ABSTRACT
Looting is a worldwide issue that occurs not only in conflict zones or areas with weak governmental control. Although national and international agencies are addressing the problem, we are far from solving it, due to its complexity and the insufficient allocation of resources. In this article, we examine the temporal and spatial patterns of looting at the single site level (Tūwāneh, southern Jordan) over the past decade. Our analysis utilized orthomosaics created in 2018 and 2019, a systematic surface survey conducted in November 2022, and publicly available satellite imagery (via Google Earth Pro) dating back to August 2013. We identified a total of 723 looting pits, of which 259 were excavated before August 2013 and 140 between August 2013 and November 2022; 324 were inconclusive due to methodological limitations. The findings suggest that looting is a persistent issue in the area, highlighting the importance of implementing effective measures to prevent the loss of archaeological heritage.

Introduction

Archaeologists all around the world are faced by the problems of looting (Atwood 2006; Mackenzie and Davis 2014; Desmarais and Desmarais 2015; Rodríguez Temiño and Roma Valdés 2015; Hardy 2016) and vandalism (Taruvinga and Ndoro 2003; Kersel 2012; Al-Houdalieh 2014; Chiovenda 2014; Cuneo et al. 2015). Although the reasons behind these phenomena may vary—times of unrest and warfare (Stone and Zimansky 1992; Chapman 1994; Casana 2015; Cuneo et al. 2015), bad economic situations (so-called subsistence digging: Staley 1993; Politis 2001, 259–261; Kersel 2007a; Parcak et al. 2016), or, on the contrary, an economic boom and related construction work (Politis 2001, 257–259; Kankpeyeng and DeCorse 2004; Dolinka 2007; Banks 2016; Rayne, Sheldrick, and Nikolaus 2017)—one thing is certain: the world's archaeological heritage is often not a priority for central and local authorities, despite official assurances to the contrary. Furthermore, in many countries, the sheer abundance of archaeological sites exceeds the capacity of available financial resources to provide them with comprehensive protection. Consequently, the level of protection they receive remains inadequate.

Taking effective action to prevent the looting of sites and illegal trafficking of antiquities is hampered not only by limited resources and leniency toward robbers in many countries (cf. Shelbourn 2014, 190–195; Makowska, Oniszczuk, and Sabaciński 2016, 173–174; Yáñez 2016) but also because we usually have only residual data on the scale of the practice (Contreras 2010, 547; Contreras and Brodie 2010b, 101). In recent decades, archaeologists have begun to pay more attention to documenting cases of illegal excavations at the sites they study. In addition, satellite imagery has begun to be used on a large scale to identify looting activity (Contreras and Brodie 2010a, 2010b; Casana 2015; Parcak 2015; Parcak et al. 2016; Danti, Branting, and

Penacho 2017; Tapete and Cigna 2019; Tapete et al. 2021). Attempts have even been made to develop methods for automatic (Bowen et al. 2017; Lasaponara and Masini 2018) or semi-automatic (Lauricella et al. 2017) identification of looting pits. While the great advantage of these methods is that they save time, they have been criticized for recording mainly pits of regular shapes while ignoring other types of damage easily seen during the much more time-consuming expert evaluation (Casana 2014, 2020). There is no doubt, however, that they are extremely helpful to both regional and supraregional studies, as they allow the extent of damage to be assessed relatively quickly and without having to visit the sites.

Here, we present our experience of recording looting pits at the site level based only on expert evaluation of publicly available satellite imagery, kite- and pole-based orthomosaics of the site, and surface survey. We present the advantages and disadvantages of each approach. Above all, we demonstrate that the effectiveness of remote analysis methods largely depends on the character, degree of preservation of architectural remains, and the topography of the site.

With access to publicly available satellite imagery (Google Earth) of sufficient quality from the last ten years (2013–2022), we were able to assess not only the overall area of damage resulting from illegal excavations but also to identify individual pits. This allowed us to subsequently quantify the temporal extent of looting activity for the specified period. Quantification of the inflicted damage due to looting, along with estimations pertaining to the time periods within which these acts occurred, provides a method to gauge the ongoing detriment experienced by archaeological sites. It also allowed us to identify the zones of the site which, at any given time, were being particularly intensively excavated. In addition, this also made it possible to show a general trend in the number of looting pits excavated annually on the site.

