overline{\mathcal{L}(\mathcal{A})}$.
For the remainder of this chapter, we fix a finite Boolean lattice $S$. Since $S$ is isomorphic to some powerset lattice, it is of size $|S|=2^{n}$ for some $n \in \mathbb{N}$. There are $n$ meet prime elements in $S$ and thus the black-box approach will need $n$ inclusion tests to solve the infimum aggregation problem.

For the complexity analyses we only compare the size of the state sets of the involved automata. This is a valid approach because the size $|\mathcal{A}|$ of an unweighted automaton $\mathcal{A}$ with state set $Q$ is polynomial in $|Q|$. For a weighted automaton, this size is expanded by a factor of $n$ since we need $n$ bits to store any element of $S$ and, e. g., the transition weight function can be represented as a $Q \times \Sigma \times Q^{k}$-table of $S$-values.$^{1}$

### 4.1 Complement of deterministic Büchi automata

The first class of automata we want to consider is that of deterministic Büchi automata. In [14, Lemma 8], a construction was presented that yields a BA $\overline{\mathcal{A}}$ recognizing the complement of a language of a given DBA $\mathcal{A}$. The idea behind this is to guess a path in the only valid run of $\mathcal{A}$ that does not fulfill the Büchi condition. This can be done by adding

[^3]
## 4 Complementation

some flags to the states of $\mathcal{A}$. These flags are used to guess a path and a position on this path after which no final state is allowed to occur. The transition relation must of course be adjusted accordingly. The resulting automaton is of size $O(|\mathcal{A}|)$.

We will first follow a glass-box approach and give a complementation construction from DWBA to WBA. Afterwards, we will compare this with the black-box approach.
Definition 4.1 Let $\mathcal{A}=(Q, \Sigma, S$, in, wt, $F)$ be a DWBA over a finite Boolean lattice $S$. Then the complement automaton $\overline{\mathcal{A}}$ is defined as the WBA ( $\bar{Q}, \Sigma, S$, $\overline{\mathrm{in}}, \overline{\mathrm{wt}}, \bar{F}$ ), where the components are defined as follows.

- $\bar{Q}:=Q \times\{0,1,2,3\}$.
- If in $(q)=0_{S}$, we set $\overline{\mathrm{in}}((q, i)):=0_{S}$. Otherwise, we define

$$
\overline{\operatorname{in}}((q, i)):=\left\{\begin{array}{ll}
\frac{1_{S}}{\operatorname{in}(q)} & \text { if } i=1 \\
\text { if } i=3 \\
0_{S} & \text { otherwise }
\end{array} .\right.
$$

- If $\operatorname{wt}\left(q_{0}, \alpha, q_{1}, \ldots, q_{k}\right)=0_{S}$, we set $\overline{\mathrm{wt}}\left(\left(q_{0}, i_{0}\right), \alpha,\left(q_{1}, i_{1}\right), \ldots,\left(q_{k}, i_{k}\right)\right):=0_{S}$. Otherwise, we define $\overline{\mathrm{wt}}\left(\left(q_{0}, i_{0}\right), \alpha,\left(q_{1}, i_{1}\right), \ldots,\left(q_{k}, i_{k}\right)\right):=$

$$
\begin{cases}\overline{\mathrm{wt}\left(q_{0}, \alpha, q_{1}, \ldots, q_{k}\right)} & \text { if } i_{0}=1 \text { and } i_{1}=\ldots=i_{k}=3 \\ 1_{S} & \text { if } \left.i_{0}=1 \text { and one } i_{j}(j \geq 1) \text { is } 1 \text { or } 2 \text { (others } 0\right) \\ 1_{S} & \text { if } \left.i_{0}=2, q_{0} \notin F \text { and one } i_{j}(j \geq 1) \text { is } 2 \text { (others } 0\right) . \\ 1_{S} & \text { if } i_{0}=\ldots=i_{k} \in\{0,3\} \\ 0_{S} & \text { otherwise }\end{cases}
$$

- $\bar{F}:=Q \times\{0,2,3\}$.

For a given input tree $t \in \Sigma^{K^{*}}$, we know that there is exactly one run $r_{t} \in Q^{K^{*}}$ with $\mathrm{wt}\left(t, r_{t}\right)>0_{S}$. That means that the behavior of $\overline{\mathcal{A}}$ on $t$ should be exactly $\overline{\mathrm{wt}\left(t, r_{t}\right)}$ if $r_{t} \in \operatorname{succ}(\mathcal{A})$. If $r_{t}$ is not successful, the behavior should be $1_{S}$.
Theorem 4.2 (Complementation Theorem (DWBA)) Let $\mathcal{A}=(Q, \Sigma, S$, in, wt, $F)$ be a $D W B A$ over a finite Boolean lattice $S$. Then $\|\overline{\mathcal{A}}\|=\overline{\|\mathcal{A}\|}$.

Proof: The idea behind the construction is that the automaton $\overline{\mathcal{A}}$ guesses a path in $r_{t}$ that violates the acceptance condition of $\mathcal{A}$. If this is possible, the corresponding run of $\overline{\mathcal{A}}$ has weight $1_{S}$, implying $(\|\overline{\mathcal{A}}\|, t)=1_{S}$. Otherwise, $\overline{\mathcal{A}}$ generates a run with weight $\overline{\mathrm{wt}\left(\overrightarrow{r_{t}(t, u)}\right)}$ for every node $u \in K^{*}$ and one run with weight $\overline{\operatorname{in}\left(r_{t}(\varepsilon)\right)}$. By taking the supremum of these run weights, we compute exactly $\overline{(\|\mathcal{A}\|, t)}=\overline{\operatorname{wt}\left(t, r_{t}\right)}$.

To show this, we consider all runs $\bar{r} \in \operatorname{succ}(\overline{\mathcal{A}})$ with $\overline{\mathrm{wt}}(t, \bar{r})>0_{S}$. This property implies that the first components of these runs must have a non-zero weight w.r.t. $\mathcal{A}$ and must thus be equal to $r_{t}$. We now classify all these runs $\bar{r}$ according to their second components:
a) The second component of every label $\bar{r}(u)$ is 3 . There is exactly one such run $\bar{r}$ and its weight is $\overline{\operatorname{in}\left(r_{t}(\varepsilon)\right)}$.
b) There is a finite path $p \in \mathcal{P a t h}\left(K^{*}, n\right)$ such that $\bar{r}(u)_{2}=1$ for each $u \in p, \bar{r}(u)_{2}=3$ for each $u>p_{n}$ and $\bar{r}(u)_{2}=0$ otherwise. For every finite path $p \in \operatorname{Path}\left(K^{*}, n\right)$ there is one such run $\bar{r}$ and its weight is $\overrightarrow{\operatorname{wt}\left(\overrightarrow{r_{t}\left(t, p_{n}\right)}\right)}$.
c) There is an infinite path $p \in \operatorname{Path}\left(K^{*}\right)$ and a node $v \in p$ such that $\bar{r}(u)_{2}=1$ for each $u \in p$ with $u \leq v, \bar{r}(u)_{2}=2$ for each $u \in p$ with $u>v$ and $\bar{r}(u)_{2}=0$ otherwise. The first component of all those nodes of $p$ labeled with 2 cannot be a final state, which means that $r_{t}$ is not successful. Such runs $\bar{r}$ exist iff $r_{t}$ is not successful and their weight is $1_{S}$.
We conclude

$$
\begin{aligned}
(\|\overline{\mathcal{A}}\|, t) & =\bigoplus_{\bar{r} \in \operatorname{succ}(\overline{\mathcal{A}})} \overline{\mathrm{wt}}(t, \bar{r}) \\
& =\bigoplus_{\substack{\bar{r} \in \operatorname{succ}(\overline{\mathcal{A}}) \\
\text { of type a) }}}^{\overline{\mathrm{wt}}(t, \bar{r}) \oplus \bigoplus_{\begin{array}{c}
\bar{r} \in \operatorname{succ}(\overline{\mathcal{A}}) \\
\text { of type b) }
\end{array}} \overline{\mathrm{wt}}(t, \bar{r}) \oplus \bigoplus_{\substack{\bar{r} \in \operatorname{succ}(\overline{\mathcal{A}}) \\
\text { of type })}} \overline{\mathrm{wt}}(t, \bar{r})} \\
& = \begin{cases}\overline{\operatorname{in}\left(r_{t}(\varepsilon)\right)} \oplus \bigoplus_{u \in K^{*}} \overline{\operatorname{wt}\left(\overline{r_{t}(t, u)}\right)} & \text { if } r_{t} \in \operatorname{succ}(\mathcal{A}) \\
1_{S} & \text { otherwise }\end{cases} \\
& = \begin{cases}\overline{\mathrm{wt}\left(t, r_{t}\right)} & \text { if } r_{t} \in \operatorname{succ}(\mathcal{A}) \\
1_{S} & \text { otherwise }\end{cases} \\
& =\overline{(\|\mathcal{A}\|, t) .}
\end{aligned}
$$

The size of the state set of the automaton $\overline{\mathcal{A}}$ from Definition 4.1 is still only $O(|Q|)$. The cost of the infimum aggregation for a DWBA $\mathcal{A}$ and a WBA $\mathcal{A}^{\prime}$ would thus be polynomial in $|Q|$ and $\left|Q^{\prime}\right|$.
Since the size of the state set of the complement automaton in the unweighted case is also $O(|Q|)$, the black-box approach for the infimum aggregation would involve $n$ inclusion tests which are polynomial in $|Q|$ and $\left|Q^{\prime}\right|$. One can see that there is no significant difference between the two approaches, since the complexity of the weighted complementation procedure is the same as in the unweighted case.