The Local Context

Although excavating without the permission of the Department of Antiquities[1] and trafficking in antiquities is prohibited in Jordan (Abu Abu Issa and Alwerikat 2023), looting activities are flourishing, supplying both the local and international markets with illegally excavated items (Kersel 2018; Kersel and Hill 2019; Kersel and Gerstenblith 2023, 4–5). Bronze Age artifacts—often associated with the biblical world (Kersel and Hill 2019, 305–306)—and Nabataean artifacts are of particular interest, but this does not mean that sites from other historical periods are safe. Individuals engaged in looting activities often claim that they are in search of gold. This assertion is based on both our personal observations[2] and the accounts provided by the staff of the Jordanian Department of Antiquities (cf. Al-Manaser and Atal 2020, 11–14). However, such an answer should be taken with a grain of salt, as cemeteries seem to be of particular interest, indicating that robbers are looking in the first place for intact artifacts of various kinds in a good state of preservation to be sold on the black market. Based on criminal statistics provided by Abu Issa and Alwerikat (2023, 478), the instances of illegal excavations that were transferred to and dealt with by the judicial system in 2019 amounted to 257, followed by 241 in 2020 and 272 in 2021.

There is no doubt that robbery activities have a very long tradition dating back to pre- and proto-historical periods. It intensified, however, in the 20th century A.D., due to both population growth and technical possibilities (e.g. the use of metal detectors). Most of this type of activity in Jordan is—it seems—economically motivated (Politis 2001, 257–258; Rose and Burke 2004; Brodie and Contreras 2012; Kersel and Hill 2019, 317–323; Al-Manaser and Atal 2020). Official government figures indicate that the unemployment rate has been rising in recent years, reaching 25% in 2021[3] (among young people under 30, it could be as high as 33%).[4] Even if part of this phenomenon is mitigated by employment in the grey and black economies, it may further fuel the looting of archaeological sites. When considering the usually slim likelihood of being apprehended and seldom, lenient penalties, looters weigh the potential risks against the possibility of earning substantial and effortless income (easy money) to support their households and often find it to be a more attractive option (Kersel 2007b; Sheftel 2012; cf. Goldin 2004).

Many instances of looting activities are known from Jordan, making it impossible to discuss all of them in such a short text. Nevertheless, we present some examples to illustrate the problem at the local level. One of the most shocking examples is the plunder of the ancient city of Zoar. As soon as the inhabitants of Ghor as-Ṣāfī (Ar.الصافي غور, Karak-Al Agbwar Al Janobeyah) realized that the workers of the Italian company preparing irrigation systems for the surrounding fields as part of a major agrarian project were interested in the antiquities, they started digging up their own gardens in search of artifacts, irretrievably destroying a part of this important site (Politis 2001, 258). Far-reaching damage was then caused to the sites of Khirbet Sheīkh ʿĪsa (Ar. عيسد الشيخ خربة), where a heap of stones collected by a bulldozer in the 1970s was the only trace of Byzantine and medieval architecture there (Politis 2001, 259, fig. 14.1), and the cemetery of an-Naq' (Ar. الــنــقــع; Politis 2001, 259–261, figs. 14.2–5). At an Early Bronze Age cemetery at Fīfā (Ar. فيفا , Karak-Al Agbwar Al Janobeyah), 3723 looting pits were recorded (Kersel and Hill 2019, 309–

310, figs. 2–3; 2020). At the same time, only a handful of graves have been excavated by professionals (Rast and Schaub 1990; Najjar 2001), as best illustrated by the plan published by Kersel and Hill (Kersel and Hill 2019, 310, fig. 3).[5] A similar degree of destruction can be found at the cemetery at Bāb edh-Dhrāʾ (Ar. Karak-Ghor Mazra'ah), dated to the same period, الذراع باب , from where the first reports of looting date back to the 1920s, from the accounts of Albright and Mallon (Albright 1924, 5–6; McCreery 1996; Contreras and Brodie 2010a, 107–109; Kersel and Chesson 2013). Adjacent to the site is the Nabataean, Roman, Byzantine, and early Islamic cemetery of Khirbet Qāzūne (Ar. قازون خربة), which was identified in 1979 (Rast et al. 1980, 40). In 1994, graves were found during road widening. There was rapid looting: a survey from 1996–1997 recorded more than 3500 looted Nabataean graves (Politis 1998). In 1996, a team from The Wadi Faynan Project (Ar. Ṭafīlah) estimated that more than 700 graves had , فينان وادي been excavated at the Late Roman and Byzantine cemetery there, accounting for more than 40% of all graves at the site (Findlater et al. 1998, 70–71). Even in Petra ('Aqaba-Wādī 'Araba), there have been incidents of robbery and vandalism (Knodell and Alcock 2011; Sinibaldi and Tuttle 2011; Alcock and Knodell 2012; Urban, Alcock, and Tuttle 2012; Urban et al. 2014), which the Brown University Petra Project team members recorded accurately (Vella et al. 2015). While robbers appear to focus primarily on Bronze Age and Nabataean sites, it's important to note that sites from other periods are also at risk. For instance, there have been illegal excavations at the Pre-Pottery Neolithic A site at Wādī Sharāra (Ar. شراره وادي, Karak-Al-Mazār al-Janūbī) (Sampson 2020) or the Early Islamic site at Wādī Shīreh (Ar. شيره وادي , 'Aqaba-Al-Qūaīrah) (Al-Bqain, Corbett, and Khamis 2015).

In addition to illegal excavations, instances of vandalism at archaeological sites are also known from Jordan. The flagship example from recent years is the destruction of the Rujm al-Faridiyyeh fort (Ṭafīlah-Al-Ḥasā) between August 2013 and January 2017 using heavy equipment (Fisher et al. 2021, 280–281, fig. 2).[6] It is, however, worth noting that damage to the eastern wall of this site by a bulldozer was reported by MacDonald as early as 1984 (MacDonald 1984, 226).

The Object of Research

Tūwāneh (Ar. توانه)[7] is a site located in the Ṭafīlah-Al-Ḥasā district in southern Jordan. The main settlement phase dates to the Nabataean, Roman, and Byzantine periods, with traces of human habitation in the Iron Age and the Mamluk period (Fiema 1993, 549; 1997, 315; MacDonald et al. 2004, 351–352; Bodzek et al. 2019, 70–71). The total area of the site is estimated at 55 ha, although architectural remains can be seen on the surface over about 35 ha. The site has not yet been the subject of large-scale archaeological research. It has primarily been the subject of two surface surveys conducted as part of the *Via Nova Traiana Project* (Fiema 1993, 1997) and the *Tafila-Busayra Archaeological Survey* (MacDonald et al. 2004, 348–354). The former was more intensive, as the site was one of the foci of the project. It was only in 2018 that a team of Polish archaeologists and surveyors began regular surveys and test excavations on the site (Bodzek et al. 2019). Although threats to the site had already been noted, most notably the construction of a road that runs through the center of the site just above the bottom of the

Figure 1. Orthomosaic (ORTHO19) of the site created in autumn 2019. Yellow boxes indicate sites where pole-based photogrammetry was carried out in 2018. Blue shapes indicate looting pits measured in 2018 with GPS.

wadi and the development of agriculture (Fiema 1997, 316; MacDonald et al. 2004, 348; Bodzek, Kopij, and Miszk 2019), it was only with the start of the Polish project that the process of documenting the looting pits began. The site is under the care of the Ṭafīlah Antiquities Office, which has appointed a warden to oversee the site. The absence of fencing around the site, coupled with the infrequent visits by the warden (due to his responsibility for numerous sites in the region), results in unrestricted access to the site.

An exceedingly crucial aspect of Tūwāneh, in the context of documenting illicit excavations, lies in its diverse characteristics, the level of architectural remains' preservation, and its topography. The site predominantly resides on the opposing slopes of two hills with varying inclinations, divided by a wadi. Portions of the site are also situated on flatter terrain, both near the hilltops, in the southern region, and adjacent to the bottom of the wadi. Furthermore, substantial portions of

the site feature architectural remnants displaying differing degrees of preservation.

Methodology

Data used for this study were collected during three seasons: 2018, 2019, and 2022. During the 2018 season, the pole photogrammetric system known as ULAPh (Ultra-Low Altitude Photogrammetry) was used to document part of the site adjacent to the so-called caravanserai (Bodzek et al. 2019, 77–78). Measurements were taken using a fairly simple system consisting of a GoPro HERO 6 Black camera on a 5 m Leveling pole. Prior to the survey, survey points were set up in the survey area, forming a square grid with 5 m sides. Oblique images were then taken at each point in eight different directions (Bodzek et al. 2019, fig. 7). In this way, photogrammetric data of an area of about 2.5 ha located

in the central part of the site (the so-called caravanserai complex with its adjacencies) (Figure 1) were acquired, with a ground sampling distance (GSD) of 4 mm. During the fieldwork, more than 4800 images were taken at 600 survey points. Additionally, 51 ground control points (GCPs) and 49 check points (CPs) were established for the purpose of georeferencing and verification of the accuracy of the photogrammetric products, with their coordinates having been

Figure 3. A plan of the pits recorded from the ORTHO19 analysis.

determined using the Real Time Kinematic (RTK) GNSS with 3D accuracy of 3 cm. The fieldwork and data collection took three days. The data obtained were processed with the use of the Structure from Motion (SfM) algorithm implemented in Agisoft Metashape Professional software. The final products—an orthomosaic with a spatial resolution of 4 cm (in this text designated as ORTHO18) and a digital elevation model (DEM) with a spatial resolution of 16 cm —were used for this study. In addition, pits located in the central part of the site outside the ULAPh area were mapped and photographed. In total, these activities covered approximately 10 ha (Supplemental Materials 1–2).[7]

Since obtaining a permit to use an unmanned aerial vehicle (UAV) in Jordan is time- and cost-consuming, in 2019, we decided to take measurements for the entire site using a kite. The survey system consisted of a GoPro Hero 6 camera mounted on a gimbal and attached to a kite.