### 4.2 Complement of looping automata

In this section we look at a different, but still rather restricted class of automata. Looping automata can be used for satisfiability checking or axiom pinpointing in certain description logics ([2]).

First, we will complement any LA into a bA (and thus a BA) and show the correctness of this approach. Afterwards, we will present the corresponding construction for WLA and again compare this with the black-box approach.

### 4.2.1 Complement of LA

Definition 4.3 For an LA $\mathcal{A}=(Q, \Sigma, I, \Delta)$, define the complement automaton $\overline{\mathcal{A}}$ as the bA $(\bar{Q}, \Sigma, \bar{I}, \bar{\Delta}, \bar{F})$ with the following components.

- $\bar{Q}:=\mathcal{P}(Q)$.
- $\bar{I}:=\{I\}$.

## 4 Complementation

- For $Q_{0}, \ldots, Q_{k} \subseteq Q$ and $\alpha \in \Sigma,\left(Q_{0}, \alpha, Q_{1}, \ldots, Q_{k}\right) \in \bar{\Delta}$ iff

$$
\underset{q_{0} \in Q_{0}}{\forall} \underset{y=\left(q_{0}, \alpha, q_{1}, \ldots, q_{k}\right) \in \Delta}{\forall} \underset{i \in K}{\exists} q_{i} \in Q_{i} .
$$

- $\bar{F}:=\{\emptyset\}$.

The idea is that, for every possible run of $\mathcal{A}$, the automaton $\overline{\mathcal{A}}$ guesses a path violating the transition relation $\Delta$. It aggregates all states that belong to a run for which we have not yet found such a counterexample into sets and will be successful iff all of these sets become empty at some point.
Theorem 4.4 (Complementation Theorem (LA)) Let $\mathcal{A}=(Q, \Sigma, I, \Delta)$ be an $L A$. Then $\mathcal{L}(\overline{\mathcal{A}})=\overline{\mathcal{L}(\mathcal{A})}$.

Proof: Let $t \in \mathcal{L}(\overline{\mathcal{A}})$. Then there is a successful run $\bar{r} \in \bar{Q}^{K^{*}}$ of $\overline{\mathcal{A}}$ on $t$. Assume that there also is a valid run $r \in Q^{K^{*}}$ of $\mathcal{A}$ on $t$. We now inductively construct a path $p \in \mathcal{P a t h}\left(K^{*}\right)$ for which $r(u) \in \bar{r}(u)$ holds for all nodes $u \in p$.

- For $u=\varepsilon$ we have $r(\varepsilon) \in I=\bar{r}(\varepsilon)$.
- Let $u \in p$ be a node for which $r(u) \in \bar{r}(u)$ holds. Since $r$ and $\bar{r}$ are valid, we have $(r(u), t(u), r(u 1), \ldots, r(u k)) \in \Delta$ and $(\bar{r}(u), t(u), \bar{r}(u 1), \ldots, \bar{r}(u k)) \in \bar{\Delta}$. By definition of $\bar{\Delta}$, there must be an $i \in K$ with $r(u i) \in \bar{r}(u i)$. We now append $u i$ to the path $p$ and continue.
Now $\bar{r}$ cannot fulfill the final state condition $\{\emptyset\}$ of $\overline{\mathcal{A}}$ on the path $p$, since every label along the path must contain at least one element. This contradicts the fact that $\bar{r}$ is successful, and thus $t$ cannot be accepted by $\mathcal{A}$.

For the other inclusion, let $t \notin \mathcal{L}(\mathcal{A})$. By Corollary 3.5, there must be a closed, finite subtree $T \subseteq K^{*}$ on which no valid subrun exists. We now inductively construct a successful run $\bar{r} \in \bar{Q}^{\bar{K}^{*}}$ of $\overline{\mathcal{A}}$ on $t$ for which every node $u \in T$ has the following property:

$$
P(u) \equiv \underset{r \in Q^{u\left[K^{*}\right]}}{\forall}\left[r(u) \in \bar{r}(u) \Rightarrow\left(\underset{w \in u\left[K^{*}\right] \operatorname{nint}(T)}{\exists} \overrightarrow{r(t, w)} \notin \Delta\right)\right]
$$

This means that every mapping $r \in Q^{u\left[K^{*}\right]}$ that starts in a state $q_{0} \in \bar{r}(u)$ at $u$ must violate $\Delta$ at some node in $\operatorname{int}(T)$ that lies below $u$.

- If we set $\bar{r}(\varepsilon):=\{I\}$, then $P(\varepsilon)$ holds because of Corollary 3.5.
- If $u$ is a leaf of $T$ or $u \notin T$, we set $\bar{r}(u i):=\emptyset$ for each $i \in K$.
- Let now $u$ be an inner node of $T$ where $\bar{r}(u)$ has already been defined and $P(u)$ holds. We initially set $\bar{r}(u i):=\emptyset$ for every $i \in K$. Thus, $P(u i)$ trivially holds for every $i \in K$, but the transition $\vec{r}(t, u)$ need not be valid. We now have to expand the label sets $\bar{r}(u i)$ in such a way that

1) the transition $\overrightarrow{\bar{r}(t, u)}$ becomes valid and
2) the properties $P(u i)$ are not violated.

We do this by checking the conditions of $\bar{\Delta}$ step by step.

- Let $q_{0} \in \bar{r}(u)$ and $y=\left(q_{0}, t(u), q_{1}, \ldots, q_{k}\right) \in \Delta$.
- Assume that for each index $i \in K$ there is a mapping $r_{i} \in Q^{u i\left[K^{*}\right]}$ with $r_{i}(u i)=q_{i}$ that does not violate $\Delta$ below $u i \operatorname{in} \operatorname{int}(T)$. Then we could join these mappings into a mapping $r \in Q^{u\left[K^{*}\right]}$ with $r(u):=q_{0}$ and $r($ uiw $):=r_{i}($ uiw $)$ for all $i \in$ $K$ and $w \in K^{*}$. This mapping does not violate $\Delta$ below $u \operatorname{in} \operatorname{int}(T)$, which contradicts $P(u)$.
- Thus we can find an index $i \in K$ such that $P(u i)$ still holds after we add $q_{i}$ to $\bar{r}(u i)$.

After we have done this for every $q_{0} \in \bar{r}(u)$ and every matching transition $y \in \Delta$, we have fully determined the successor labels $\bar{r}(u i)$ and $P(u i)$ still holds for every $i \in K$. Additionally, $\overrightarrow{\bar{r}(t, u)}$ now is a valid transition in $\bar{\Delta}$.
To show that $\bar{r}$ is a valid run of $\overline{\mathcal{A}}$ on $t$, we need to show that every transition is compatible with $\bar{\Delta}$. If the transition fully lies in $T$ or $\bar{T}$, this is clear from the construction.

Let now $u \in \operatorname{fr}(T)$. Since $P(u)$ holds, all mappings $r \in Q^{u\left[K^{*}\right]}$ with $r(u) \in \bar{r}(u)$ must violate $\Delta$ in $u\left[K^{*}\right] \cap \operatorname{int}(T)=\emptyset$, which is clearly not possible. This implies that $\bar{r}(u)=\emptyset$, and thus, the transition $\vec{r}(t, u)=(\emptyset, t(u), \emptyset, \ldots, \emptyset)$ is valid in $\bar{\Delta}$.

It is clear that $\bar{r}$ is successful since every infinite path must leave $T$ at some node $u$ and thus has the label $\emptyset$ at every node below $u$. This implies $t \in \mathcal{L}(\overline{\mathcal{A}})$.

### 4.2.2 Complement of WLA

We now augment the construction from the previous section to work with an arbitrary Boolean lattice $S$. For this the powerset $2^{Q}$ is replaced by the set $S^{Q}$ of all functions mapping the states of $\mathcal{A}$ to lattice values. The other parts of the complement automaton similarly arise from adapting the old definitions to the more general setting.
Definition 4.5 For a WLA $\mathcal{A}=(Q, \Sigma, S$, in, wt), define the complement automaton as the $\mathrm{WbA} \overline{\mathcal{A}}=(\bar{Q}, \Sigma, S, \overline{\mathrm{in}}, \overline{\mathrm{wt}}, \bar{F})$ with the following components.

- $\bar{Q}:=S^{Q}$.
- For $\varphi \in \bar{Q}, \overline{\operatorname{in}}(\varphi):=\left\{\begin{array}{ll}1_{S} & \text { if } \varphi(q) \geq \operatorname{in}(q) \text { for all } q \in Q \\ 0_{S} & \text { otherwise }\end{array}\right.$.
- For $\varphi_{0}, \ldots, \varphi_{k} \in \bar{Q}$ and $\alpha \in \Sigma, \overline{\operatorname{wt}}\left(\varphi_{0}, \alpha, \varphi_{1}, \ldots, \varphi_{k}\right):=$

$$
\bigotimes_{y=\left(q_{0}, \alpha, q_{1}, \ldots, q_{k}\right) \in Q \times\{\alpha\} \times Q^{k}} \overline{\varphi_{0}\left(q_{0}\right)} \oplus \overline{\mathrm{wt}(y)} \oplus \bigoplus_{i \in K} \varphi_{i}\left(q_{i}\right) .
$$

- $\bar{F}:=\left\{\underline{0_{S}}\right\}$ where $\underline{0_{S}}: Q \rightarrow S: q \mapsto 0_{S}$.

We now fix a WLA $\mathcal{A}=(Q, \Sigma, S$, in, wt $)$ and an input tree $t \in \Sigma^{K^{*}}$. To show the correctness of the above construction, we need to show that $(\|\overline{\mathcal{A}}\|, t)=\overline{(\|\mathcal{A}\|, t)}$ holds. The next two sections are dedicated to the two halves of this proof.

## Proof of $(\|\overline{\mathcal{A}}\|, t) \geq \overline{(\|\mathcal{A}\|, t)}$

In order to prove this, we define a successful run $\bar{r} \in \bar{Q}^{K^{*}}$ of $\overline{\mathcal{A}}$ with the $t$-weight $\overline{(\|\mathcal{A}\|, t)}$.
From Corollary 3.3 we know that there must be a closed, finite subtree $T \subseteq K^{*}$ such that for the computation of the weight $(\|\mathcal{A}\|, t)$, we only need to consider the nodes in $T$.
Definition 4.6 Let the run $\bar{r} \in \bar{Q}^{K^{*}}$ be inductively defined as follows:

- $\bar{r}(\varepsilon):=\mathrm{in}$.
- If $u \in \operatorname{fr}(T)$ or $u \notin T$, set $\bar{r}(u i):=\underline{0_{S}}$ for each $i \in K$.
- If $u \in \operatorname{int}(T)$ is a node where $\bar{r}(u)$ has already been defined, set

$$
\bar{r}(u i)(q):=\bigotimes_{\substack{r \in Q^{u i\left[K^{*}\right]} \\ r(u i)=q}} \bigoplus_{w \in u i\left[K^{*}\right] \operatorname{int}(T)} \overline{\operatorname{wt}(\overline{r(t, w)})}
$$

for each $i \in K$ and $q \in Q$.
From this definition, it is already clear that $\bar{r}$ is a successful run of $\overline{\mathcal{A}}$, since every path will be labeled by $\underline{0_{S}}$ from some point on.

We additionally define a value $P(u)$ for each node $u \in T$ :

$$
P(u):=\bigotimes_{r \in Q^{u\left[K^{*}\right]}} \overline{\bar{r}(u)(r(u))} \oplus \bigoplus_{w \in u\left[K^{*}\right] \operatorname{nint}(T)} \overline{\operatorname{wt}(\overline{r(t, w)})}
$$

Lemma 4.7 The following hold:

- $P(\varepsilon)=\overline{(\|\mathcal{A}\|, t)}$.
- $P(u i)=1_{S}$ for all $u i \in T$.

Proof: The first claim is easily proven by considering the definitions and Corollary 3.3 .
Additionally, for any $u i \in T$ we have

$$
\begin{aligned}
P(u i) & =\bigotimes_{r \in Q^{u i\left[K^{*}\right]}} \overline{\bar{r}(u i)(r(u i))} \oplus \bigoplus_{w \in u i\left[K^{*}\right] \operatorname{nint}(T)} \overline{\mathrm{wt}(\overline{(r(t, w)})} \\
& \geq \bigotimes_{r \in Q^{u i\left[K^{*}\right]}} \overline{\left(\bigoplus_{w \in u i\left[K^{*}\right] \operatorname{nint}(T)} \overline{\mathrm{wt}(\overline{r(t, w)})}\right)} \oplus\left(\bigoplus_{w \in u i\left[K^{*}\right] \operatorname{int}(T)} \overline{\mathrm{wt}(\overline{r(t, w)})}\right) \\
& =1_{S} .
\end{aligned}
$$

We now show that the run $\bar{r}$ has the claimed $t$-weight.
Lemma 4.8 The following hold:
a) $\overline{\operatorname{in}}(\bar{r}(\varepsilon))=1_{S}$.
b) $\overline{\mathrm{wt}}(\overrightarrow{\bar{r}}(t, u))=1_{S}$ for all $u \notin T$.
c) $\overline{\mathrm{wt}}(\overrightarrow{\bar{r}}(t, u))=P(u)$ for all $u \in T$.

Proof: a) holds by definition of $\overline{\text { in }}$ and $\bar{r}(\varepsilon)$ and b) follows from the fact that $\bar{r}(u)=\underline{0_{S}}$ holds for all $u \notin T$. For c), we consider two cases:

- $\overline{\mathrm{wt}}(\overrightarrow{\bar{r}}(t, u))=P(u)$ for every $u \in \operatorname{fr}(T)$ :

$$
\begin{aligned}
\overline{\mathrm{wt}}(\overrightarrow{\bar{r}(t, u)}) & =\bigotimes_{y=\left(q_{0}, t(u), q_{1}, \ldots, q_{k}\right)} \overline{\bar{r}(u)\left(q_{0}\right)} \oplus \overline{\mathrm{wt}(y)} \\
& =\bigotimes_{r \in Q^{u\left[K^{*}\right]}} \overline{\bar{r}(u)(r(u))} \oplus \overline{\mathrm{wt}(\overline{r(t, u)})} \\
& =P(u) .
\end{aligned}
$$

The second equation holds because of idempotency of $\otimes$. We consider any transition $y$ at $u$ as the beginning of every run $r \in Q^{u\left[K^{*}\right]}$ with $\overrightarrow{r(t, u)}=y$.