Approximately 6900 images with a 30 mm GSD were acquired over the three days. The 55 ha surveyed area covered the entire site. A total of 166 GCPs and CPs were also established during the survey. They were distributed evenly over the study area in a 70 m grid. Their coordinates were measured with the RTK GNSS method with 3D accuracy of 3 cm. Photogrammetric data was processed using Agisoft Metashape Professional. The final products used in this study, an orthomosaic (ORTHO19) and a DEM, had spatial resolutions of 3 cm and 12 cm, respectively. These became the basis for the inventory of aerially visible looting pits within the entire site (Bodzek et al. 2022, 25) (Supplemental Materials 3–4).

In the 2022 season, we implemented a systematic survey of the entire site, mapping all visible looting pits using the RTK GNSS (in this text designated as INV22) and taking photos of them. The manner in which the intensive survey
Figure 4. A plan of the pits recorded during the systematic ground survey (INV22).

was carried out was modeled on a similar study of Petra's hinterland (except that the survey there covered a much larger area) (Knodell and Alcock 2011, 492–495; Vella et al. 2015, 40:225). The inventory thus created served as a reference point for the study, as it was the most complete inventory of looting pits at the site (Supplemental Material 5). The inventory of the roughly 55 ha site was completed in three days, which is equivalent to approximately 16–18 hours.

ArcGIS Pro 3.0.2 software was used for further processing of the survey data. The first step was to import the coordinates of the outer contours of the looting pits (for the 2018 data), or the central points of the pits (for the 2022 data), collected during the surface surveys. These were determined in the WGS84 system and thus had to be converted to the Jordanian system (EPSG:3066). Then, using photogrammetric products available from the inventory documentation where possible, all pits were vectored.

In 2018, measurements were taken for the area limited to the so-called caravanserai complex. In 2019, measurements were taken for the entire site. This allowed us to compare if new looting pits emerged near the so-called caravanserai over the year. The comparison was done systematically using imagery, including orthomosaics and DEMs. The next step was to compare the orthomosaic and DEM of the entire site with publicly available satellite imagery (via Google Earth Pro). To perform this operation, the images were downloaded at the best possible resolution (approximately 200 cm), and they were then transferred to the ArcGIS Pro environment, where they were assembled and georeferenced to make the comparison as simple as possible. The method of analyzing satellite imagery was primarily inspired by publications by Parcak (Parcak 2015; Parcak et al. 2016, 190–191). Nine images with resolutions sufficient to detect at least a portion of the looting pits covering the area of the
Figure 5. A plan of the pits excavated before August 2013 (marked in blue; red indicates all the pits documented). Based on analysis of satellite imagery available on Google Earth.

entire site are available on the platform. They come from 10 August 2013, 12 October 2014, 22 May 2016, 3 January 2017, 4 February 2018, 10 September 2019, 15 June 2020, 6 August 2020, and 18 April 2021 (in this text, they are designated as GE8.13, GE10.14, GE5.16, GE1.17, GE2.18, GE9.19, GE6.20, GE8.20, and GE4.21, respectively). Regrettably, we did not document the precise time it took to analyze the images, which would have given us a better understanding of how time-consuming the process was. All we know is that the analysis took 19 days (though we are unable to determine the exact number of hours it consumed). By comparing the imagery, we were able, in some cases, to narrow down the time of the occurrence of the looting pits. Figure 2 shows pit LP.18/002, which is clearly visible in all the images. A similar temporal analysis, albeit on a smaller timescale, has already been applied to sites in war-torn Syria, e.g. at

Apamea (Tapete, Cigna, and Donoghue 2016; Agapiou 2020). On a smaller time scale, in the context of Jordan, the process of looting the Fīfā cemetery was studied using surface survey and UAV orthomosaic analysis (Kersel and Hill 2019, 2020). In contrast, a similar time scale analysis was carried out by Parcak (Parcak 2015; Parcak et al. 2016) for 267 sites in Egypt, where looting activity increased after the 2011 Egyptian revolution. In this case, however, we are dealing with sites with different characteristics than Tūwā- neh, as these were cemeteries.

Results

The fact that the site is dotted with looting pits was made clear to us by our first reconnaissance visit to Tūwāneh in the fall of 2017, which lasted only a few hours. During our

Figure 6. A plan of the pits excavated between August 2013 and October 2014 (marked in blue; red indicates all the pits documented). Based on analysis of satellite imagery available on Google Earth.

first research season in 2018, we also noticed that the plunder was progressing, as evidenced by the changes that had taken place within the ruins of the ancient baths. Based on 2018 data, we recorded a total of 191 looting pits based on direct measurements (119) (Bodzek et al. 2019, 81, figs. 3, 14) and later by the ORTHO18 analysis (72) (see Figure 1).

A comparison of ORTHO18 with ORTHO19 (and the corresponding DEMs) indicated that between the creation of these images, four new looting pits were excavated in the area covered by both of them. For three of these, we are certain (LP.19/007, LP.19/008, and LP.19/014) (Supplemental Material 6)[8] that they were dug between early November 2018 and early November 2019, while for the other (LP.22/039), we cannot say with more precision when it was created, as it is a small and shallow pit that cannot be seen well on the imagery.

Analysis of the ORTHO19 revealed the presence of 175 further pits in addition to the 191 recorded the year before (Figure 3). Recognizing the limitations of the method of identifying trenches on the imagery (discussed below), we conducted a systematic survey of the site in 2022. It revealed the presence of a further 356 looting pits (Figure 4).

We then analyzed satellite imagery from Google Earth Pro. The analysis of the initial imagery and its comparison with the INV22 shows that 259 of them were certainly excavated prior to GE8.13 (Figure 5). In the case of 324, we cannot say whether they already existed at that time, for various reasons which we will discuss below. The analysis of the imagery suggests that 20 new looting pits were excavated between GE8.13 and GE10.14 (Figure 6), 15 between GE10.14 and GE5.16 (Figure 7), 27 between GE5.16 and GE1.17 (Figure 8), 10 between GE1.17 and GE2.18 (Figure 9), 14 between GE2.18 and GE9.19

Figure 7. A plan of the pits excavated between October 2014 and May 2016 (marked in blue; red indicates all the pits documented). Based on analysis of satellite imagery available on Google Earth.

(Figure 10), 20 between ORTHO19 and GE6.20 (Figure 11), three between GE6.20 and GE8.20 (Figure 12), and six between GE8.20 and GE4.21 (Figure 13) (see Supplemental Material 6 for a full tabular summary of pits).

The average annual number of looting pits created after August 2013 is 15.6. However, as can be seen in Figure 14, the number of looting pits created on an annual basis varied considerably from year to year. There was a particular spike of illegal excavations during the periods GE5.16–GE1.17 and ORTHO19–GE6.20. Both of these periods covered approximately 7.5 months, during which 27 new pits were excavated in the former and 20 in the latter. The overall data show a very slight downward trend, yet the extremely low R^2 value (0.0058) indicates that, in practice, the average annual number of trenches has remained constant during the investigated period.

Analysis of the imagery indicates that over the last decade (post-GE8.13), illegal excavation activity has been mainly concentrated in the eastern part of the site (i.e. east of the modern road). It is worth noting, however, that in the western part, we are faced with tightly packed ruins consisting of structures with small rooms, whose walls are preserved to a considerable height in places (usually to a height of 1–1.5 m from ground level, even higher in places). The shadows they cast make it difficult (and sometimes impossible) to identify the looting pits on the basis of imagery analysis. An additional complication is that the interiors are filled with debris, in which it is difficult to see the looting pits.

Illegal excavations of the cemetery in the southern part of the site, which commenced prior to GE8.13, persisted intensely until GE1.17. This intensity was particularly notable between GE5.16 and GE1.17, during which we documented

Figure 8. A plan of the pits excavated between May 2016 and January 2017 (marked in blue; red indicates all the pits documented). Based on analysis of satellite imagery available on Google Earth.

as many as 12 new pits in this zone. Subsequently, the intensity of excavations gradually declined, with the final trenches we observed in this area appearing before GE6.20. The situation is similar in the cemetery located at the eastern boundary of the site, adjacent to the so-called caravanserai. The intensity of illegal excavations here is lower than in the southern cemetery: between GE1.13 and GE9.19, two or three pits were explored per period between consecutive images (except for the period between GE1.17 and GE2.18, when no pits were excavated in this zone). After GE2.19, only single pits were excavated in the boundary zone, where the remains of stone structures are located (at this point, we cannot say whether these structures have an ancient provenance or whether they were made in modern times in connection with nomadic and pastoral activities).

In the period after GE1.17, illegal excavation seems to have ceased in the area of the baths, i.e. in the area to the west of the so-called caravanserai complex, just off the eastern bank of the wadi valley (previously, two to four trenches were excavated here between consecutive images). The sole indications of looting activity that we documented within this area are not discernible in the imagery and were linked to the gradual excavations of the baths that took place between our visits in November 2017 and November 2018. Two instances of looting pits resurface here once more, occurring between GE4.21 and the INV22. In addition, during our visit to the site in autumn 2023, we observed that robbers had exposed our excavation trench dug the year before (TTIV), which we had backfilled with large stones and soil after exploration. This further confirms that the activity of professional

Figure 9. A plan of the pits excavated between January 2017 and February 2018 (marked in blue; red indicates all the pits documented). Based on analysis of satellite imagery available on Google Earth.

archaeologists can inspire robbers to search in the same places.