- $\overline{\mathrm{wt}}(\overrightarrow{\bar{r}(t, u)})=P(u)$ for every $u \in \operatorname{int}(T)$ :

$$
\begin{aligned}
& \overline{\mathrm{wt}}(\overrightarrow{\bar{r}}(t, u))=\bigotimes_{y=\left(q_{0}, t(u), q_{1}, \ldots, q_{k}\right)} \overline{\bar{r}(u)\left(q_{0}\right)} \oplus \overline{\mathrm{wt}(y)} \oplus \bigoplus_{i \in K} \bar{r}(u i)\left(q_{i}\right) \\
& =\bigotimes_{y=\left(q_{0}, t(u), q_{1}, \ldots, q_{k}\right)} \overline{\bar{r}(u)\left(q_{0}\right)} \oplus \overline{\mathrm{wt}(y)} \oplus \bigoplus_{i \in K^{2}} \bigotimes_{\substack{r_{i} \in Q^{u i\left[K^{*}\right]} \\
r_{i}(u i)=q_{i}}} \bigoplus_{w \in u i\left[K^{*}\right] \cap \operatorname{nint}(T)} \overline{\mathrm{wt}\left(\overline{r_{i}(t, w)}\right)} \\
& =\bigotimes_{y=\left(q_{0}, t(u), q_{1}, \ldots, q_{k}\right)} \overline{\bar{r}(u)\left(q_{0}\right)} \oplus \overline{\mathrm{wt}(y)} \oplus \\
& \bigotimes_{\substack{r_{1} \in Q^{u 1\left[K^{*}\right]} \\
r_{1}(u 1)=q_{1}}} \ldots \bigotimes_{\substack{r_{k} \in Q^{u k\left[K^{*}\right]} \\
r_{k}(u k)=q_{k}}} \bigoplus_{i \in K} \bigoplus_{w \in u i\left[K^{*}\right] \operatorname{nint}(T)} \overline{\mathrm{wt}\left(\overline{r_{i}(t, w)}\right)} \\
& \text { (by distributivity of } S \text { ) } \\
& \text { (by distributivity of } S \text { ) } \\
& \overline{\bar{r}(u)\left(q_{0}\right)} \oplus \overline{\mathrm{wt}(y)} \oplus \bigoplus_{i \in K} \bigoplus_{w \in u i\left[K^{*}\right] \operatorname{nint}(T)} \overline{\mathrm{wt}\left(\overline{\left(r_{i}(t, w)\right.}\right)} \\
& \text { (concatenate } y \text { and } r_{1}, \ldots, r_{k} \text { to } r \text { ) } \\
& =\bigotimes_{r \in Q^{u\left[K^{*}\right]}} \overline{\bar{r}(u)(r(u))} \oplus \bigoplus_{w \in u\left[K^{*}\right] \operatorname{nint}(T)} \overline{\mathrm{wt}(\overline{r(t, w)})} \\
& =P(u) \text {. }
\end{aligned}
$$

This completes the first half of the proof of correctness.
Lemma $4.9(\|\overline{\mathcal{A}}\|, t) \geq \overline{(\|\mathcal{A}\|, t)}$.
Proof: Combining Lemmata 4.7 and 4.8 , we get

$$
(\|\overline{\mathcal{A}}\|, t) \geq \overline{\mathrm{wt}}(t, \bar{r})=\overline{\mathrm{in}}(\bar{r}(\varepsilon)) \otimes \bigotimes_{u \in K^{*}} \overline{\mathrm{wt}}(\overline{\bar{r}(t, u)})=\overline{(\|\mathcal{A}\|, t)} .
$$

Proof of $(\|\overline{\mathcal{A}}\|, t) \leq \overline{(\|\mathcal{A}\|, t)}$
We show this direction by proving the inequality $\overline{\mathrm{wt}}(t, \bar{r}) \leq \overline{\mathrm{wt}(t, r)}$ for all $\bar{r} \in \operatorname{succ}(\overline{\mathcal{A}})$ and $r \in Q^{K^{*}}$. If $\overline{\mathrm{wt}}(t, \bar{r})=0_{S}$ or $\mathrm{wt}(t, r)=0_{S}$ this is trivially satisfied, so we fix two runs $\bar{r} \in \operatorname{succ}(\overline{\mathcal{A}})$ and $r \in Q^{K^{*}}$ with $\overline{\mathrm{wt}}(t, \bar{r})>0_{S}$ and $\mathrm{wt}(t, r)>0_{S}$.

We proceed by showing that $\overline{\mathrm{wt}}(t, \bar{r}) \otimes \mathrm{wt}(t, r)$ is smaller than $a \otimes \bar{a}=0_{S}$ for some suitably chosen $a \in S$. Looking at Theorem 4.4 one can already guess that this argument has to do with paths $p \in \mathcal{P}$ ath $\left(K^{*}\right)$ for which $r(u) \in \bar{r}(u)$ holds for all $u \in p$. In the weighted case, this property is replaced by the value $\bigotimes_{u \in p} \bar{r}(u)(r(u))$. To be exact, $a$ has the form

$$
\bigoplus_{p \in \operatorname{Path}\left(K^{*}, n\right)} \bigotimes_{u \in p} \bar{r}(u)(r(u))
$$

for some $n \in \mathbb{N}$.
Lemma 4.10 There is a depth $m \in \mathbb{N}$ such that

$$
\overline{\mathrm{wt}}(t, \bar{r}) \leq \bigotimes_{p \in \mathcal{P a t h}\left(K^{*}, m\right)} \bigoplus_{u \in p} \overline{\bar{r}}(u)(r(u))
$$

Proof: Since $\bar{r}$ is successful, there is a minimal depth $m \in \mathbb{N}$ such that any path $p$ visits at least one node labeled by $\underline{0_{S}}$ before reaching depth $m$.

Let now $p$ be a path of length $m$ in $K^{*}$ and assume that $\overline{\mathrm{wt}}(t, \bar{r}) \not \leq \bigoplus_{u \in p} \overline{\bar{r}}(u)(r(u))$. Then $\bigoplus_{u \in p} \overline{\bar{r}}(u)(r(u))<1_{S}$ and thus $\bar{r}(u)(r(u))>0_{S}$ holds for every $u \in p$. Hence there cannot be a node labeled with $\underline{0_{S}}$ along $p$ in $\bar{r}$, which contradicts the above choice of $m$.
Lemma 4.11 For all $n \in \mathbb{N}$ the following inequation holds:

$$
\mathrm{wt}(t, r) \otimes \overline{\mathrm{wt}}(t, \bar{r}) \leq \bigoplus_{p \in \mathcal{P a t h}\left(K^{*}, n\right)} \bigotimes_{u \in p} \bar{r}(u)(r(u))
$$

Proof: For $n=0$ we have

$$
\mathrm{wt}(t, r) \otimes \overline{\mathrm{wt}}(t, \bar{r}) \leq \mathrm{wt}(t, r) \leq \operatorname{in}(r(\varepsilon)) \leq \bar{r}(\varepsilon)(r(\varepsilon))=\bigoplus_{p \in \mathcal{P a t h}\left(K^{*}, 0\right)} \bigotimes_{u \in p} \bar{r}(u)(r(u))
$$

This holds since $\overline{\mathrm{wt}}(t, \bar{r})>0_{S}$ and thus $\overline{\mathrm{in}}(\bar{r}(\varepsilon))>0_{S}$ and $\bar{r}(\varepsilon)(r(\varepsilon)) \geq \operatorname{in}(r(\varepsilon))$.
Let now the inequation hold for some $n \in \mathbb{N}$. For $p \in \mathcal{P a t h}\left(K^{*}, n\right)$, we know that

$$
\mathrm{wt}(t, r) \otimes \overline{\mathrm{wt}}(t, \bar{r}) \leq \mathrm{wt}\left(\overrightarrow{r\left(t, p_{n}\right)}\right) \otimes \overline{\mathrm{wt}}\left(\overrightarrow{\bar{r}\left(t, p_{n}\right)}\right),
$$

and thus

$$
\mathrm{wt}(t, r) \otimes \overline{\mathrm{wt}}(t, \bar{r}) \leq \bigotimes_{p \in \mathcal{P a t h}\left(K^{*}, n\right)} \mathrm{wt}\left(\overrightarrow{r\left(t, p_{n}\right)}\right) \otimes \overline{\mathrm{wt}}\left(\overrightarrow{\bar{r}\left(t, p_{n}\right)}\right)
$$

Furthermore,

$$
\begin{aligned}
\bar{r}\left(p_{n}\right)\left(r\left(p_{n}\right)\right) & \otimes \\
& =\frac{\mathrm{wt}\left(\overrightarrow{r\left(t, p_{n}\right)}\right) \otimes \overline{\overline{\mathrm{wt}}\left(\overline{\bar{r}\left(t, p_{n}\right)}\right)}}{} \quad \bigotimes_{y=\left(q_{0}, t\left(p_{n}\right), q_{1}, \ldots, q_{k}\right)} \overline{\left(\overline{\left.\bar{r}\left(p_{n}\right)\right)} \oplus \overline{\mathrm{wt}\left(\overline{r\left(t, p_{n}\right)}\right)}\right)} \otimes
\end{aligned}
$$

(by de Morgan's law)