The northeastern zone of the site is interesting, as there we do not record robber activity between GE8.13 and GE4.21. In contrast, four new pits were excavated here between GE4.21 and the INV22. Between GE8.13 and GE9.19, we also noted no illegal excavations in the area adjacent to the caravanserai complex to the south and southwest. However, robbers became active here between GE9.19 and GE.8.20, when three new pits were explored here. The vast majority of the pits in the zone between the wadi and the modern road were dug before GE8.13 (some, incidentally, may have been related to the construction of the road itself in the late 1980s). Only between GE4.21 and INV22 were five new pits excavated here. In addition to identifying periods when some of the pits are likely to have been

excavated, our analysis also revealed other interesting changes to the site. One interesting case is LP.18/018, which is visible in GE10.14, invisible in GE8.13 and later in GE5.16, then clearly visible in GE1.17, GE2.18, GE9.19, and ORTHO19, and then again invisible and not measured at the time of the INV22. As it lies in the immediate vicinity of the wadi, approximately 8.8 m from the main bed, it is possible that it was covered by flows of water after heavy rainfalls. Another interesting case is pit LP.19/006. Based on the analysis of the satellite images, it is difficult to say when the pit was originally dug, but the analysis of the ORTHO18 and the ORTHO19 indicates that the pit was enlarged between these two measurements.

Yet another curious case, this time unrelated to the excavation of the looting pits but to the modification of the stone structures that we observed on the satellite imagery, is the

Figure 10. A plan of the pits excavated between February 2018 and September 2019 (marked in blue; red indicates all the pits documented). Based on analysis of satellite imagery available on Google Earth.

formation of an animal pen between GE10.14 and GE5.16, followed by its enlargement between GE2.18 and GE9.19 (Figure 15). Probably, this is the result of the activity of nomads who periodically camp in the immediate vicinity of or on the site. The presence of nomadic camps and their possible impact on the site's preservation has been noted previously (Bodzek, Kopij, and Miszk 2019, 45–47, fig. 12). Based on the analysis of the traces that remain of the encampments visible in ORTHO19, we can pinpoint the places where the nomads camped (Figure 16). The construction and use of the camps involved the creation of some of the pits, which were probably of a utilitarian nature, e.g. rubbish dumps or food preparation areas. An example of such an object is LP.22/157, which is not visible on any imagery. It is possible that it was excavated during the construction, operation, or rolling up of the camp that can be seen adjacent

to the pit in GE4.21. With that said, we have no indication that the nomads themselves are involved in the process of illegal excavation in Tūwāneh, despite reports from other sites and studies focused on the illegal trade in antiquities (Kersel 2007b; Gebel et al. 2011). Rather, representatives of the Department of Antiquities pointed to the nearby town dwellers.

Discussion and Limitations

Each of the methods we used—systematic surface survey, analysis of orthomosaics taken from the air, and analysis of satellite imagery—has its pros and cons. By far the most effective in identifying illegal excavation is the first method. Using it, we were able to record as many as 634 pits. However, it should be noted right away that not all

Figure 11. A plan of the pits excavated between November 2019 and June 2020 (marked in blue; red indicates all the pits documented). Based on analysis of satellite imagery available on Google Earth and ORTHO19.

the pits we had already recorded before were documented by us during the INV22. We omitted 65 pits for various reasons. In some cases, during the INV22, the previously recorded pits were considered to be part of a larger whole (e.g. LP.18/023, LP.18/026, LP.18/103, or LP.18/104). Others were already shallow and poorly visible at the time of recording and so may no longer have been visible in the field (e.g. LP.18/101). Moreover, some of the pits are on the periphery of the site, which we did not cover with the INV22 (e.g. LP.19/079, LP.19/143, or LP.19/144). The latter group represents the largest, together with the pits that we simply did not notice during the survey. This clearly shows that, although the systematic surface survey is the most effective method for recording looting pits, only a combination of several methods allows all disturbances to be recorded.

Needless to say, as already noted in the literature (Casana and Panahipour 2014; AAAS 2015; Casana 2015), not all sites are always available for such a survey, which may be due to complex political situations, including armed conflict. However, our study confirms that the analysis of aerial and publicly available satellite imagery is a good complement to the surface survey in countries at peace, as well, and, above all, it provides a glimpse of the history of looting activity on sites that have not been intensively studied by archaeologists. It makes it possible not only to determine the overall scale of robbery activity (cf. Contreras and Brodie 2010b) but also its progress over at least the previous 10 years.[9] Thus, not only does it allow monitoring the situation to some extent on sites that are not the subject of active investigations by surveys and/or excavation, but it can also be one of the first research activities on sites where archaeological work is initiated and

Figure 12. A plan of the pits excavated between June 2020 and August 2020 (marked in blue; red indicates all the pits documented). Based on analysis of satellite imagery available on Google Earth.

where traces of illegal excavations are visible. It is worth noting right away that the mere initiation of research, even more so when given publicity (Kersel, Chesson, and Hill 2021), can stimulate robber activity, even if, as with Tūwāneh, it is a well-known site with remains still visible on the surface today. We suspect that the excavation of the two new trenches between GE4.21 and INV22 in the area of the baths may have been related to the test excavation we started during the 2019 season. Indeed, it appears that previous robbing activity in this area ceased after GE1.17 was taken. Thus, it is not only the sharing of research results (including, above all, the coordinates of previously unknown sites) in open-access mode that can stimulate robbery activities, as has already been raised in the literature (Ur 2006, 37; Parcak 2009, 220–232, esp. 224, 230), but even the initiation of research on known sites that have already been the subject

of large-scale illegal activities, as well as excavations. Indeed, at Tūwāneh, the publication of the research report for the 2019 season did not take place until the end of 2022 (Bodzek et al. 2022), so mere observation of our activities may have inspired the robbers to re-establish themselves in the area of the baths.

Our study shows that both the analysis of satellite imagery as well as the pole- and kite-based orthomosaics, where possible, should be accompanied by a surface survey. This is because not all parts of sites such as Tūwāneh give an equally clear image to locate looting pits. Our study clearly shows that it is relatively easy to identify pits on flat surfaces with no visible remains of buildings or where these buildings are very loosely spaced and the visible walls are at a distance from each other. The heaps surrounding the trenches, which have a distinctive bagel/donut shape and are often distinguished

Figure 13. A plan of the pits excavated between August 2020 and April 2021 (marked in blue; red indicates all the pits documented). Based on analysis of satellite imagery available on Google Earth.

by their color, as Parcak has pointed out (Parcak 2015, 197), are a considerable help here. The analysis of the gradual excavations of the cemeteries gave particularly good results, thus confirming the spectacular results for this type of site obtained by Parcak for 267 sites in Egypt (Parcak 2015; Parcak et al. 2016) and Kersel and Hill for Fīfā (Kersel and Hill 2019). Looting pits within cemeteries are also more easily recognizable on lower-resolution imagery than trenches within the settlement areas of sites, especially those with relatively well-preserved architectural remains. At the same time, comparison of satellite imagery with higher-resolution orthomosaics makes it possible to distinguish pits from larger stones and clusters of stones, which may be mistaken for pits on lower-quality imagery.

The analysis of the imagery of the parts of the site where the remains of dense development are located yields much

worse results. Here, both the walls themselves (casting shadows that make identification of the trench difficult) and the debris are in the way. In this case, the ORTHO19 analysis yielded only marginally better results than the analysis of satellite imagery. The majority of such pits were only recorded during the INV22. This is well illustrated by comparing the number of looting pits recorded during ORTHO19 and INV22 for different parts of the site. Only 16 pits were documented during the ORTHO19 analysis in the western part of the site (west of the wadi) in a zone with well-preserved architectural remains covering an area of approximately 4 ha. In contrast, during the INV22 surface survey in this zone of the site, we recorded as many as 140 pits that had not been previously documented. Even if we add the annual average number of pits resulting from our analysis that could have been excavated in the three years between consecutive
A

B

Figure 14. A) Number of looting pits excavated between consecutive images. The exclusion of the period between GE9.19 and ORTHO19 is due to the fact that the increase in the number of pits may have been due not only to the number of pits actually excavated but also to the much better resolution of ORTHO19, which allowed previously invisible pits to be seen. B) Number of looting pits excavated between consecutive images averaged over 12 months with a linear trend line (y = -0.3996x + 20.31; $R^2 = 0.0058$).

measurements (47), this would still give us a total of 63 pits: that is, only 30% of the total number of pits recorded in this area. It is worth noting, however, that our observations of the state of the pits indicate that only a few of these may have been excavated in recent years.

In the much smaller area of architectural remains in the southern part of the site (immediately adjacent to the southern cemetery), covering an area of approximately 1 ha, the ORTHO19 analysis revealed the presence of 15 pits, while INV22 revealed 30 previously unrecorded pits. Although, in this case, it is theoretically possible that all these pits were excavated after ORTHO19, our observations indicate that the vast majority of them were pits that had been excavated earlier. In comparison, in the flat area of the southern cemetery, the ORTHO19 survey identified 68 pits, while the INV22 survey identified only eight previously unrecorded pits. This clearly highlights the variations in pit

recording capabilities among different methods, depending on the preservation status of architectural remains and the site's topography.

In the rubble, rather large pits are visible, as are those that have been made relatively recently. In the case of the latter, especially if they are relatively deep, the heaps may still show soil layers removed during exploration. In the case of older pits, such soil has been gradually washed away between the stones, making it difficult to see the pit. At the same time, gradual excavations mean that earlier pits are swamped with debris by robbers, making it virtually impossible to see them from the air. Only field reconnaissance shows a depression in the ground: evidence of a former pit. Undoubtedly, the surface survey is significantly more time- and cost-intensive compared to the imagery analysis. However, it's important to highlight that our survey of the site of approximately 55 ha, characterized by the presence of stone architecture

remnants protruding above ground level at various heights, presenting difficulties in navigating, required a total of approximately 16–18 hours. It yielded significantly superior results compared to remote analysis in areas of the site characterized by well-preserved architectural remains and instances where heaps of new pits obscured the old ones.