Using the above inequations we get

$$
\begin{aligned}
& \mathrm{wt}(t, r) \otimes \otimes \overline{\mathrm{wt}}(t, \bar{r}) \\
& \leq\left(\bigoplus_{p \in \mathcal{P a t h}\left(K^{*}, n\right)} \bigotimes_{j=0}^{n} \bar{r}\left(p_{j}\right)\left(r\left(p_{j}\right)\right)\right) \otimes\left(\bigotimes_{p \in \mathcal{P a t h}\left(K^{*}, n\right)} \mathrm{wt}\left(\overrightarrow{r\left(t, p_{n}\right)}\right) \otimes \overline{\mathrm{wt}}\left(\overrightarrow{\bar{r}\left(t, p_{n}\right)}\right)\right) \\
& \quad \text { (by induction hypothesis and the first inequation) } \\
& \leq \bigoplus_{p \in \operatorname{Path}\left(K^{*}, n\right)}\left(\bigotimes_{j=0}^{n-1} \bar{r}\left(p_{j}\right)\left(r\left(p_{j}\right)\right)\right) \otimes \bar{r}\left(p_{n}\right)\left(r\left(p_{n}\right)\right) \otimes \mathrm{wt}\left(\overrightarrow{r\left(t, p_{n}\right)}\right) \otimes \overline{\mathrm{wt}}\left(\overrightarrow{\bar{r}\left(t, p_{n}\right)}\right) \\
&\quad(\text { by Lemma } 2.2 \mathrm{Lb})) \\
& \leq \bigoplus_{p \in \operatorname{Path}\left(K^{*}, n\right)} \bigoplus_{i \in K}\left(\bigotimes_{j=0}^{n-1} \bar{r}\left(p_{j}\right)\left(r\left(p_{j}\right)\right)\right) \otimes \bar{r}\left(p_{n}\right)\left(r\left(p_{n}\right)\right) \otimes \operatorname{wt}\left(\overrightarrow{r\left(t, p_{n}\right)}\right) \otimes \bar{r}\left(p_{n} i\right)\left(r\left(p_{n} i\right)\right)
\end{aligned}
$$

(by the second inequation and distributivity of $S$ )

$$
\leq \bigoplus_{p \in \mathcal{P a t h}\left(K^{*}, n+1\right)} \bigotimes_{u \in p} \bar{r}(u)(r(u))
$$

$$
\left(\text { combining } p \text { with } p_{n} i\right)
$$

This allows us to conclude the second half of the proof of correctness.
Lemma $4.12(\|\overline{\mathcal{A}}\|, t) \leq \overline{(\|\mathcal{A}\|, t)}$.
Proof: Combining Lemmata 4.10 and 4.11, we get $\mathrm{wt}(t, r) \otimes \overline{\mathrm{wt}}(t, \bar{r}) \leq 0_{S}$. Lemma 2.2 now implies $\overline{\mathrm{wt}}(t, \bar{r}) \leq \overline{\mathrm{wt}(t, r)}$.

Since this holds for all $\bar{r} \in \operatorname{succ}(\overline{\mathcal{A}})$ and all runs $r$ of $\mathcal{A}$, we have $(\|\overline{\mathcal{A}}\|, t) \leq \overline{(\|\mathcal{A}\|, t)}$.
Theorem 4.13 (Complementation Theorem (WLA)) Let $\mathcal{A}$ be a WLA over a finite Boolean lattice. Then $\|\overline{\mathcal{A}}\|=\overline{\|\mathcal{A}\|}$.

Proof: Since the construction of $\overline{\mathcal{A}}$ does not depend on the input tree $t$, this follows from Lemmata 4.9 and 4.12 .

$$
\begin{aligned}
& \leq \overline{\left(\overline{\bar{r}\left(p_{n}\right)\left(r\left(p_{n}\right)\right)} \oplus \overline{\mathrm{wt}\left(\overline{r\left(t, p_{n}\right)}\right)}\right)} \otimes \\
& \left(\left(\overline{\bar{r}\left(p_{n}\right)\left(r\left(p_{n}\right)\right)} \oplus \overline{\mathrm{wt}\left(\overline{r\left(t, p_{n}\right)}\right)}\right) \oplus \bigoplus_{i \in K} \bar{r}\left(p_{n} i\right)\left(r\left(p_{n} i\right)\right)\right) \\
& \text { (choose } \left.y=\overrightarrow{r\left(t, p_{n}\right)}\right) \\
& =\bar{r}\left(p_{n}\right)\left(r\left(p_{n}\right)\right) \otimes \mathrm{wt}\left(\overline{r\left(t, p_{n}\right)}\right) \otimes \bigoplus_{i \in K} \bar{r}\left(p_{n} i\right)\left(r\left(p_{n} i\right)\right) \\
& \text { (by distributivity of } S \text { ) } \\
& =\bigoplus_{i \in K} \bar{r}\left(p_{n}\right)\left(r\left(p_{n}\right)\right) \otimes \mathrm{wt}\left(\overrightarrow{r\left(t, p_{n}\right)}\right) \otimes \bar{r}\left(p_{n} i\right)\left(r\left(p_{n} i\right)\right) .
\end{aligned}
$$

## Comparison to black-box approach

We will now see whether a black-box approach or the presented glass-box algorithm is better suited for solving the infimum aggregation problem with WLA.

- The construction from Definition 4.3 yields a BA $\overline{\mathcal{A}}$ with a state set of size $2^{|Q|}$. Since intersection of Büchi automata and the emptiness test for Büchi automata are of polynomial time complexity, the time complexity for the inclusion test is polynomial in $\left|Q^{\prime}\right|$ and $2^{|Q|}$. If we then apply the black-box algorithm from Section 3.2.2, we get an additional factor of $n$.
- The glass-box algorithm from Definition 4.5 yields a WBA $\overline{\mathcal{A}}$ with a state set of size $|S|^{|Q|}=2^{n|Q|}$. If we use this algorithm to solve the infimum aggregation problem, we would have a time complexity polynomial in $\left|Q^{\prime}\right|$ and $2^{n|Q|}$.

In the case of looping automata, the proposed glass-box complementation construction is clearly inferior to the naive black-box approach. This is in part due to the fact that the complementation construction for unweighted looping automata is already of exponential time complexity. Another reason is that the weighted construction is simply too wasteful since it uses all functions $Q \rightarrow S$ as states. It remains an open problem to find a better construction for the complement of WLA that uses a smaller state set.

### 4.3 Complement of co-Büchi automata

In this section we present an exponential construction yielding a GBA that recognizes the complement of the tree series recognized by a given CA. This construction originates in the Simulation Theorem from [10]. Among other things, this theorem states that any alternating Büchi automaton can be simulated by a non-deterministic Büchi automaton.

To get from a CA to a GBA recognizing the complement, we first express the CA as an ACA (see Example 3.8), then complement it, which is easy for alternating automata. In the process, the acceptance condition is transformed into a Büchi condition. Using [10, Theorem 1.2], we arrive at a GBA recognizing the complement of the original language. This can be simulated by a BA of polynomial size (see Lemma 3.1).

In the following, we present the whole procedure as a self-contained construction and include a new proof which is similar to the proof of Theorem 4.4.
Definition 4.14 For a $\operatorname{CA} \mathcal{A}=(Q, \Sigma, I, \Delta, F)$, the complement automaton $\overline{\mathcal{A}}$ is the GBA $\left(\bar{Q}, \Sigma, \bar{I}, \bar{\Delta}, \bar{F}_{1}, \ldots, \bar{F}_{|F|+1}\right)$ with the following components.

- $\bar{Q}:=\left\{\left(Q_{0}, Q_{1}, \ldots, Q_{|F|+1}\right) \in \mathcal{P}(Q \backslash F) \times \mathcal{P}(F)^{|F|+1} \mid Q_{1}, \ldots, Q_{|F|+1}\right.$ are disjoint $\}$
- $\bar{I}:=\{(I \backslash F, I \cap F, \emptyset, \ldots, \emptyset)\}$.
- $\left(\left(Q_{0}^{(0)}, Q_{1}^{(0)}, \ldots, Q_{|F|+1}^{(0)}\right), \alpha,\left(Q_{0}^{(1)}, Q_{1}^{(1)}, \ldots, Q_{|F|+1}^{(1)}\right), \ldots,\left(Q_{0}^{(k)}, Q_{1}^{(k)}, \ldots, Q_{|F|+1}^{(k)}\right)\right) \in \bar{\Delta}$
- $\bar{F}_{j}:=\left\{\left(Q_{0}, Q_{1}, \ldots, Q_{|F|+1}\right) \in \bar{Q} \mid Q_{j}=\emptyset\right\}$ for $j \in\{1, \ldots,|F|+1\}$.