The varying effectiveness of remotely analyzing illegal excavations on sites with more intricate characteristics does not, of course, render such endeavors meaningless. Firstly, they offer at least a partial glimpse into the history of looting activities that have otherwise gone unrecorded. This, in turn, enables the assessment of trends and perhaps even the identification of periods during the year when looting is most rampant. Secondly, given the limited resources that authorities can allocate to monitoring archaeological sites and combating looting, recognizing the differing impact of remote analysis can lead to a more optimal distribution of resources.

Sites conducive to remote analysis, like cemeteries or settlement sites lacking visible surface architectural remains, or where such remnants are poorly preserved, can be primarily monitored using this approach. Consequently, more resources can be dedicated to monitoring sites where remote analysis of looting activity is especially challenging. Furthermore, for sites characterized by diverse characteristics and topography, such as Tūwāneh, it becomes feasible to segregate zones where remote analysis proves effective from those where it does not. This way, authorities can curtail the resources allocated to on-site monitoring of looting activities, focusing mainly on sections of sites where remote analysis would not yield satisfactory results, i.e. would not provide a comprehensive understanding of the phenomenon.

Conclusion

During our surveys at Tūwāneh, we recorded 723 looting pits by surface surveys and the analysis of orthomosaics created based on the pole- and kite-based photogrammetry. Comparing these results with the analysis of satellite imagery available for free via Google Earth has given us insight into the last 10 years of robbery activity at the site (2013–2022). At least 259 looting pits were certainly excavated before 10 August 2013. For 324, we cannot be sure whether they were created before or after this date, due to the limitations of the method used. The remaining 140 pits were created between 10 August 2013 and the beginning of November 2022, giving an average of 15.5 new pits per year (in reality, the rate varies between 8.6 and 43 pits per year). Thus far, we have been unable to pinpoint any specific time of the year when looting activity would significantly intensify. The three pits excavated within 1.7 months between GE6.20 and GE8.20 are closely aligned with the monthly average of 2.2, making it challenging to arrive at definitive conclusions. Nevertheless, we anticipate that as more data is collected in the future, we will be better poised to ascertain the occurrence of periods with heightened illegal excavation activity. Considering the restricted resources allocated to safeguarding cultural heritage, acquiring information regarding any specific period or periods of the year when looting activities commonly occur would aid the authorities in directing their resources effectively. For example, this could involve enhancing the frequency of site visits by the warden or law enforcement officers.

The study of satellite imagery for a site as complex as Tūwāneh has shown the limitations of this method. It is clearly evident that an analysis of the imagery for some parts of the site (flat areas with little or no architectural remains visible on the surface, e.g. cemeteries) gave much better results than an analysis of other parts (mainly densely built-up with a lot of debris). This clearly shows that such an analysis must also be accompanied by a surface survey wherever possible.

Certain sites, such as cemeteries or settlements lacking visible architectural remnants, are well-suited for remote analysis. This enables a more focused approach on sites that present challenges for remote analysis. In the case of diverse sites like Tūwāneh, it becomes possible to differentiate areas where remote analysis is successful from those where it is not viable, facilitating precise resource allocation. This aids authorities in prioritizing on-site monitoring in areas where remote analysis does not sufficiently offer a comprehensive understanding of looting activities.

In the future, we hope that by obtaining more satellite and aerial imagery (including that commercially available) we will be able to extend the temporal dimension of our research and reach further into the past. All this will allow us to determine the pace of looting activity even more effectively and identify possible trends. This, in turn, will help us to develop, together with the Department of Antiquities of the Kingdom of Jordan, a more effective strategy to protect Tūwāneh from further destruction.

Endnotes

1. Article (26/a/1) of the Antiquities Law of the Hashemite Kingdom of Jordan reads: "whoever excavated for antiquities without obtaining a license under the provisions of this law, shall be punished by imprisonment for no less than one year and not exceeding three years, and a fine of no less than three thousand dinars, and in proportion to antiquities' value" (cf. Abu Issa and Alwerikat 2023, 478).
2. For example, a passerby once stopped while driving through the site and mentioned that a mosaic had been discovered at the site but was destroyed due to the presence of gold underneath. While we maintain skepticism regarding the authenticity of this account, it does illustrate the mindset of the diggers.

9. The possibility of such a use for Google Earth has already been signaled by Myers (Myers 2010, 9). In practice, meanwhile, the method has already been used to analyze looting activity in Syrian Apamea but on a much smaller time scale (1–2 years) (Tapete, Cigna, and Donoghue 2016; Agapiou 2020) than in our study. The Parcak study (Parcak 2015; Parcak et al. 2016) is closer to ours, although it deals with sites with very different characteristics than Tūwāneh.