The states of the complement automaton are tuples of state sets. The first set contains only non-final states, while the remainder are disjoint sets of final states. The idea is that for every run of the original automaton the complement automaton guesses a path which violates the acceptance condition. It accepts iff it is able to find such a path for each run.

If the automaton is in state $\left(Q_{0}, \ldots, Q_{|F|+1}\right)$ at node $u$, it guesses for each state $q \in Q_{j}$ and possible transition $y=\left(q, t(u), q_{1}, \ldots, q_{k}\right)$ which direction $i \in K$ to take. The corresponding state $q_{i}$ is then put in the appropriate set, depending on whether it is a final state or not.

If $q$ and $q_{i}$ are final states, $q_{i}$ is added to the $j$-th component or some component with a greater index. This possibility exists to allow the disjointness condition to be satisfied. If the state $q_{i}$ is required by several different transitions originating from several components $j$, it suffices to put $q_{i}$ in the largest of these components to satisfy all the conditions.

In the end it is checked whether in each component and each path we encounter infinitely many empty sets, which is equivalent to checking whether there are infinitely many nonfinal states in every guessed path.

We will now show the correctness of the construction in two steps.
Lemma 4.15 Let $\mathcal{A}=(Q, \Sigma, I, \Delta, F)$ be a $C A$. Then $\mathcal{L}(\overline{\mathcal{A}}) \subseteq \overline{\mathcal{L}(\mathcal{A})}$.
Proof: Let $t \in \mathcal{L}(\overline{\mathcal{A}})$, i. e., there is a successful run $\bar{r} \in \bar{Q}^{K^{*}}$ of $\overline{\mathcal{A}}$ on $t$, and assume that there also is a successful run $r \in Q^{K^{*}}$ of $\mathcal{A}$ on $t$. For a node $u \in K^{*}$, define $\bar{R}(u):=\bigcup_{j=0}^{|F|+1} \bar{r}(u)_{j}$. Then we can inductively construct an infinite path $p \in \mathcal{P} a t h\left(K^{*}\right)$ for which $r(u) \in \bar{R}(u)$ holds for all $u \in p$ :

- Since $r(\varepsilon) \in I$, either $r(\varepsilon) \in I \backslash F=\bar{r}(u)_{0}$ or $r(\varepsilon) \in I \cap F=\bar{r}(u)_{1}$ must hold, and thus $r(\varepsilon) \in \bar{R}(\varepsilon)$.
- Let $u \in p$ be a node with the property $r(u) \in \bar{R}(u)$. Since $\overrightarrow{r(t, u)} \in \Delta$ and $\overrightarrow{\bar{r}(t, u)} \in \bar{\Delta}$, there must be an $i \in K$ such that $r(u i) \in \bar{r}(u i)_{j}$ holds for some $j \in\{0, \ldots,|F|+1\}$. Thus $r(u i) \in \bar{R}(u i)$ holds and we can append $u i$ to the path $p$.
Since $r$ is successful, there must be a node $u_{0} \in p$ such that $r(u) \in F$ holds for all nodes $u \in p \cap u_{0}\left[K^{*}\right]$ that occur below $u_{0}$ along the path $p$. That means that $r(u)$ always occurs in a component $\bar{r}(u)_{j}$ with $j \geq 1$. The index $j$ of this component can only grow bigger or stay the same with each transition, and thus there must be a node $u_{1} \in p$ after which $r(u) \in \bar{r}(u)_{j}$ always holds for some fixed $j \in\{1, \ldots,|F|+1\}$. Thus $\bar{r}(u)_{j}$ can never be empty after the node $u_{1}$ along the path $p$, which contradicts the success of $\bar{r}$.

For this direction, it is easy to see the similarity to the proof of Theorem 4.4. The other direction is also similar. The property $P(u)$ is replaced by a more complex property $\operatorname{Fail}(u)$ and the proof is generally more complex to account for the different components of each state. Instead of Corollary 3.5, we have to use the more general version in Corollary 3.4 for this proof.

Lemma 4.16 Let $\mathcal{A}=(Q, \Sigma, I, \Delta, F)$ be a $C A$. Then $\mathcal{L}(\overline{\mathcal{A}}) \supseteq \overline{\mathcal{L}(\mathcal{A})}$.
Proof: Let $t \notin \mathcal{L}(\mathcal{A})$. We inductively construct a successful run $\bar{r} \in \bar{Q}^{K^{*}}$ of $\overline{\mathcal{A}}$ on $t$. For

## 4 Complementation

every node $u \in K^{*}$ the following property $\operatorname{Fail}(u)$ will be satisfied.

$$
\begin{aligned}
\operatorname{Fail}(u) & \equiv \forall_{j=0}^{|F|+1} \underset{\substack{ \\
\forall} Q^{u\left[K^{*}\right]}}{\forall} r(u) \in \bar{r}(u)_{j} \Rightarrow \underset{w \in u\left[K^{*}\right]}{\exists} \operatorname{Fail}(w, \overrightarrow{r(t, w)}) \\
\operatorname{Fail}\left(u, y=\left(q_{0}, \ldots\right)\right) & \equiv y \in \Delta \Rightarrow\left(q_{0} \notin F \wedge \underset{\substack{r^{\prime} \in Q^{u\left[K^{*}\right]} \\
r^{\prime}(u)=q_{0}}}{\forall} \neg \operatorname{Valid}\left(r^{\prime}, u\right) \vee \neg \operatorname{Success}\left(r^{\prime}, u\right)\right) \\
\operatorname{Valid}(r, u) & \equiv \underset{w \in u\left[K^{*}\right]}{\forall} \overrightarrow{r(t, w)} \in \Delta \\
\operatorname{Success}(r, u) & \equiv \underset{p \in \operatorname{Path}\left(u\left[K^{*}\right]\right)}{\forall} \operatorname{Inf}(r, p) \backslash F=\emptyset
\end{aligned}
$$

Success $(r, u)$ expresses that a run $r$ is "successful below $u$ ", i. e., all infinite paths starting from $u$ must contain only finitely many states from $Q \backslash F$. The property $\operatorname{Valid}(r, u)$ ensures that all transitions of a run $r$ below a node $u$ are valid transitions of $\mathcal{A}$. Using these two properties, we formulate $\operatorname{Fail}(u, y)$ by saying that if $y$ is a valid transition at $u$, then the current state must be non-final and no valid run starting from this state can be successful. Finally, $\operatorname{Fail}(u)$ says that every run starting in a state occurring in $\bar{r}(u)$ must fail somewhere below $u$.

The property $\operatorname{Fail}(u, y)$ is clearly of the form required by Corollary 3.4 and thus $\operatorname{Fail}(u)$ is equivalent to a property $\operatorname{Fail}\left(u,\left(T_{j, u}\right)\right)$ for closed, finite trees $T_{j, u} \subseteq u\left[K^{*}\right](j \in\{1, \ldots,|F|+$ $1\}$ ). This property is the same as $\operatorname{Fail}(u)$, except that " $w \in u\left[K^{*}\right]$ " is replaced by " $w \in$ $T_{j, u}$, " ${ }^{2}$

To start the construction of $\bar{r}$, we set $\bar{r}(\varepsilon):=(I \backslash F, I \cap F, \emptyset, \ldots, \emptyset)$ and deduce $\operatorname{Fail}(\varepsilon)$ as follows. If $\operatorname{Fail}(\varepsilon)$ was not fulfilled, there would be a run $r \in Q^{K^{*}}$ with $r(\varepsilon) \in I$ for which all transitions are valid and for every $w \in K^{*}$ with $r(w) \notin F$ there would be a run $r_{w}^{\prime} \in Q^{w\left[K^{*}\right]}$ with $r_{w}^{\prime}(w)=r(w)$ that is both valid and successful below $w$. Then we could construct a run $r^{\prime} \in Q^{K^{*}}$ by replacing the labels of $r$ on the subtree $w\left[K^{*}\right]$ with those of $r_{w}^{\prime}$ at every such node $w \in K^{*} \cdot{ }^{3}$ This run $r^{\prime}$ would be a valid and successful run of $\mathcal{A}$ on $t$, which contradicts the assumption $t \notin \mathcal{L}(\mathcal{A})$.

Suppose now that $u \in K^{*}$ is a node where $\bar{r}(u)$ has already been defined and for which $\operatorname{Fail}\left(u,\left(T_{j, u}\right)\right)$ holds for some finite trees $T_{j, u} \subseteq u\left[K^{*}\right](j \in\{1, \ldots,|F|+1\})$. For every $i \in K$ we construct $\bar{r}(u i)$ from $\bar{r}(u)$ in several steps.

- First we determine an index $\widetilde{j} \in\{1, \ldots,|F|+1\}$ with $\bar{r}(u)_{\tilde{j}}=\emptyset$. Since we will keep the sets $\bar{r}(u)_{j}(j \in\{1, \ldots,|F|+1\})$ disjoint, there can be at most $|F|$ non-empty sets and thus such an index $\widetilde{j}$ can always be chosen.

[^4]- We initially set $\bar{r}(u i):=(\emptyset, \ldots, \emptyset)$ for each $i \in K$, and thus $\operatorname{Fail}(u i)$ holds for our initial definiton of $\bar{r}(u i)$. But clearly, the resulting transition $\overrightarrow{\bar{r}(t, u)}$ need not satisfy the transition relation $\bar{\Delta}$. We now enlarge the sets $\bar{r}(u i)$ in such a way that $\operatorname{Fail}(u i)$ remains satisfied and $\overrightarrow{\bar{r}(t, u)}$ becomes a valid transition.
- For every $j \in\{0, \ldots,|F|+1\}, q \in \bar{r}(u)_{j}$ and $y=\left(q, t(u), q_{1}, \ldots, q_{k}\right) \in \Delta$, we do the following.
- We choose one index $i \in K$ for which $q_{i}$ is added to a component of $\bar{r}(u i)$. The index of this new component is determined as follows:
* If $q_{i} \notin F$, we set $\bar{r}(u i)_{0}:=\bar{r}(u i)_{0} \cup\left\{q_{i}\right\}$.
* If $j>0$ and $q_{i} \in F$, we set $\bar{r}(u i)_{j}:=\bar{r}(u i)_{j} \cup\left\{q_{i}\right\}$.
* If $j=0$ and $q_{i} \in F$, we set $\bar{r}(u i)_{\tilde{j}}:=\bar{r}(u i)_{\tilde{j}} \cup\left\{q_{i}\right\}$.

We choose $i$ such that $\operatorname{Fail}(u i)$ remains satisfied after we add $q_{i}$ to $\bar{r}(u i)$ as specified above. As we will show in the following, such an index always exists. For this, we make a case distinction depending on whether $q \in F$ or not.

* Let $q \notin F$, i. e., $j=0$ and assume that $\operatorname{Fail}(u i)$ is violated by adding $q_{i}$ to $\bar{r}(u i)$. Then there are subruns $r_{i} \in Q^{u i\left[K^{*}\right]}$ with the properties

$$
\cdot r_{i}(u i)=q_{i} \text { and }
$$

- $\operatorname{Fail}\left(w, \overrightarrow{r_{i}(t, w)}\right)$ is not satisfied for any $w \in u i\left[K^{*}\right]$, i. e., if $w \notin F$, then there is a valid and successful subrun $r_{w}^{\prime} \in Q^{w\left[K^{*}\right]}$ with $r_{w}^{\prime}(w)=r_{i}(w)$.
As in the argument for $\operatorname{Fail}(\varepsilon)$, we can now construct a subrun $r^{\prime} \in Q^{u\left[K^{*}\right]}$ with $\overrightarrow{r^{\prime}(t, u)}=y$ which is valid and successful. This means that $\operatorname{Fail}(u, y)$ is not satisfied. If we now construct the subrun $r \in Q^{u\left[K^{*}\right]}$ by concatenating $y$ and the subruns $r_{i}, \operatorname{Fail}(w, \overrightarrow{r(t, w)})$ is not satisfied for any $w \in u\left[K^{*}\right]$, which is a contradiction to $\operatorname{Fail}(u)$.
* If $q \in F$, i. e., $j \geq 1$, we could use the same argument as above. However, in this case we take a closer look at the finite tree $T_{j, u i}$ because this will later enable us to show that $\bar{r}$ is successful. Since all $q_{i}$ are added to either $\bar{r}(u i)_{0}$ or $\bar{r}(u i)_{j}$, we need only be concerned with the trees $T_{0, u i}$ and $T_{j, u i}$. We will show that we can choose $i \in K$ such that the property $\operatorname{Fail}\left(u i,\left(T_{j^{\prime}, u i}\right)\right)$ remains satisfied if we set $T_{0, u i}:=T_{j, u i}:=T_{j, u} \cap u i\left[K^{*}\right]$.
If we assume the converse, we could deduce that there exist subruns $r_{i} \in$ $Q^{u i\left[K^{*}\right]}$ with the following properties:

$$
\cdot r_{i}(u i)=q_{i}
$$

- $\operatorname{Fail}\left(w, \overrightarrow{r_{i}(t, w)}\right)$ is not satisfied for any $w \in T_{j, u} \cap u i\left[K^{*}\right]$.

If we now construct the subrun $r \in Q^{u\left[K^{*}\right]}$ by concatenating the transition $y$ and the subruns $r_{i}$, then it is easily seen that $r$ starts in $r(u)=q$ and no $\operatorname{Fail}(w, \overrightarrow{r(t, w)})$ is satisfied for any $w \in T_{j, u} \cap u i\left[K^{*}\right]$ and for any $i \in K$. Furthermore, $\operatorname{Fail}(u, \overrightarrow{r(t, u)})$ is also not satisfied, since $\overrightarrow{r(t, u)}=y \in \Delta$, but $q \in F$. This means that $r$ is a counterexample to $\operatorname{Fail}\left(u,\left(T_{j^{\prime}, u}\right)\right)$.

- After we have done this for every $j, q$ and $y$, the transition $\overrightarrow{\bar{r}(t, u)}$ is valid and the properties Fail(ui) still hold.
- As a last step, we need to make sure that the sets $\bar{r}(u i)_{1}, \ldots, \bar{r}(u i)_{|F|+1}$ are disjoint for every $i \in K$. To do this, we remove all but the rightmost occurrence of each state $q \in F$ in these sets. The transition $\overrightarrow{\bar{r}(t, u)}$ remains valid, because $\bar{\Delta}$ only requires a state $q_{i}$ to be present in some position $l$ that is greater than or equal to $\max \{j, 1\}$. The properties Fail(ui) also still hold, because we only removed states from some of the components of $\bar{r}(u i)$.
- Since $\operatorname{Fail}(u i)$ holds, there are finite trees $T_{j, u i}(j \in\{1, \ldots,|F|+1\})$ such that $\operatorname{Fail}\left(u i,\left(T_{j, u i}\right)\right)$ holds. These trees can be determined as follows.
- $T_{0, u i}$ can be set to $\{u i\}$ since $\operatorname{Fail}(u i)$ implies that for any run $r \in Q^{u i\left[K^{*}\right]}$ with $r(u i) \in \bar{r}(u i)_{0}$ the property $\operatorname{Fail}(u i, \overrightarrow{r(t, u i})$ must hold.
- $T_{\tilde{\jmath}, u i}$ must be determined from $\operatorname{Fail}(u i)$ using Corollary 3.4 .
- For any $j$ that is not 0 or $\widetilde{j}$, we can set $T_{j, u i}:=T_{j, u} \cap u i\left[K^{*}\right]$. This is possible because of the way we constructed $\bar{r}(u i)_{j}$.
It remains to show that $\bar{r}$ is a successful run of $\overline{\mathcal{A}}$. For this we assume that there is a path $p \in \mathcal{P a t h}\left(K^{*}\right)$ such that for some $j \in\{1, \ldots,|F|+1\}$ the set $\bar{r}(u)_{j}$ is empty only finitely often for nodes $u \in p$. Then there is a node $u \in p$ after which no empty set occurs in the $j$-th component of $\bar{r}$ along $p$. By construction of $\bar{r}$, the property $\operatorname{Fail}\left(u,\left(T_{j^{\prime}, u}\right)\right)$ must be satisfied for finite trees $T_{j^{\prime}, u} \subseteq u\left[K^{*}\right]$.

Let $v$ be the first node of $p$ that lies outside of $T_{j, u}$. By construction of $\bar{r}, \operatorname{Fail}\left(v,\left(T_{j^{\prime}, v}\right)\right)$ must hold for finite trees $T_{j^{\prime}, v} \subseteq v\left[K^{*}\right]$. The tree $T_{j, v}$ can be chosen to be $T_{j, u} \cap v\left[K^{*}\right]=\emptyset$ since no empty set occurred in the $j$-th component along the path from $u$ to $v$. Since $\operatorname{Fail}\left(v,\left(T_{j^{\prime}, v}\right)\right)$ is satisfied, this means that $\bar{r}(v)$ must be empty, which contradicts the assumption. Thus, $\bar{r}$ is a successful run of $\overline{\mathcal{A}}$ on $t$ and $t \in \mathcal{L}(\overline{\mathcal{A}})$.

The above two lemmata now allow us to conclude that the complementation construction is correct.
Theorem 4.17 (Complementation Theorem (CA)) Let $\mathcal{A}$ be a CA. Then $\mathcal{L}(\overline{\mathcal{A}})=$ $\overline{\mathcal{L}(\mathcal{A})}$.

This time, we will not follow a glass-box approach to develop a complementation construction for WCA. As was already seen in the previous section, the black-box approach is superior if the unweighted construction is already of exponential complexity. Since the construction from Definition 4.14 is a more general version of Definition 4.3, a similar glass-box approach as in the previous section would again lead to an algorithm that is too expensive. It remains an open problem to find a more efficient complementation construction.

### 4.4 Another Infimum Aggregation Problem

We now want to look at a modified infimum aggregation problem where $\mathcal{A}$ is a Büchi automaton and $\mathcal{A}^{\prime}$ is a co-Büchi automaton. Luckily, co-Büchi automata exhibit many of the
properties we have used for Büchi automata so far: GCA are polynomially equivalent to CA (see Lemma 4.18 below), there are polynomial constructions for union and intersection ([15, Theorem 4]) and emptiness can be checked in polynomial time ([15, Theorem 9] ${ }^{4}$. Although no explicit generalizations to weighted co-Büchi automata exist, these should be as easy to obtain as the corresponding algorithms for weighted Büchi automata (see [2, 4]).
Lemma 4.18 Let $\mathcal{A}=\left(Q, \Sigma, I, \Delta, F_{1}, \ldots, F_{m}\right)$ be a $G C A$ and let the $C A \mathcal{A}^{\prime}$ be defined as $\left(Q^{\prime}, \Sigma, I^{\prime}, \Delta^{\prime}, F^{\prime}\right)$ with

- $Q^{\prime}:=Q \times\{1, \ldots, m\}$,
- $I^{\prime}:=I \times\{1, \ldots, m\}$,
- $\Delta^{\prime}:=\left\{\left(\left(q_{0}, i_{0}\right), \alpha,\left(q_{1}, i_{1}\right), \ldots,\left(q_{k}, i_{k}\right)\right) \mid\left(q_{0}, \alpha, q_{1}, \ldots, q_{k}\right) \in \Delta\right.$ and $\left.i_{0}=\ldots=i_{k}\right\}$,
- $F^{\prime}:=\bigcup_{i=1}^{m} F_{i} \times\{i\}$.

Then we have $\mathcal{L}\left(\mathcal{A}^{\prime}\right)=\mathcal{L}(\mathcal{A})$.
Proof: Let $t \in \Sigma^{K^{*}}$ be an input tree and $r \in Q^{K^{*}}$ be a valid run of $\mathcal{A}$ that is accepted by some $F_{i}(i=1, \ldots, m)$. Then the run $r^{\prime} \in Q^{\prime K^{*}}$ defined by $r^{\prime}(u):=(r(u), i)$ for all $u \in K^{*}$ is a successful and valid run of $\mathcal{A}^{\prime}$, because $\operatorname{Inf}\left(r^{\prime}, p\right) \backslash F^{\prime}=(\operatorname{Inf}(r, p) \times\{i\}) \backslash\left(F_{i} \times\{i\}\right)=\emptyset$ holds for all $p \in \mathcal{P}$ ath $\left(K^{*}\right)$.

Also, all valid runs $r^{\prime}$ of $\mathcal{A}^{\prime}$ have this form, i.e., have a constant second component $i \in\{1, \ldots, m\}$ in all labels. The first component of a successful and valid run $r^{\prime}$ of $\mathcal{A}^{\prime}$ is thus a successful and valid run $r$ of $\mathcal{A}$, because $(\operatorname{Inf}(r, p) \times\{i\}) \backslash\left(F_{i} \times\{i\}\right)=\operatorname{Inf}\left(r^{\prime}, p\right) \backslash F^{\prime}=\emptyset$ and thus $\operatorname{Inf}(r, p) \backslash F_{i}=\emptyset$ hold for all $p \in \operatorname{Path}\left(K^{*}\right)$.

As always, the problem with the inclusion test (or infimum aggregation) lies in the complementation step. CA are not closed under complement ([15, Theorem 5]) and, even worse, there are tree languages recognized by Büchi automata whose complement cannot be recognized by a co-Büchi automaton ([14, Lemma 3]). This means that a construction similar to that in Definition 4.14 is not possible when the roles of Büchi and co-Büchi automata are reversed.

This means that co-Büchi automata are in some sense "weaker" than Büchi automata and their class of recognized languages is "smaller". Due to this fact, the utility of this modified infimum aggregation problem is limited.

[^5]
## 5 Conclusions

In this work the infimum aggregation problem for weighted tree automata was introduced and several algorithms to solve it for various acceptance conditions were demonstrated. For deterministic Büchi automata, this problem can be solved in P, for non-deterministic looping, Büchi and co-Büchi automata it was shown to be in EXPTIME.

All of these algorithms were based on solutions for the corresponding unweighted inclusion problems. A black-box approach was used to lift these to the weighted case, adding only a small factor to the overall complexity. A glass-box approach was found to be of the same complexity only in the case of deterministic Büchi automata. For more expressive automata models, the black-box approach is preferable.

Although the presented glass-box algorithm for the complement of weighted looping automata was too expensive, it nevertheless provided valuable insights into the structure of the unweighted construction. To develop a construction for weighted automata using a glass-box approach one is forced to review the arguments of the unweighted version in more detail. The proof of correctness of the weighted construction also demonstrated several techniques that can be used to lift an unweighted to a weighted argument.

It remains to see whether there are more efficient constructions for the complement of the classes of weighted tree automata presented here. It seems unlikely, since the black-box approach already adds so little to the complexity of the unweighted algorithm.

For the presented constructions not to stay purely theoretical, interesting applications for the inclusion problem and the infimum aggregation problem for weighted tree automata would need to be found. Obvious candidates are the various logics that have been found to be equivalent to certain tree automata. The inclusion problem may be used, e.g., to check for subsumption in description logics where this cannot easily be checked by other methods.

## ERKLÄRUNG

Hiermit erkläre ich, dass ich die am heutigen Tag eingereichte Diplomarbeit zum Thema "The Infimum Problem as a Generalization of the Inclusion Problem for Automata" unter Betreuung von Prof. Dr.-Ing. Franz Baader selbstständig erarbeitet, verfasst und Zitate kenntlich gemacht habe. Andere als die angegebenen Hilfsmittel wurden von mir nicht benutzt.

Datum

[^0]:    ${ }^{1}$ We will usually represent the lattice by the underlying set and assume that infimum and supremum are implicitly known.

[^1]:    ${ }^{1}$ Thanks to Christof Löding for the proof idea.

[^2]:    ${ }^{2}$ In [16] alternating automata are defined differently, but the two descriptions can be transformed into each other in polynomial time.
    ${ }^{3}$ The factorial $x$ ! is bounded by $x^{x}=2^{x \log x} \leq 2^{x^{2}}$.

[^3]:    ${ }^{1}$ This simplification is only valid for the automata models used in this chapter, i.e., automata with acceptance conditions of size polynomial in $|Q|$.

[^4]:    ${ }^{2}$ The tree $T_{0, u}$ can always be chosen to be the singleton tree $\{u\}$ : If every valid run starting in a state from $Q \backslash F$ at $u$ must contain a node $w$ with $\operatorname{Fail}(w, \overrightarrow{r(t, w)})$, then for every such run $\operatorname{Fail}(u, \overrightarrow{r(t, u)})$ will already be satisfied. This is because any path containing $w$ must also contain $u$.
    ${ }^{3}$ We only do this replacement for the first occurrence of a state from $Q \backslash F$, not in a subtree that has already been replaced.

[^5]:    ${ }^{4}$ In [15], GCA are called Landweber tree automata.
